INTRODUCTION

More than 75 million Americans have chronic pain.[1] Pain accounts for 20% of all outpatient visits[2] and over $100 billion dollars per year in direct and indirect costs;[3] analgesics account for 12% of all prescriptions.[4]Our aims were to review recent pain medicine studies and their key findings, and to discuss the implications of these findings for generalist clinical practice.

We systematically searched from January 1, 2008 through December 31, 2009 for peer-reviewed articles that could potentially change generalist care of patients with chronic pain. We searched MEDLINE and PubMed using the medical subject heading (MeSH) terms Pain, Arthritis, Fibromyalgia, Headache Disorders, Pain Measurement, Analgesics or *Narcotics*, and keywords for chronic, persistent, noncancer or primary care, excluding acute pain, postoperative pain, cancer pain, chest pain and pediatrics, and limiting to humans, English language and study type (trial, epidemiologic, review, meta-analysis or guideline). Members of the Society of General Internal Medicine's Pain Medicine Interest Group also suggested relevant articles. The search produced 1,051 references that were narrowed down to 47 based on relevance to generalist practice. Using a 5-point Likert scale, we independently rated these articles on impact on general internal medicine clinical practice, clinical policy and research and quality of study methods. We selected ten articles with the highest ratings.

ASSESSMENT

Krebs EE, Lorenz KA, Bair MJ et al. Development and initial validation of the PEG, a three-item scale assessing pain intensity and interference. J Gen Intern Med. 2009; 24 (6):733–738.

Received June 3, 2010
Revised June 18, 2010
Accepted June 30, 2010
Published online July 15, 2010

Single-item pain assessments do not adequately measure chronic pain, yet multi-dimensional pain scales such as the Brief Pain Inventory (BPI) are impractical for use in primary care. This study developed an ultra-brief pain measure derived from the BPI. Krebs et al. conducted a secondary data analysis of two primary care studies: a longitudinal study of 500 patients with chronic pain and a cross-sectional study of 646 veterans.

The authors assessed reliability (Cronbach's alpha), construct validity (Pearson's correlation coefficients) relative to other measures of pain and function, and responsiveness to change. The resulting scale consists of three items ("Pain average," "interference with Enjoyment of life" and "interference with General activity," or PEG). The PEG demonstrated good internal consistency (alpha 0.73–0.89), construct validity (r=0.6–0.95) and responsiveness to change.

Implications for Practice

The PEG is an appealing instrument to use in primary care because of its brevity and assessment of multiple domains of pain. This study suggests that the PEG has good psychometric properties, and its responsiveness to change is equivalent to the full BPI, from which it is derived. Replacing the commonly used single-item 0–10 Numeric Rating Scale with the three-item PEG may be a desirable strategy in primary care settings. The incremental "cost" of asking three items instead of one appears to be small relative to the potential gain in a more comprehensive understanding of patients' pain experiences.

COLLABORATIVE CARE

Becker A, Leonhardt C, Kochen MM, et al. Effects of two guideline implementation strategies on patient outcomes in primary care: a cluster randomized controlled trial. Spine. 2008;33(5): 473–480.

Although high-quality low back pain (LBP) guidelines are widely available, evidence-based LBP management strategies are inconsistently applied in primary care. The best methods of LBP guideline implementation are unclear. This trial randomized 118 German primary care practices to one of two LBP guideline implementation strategies or to a mailed guidelines control. The implementation strategies included physician education (three seminars and two academic detailing sessions) alone or physician education plus nurse training in motivational counseling (two full-day seminars and one to

three supervised practice sessions). Participating physicians enrolled 1,278 patients (fewer than the enrollment target of 1,874).

Most participants were male (58%) and employed (55%). Compared with those in the control group, patients in the nurse training group improved significantly more on the primary outcome of functional capacity at 6 months (p=0.032). There was no difference between the physician education only and control groups (p=0.120). Intervention patients reported fewer days in pain than control patients (16.4 and 17.9 fewer days).

Implications for Practice

Intervention effects were small, but the results have significant implications for generalist practice. First, the study enrolled a broad group of patients with LBP, of whom <50% had pain at follow-up. Many patients had resolution of their pain, which may partially explain the modest intervention effects on pain-related function. Second, the intervention was relatively non-intensive and was delivered distal to the clinical encounter. Although this likely reduced the intervention effect, implementation of a similar intervention in actual practice would be more feasible. Considering these factors, the finding of a small improvement in patient function is impressive.

The trial's finding that training both clinic nurses and physicians improved patient function, whereas training physicians alone did not, supports the concept of team-based primary care for back pain. Although some guideline-recommended practices can be implemented by physicians alone (e.g., limiting imaging tests), others may be challenging for physicians to implement without support (e.g., counseling for increased physical activity).[5] Nurses may be better equipped to provide patient education and counseling interventions.

Dobscha SK, Corson K, Perrin NA et al. Collaborative care for chronic pain in primary care: a cluster randomized trial. JAMA. 2009; 301(12):1242–1252.

Collaborative interventions based on the chronic care model have been studied in numerous conditions,[6] but have not been rigorously evaluated for chronic pain management. Dobscha et al. evaluated a multifaceted collaborative care intervention for chronic musculoskeletal pain in five Veterans Affairs (VA) primary care clinics. They randomized 42 primary care clinicians to the collaborative care intervention or usual care control. The intervention included pain management training for clinicians, pain education classes for patients, and care management by a full-time psychologist who assessed patients, developed tailored care recommendations collaboratively with a pain consultant and followed up with patients by phone. Patients (n=401) with chronic musculoskeletal pain of at least moderate pain severity and disability were enrolled.

Most participants were male (92%) and had long-standing pain (mean=10 years); 32% were employed. The mean number of contacts with the collaborative care team was ten, including an average of five phone contacts. On the primary outcome (pain-related disability) at 12 months, intervention patients improved significantly more than controls (p=0.004). A higher proportion of intervention patients experienced clinically important improvements of ≥30% than controls (22% vs. 14%, p=0.04, NNT=12.7). Secondary outcomes of pain intensity and depression severity were also improved in the intervention group. The intervention cost $1,200 per patient.

Implications for Practice

This trial showed that a collaborative primary care-based intervention can lead to modest, yet important improvements in pain outcomes among highly disabled, long-term pain sufferers. The collaborative care team directly intervened with patients by clinically assessing and reassessing them, delivering education to them, and providing their clinicians with individualized treatment recommendations. Even then, the intervention was relatively inexpensive, as it involved only one additional full-time clinician (the psychologist care manager) and 10% of an internist consultant's time. Considering the amount of health care consumed by patients with severe chronic pain,[7] an investment in collaborative care could be a bargain.

Clinician satisfaction, an important outcome, was not reported in this study. In a previous paper, Dobscha et al. reported three-fourths of VA primary care clinicians rated chronic pain management as a major source of frustration.[8] Improving satisfaction of primary care providers is another compelling reason to implement collaborative care interventions that support both patients and providers in addressing chronic pain.

CHRONIC PAIN AND DEPRESSION

Kroenke K, Bair MJ, Damush TM, et al. Optimized antidepressant therapy and pain self-management in primary care patients with depression and musculoskeletal pain: a randomized controlled trial. JAMA. 2009;301(20): 2099–2110.

Pain and depression frequently coexist (30%–50% co-occurrence), leading to poor health-related quality of life (HRQoL).[9,10] This study evaluated a stepped-care intervention including optimized antidepressant therapy combined with a pain self-management program to improve pain and depression outcomes. The study randomized 250 patients with chronic low back, hip, or knee pain of moderate severity and depression of moderate severity to intervention versus usual care. At 12 months, intervention patients were more likely than controls to experience a 50% reduction from baseline in depression severity (37.4% versus 16.5%, RR 2.3, p<0.001). Intervention patients also showed statistically significant improvements in pain severity and interference and in secondary outcomes (anxiety and HRQoL).

Implications for Practice

This trial demonstrated that optimized antidepressant therapy combined with a pain self-management program was beneficial for treating patients with co-occurring depression and pain. Improvements in depression and pain were seen early and sustained over 12 months. The improvements in pain severity and interference are noteworthy since analgesics were not a specific intervention component. The optimized antidepressant therapy included an algorithmic approach using several classes of antidepressants. This pragmatic, patient-tailored approach is more similar to clinical practice than an

inflexible testing of a single drug or class. Practitioners should screen for co-morbid depression and pain in their patients, and consider optimized antidepressant therapy and self-management strategies as essential tools in the treatment of these patients.

OPIOIDS AND CHRONIC PAIN

Weisner CM, Campbell CI, Ray GT, et al. Trends in prescribed opioid therapy for non-cancer pain for individuals with prior substance use disorders. Pain 2009;145(3): 287–293.

The efficacy and risks of long-term opioids in patients with substance abuse histories are poorly understood and prescribing practices not well described. Experts recognize that patients with substance use disorders commonly have pain that needs to be treated, but advise caution when prescribing opioids in this context. This study examined trends and characteristics of long-term opioid use in patients with non-cancer pain and substance use disorders (SUD). Administrative data from two large community health plans (Kaiser Permanente of Northern California and Group Health Cooperative of Seattle Washington) were evaluated. Long-term opioid use was defined as treatment >90 days. From 1997–2005, opioid prescribing increased dramatically for patients with SUD diagnosed prior to opioid prescription and was highest for those with an opioid use disorder. Patients with a SUD history were prescribed significantly more opioids (dose, potency and supply) and more concurrent sedative-hypnotics compared to patients without SUD histories. Additional findings were that more than a third of patients with a SUD history and almost three-fourths with a prior opioid use disorder received these diagnoses from addiction or psychiatric providers, rather than from the prescriber of the long-term opioid.

Implications for Practice

The increasing opioid prescribing for patients with SUD reported in this study are of unclear clinical appropriateness. Experimental studies[11] have shown higher pain sensitivity among these patients, and observational studies[12] have shown they have a greater risk of prescription opioid misuse. This study did not examine whether opioid prescribers were aware of their patients' substance use histories. At a minimum, generalists should screen all patients with chronic pain for a history of substance abuse before prescribing long-term opioids. Single-item screening[13,14] tests for at-risk substance use are now available. Patient monitoring with "universal precautions[15]," including opioid treatment agreements and urine drug testing, are recommended for all patients prescribed long-term opioids for chronic pain. The level of monitoring may be reasonably intensified (e.g., pill counts and random urine drug testing) for patients with a history of substance use disorders. In addition, based on the high rate of concurrent sedative use, generalists should carefully educate these patients about the risk of over-sedation.

Chou R, Fanciullo GJ, Fine PG et al. Clinical guidelines for the use of chronic opioid therapy in chronic noncancer pain. J Pain.2009;10(2):113–130.

A multidisciplinary expert panel, commissioned by the American Pain Society and the American Academy of Pain Medicine, conducted a systematic review of the evidence and developed evidence-based guidelines for use of chronic opioid therapy in chronic non-cancer pain. They reviewed the literature through November 2007, including 8,034 relevant abstracts. The expert panel met three times between September 2006 and January 2008, using methods adapted from the GRADE working group and multi-stage Delphi process. The panel found that evidence was limited, with many "research gaps," but concluded that chronic opioids "can be an effective therapy for carefully selected and monitored patients with chronic non-cancer pain." Recommendations were provided on topics including: patient selection, medication management plans, monitoring strategies, prevention and management of adverse effects, and use of psychotherapeutic co-interventions.

Implications for Practice

These recommendations provide a reasonable and comprehensive guide for general internists when prescribing long-term opioids for chronic pain. As the authors acknowledge, many of their recommendations are limited by reliance on low-quality evidence. The Chou et al. companion paper on research gaps in opioid use provides important background to the guidelines.[16] Recommendations related to assessing substance abuse risk, using informed consents and monitoring strategies, including urine drug testing for "high risk" patients, and counseling patients about driving risk are likely to become accepted "standard of care" until research emerges to better guide clinical practice.

CANNABIS AND CHRONIC PAIN

Martin-Sanchez E, Furukawa TA, Taylor J, Martin JLR. Systematic review and meta-analysis of cannabis treatment for chronic pain. Pain Med 2009;10(8):1353–1368.

Cannabis has been used for the treatment of various conditions, including chronic pain; however, little is known about its effectiveness or harms. The authors conducted a systematic review and meta-analysis of double-blind randomized controlled trials comparing cannabis preparations to placebo in patients with chronic pain. Cannabis preparations varied in dose, duration and route of administration (oral or nasal). The authors excluded one study of smoked cannabis on "ethical grounds." Of 229 studies, 18 met the inclusion criteria, but only 7 trials could be quantitatively analyzed because of data reporting limitations.

Cannabis reduced pain intensity compared to placebo, with an overall effect size of -0.61 (-0.84 to -0.37). The identified harms included euphoria (OR 4.11; NNH 8), dysphoria (OR 2.56; NNH 29), disturbances in perception (OR 4.5; NNH 7) and motor function (speech, ataxia, twitching, numbness; OR 3.9; NNH 5), altered cognitive function (OR 4.4; NNH 8) and gastrointestinal side effects (risks noted, but no summary due to heterogeneity.)

Implications for Practice

This study summarizes the evidence for benefits and harms of cannabis-derived compounds in the treatment of chronic pain. Notable limitations of the existing literature include small

sample sizes (n=13–177), short follow-up periods (mean=25 days), incomplete outcome reporting and exclusion of studies of smoked cannabis. Benefits and risks do not seem very dissimilar from other pharmacologic treatments (e.g., opioids) for chronic pain. This study offers preliminary evidence to inform the complex clinical decisions of risk-benefit for individual patients. Clearly, more rigorous studies are needed to better understand the risks and benefits of cannabis preparations for treating chronic pain.

COMPLEMENTARY AND ALTERNATIVE TREATMENTS

Cherkin DC, Sherman KJ, Avins AL, et al. A randomized trial comparing acupuncture, simulated acupuncture, and usual care for chronic low back pain. Arch Intern Med. 2009;169(9):858–866.

Back pain is the leading reason for visits to acupuncturists.[17] Several recent European trials have suggested that real acupuncture and "sham" acupuncture are equally effective.[18–20] This four-arm randomized controlled trial compared individually tailored acupuncture, standard acupuncture, simulated acupuncture (non-insertive) and usual care for 638 adults with mechanical low back pain. Detailed blinding procedures prevented acupuncture patients from knowing their treatment assignment. At 8 weeks, all three acupuncture arms had significantly lower pain disability scores than the usual care arm. Clinically meaningful improvements occurred in 60% of acupuncture patients compared with 30% in usual care (P<0.001). Improvements persisted at 1 year. There were no differences between individually tailored, standard and simulated acupuncture.

Implication for Practice

Acupuncture appears to be effective for improving back pain-related disability. Interestingly, insertion of needles and individual tailoring by acupuncturists did not make a difference in outcomes. For practitioners, the mechanism for effectiveness may not be as relevant as having an effective non-pharmacological therapy with minimal risks in the armamentarium of treatment options for the low back pain. Clinical trials evaluating the efficacy of acupuncture for various conditions have been conducted; however, most were poorly designed, and few included treatment protocols that can be applied in actual clinical practice. This study was rigorously conducted and raises questions about the putative mechanism of action for acupuncture's effectiveness. Similarly, although exercise for back pain has been shown to improve work disability,[21] it doesn't appear that the type of exercise itself makes the difference.[22] Thus, physicians should encourage patients who express interest in acupuncture to pursue it as a reasonable option.

TREATMENT FOR SPECIFIC TYPES OF CHRONIC PAIN

Chou R, Carson S, Chan BK. Gabapentin versus tricyclic antidepressants for diabetic neuropathy and post-herpetic neuralgia: discrepancies between direct and indirect meta-analyses of randomized controlled trials. J Gen Intern Med. 2009;24(2):178–188.

Tricyclic antidepressants (TCA) and gabapentin have been recommended as first-line treatments for neuropathic pain.[23] Previous systemic reviews have suggested that TCAs were superior to gabapentin, but head-to-head trials were not included in those analyses. Additionally, the quality and interpretability of neuropathic pain trials have been questioned because many of the placebo-controlled trials were published in different time periods (TCAs before 1991 and gabapentin after 1998).

The authors performed two meta-analyses that evaluated the effects of gabapentin versus TCAs in direct (head-to-head) and indirect comparisons (each drug versus placebo). Included trials were rated for quality (randomization, allocation concealment, blinding and intention-to-treat analysis). Gabapentin was superior to placebo for pain relief in six trials (RR 2.18, 1.78–2.67, p<0.00001), and TCAs were also superior to placebo for pain relief in nine trials (RR 5.27, 3.05–9.11, p<0.0001). Indirect comparisons of these 15 trials suggest gabapentin to be inferior to TCAs (RR 0.41, 0.23–0.74), but the direct, head-to-head comparisons (n=3 trials) showed no difference (RR=0.99, 0.76–1.29).

Implications for Practice

This study suggests that gabapentin and TCAs do not differ in efficacy when compared head-to-head, but that TCAs are slightly superior to gabapentin in indirect comparisons. For several reasons, trial results should be interpreted with caution. First, the placebo response rates were considerably different between gabapentin (24%) and TCAs (6%). Second, sample sizes were markedly different between trials (gabapentin median 112 and TCAs median 26). Third, none of the TCA trials met methodological quality standards. Lastly, none of the trials for either drug lasted longer than 12 weeks. Clinicians should be aware of the possible differences in outcomes due to quality and methodological variations in trials. The treatment of neuropathic pain with either gabapentin or TCAs is reasonable and should depend on factors such as patient preference, cost or side effects.

Hauser W, Bernardy K, Uceyler N, Sommer C. Treatment of fibromyalgia syndrome with antidepressants: a meta-analysis. JAMA. 2009;301(2):198–209.

Although prior meta-analyses have shown tricyclic antidepressants (TCA) to be effective in reducing pain in fibromyalgia syndrome (FMS),[24,25] newer classes of anti-depressants have not been evaluated. This meta-analysis reviewed 18 randomized controlled trials (2,296 total patients) comparing antidepressant with pharmacological placebo for treatment of FMS. Outcomes included standardized measures of pain, fatigue, sleep quality, depressed mood and HRQoL. The authors compared antidepressant classes as well as individual antidepressants.

Overall, antidepressants significantly improved pain [effect size (ES)=-0.43, p<0.001)], depressed mood (ES=-0.26, p<0.001), sleep (ES=-0.32, p<0.001) and HRQoL (ES=-0.31, p<0.001), but had no effect on fatigue. TCAs showed large effects for pain, fatigue and sleep, a small effect for HRQoL and no effect for depressed mood. Selective serotonin reuptake inhibitors (SSRI) showed a small effect for pain, depressed mood and HRQoL, but no effect on fatigue or sleep. Serotonin-norepinephrine reuptake inhibitors (SNRI) showed small effects for pain, sleep,

depressed mood and HRQoL, and no effect on fatigue. MAO inhibitors showed a moderate effect for pain, but none for fatigue, sleep or depressed mood. Amitriptyline and duloxetine had the strongest evidence for symptom improvement of the individual medications.

Implications for Practice

When considering pharmacotherapy for FMS, antidepressants should be among the first choices. Among the antidepressant choices, TCAs, particularly amitriptyline, has consistently been shown to have a strong effect on many FMS symptoms, an effect that has been stronger than with SSRIs and SNRIs, albeit with a higher rate of side effects. Providers should educate patients to expect only small to moderate improvement in symptoms that characterize FMS—pain, sleep disturbance and depressed mood—as well as in HRQoL. Fatigue is unlikely to improve with antidepressants. Side effect profiles should be weighed against expected improvement in symptoms. In addition, treatment should include evidence-based non-pharmacological treatments, such as such as tailored exercise, heated pool therapy, cognitive behavioral therapy and relaxation techniques.[26]

Do attitudes about unhealthy alcohol and other drug (AOD) use impact primary care professionals' readiness to implement AOD-related preventive care?

MICHAELA B. AMARAL-SABADINI[1], RICHARD SAITZ[2,3] &
MARIA LUCIA O. SOUZA-FORMIGONI[1]

[1]*Department of Psychobiology, Federal University of Sao Paulo, Sao Paulo, Brazil,* [2]*Clinical Addiction Research and Education (CARE) Unit, Section of General Internal Medicine, Department of Medicine, Boston Medical Center and Boston University School of Medicine, Boston, USA, and* [3]*Department of Epidemiology, Boston University School of Public Health, Boston, USA*

Abstract

Introduction and Aims. *To explore the association between primary care professionals' (PCPs) attitudes towards unhealthy alcohol and other drug (AOD) use (from risky use through dependence) and readiness to implement AOD-related preventive care.* ***Design and Methods.*** *Primary care professionals from five health centres in Sao Paulo were invited to complete a questionnaire about preventive care and attitudes about people with unhealthy AOD use. Logistic regression models tested the association between professional satisfaction and readiness. Multiple Correspondence Analysis assessed associations between stigmatising attitudes and readiness.* ***Results.*** *Of 160 PCPs surveyed, 96 (60%) completed the questionnaire. Only 25% reported implementing unhealthy AOD use clinical prevention practices; and 53% did not feel ready to implement such practices. Greater satisfaction when working with people with AOD problems was significantly associated with readiness to implement AOD-related preventive care. In Multiple Correspondence Analysis two groups emerged: (i) PCPs ready to work with people with unhealthy AOD use, who attributed to such patients lower levels of dangerousness, blame for their condition and need for segregation from the community (suggesting less stigmatising attitudes); and (ii) PCPs not ready to work with people with unhealthy AOD use, who attributed to them higher levels of dangerousness, blame, perceived level of patient control over their condition and segregation (suggesting more stigmatising attitudes).* ***Discussion and Conclusions.*** *More stigmatising attitudes towards people with unhealthy AOD use are associated with less readiness to implement unhealthy AOD-related preventive care. Understanding these issues is likely essential to facilitating implementation of preventive care, such as screening and brief intervention, for unhealthy AOD use.* [Amaral-Sabadini MB, Saitz R, Souza-Formigoni MLO. Do attitudes about unhealthy alcohol and other drug (AOD) use impact primary care professionals' readiness to implement AOD-related preventive care? *Drug Alcohol Rev* 2010;29;655–661]

Key words: alcohol, drug, primary health care, attitude, stigmatisation.

Introduction

The use of alcohol and other drugs (AOD) can be perceived as positive or negative depending on many factors. In many situations alcohol use is associated with prestigious activities and social status. On the other hand, the use of illegal drugs and the way some substances are used seems to attract stigma, marginalisation and negative emotional reactions [1–3].

Received 31 December 2009; accepted for publication 17 June 2010.
Place where the work was undertaken: Department of Psychobiology, Universidade Federal de São Paulo (Federal University of São Paulo—UNIFESP), Brazil.
This study was presented in abstract (poster) form at the INEBRIA Meeting (International Network on Brief Interventions for Alcohol Problems), 8th and 9th October 2009, Newcastle Gateshead (England).

Alcohol and other drug-related attitudes may develop from and impact people's personal and professional experiences and behaviours. Attitude is a hypothetical construct that represents the person's perspective (positive or negative) towards a specified target (person, place, thing or event). Attitudes are generally defined as being composed of three components: cognitive (beliefs), affective (emotions) and behavioural (verbal or typical behavioural tendency). The three components are interlinked and negative beliefs, for example, are associated with stigmatising attitudes [4]. Link and Phelan [5] defined stigma as the co-occurrence of labelling, stereotyping, separation, status loss and discrimination. Weiner [6] applies the attribution theory to understand the perceived cause of stigma. According to this theory, attributions of responsibility will determine affective reactions towards the stigmatised person (e.g. anger or pity), future expectations regarding the individual (e.g. likelihood of recovery) and a variety of behavioural responses, including altruistic actions [7].

Health professionals' negative attitudes, particularly about AOD use, have been cited as important barriers to the implementation of clinical prevention practices [8–10]. Some health professionals consider AOD-related problems difficult issues to discuss, and many report a lack of skills, confidence, satisfaction and competence to identify and manage these problems [11–13]. Ronzani *et al.* [14] pointed out that unhealthy AOD use (the spectrum from risky use through dependence) was the most negatively judged behaviour by health professionals when compared with other health conditions, such as Hansen's disease, obesity, HIV and others.

In order to reach a broad range of people for early intervention, decrease stigma and improve attitudes and care, many have advocated addressing unhealthy AOD use in primary health-care settings [12,15,16], where the focus is on prevention, health promotion and longitudinal comprehensive care. This laudable goal has the potential to make addressing unhealthy AOD use a mainstream health issue and risk behaviour, managed like others addressed routinely in these settings. However, few studies about health professionals' attitudes related to unhealthy AOD use have examined the association between them and the professional's clinical practices. The present study aimed to explore the association between primary care professionals' (PCP) attitudes about people with unhealthy AOD use (including stigma) and PCPs' readiness to implement AOD clinical prevention practices. We anticipated that negative attitudes about people with unhealthy AOD use would influence PCPs' readiness to implement AOD-related preventive care; and that PCPs' satisfaction when working with people with unhealthy AOD use would be associated with readiness to implement AOD-related preventive care.

Methods

Study sample

Physicians, nurses, nursing assistants and community health workers (community health workers are people from the community where the health centre is located, trained and hired to work on community health activities, such as screening and education about health issues) from five primary health-care centres in Sao Paulo, Brazil, were invited to participate in the study. These centres were randomly selected from 222 centres in total, one centre from each of the city's regions—North, South, Southeast, Center-west and East. All the health professionals from each centre were invited to participate ($n = 160$) and 96 completed the survey, giving a response rate of 60%. The participants were physicians or nurses (31%), nursing assistants (19%) and community health workers (50%).

As regards sociodemographic characteristics, 87% were women, 60% single, mean age 40.6 (SD 9.7); 49% were Catholic, 25% Protestant, 24% had other religions or did not have a religion.

Data collection

The first step was to present the study to the primary care unit managers. They were responsible for inviting all the health professionals in the unit to participate. Before agreeing to participate, professionals were told about the aims of the project and informed about the confidentiality of the data (it was an anonymous survey), were asked to sign informed consent and instructed about how to complete the questionnaire. All participants received the questionnaire in an envelope. The researcher waited outside of the room to receive the envelope containing the completed survey, or in some cases, returned to the health centre to pick it up on another day.

Instrument

The instrument was composed of three parts. The first part was a questionnaire developed by the authors, with multiple response options: sociodemographic data, clinical prevention practices, beliefs and satisfaction when working with people with AOD problems and readiness to implement preventive interventions with people with risky AOD use. Readiness was evaluate in two items, one for alcohol, one for drugs ('On a

scale of one to five, where 1 means not even a little ready, and 5 totally ready, how ready do you feel to carry out preventive interventions for risky alcohol/drug use?'). For the questions about beliefs, satisfaction and readiness Likert scales ranging from 1 to 5 were used. AOD-related preventive care was defined as any type of screening or early intervention done in the primary care setting studied. The second questionnaire was an adaptation made by the authors of the Attribution Questionnaire Short Form [3,17], a stigma measure. The Adapted version of the Attribution Questionnaire (AAQ) addressed health professionals' attributions for different health conditions represented by hypothetical vignettes about people with: (i) risky alcohol use; (ii) alcohol abuse; (iii) alcohol dependence; (iv) drug dependence; (v) hypertension; (vi) depression; (vii) schizophrenia; and (viii) HIV-AIDS. Participants were instructed to read the eight vignettes and score nine different items: pity for the patient, dangerousness of the patient, fear of the patient, blame (patient is responsible for his condition), segregation (would be better for the community for the patient to be removed from it for treatment), anger (about or towards the patient), likelihood that the professional would help the patient, avoidance (of taking care of the patient) and control (how much the patients have control over for the solutions of their problems), on a 9-point agreement scale ranging from none/a little (1) to a lot (9). The 'help' item was reverse-coded. Internal consistency (Cronbach's alpha) for each factor was tested: pity: 0.89; dangerousness: 0.77; fear: 0.72; blame: 0.65; segregation: 0.82; anger: 0.77; help: 0.83; avoidance: 0.71; and control: 0.72. We added a final question across the eight vignettes to assess PCPs' opinions about each health condition: 'If you were this person, how would you define your health condition? From 1 (very bad health) to 10 (very good health).' Each vignette was developed considering PCPs' daily practice, including health conditions typically associated with stigma and others, which were not expected to be associated with stigma.

The last part of the instrument was the ASSIST (Alcohol, Smoking and Substance Involvement Screening Test) [18–20] aiming to evaluate the PCPs' AOD use. The ASSIST score categorises respondents as low risk/no use (should receive information), moderate risk (should receive a brief intervention) and high risk (should receive more intensive care).

Statistical analysis

The Pearson χ^2-test was applied to assess the association between categorical independent variables and readiness to implement AOD clinical prevention practices. In logistic regression models, we tested the association between satisfaction when working with people with unhealthy AOD use and readiness to implement AOD-related preventive care. Satisfaction was categorised as 'none' (1 + 2), 'some' (3) and 'a great deal' (4 + 5) and readiness was coded as a binary variable [not ready (1–3) vs. ready (4 + 5)]. $P < 0.05$ was considered statistically significant.

Non-parametric analyses using median regression, with bootstrap estimation were used to compare the participants' opinion about each health condition of the vignettes. Multiple Correspondence Analysis (MCA) was used to assess patterns of associations among the items in the AAQ (medians) and readiness to implement AOD clinical prevention practices (binary). MCA is an exploratory technique (not inferential) that is a generalisation of a principal component analysis for categorical variables. This approach allows testing each difference among groups. Its interpretation can be based upon proximities between points in a low dimensional map, where the axes are the coordinates, the geometric figures represent the different variables in the model and the proximities reflect the strength of associations [21].

Ethics

All the study procedures were approved by the Ethics Committee of the Universidade Federal de São Paulo, project number CEP1581/07.

Results

Over half (56%) of the 96 respondents reported always or almost always implementing general clinical prevention practices, but only 25% reported implementing clinical prevention practices targeting unhealthy AOD use; 53% felt only a little or not at all ready to implement clinical prevention practices for unhealthy AOD use. In spite of that, the majority expressed positive beliefs about working with people with unhealthy AOD use, even though around 60% reported not having adequate training to do so. Sixty-eight per cent of the respondents believed that their amount of work would increase if they start to identify unhealthy AOD use in their clinical routine.

Based on the ASSIST questionnaire, 6.2% of the PCPs used alcohol and 14.6% used tobacco at moderate-risk levels for which receipt of a brief counselling intervention would be appropriate. One used alcohol at a high-risk level. None used drugs. Alcohol and tobacco risk levels were not significantly associated with readiness to implement AOD preventive care for patients with risky use. The proportion ready to implement alcohol preventive care was 24% of those at lower tobacco risk, 43% for moderate risk and 25% of never

Satisfaction when working with people with unhealthy drug use	None	1.0
	Some	4.0 (0.6–26.3)
	A great deal	18.5 (3.8–89.2)

CI, confidence interval; OR, odds ratio.

smokers; 28% of those at lower alcohol risk, 17% for moderate risk and 25% of never drinkers. The proportion ready to implement drug preventive care was 22% of those at lower tobacco risk, 36% for moderate risk and 25% of never smokers; 25% of those are lower alcohol risk, 17% for moderate risk and 25% of never drinkers.

Greater professional satisfaction when working with people with AOD problems was significantly associated with readiness to implement AOD-related preventive care (Tables 1 and 2). For example, compared with none, having a great deal of professional satisfaction when working with people with alcohol problems increased the odds of readiness to carry out preventive interventions for risky use 6.2 times and the odds of readiness to carry out drug preventive interventions 10.6 times.

We did not find statistically significant differences between professional categories and readiness to implement AOD-related preventive care. For physicians/nurses, nursing assistants and community health workers 37%, 22% and 23%, respectively, were ready to implement alcohol preventive care; similarly, 30%, 22% and 21%, respectively, were ready to implement drug preventive care.

PCPs rated drug dependence, alcohol dependence and alcohol abuse as conditions representing worse health than HIV-AIDS, depression, hypertension and schizophrenia (overall $P < 0.01$ except for schizophrenia) (Figure 1).

The MCA suggested two distinct groups—PCPs that feel ready to carry out preventive interventions for risky AOD use and PCPs that do not (Figure 2). Two patterns of associations between AAQ attitudes and readiness emerged: (i) professionals ready to carry out preventive interventions for risky AOD use, who attributed lower levels of dangerousness, blame (patient is responsible for his condition) and segregation (would be better for the community for the patient to be removed from it for treatment) to such patients (suggesting less stigmatising attitudes); and (ii) professionals not ready to carry out preventive interventions for risky AOD use, who attributed higher levels of dangerousness, blame, control (how much the patient has for the solutions of his problems) and segregation to such patients (suggesting more stigmatising attitudes). Also, within the group of PCPs that do not feel ready, there appear to be two subgroups: those who attribute higher levels of dangerousness and segregation, and those who attribute higher levels of blame and control.

Discussion

The aim of this study was to explore the association between PCPs' attitudes about unhealthy AOD use and their readiness to implement AOD-related preventive care. Our key findings suggest that health professionals' attitudes appear to influence clinical practices, at least self-reported practices, with more stigmatising attitudes associated with lower readiness to implement unhealthy AOD-related preventive care. Moreover, PCPs who endorsed more negative attitudes were also the ones that attributed more blame (responsibility for causing the problem) and control (for the solutions of the problem) to patients with unhealthy AOD use. These findings are consistent with Weiner's attributional theoretical framework [6] and confirm other findings in the literature [3,13].

Health professionals' satisfaction when working with people with unhealthy AOD use was associated with their readiness to implement AOD-related preventive care. In the same direction, Saitz and colleagues [11] showed that health professionals' greater satisfaction caring for patients with substance problems was associated with positive attitudes towards addiction treatment.

Previous research has found that health professionals tend to be positive about working with people with unhealthy AOD use [12,15]; however, this seems to be more associated with a sense of professional responsibility, rather than personal interest, as at the same

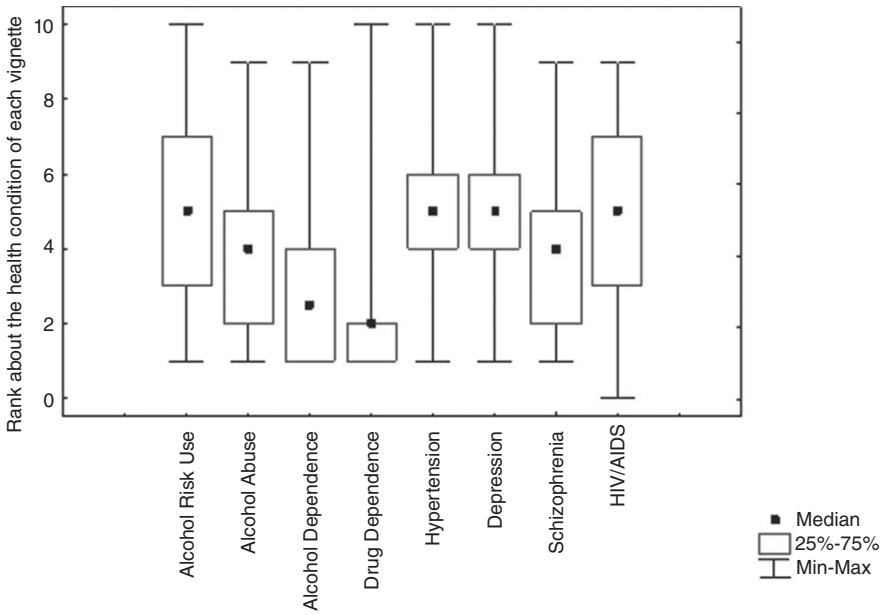

Figure 1. *Primary care professionals rating of the health condition presented in each vignette [from very bad (0) very good (10) health]. *Alcohol abuse rating differs significantly from all other ratings (*$P < 0.01$*) except Schizophrenia. **Alcohol and drug dependence ratings differ significantly (*$P < 0.05$*) from all others.*

time, they tend to report low levels of professional satisfaction when working with this population. This discrepancy between perceived role responsibility and other attitudes and satisfaction seems to be even more evident for professionals' views regarding people with unhealthy drug use in particular, as this study also showed. The illegal status of these substances can reinforce stereotypes of dangerousness, creating safety concerns among health professionals [22–24], leading to discrimination against the patient, and poor quality of care [25].

The present study has some limitations. Causality cannot be determined from a cross-sectional survey and we did not adjust for potential confounders in part because of the relatively small sample size. We assessed readiness to implement AOD-related preventive care, not actual implementation of practices, and similarly, instead of observing actual practice with patients, we used vignettes of hypothetical cases that may or may not reflect how health professionals would feel or respond in real situations. Social desirability and selection bias may also have biased PCPs' responses towards more positive attitudes. For example, we found no association between PCP AOD use and readiness while others have suggest such a relation [26]. On the other hand, the fact that PCPs did report substantial lack of readiness and negative attitudes argues against such biases. In addition, the fact that the survey was anonymous likely minimised these biases. And the response rate was similar to that seen often in surveys of health professionals [24]. The generalisability of this study may be limited as this is a relatively small sample, from one city in Brazil. However, at a minimum the results likely apply to the many health centres in Sao Paulo and other urban centres in Brazil. Also, as the findings seem consistent with studies carried out in other countries [9,12,15], there is little reason to suspect that the findings would differ if the study were repeated elsewhere.

Despite the study limitations, the findings have important practical implications. We found associations between attitudes, including stigmatising attitudes, and clinicians' readiness to implement AOD-related preventive care. We have no reason to believe that these associations would not apply to PCPs in various contexts, and in developing and developed nations alike. These associations suggest that the way unhealthy AOD use is perceived by PCPs has implications for the relationship between the patient and clinician, and for the quality of care they receive. The development of positive attitudes and practices among health professionals in regard to AOD-related work must involve interventions that go beyond the individual [27,28]. Training and education are strategies that may be necessary but not sufficient to change health professionals' attitudes and practices [10,13]. Yet knowing that attitudes are important in determining practices suggests avenues for change and improvement of care. Multifaceted approaches, including education, training, practice guidelines, systems

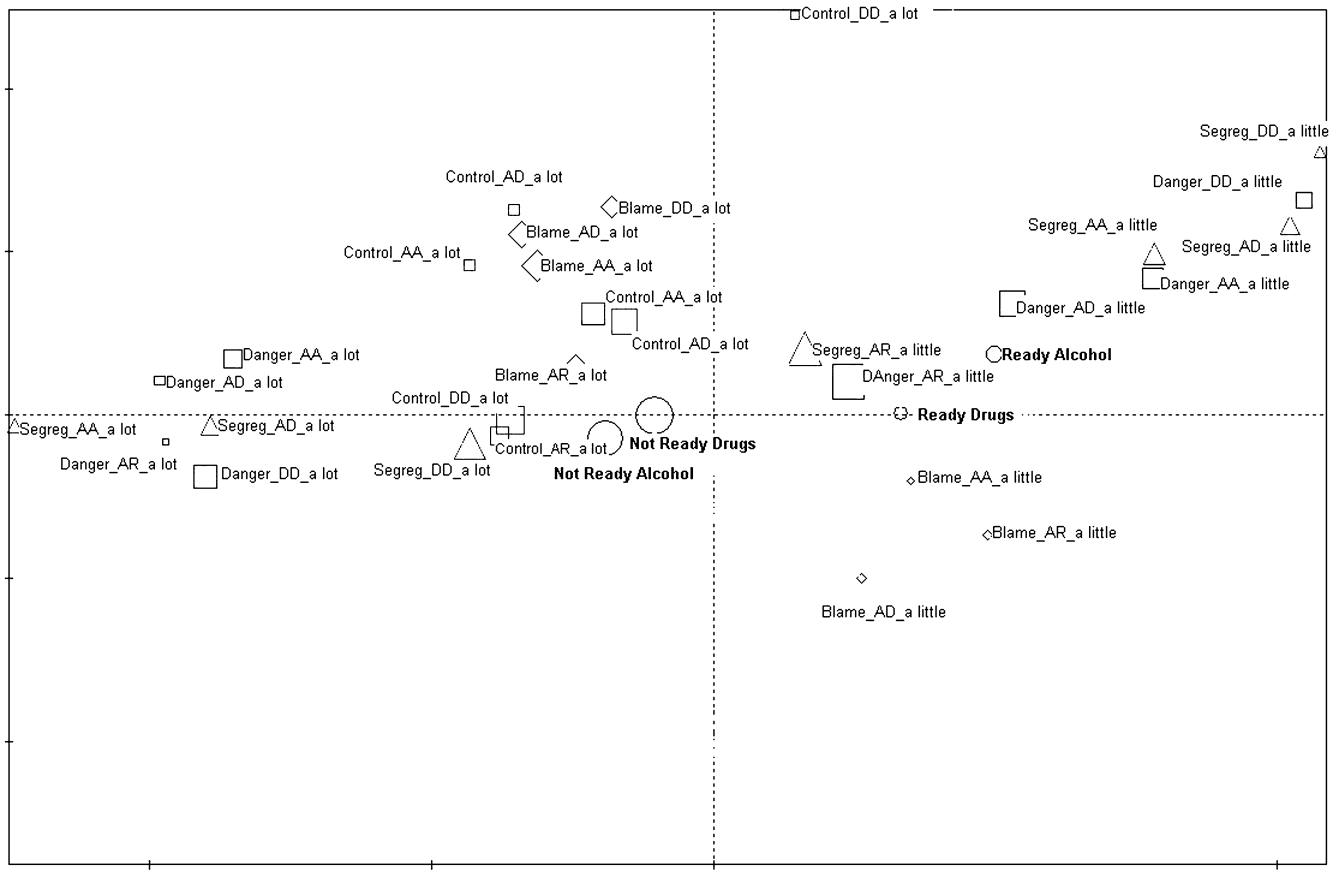

Figure 2. *Multiple Correspondence Analysis map of the associations between the items in the Adapted Attribution Questionnaire and primary care professionals' readiness to implement alcohol and other drug clinical prevention practices. Different geometric figures represent the different variables in the model that are significantly associated with readiness, and the proximities reflect the strength of associations. Vignette conditions: AA, alcohol abuse; AD, alcohol dependence; AR, risky alcohol use; DD, drug dependence. Not ready/Ready, to carry out preventive interventions for risky alcohol/drug use. Control, danger(ousness), segreg(ation) and blame are items from the Adapted Attribution Questionnaire addressing stigmatising attitudes.*

approaches, policy changes and attention to societal norms, may improve PCP's attitudes and have substantial impact on patient care. Such approached will likely need to be adapted to local conditions and circumstances. Efforts in these areas should be pursued and studied to improve the care of primary care patients with unhealthy AOD use.

Race Differences in Cardiac Catheterization: The Role of Social Contextual Variables

Brian J. Ayotte, PhD[1,2] and Nancy R. Kressin, PhD[2,3,4]

BACKGROUND: Race differences in the receipt of invasive cardiac procedures are well-documented but the etiology remains poorly understood.

OBJECTIVE: We examined how social contextual variables were related to race differences in the likelihood of receiving cardiac catheterization in a sample of veterans who were recommended to undergo the procedure by a physician.

DESIGN: Prospective observational cohort study.

PARTICIPANTS: A subsample from a study examining race disparities in cardiac catheterization of 48 Black/African American and 189 White veterans who were recommended by a physician to undergo cardiac catheterization.

MEASURES: We assessed social contextual variables (e.g., knowing somebody who had the procedure, being encouraged by family or friends), clinical variables (e.g., hypertension, maximal medical therapy), and if participants received cardiac catheterization at any point during the study.

KEY RESULTS: Blacks/African Americans were less likely to undergo cardiac catheterization compared to Whites even after controlling for age, education, and clinical variables (OR=0.31; 95% CI, 0.13, 0.75). After controlling for demographic and clinical variables, three social contextual variables were significantly related to increased likelihood of receiving catheterization: knowing someone who had undergone the procedure (OR=3.14; 95% CI, 1.70, 8.74), social support (OR=2.05; 95% CI, 1.17, 2.78), and being encouraged by family to have procedure (OR=1.45; 95% CI, 1.08, 1.90). After adding the social contextual variables, race was no longer significantly related to the likelihood of receiving catheterization, thus suggesting that social context plays an important role in the relationship between race and cardiac catheterization.

CONCLUSIONS: Our results suggest that social contextual factors are related to the likelihood of receiving recommended care. In addition, accounting for these relationships attenuated the observed race disparities between Whites and Blacks/African Americans who were recommended to undergo cardiac catheterization by their physicians.

Race differences in the receipt of invasive cardiac procedures have been well-documented,[1,2] but their etiology remains poorly understood. Although the magnitude of these differences may vary according to sample characteristics, data sources, and study methodology, the preponderance of research suggests that Blacks/African Americans are less likely to receive invasive diagnostic or revascularization procedures for coronary artery disease compared to Whites. Although all of the sources of these disparities are not known, it is clear that the mechanisms underlying race differences in cardiac care are complex and multidimensional and include individual patient factors (e.g., clinical characteristics, health beliefs), physician factors (e.g., practice patterns, availability of technology, stereotypes), and structural factors (e.g., access to and reimbursement for care).[1,3] Identifying sources of the disparities in cardiac care remains critical given the persistent differences in cardiovascular disease between Whites and Blacks/African Americans, and their contribution to excess mortality among the latter.[4]

One possible explanation for disparities in cardiac care could be patient treatment preference.[5] Black/African Americans are significantly less likely to prefer surgical or invasive treatment for a number of conditions, including spinal conditions,[6] cancer screening,[7] and invasive cardiovascular procedures.[8] Studies have found that Blacks/African Americans are more likely to refuse recommended invasive cardiac procedures,[9] even within the VA where financial issues are not a concern.[10] Few studies, however, have examined factors associated with refusal or non-receipt of recommended cardiac procedures in the context of race. Qualitative studies examining race differences in cardiac patients' treatment decision making suggest three levels of factors associated with decision making among Blacks and Whites: (a) health care system (e.g., number of doctors involved with care); (b) personal/social (e.g., role of family); (c) and physician (e.g., quality of communication).[3,11] In these studies, Blacks/African Americans reported several additional factors, including discrimination in the health care system, religion and faith in God, and the need for a physician who understands their symptoms and complaints. In addition, mistrust of the health care system in general might contribute to treatment preference and refusal of recommended care.[12]

The relationship between social factors and treatment preferences is also important to understand.[5] Ferguson identified a number of social contextual factors associated with treatment preference, including discussions with family members, knowing somebody who had the procedure, and religious beliefs. Similarly, a study by Whittle and colleagues found that knowing somebody who had undergone an invasive cardiac procedure was related to increased willingness to undergo a hypothetical invasive cardiac procedure if it was recommended by a physician.[13] In addition, religiosity and attendance at religious services are important in treatment decision making[14] and may reflect an important source of social support.[15,16] Focusing on social contextual factors is particularly useful given the benefits of interventions aimed at social contextual variables and cardiac care. For example, an intervention involving peer support increased participants' self-care behaviors associated with the prevention of heart disease.[17]

The purpose of the current study was to expand upon prior findings and examine how social contextual variables were related to the actual receipt of cardiac catheterization among Blacks/African Americans and Whites who were recommended to have cardiac catheterization by their physician, while simultaneously controlling for clinical and sociodemographic factors that are also known to influence procedure use. We hypothesized that social contextual variables would account for at least some of the race differences in the receipt of recommended cardiac catheterization, after adjusting for other known confounders.

METHOD

Study Setting and Sample

The study methodology has been described in detail elsewhere.[1] Briefly, the study was conducted at five large, urban, academically-affiliated Department of Veterans Affairs (VA) Medical Centers with on-site catheterization laboratories (Houston, Pittsburgh, Atlanta, Durham, St. Louis). A prospective cohort of patients likely to have coronary artery disease was established by screening the results of all cardiac nuclear imaging studies performed between August, 1999, and January, 2001. Nuclear imaging study results were considered positive if there was any evidence of reversible cardiac ischemia (evidenced by reversible defects or redistribution). A total of 1,045 (23% African American, 77% White) patients were included in the final overall baseline sample (a 76% response rate); we selected a subsample for the present analysis.

We used a two-step process to identify patients recommended for catheterization. First, we identified patients who responded positively to an item asking if he or she was offered the option of cardiac catheterization by their physician. Second, we checked these patient reports against physicians' reports of referral for cardiac catheterization. Only patients whose self-report and physician report both indicated that the patient was offered the option of catheterization were included in the current analyses. In total, 417 patients reported that they were not given the option of catheterization, 187 were missing data on this item, and 160 patients reported being given the option of catheterization while their physician indicated that they were not referred for cardiac catheterization. An additional 44 patients were excluded due to missing data on one or more of the other study variables. The final sample consisted of 237 patients.

Procedure

Data were collected from two serially administered questionnaires which included non-overlapping content: one completed within four weeks after the patient's nuclear imaging study and one completed after the patient reported having received the nuclear imaging study results. Patients were contacted by the study research assistant in person or by phone.

Measures

Sociodemographic Information. Patients were asked about their age, education and self-reported race (0=White, 1=Black).

Clinical and Treatment Variables. Clinical and treatment variables were collected by trained nurses who abstracted each patient's medical records. Clinical variables included cardiac symptoms, and medical history (including prior myocardial infarction, hypertension, diabetes, congestive heart failure, renal dysfunction, and lung disease). Maximal medical therapy was identified by using the definition used by the American College of Cardiology/American Heart Association guidelines for coronary angiography and the management of patients with chronic stable angina.[18,19] Data regarding receipt of catheterization was also collected from patients' medical records. These variables were coded as 0=No and 1=Yes. As part of the study questionnaire, patients were also queried about their anginal symptoms, resulting in two scores: anginal stability (0–100 with higher scores indicating greater stability) and anginal frequency (0–100 with higher scores indicating less frequency). Participants who reported no angina received scores of 100 on both variables.

Social Contextual Variables. We included several social contextual variables in our model. Social support was assessed using three items: (a) satisfaction with family relationships, (b) satisfaction with frequency of social contact with friends and relatives, and (c) satisfaction with frequency of contact with someone the patient trusts and can confide in.[20] Respondents answered yes or no with scores reflecting the number of items to which the respondent answered "yes." This scale had acceptable internal reliability for a brief scale among Whites (Cronbach α=0.60) and Black/African Americans (α=0.62). We also assessed whether patients knew any family or friends who had a heart catheterization (0=No, 1=Yes), how well they knew the person who gave him or her the nuclear imaging results (1=Not at all to 5=Very well), if it would be hard on their family if they were in the hospital for more than a couple of days (1=Not at all to 5=Extremely so), and if their family encouraged them to have a heart catheterization (1=Not at all to 5=Extremely so). Marital status was assessed by self-report and was coded as 0=Not Married, 1=Married. Finally,

we assessed religiosity using one item asking about how often patients attend religious services (1=Never/almost never, 8= Daily/more often).

Analyses

Logistic regression models were fit to test the association of social contextual variables with the receipt of heart catheterization after accounting for other factors that might also influence the outcome, as well as clustering of patients within site of care. The first step of the model included the demographic variables of age, education, and race. The second step added clinical (prior myocardial infarction, hypertension, diabetes, congestive heart failure, renal dysfunction, anginal frequency, anginal severity, and lung disease) and treatment variables (maximal medical therapy). The third and final step included the social contextual variables of marital status, social support, familiarity with person who gave results, knowing somebody who had catheterization, perceived difficulty for family if patient was hospitalized, being encouraged by family to have catheterization, and religiosity. The predictive power of the models was examined by use of the area under the ROC curve (*C* statistic). Values near 0.50 reflect a model with no apparent accuracy, while a value of 1.0 reflects perfect accuracy. Clustering of patients within site of care was not significantly related to the outcome variable so it is not reported for efficiency of presentation.

RESULTS

Sample characteristics are presented in Table 1. In terms of race differences in clinical/treatment variables, fewer Blacks/African Americans reported prior revascularization (22.9%) compared to Whites (37.9%), but significantly more Blacks/African Americans reported hypertension (91.7% versus 77.0%). There were also race differences in social contextual variables, with significantly fewer Blacks/African Americans reporting being married (47.9% versus 62.2%) or knowing a family member or friend who had catheterization (62.5% versus 78.8%). However, Blacks/African Americans reported higher religiosity scores (M=6.18, SD=1.46) than Whites (M= 4.63, SD=2.13). Finally, among this subsample of patients referred for catheterization, fewer Blacks/African Americans ultimately received catheterization (77.1%) compared to Whites (89.7%).

The logistic regression model revealed a number of associations with the likelihood of receiving catheterization among this subsample of patients (see Table 2). The baseline model (*C*= 0.60) including the demographic variables of age, education, and race indicated that Blacks/African Americans were significantly less likely than Whites to have catheterization (OR= 0.34; 95% CI, 0.15, 0.79). Age and education were not associated with the likelihood of receiving catheterization.

Adding the clinical and treatment variables in the second model (*C*=0.67) resulted in a slightly lower but still significant OR for Blacks/African Americans (OR=0.31; 95% CI, 0.13, 0.75) compared to the first step of the model. However, none of the clinical or treatment variables were related to the likelihood of receiving catheterization.

In the third model (*C*=0.79), three of the social contextual variables were related to the likelihood of receiving catheterization. First, knowing somebody who had catheterization was related to an increased likelihood of receiving catheterization (OR=3.14; 95% CI, 1.13, 8.74). Second, higher levels of social support were related to increased likelihood of catheterization (OR=2.05; 95% CI, 1.17, 3.60). Third, higher scores on the item assessing if family members encouraged the patient to have catheterization were related to increased likelihood of receiving

catheterization (OR=1.45; 95% CI, 1.02, 2.06). Interestingly, the addition of social contextual variables into the model resulted in the race variable becoming non-significant (OR= 0.46; 95% CI, 0.17, 1.29).

DISCUSSION

The purpose of this study was to examine the role of race and social contextual variables on cardiac catheterization use among patients who were recommended to receive the procedure. Results from the models that adjusted for demographic and clinical/treatment variables indicated that Blacks/African Americans were less likely to receive catheterization than Whites. However, this relationship became non-significant when social contextual variables were added to the model, suggesting that social contextual variables might play an important part in the relationship between race and the receipt of recommended cardiac catheterization, among those referred for the procedure.

Our findings are consistent with the notion that social contextual variables can influence the acceptability of medical treatments.[21] Three of the social contextual variables were significantly related to the likelihood of receiving catheterization. First, knowing somebody who had cardiac catheterization was related to increased likelihood of receiving the recommended treatment. This is consistent with previous qualitative findings that knowing somebody who had a procedure influenced cardiac patients' treatment decision making.[3] Second, having family members who encouraged the patient to undergo cardiac catheterization was related to an increase in the likelihood of actually undergoing the procedure. Again, this finding supports previous findings indicating that family members play an important role in cardiac treatment decisions.[3,22] Finally, overall social support was related to increased likelihood of receiving catheterization. This finding is similar to previous research that suggests that social support is related to less aversion to invasive procedures among Blacks/African Americans and Whites.[21]

Interestingly, none of the clinical variables included in our model were related to the receipt of cardiac catheterization. This finding may, however, be due to the homogeneous nature of the sub-sample we examined. All of the patients in our sample were recommended to have cardiac catheterization by their physician. Thus, it is likely that the clinical characteristics of the patients were already considered by the physician prior to recommending catheterization, thus resulting in less variability in clinical variables compared to the parent sample.

The reported results should be interpreted in the context of the study limitations. First, our sample consisted of male veterans using VA care, and the results may not generalize to the general population. Second, although the items were from established measures or were constructed based on findings from focus groups,[23] a number of the social contextual variables were single items, which may limit their reliability and validity. Third, the reasons for the patient not receiving the recommended procedure are unknown. Fourth, the study was conducted within the equal-access VA health care system, thus perhaps limiting the generalizability of the findings to the broader health care system where cost is a greater consideration. Fifth, our sample did not include other minority groups (e.g., Hispanic/Latinos) due to the focus of previous literature on differences between Whites and Black/African Americans and the lack of resources to recruit a sufficient number of Hispanic/Latino patients, thus limiting the study generalizability. Finally, we did not include physician characteristics in our model because we chose to focus primarily on individual-level factors that are related to the receipt of recommended care, and

we also had only limited data on physician characteristics. Factors such as communication skills, years of practice, and patient volume (which we did not assess) might influence patients' decisions to undergo certain procedures.

Despite these limitations, the results of this study have implications for the care of patients who are recommended to receive cardiac catheterization. First, our results indicate that physicians should consider the social context in which patients make treatment decisions, and when facing resistance from patients to adhering to recommendations, to explore the possible negative influences of the patient's social system. For example, physicians could ask patients if family and friends are encouraging a particular decision or behavior or if they know anybody who had a similar procedure. Second, the findings suggest that race differences in the likelihood of undergoing a recommended procedure may be, at least in part, due to social contextual variables, suggesting that clinical treatment decision making processes might capitalize on social contextual variables to encourage patients to have needed procedures. For example, encouraging and assisting family members to talk to patients about the benefits of cardiac catheterizations could increase the chances that the patient follows physician recommendations for such procedures. For example, group interventions involving the patient and his or her family could focus on the benefits of a particular procedure and effective communication techniques for discussing medical decisions (e.g., discuss concerns, treatment values). Likewise, the finding that knowing somebody who has undergone cardiac catheterization increased the likelihood of having the procedure suggests that perhaps pairing patients with similar others who have had the procedure (e.g. peer health educators) could maximize the likelihood of the patient feeling more comfortable with the procedure and thus deciding to have the procedure him or herself. This might be particularly important among Black/African Americans because, according to our data, they are less likely to have family or friends who have undergone the procedure.

CONCLUSION

Despite numerous efforts to understand race differences in cardiac care, they remain persistent and widespread. Identifying correlates of receiving recommended care could reduce these disparities and maximize the likelihood that patients undergo recommended cardiac procedures. Our results suggest that social contextual factors are related to the likelihood of receiving recommended care and that interventions aimed at this dimension may help to reduce race differences in the receipt of recommended care. Future research is needed to verify these findings and to identify specific modifiable targets for interventions aimed at increasing the likelihood of patients receiving recommended cardiac care.

Predictors of Timely Follow-Up After Abnormal Cancer Screening Among Women Seeking Care at Urban Community Health Centers

Tracy A. Battaglia, MD, MPH[1]; M. Christina Santana, MPH[1]; Sharon Bak, MPH[1]; Manjusha Gokhale, MA[2]; Timothy L. Lash, DSc[3]; Arlene S. Ash, PhD[4]; Richard Kalish, MD, MPH[5]; Stephen Tringale, MD[6]; James O. Taylor, MD[7]; and Karen M. Freund, MD, MPH[1]

BACKGROUND: We sought to measure time and identify predictors of timely follow-up among a cohort of racially/ethnically diverse inner city women with breast and cervical cancer screening abnormalities. **METHODS:** Eligible women had an abnormality detected on a mammogram or Papanicolaou (Pap) test between January 2004 and December 2005 in 1 of 6 community health centers in Boston, Massachusetts. Retrospective chart review allowed us to measure time to diagnostic resolution. We used Cox proportional hazards models to develop predictive models for timely resolution (defined as definitive diagnostic services completed within 180 days from index abnormality). **RESULTS:** Among 523 women with mammography abnormalities and 474 women with Pap test abnormalities, >90% achieved diagnostic resolution within 12 months. Median time to resolution was longer for Pap test than for mammography abnormalities (85 vs 27 days). Site of care, rather than any sociodemographic characteristic of individuals, including race/ethnicity, was the only significant predictor of timely follow-up for both mammogram and Pap test abnormalities. **CONCLUSIONS:** Site-specific community-based interventions may be the most effective interventions to reduce cancer health disparities when addressing the needs of underserved populations. ***Cancer*** **2010;116:913–21.** © *2010 American Cancer Society.*

Despite increasing gains in cancer care,[1] disparities in cancer outcomes are well documented for racial/ethnic minorities and those of low socioeconomic status.[2] In Massachusetts, non-Hispanic black women have higher mortality from breast cancer than their white counterparts (35.5 and 23.3 per 100,000, respectively).[3] The age-adjusted cervical cancer incidence rates in Massachusetts are 5.8 per 100,000 for white women, 9.2 for black women, and 13.1 for Hispanic women.[4] Differences in access to care along the entire cancer care continuum, from screening through diagnostic care to treatment and survivorship, and barriers to using otherwise accessible care, may contribute to these disparities.

Parity in receipt of cancer screening has been achieved in many settings, including Massachusetts.[5] The Centers for Disease Control-funded National Breast and Cervical Cancer Early Detection Program provides millions of dollars annually to ensure that those most at risk have access to breast and cervical cancer screening.[6] However, the prevention potential of cancer screening requires timely diagnostic follow-up once an abnormality has been detected. Delays in diagnosis and treatment as little as 3 months have been shown to increase recurrence[7] and reduce survival rates.[8,9] The belief that these delays contribute to cancer disparities is evident in the emergence of innovative programs that aim to reduce delays in receipt of cancer care services. In 2005, the National Cancer Institute's Center to Reduce Cancer Health Disparities and the American Cancer Society funded 9 programs to participate in a Cooperative Group (the Patient Navigation Research

Program)[10-12] to evaluate patient navigation interventions to reduce time to diagnosis and treatment for at-risk underserved populations with abnormal cancer screening or newly diagnosed cancer.

The time it takes to complete diagnostic evaluation varies widely, with the uninsured or underinsured and racial/ethnic minorities often having the longest delays.[13-18] Relevant literature is limited by a lack of consistency in reported outcomes. Most studies are small, limited to a single site of care, and include diverse socioeconomic strata. Therefore, we sought to describe delays in receipt of diagnostic services for abnormal mammography and Papanicolaou (Pap) test screening among inner city women seeking care at 6 community health centers in Boston, which serves as the baseline cohort for the Boston Patient Navigation Research Program. These centers serve a high proportion of the city's racial and ethnic minority populations and those of lower socioeconomic status.

MATERIALS AND METHODS

Study Design

This study was conducted to provide baseline estimates of time to diagnostic resolution for a prospective multisite intervention study, the Boston Patient Navigation Research Program. One of 9 groups in the national Patient Navigation Research Program Cooperative Group,[10-12] the Boston Patient Navigation Research Program partnered with 6 independent community health centers (CHCs) in Boston to perform the study. Concurrent baseline data were collected via retrospective medical chart review to determine time to diagnostic resolution for women with mammogram and Pap test abnormalities. The Boston University Medical Center Institutional Review Board reviewed and approved this study.

Study Population

Eligible subjects for the baseline Patient Navigation Research Program cohort included adult women with an abnormality detected by a screening Pap test or mammogram performed between January 1, 2004 and December 30, 2005 at 1 of the 6 CHCs. Women were excluded if they were pregnant or younger than 18 years of age at the time of their abnormality. Eligible mammography results included any Breast Imaging Reporting and Data System (BIRADS) score indicating need for follow-up (BIRADS 0, 3, 4, and 5). Eligible Pap test results included any cellular abnormality indicating need for follow-up. These include atypical squamous cells of undetermined significance positive for human papillomavirus (ASCUS/HPV+), low-grade squamous intraepithelial lesion (LGSIL), high-grade squamous intraepithelial lesion (HGSIL), and carcinoma. All subjects with high-grade abnormalities were included (BIRADS 4, 5; HGSIL), and a random sample of low-grade abnormalities (BIRADS 0, 3; ASCUS/HPV+; LGSIL) were used to reach a sample of approximately 100 screened-positive women per site. At sites with fewer than 100 eligible cases, all eligible subjects were included.

Data Collection

Chart abstraction began in July 2006. If an abnormality had not reached diagnostic resolution by the time of abstraction, the patient's chart was reviewed again, if necessary, at least 365 days after the index event to ascertain resolution. The majority of the abstraction was completed using the electronic medical record; occasionally, missing clinical data needed to be abstracted from the paper chart (approximately 4%). One of 2 authors (M.C.S., S.B.) then reviewed data abstraction forms for completeness, accuracy, and internal consistency, and then entered the data into a secure, password-protected study database.

Study Variables

Variables were selected based on both 1) availability in the medical record and 2) consistency with the data dictionary developed by the Design and Analysis Committee of the National Cancer Institute Patient Navigation Research Program, to enable future comparisons with data from other Patient Navigation Research Programs.[12]

Independent Variables

Race/Ethnicity was documented in the electronic medical record as mutually exclusive response values: White, Black/African American, Asian, Native Hawaiian/ Pacific Islander, Native American/ Alaskan Native, Hispanic Latino, or Other. With the exception of White, Black, and Hispanic, the remaining race categories were collapsed into Other because there were too few subjects in the individual racial categories to yield meaningful analyses. For individuals in >1 category, only the first of Hispanic, Black, White, or Other (in that order) was used. Age was calculated from month and year of birth to the date of the screening test. Different age categories were used for the 2 screening populations; each screening population was separately categorized into 1 of 4 clinically relevant age groups. Primary Language was categorized as English, Spanish, or Other. Primary care status was determined by the presence of a named physician appearing in

the electronic medical record. Primary and secondary insurance as documented in the electronic medical record were used to create the following 3 mutually exclusive categories: No Health Insurance, Publicly Financed Health Insurance Only (Medicare and/or Medicaid as sole insurers), or Some Form of Private Health Insurance.

Outcome Variables

Our primary outcome of interest was time from index screening abnormality to diagnostic resolution. *Diagnostic resolution* was defined as definitive tissue diagnosis (biopsy with pathology report) or clinical evaluation (such as colposcopy) indicating no further need for evaluation, in concordance with the Patient Navigation Research Program.[12] Clinical evaluation was included to account for variation in clinical practices. Because of the variability in the number of days to resolution, and the likelihood of outliers that would result in skewed data, we censored this outcome at a maximum of 180 days for outcomes analyses. Because there are clinical implications to delays as short as 90 days, the authors felt that a 180-day cutoff for timely resolution has adequate clinical significance.[19,20] Subjects were categorized as having timely resolution if their diagnostic resolution occurred within 180 days from the index abnormality. For subjects eligible because of a BIRADS 3 result, the earliest date for resolution or "time 0" began 6 months from the date of the index abnormality, because clinical practice guidelines for follow-up call for a repeat mammogram 6 months after the index abnormality.[21]

Data Analysis

Subjects with abnormal mammogram and Pap tests were analyzed separately. In addition to having 2 different clinical screening programs, the 2 study populations differed markedly by age, racial/ethnic distribution, and proportion with a final diagnosis of cancer. Results are presented in parallel here to provide the opportunity to see whether particular CHCs are consistently better (or worse) than others on both types of cancer screening follow-up.

Descriptive statistics were performed to report the sociodemographic characteristics of the 2 study populations, and to determine median time to resolution and the rate of resolution at different time cutoffs. We calculated *P* values within CHC sites using analysis of variance for continuous variables and chi-square for categorical variables.

Univariate Cox proportional hazard ratios (HRs) were generated to test the association of each subject characteristic with "timely resolution," such that larger hazards ratios are associated with shorter time to resolution. For our multivariate analysis, we predicted timely resolution using Cox-proportional hazards modeling. In the final models, we included only those categorical variables for which the group had a significant *P* value ($<.05$) under a univariate Cox model. The CHC site with the largest study enrollment was chosen as the referent group in both cohort regression models for ease of comparison. All analyses were conducted using SAS 9.1 (SAS Institute, Cary, NC). A 2-sided *P* value $<.05$ was considered statistically significant for reporting associations. We hypothesized that systems issues were extremely important, that is, CHC site was a key explanatory variable, not a confounder. To see if nesting with CHCs had confounded the relationship between patient factors (which differed substantially across CHCs) and timely resolution, we also performed regressions treating CHC as a hierarchical clustering variable. Because these analyses did not change any of our findings, they are not reported. Thus, we did not conduct analyses within strata as defined by CHC site.

RESULTS

A total of 997 women were included in the study (523 with mammogram and 474 with Pap test abnormality). Tables 1 and 2 display subject characteristics by CHC site for mammogram and Pap test subjects, respectively. The different age distributions for each cohort reflect recommended screening guidelines for that cancer site. For both screening groups, the majority were nonwhite, with 19% to 27% Hispanic, 33% to 34% black, and 11% to 14% other. Less than 1/3 had private health insurance. In each screening group, about 1/3 spoke a language other than English as their primary language; Spanish was the most common non-English language spoken (about 15%). The majority of screening abnormalities were low grade in their suspicion for cancer, including BIRADS 0 (67%) and BIRADS 3 (25%) for mammogram and LGSIL (87%) for Pap test subjects.

Subjects across CHCs differed significantly on all demographic characteristics, reflecting the singular populations specific to the communities they serve. For example, the proportion of black subjects ranged from 3% to 88% across the 6 CHCs. Those sites with largely white populations, as demonstrated by Health Center D, which had 92% white subjects, also had the lowest rate of private health insurance (9%), demonstrating a socioeconomically disadvantaged group. Although the data are not

PNRP indicates Patient Navigation Research Program; BIRADS, Breast Imaging Reporting and Data System.
[a]Each *P* value is from a chi-square test for independence between the distribution of the row categorical variable and the community health center site.
[b]Any race other than Hispanic, black, or white. Due to differences in race/ethnicity reporting, numbers for collapsed racial/ethnic categories are unavailable. Assignment is to 1 category only, with each category dominating the category below it.
[c]Any language other than English or Spanish. Includes Albanian, Arabic, French, Greek, Italian, Polish, and Portuguese.

shown here, we know that this CHC serves a largely immigrant, Albanian population.

During the 1-year of follow-up, 20 breast and 4 gynecological cancers were diagnosed from the abnormal screening tests. Most cancers occurred in patients whose index abnormality was high grade, including BIRADS 4 or 5 on mammography (11 breast cancers), and carcinoma on Pap test (all 4 gynecologic cancers). The remaining breast cancers occurred in women with a low-grade index mammogram result, including BIRADS 0 (8 cancers) and BIRADS 3 (1 cancer).

Time to diagnostic resolution by screening abnormality is displayed in Table 3. Overall, median time to resolution was shorter for mammogram abnormalities compared with Pap test abnormalities (median Day 27 vs Day 85, respectively). Ninety-two percent of all mammogram abnormalities achieved diagnostic resolution by 180 days, compared with only 65% of Pap test abnormalities. However, almost all abnormalities were resolved within 12 months (97% of mammogram and 93% of Pap test abnormalities). Time to resolution differed by screening abnormality; subjects with high-grade mammogram lesion (BIRADS 4,5) had the longest median time to resolution (36 days), followed by BIRADS 0 (28 days). This same pattern was not observed for high-grade Pap test abnormalities; HGSIL had the shortest time to resolution (median Day 56) compared with the lower grade Pap test lesions ASCUS/HPV+ and LGSIL (median Day 89 and Day 84, respectively). We found little variability across CHCs in the time to diagnostic resolution for a breast abnormality (data not shown). Median time to resolution ranged from 24 to 30 days across CHCs. Minimal increase in proportion of resolved abnormalities was noted beyond 6 months for abnormal mammography screening; increases in diagnostic resolution rates from 6 to 12 months across CHCs ranged from 0% to 8%. In contrast, resolution of Pap test abnormalities was more variable across CHCs, with a median time to resolution range of 59 to 181 days, with as many as

Pap indicates Papanicolaou.
[a]Each *P* value is from a chi-square test for independence between the distribution of the row categorical variable and the community health center site.
[b]Any race other than Hispanic, black, or white. Due to differences in race/ethnicity reporting, numbers for collapsed racial/ethnic categories are unavailable. Assignment is to 1 category only, with each category dominating the category below it.
[c]Any language other than English or Spanish. Includes Arabic, Irish, Polish, and Portuguese.
[d]Includes Pap test results: atypical squamous cells of undetermined significance/human papillomavirus+ and low-grade squamous intraepithelial lesion.
[e]Includes Pap test results: high-grade squamous intraepithelial lesion, carcinoma.

an additional third of diagnostic resolution completed between 181 and 365 days after the index abnormality. Examination of differences in race showed greater variation by CHC than by racial category (data not shown).

Tables 4 and 5 present the univariate and multivariate findings from the Cox proportional hazard models predicting timely resolution for mammogram and Pap test abnormalities, respectively. Univariate analysis of subjects with abnormal mammograms found that CHC and BIRADS designation were significantly associated with timely resolution, but neither composite variable was statistically significant in the multivariate (Table 4). However, there were still intergroup differences, with CHC C (HR, 1.56; confidence interval [CI], 1.02-2.38) and CHC F (HR, 1.41; CI, 1.02-1.95) more likely to have timely resolution compared with referent group CHC A, and BIRADS 0 abnormalities less likely to have timely resolution (HR, 0.79; CI, 0.64-0.98) in comparison to BIRADS 3 abnormalities.

Univariate analysis of subjects with abnormal Pap tests found CHC, race, insurance status, and language to be significantly associated with timely resolution (Table 5). In the multivariate model, CHC was the only composite variable predicting timely resolution ($P<.001$). Intergroup differences found 3 sites, CHC C (HR, 0.39; CI, 0.24-0.64), CHC E (HR, 0.53; CI, 0.35-0.81), and CHC F (HR, 0.40; CI, 0.26-0.62), significantly less likely to have timely diagnostic resolution compared with referent group CHC A. In addition, although insurance status was not significant as a composite predictor, those with no health insurance (HR, 0.71; CI, 0.51-0.98) were less likely to have timely follow-up compared with those with private insurance.

DISCUSSION

This study describes delays in diagnostic resolution after an abnormal breast or cervical cancer screening test among a representative population of primarily minority, urban

Table 3. Uncensored Time to Resolution by Type of Screening Abnormality in the Boston PNRP Baseline Cohort

Abnormality	No.	Median Days to Resolution (Q1, Q3)	% Resolved at 6 Months	% Resolved at 12 Months
Mammogram		27		
All	523	27 (15, 52)	92	97
BIRADS 0	352	28 (20, 56)	92	97
BIRADS 3	130	11 (2, 37)	89	94

High grade	60	56 (34, 175)	65	92

PNRP indicates Patient Navigation Research Program; Q, quartile; BIRADS, Breast Imaging Reporting and Data System.

women from a homogeneous socioeconomic strata most at risk for adverse cancer outcomes. The diversity in race/ethnicity across the 6 CHCs is typical of the heterogeneity of populations who receive healthcare at urban safety net institutions.[22-24] After a full year of follow-up, diagnostic resolution for all cancer screening abnormalities reached over 90%; however, significant delays existed in those screening abnormalities most likely to lead to a breast cancer diagnosis. Site of care, rather than any sociodemographic characteristic of individuals including race/ethnicity, was the only significant predictor of delay in both cancer screening groups.

We found that any racial/ethnic differences in timely diagnostic resolution were explained by differences in site of care, suggesting that observed differences in timely follow-up may be primarily because of systems issues within each CHC rather than differences in the populations served. These findings are in contrast to much of the published literature, which repeatedly report minority race/ethnicity to predict delays in diagnostic care.[8,13,15,16,18,25-27] This inconsistency may be explained by the homogeneity in socioeconomic status of this cohort, as suggested by the low rates of private health insurance, even among white subjects—a factor that often confounds racial comparisons. Comparisons to this literature are thus limited by differences in study populations, such that many published studies include diverse socioeconomic strata with various methods of controlling for socioeconomic status.[8,15,16] One study did identify location of care as an important determinant of timely follow-up[16]; however, another study including exclusively uninsured and underinsured women did not include such analyses.[13]

In our study, CHCs with more timely resolution outcomes for a cancer screening test often had delayed resolution for the other cancer screening test. This reinforces the presence of systematic issues within CHCs such that a CHC may have systems to address a particular screening disease, but lack resources for another screening disease. This difference may reflect resource constraints of CHCs and how they prioritize their population's healthcare needs. Although each of the 6 CHC sites had similar resources, such as on-site screening mammography and colposcopy services, programmatic and staffing differences surely existed yet were not measured. Observed differences may reflect systems put in place to reach patients who are at highest risk for delayed follow-up (eg, systems tailored to enhance follow-up of cervical cancer screening abnormalities). The same CHC may not be equipped to handle the systems issues for an older population of breast screening abnormalities.

An alternative explanation for differential outcomes by cancer screening site may be inherent differences in the clinical care for breast and cervical cancer screening. Women screened for breast cancer are willingly participating with forethought; the woman must come to the radiology facility, usually after having made an appointment. This may even be reinforced by the media attention paid to breast cancer screening. In contrast, cervical cancer screening may happen during another healthcare or family planning visit, and may not have been purposeful. In fact, the literature shows improved adherence with cervical cancer screening in vulnerable populations when the screening is done during urgent care visits,[28] yet finds longer delays in follow-up care after screening is done in these urgent care settings.[29]

Finally, subjects across CHCs may differ on their perceptions of cancer risk, which could affect their timely resolution of cancer screening. Although some studies

have found differences in the perception of cancer risk in the different ethnic populations,[30] survey data from the same health centers failed to identify differences in cancer risk perception (T. A. Battaglia et al, unpublished data).

We found sociodemographic characteristics of study subjects to differ substantially across CHCs, reflecting the sociocultural differences among populations served at health centers within the same zip code. Even within CHCs, we found differences in sociodemographic characteristics for the 2 cancer screening populations, reflecting generational shifts in the community populations given the changing composition of modern cities and immigration patterns. These findings are particularly important given the emerging role of the community health center model in caring for the country's most vulnerable populations.[22-24,31] Our findings highlight the potential diversity both across and within CHCs, underscoring the need to understand the specific sociodemographics of the populations served.

Well over 90% of our subjects achieved diagnostic resolution, supporting the Institute of Medicine's 2002 recognition of the importance of CHCs in increasing access to care and in improving health outcomes for all patients, especially minorities.[32] Our findings also support the notion that absence of racial disparities may be related to CHCs' culturally sensitive practices and community involvement—features that other primary care settings may lack—and speaks to the success of CHC

models in improving health outcomes for these most vulnerable patients.[23,33,34]

It is important to note that we found the longest delays in follow-up occurred among those most likely to be diagnosed with breast cancer (BIRADS 0, 4, or 5), although this was not true for Pap test abnormalities. This may reflect inherent differences in perception of meaning for different cancer screening abnormalities, including fear of possible cancer. Alternatively, it may reflect system issues in accessing timely breast imaging. Although there is no consensus regarding how long a delay ultimately impacts outcomes, it is clinically feasible that these delays may be a mechanism for the persistent gap in cancer outcomes for vulnerable populations. As such, they speak to the need for community-based interventions targeting such at-risk groups. Patient navigation, an emerging model to address cancer health disparities, is an example of a promising community-based approach to address this gap.[11,12]

This study has several limitations, principally that data were collected by retrospective chart review at a single institution for each subject. Specifically, we were limited by CHC record keeping for the years 2004 through 2006; therefore, subjects who achieved diagnostic resolution outside the system will be misclassified as unresolved. In addition, other site-level measures, such as specific funding resources for site-specific cancer programs, were not available from the medical record review. Demographic information was collected at the time of chart abstraction, whereas the abnormality had occurred earlier; thus, for example, our insurance information may not reflect the status at the time the abnormality occurred. We are unaware of any major changes to healthcare coverage in the state during this time period. Provider-level cluster analyses were not performed, as the study sites were not provider-specific systems.

Conclusions

This study found that delays in diagnostic resolution after an abnormal screening test in an urban safety net system are most strongly associated with site of care. Our data support the need for community-based interventions, such as patient navigation, which are culturally targeted, to close the gap in cancer health disparities.

CONFLICT OF INTEREST DISCLOSURES

Editorial

The Clock Is Ticking: The Case for Achieving More Rapid Control of Hypertension

Dan R. Berlowitz, MD, MPH;[1,2] Stanley Franklin, MD;[3]

Start low, go slow for many years has been the paradigm guiding drug treatment of hypertension. Patients start on low doses of a single medication; if control is not achieved the dosage is gradually increased or additional medications are started. Yet studies persistently show that by this method the majority of patients with hypertension do not achieve adequate blood pressure control.[1] While there are many reasons, including patient nonadherence with recommended therapies and resistant hypertension,[2,3] a growing literature highlights the role of therapeutic inertia.[4,5] Consistent with the *go slow* paradigm, patients with elevated blood pressures are seen repeatedly by clinicians but therapy is not intensified. As a result, many patients with inadequate blood pressure control are treated with only one or two antihypertensive medications, often at low dosages, for prolonged periods.

The evidence now suggests that to improve cardiovascular outcomes, we require a new paradigm that emphasizes rapid achievement of blood pressure control.[6] We believe that central to this paradigm should be an explicit expectation of the timeframe in which blood pressure control should be achieved. While existing guidelines increasingly emphasize the use of drug combinations to achieve more rapid control, they are surprisingly quiet on this issue of time to control. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends: "once antihypertensive drug therapy is initiated, most patients should return for follow-up and adjustment of medications at approximately monthly intervals until the blood pressure goal is achieved," and that more frequent visits will be necessary for patients with stage 2 hypertension.[1] Recently published guidelines from the European Society of Hypertension and European Society of Cardiology make no reference to the time between follow-up visits or to achieve control.[7] We now argue for an explicit expectation that anticipates blood pressure control within 3 months of initiating therapy.

BENEFITS OF ACHIEVING RAPID BLOOD PRESSURE CONTROL

Recent hypertension clinical trials with major cardiovascular endpoints have highlighted two key facts about blood pressure control. First, early differences in achieved blood pressures among comparative treatment arms, even when managed by experienced clinician-investigators, are not easily eliminated despite continuing efforts to reach specified targets. Thus, initial failure to treat aggressively makes it less likely that control will ever be achieved. Second, the resulting small differences in achieved blood pressures account for significant differences in clinical event rates.

One strong example of this was the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), in which high risk hypertensive patients randomized to diuretic-based treatment had persistently lower blood pressures than those starting with either an angiotensin-converting enzyme (ACE) inhibitor or a calcium channel blocker.[8] The resulting blood pressure inequalities among the treatment groups, which were most prominent in the early study months, remained throughout the 5 year trial despite repeated exhortations to investigators to seek blood pressure control.

The effects on major cardiovascular endpoints of the speed and completeness of blood pressure control were explored in the Valsartan Antihypertensive Long-Term Use Evaluation (VALUE) trial.[9] In a cohort of hypertensive patients at high cardiovascular risk, a calcium channel blocker achieved greater blood pressure reductions in the early part of the study than an angiotensin receptor blocker, which persisted for the 5-year duration of the study. This difference in achieved blood pressure appeared to account for significant differences in clinical events; when patients from the two study groups were matched on the basis of identical achieved blood pressures as well as other key clinical and demographic features, there were no endpoint differences between the treatments.[10] The importance of achieving systolic blood pressure control (<140 mm Hg), regardless of drug assignment, within the study's initial 6-month treatment titration period was also demonstrated. Subsequent fatal and nonfatal cardiovascular events were sharply lower, with a hazard ratio of 0.75 in patients achieving blood pressure control as compared with those who did not.[9] Indeed, there was an indication that blood pressures achieved by just 1 month of study treatment were predictive of outcomes during the following 5 years.

Another high profile hypertension outcomes study affected by early blood pressure differences between treatment groups was the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) in which the amlodipine-perindopril arm had a 5.9/2.4 mm Hg lower blood pressure at 3 months compared to atenolol-bendroflumethiazide.[11] This trial was stopped earlier than planned when the safety committee noted that mortality and other endpoints were higher in patients randomized to β-blocker/thiazide treatment than in those randomized to calcium channel blocker/ACE inhibitor treatment. At least part of these differences in event rates could be explained by the differences in blood pressure control.[11]

SAFETY OF RAPID BLOOD PRESSURE CONTROL

A concern when starting antihypertensive therapy is an excessive fall in blood pressure. Certainly, this was an issue with the drugs used 3 or 4 decades ago that worked primarily by interrupting the sympathetic nervous system. The traditional injunction to *start low, go slow* was appropriate with drugs that could produce dizziness and postural hypotension. This concern, however, is less justified with modern drugs. For instance, in the registration studies performed with the combination of irbesartan and hydrochlorothiazide in patients with severe hypertension (baseline diastolic blood pressures >110 mm Hg), there were few symptomatic complaints when therapy was started with this combination.[12] In only 3 out of 328 patients was hypotension observed, and even then only after protocol-mandated up-titration to the maximum dose in patients who had already achieved major blood pressure reductions with the starting dose. A further study in patients with less severe hypertension provided additional reassurance.[13] Despite lower baseline blood pressure values, there was a similarly low incidence of observed hypotension, again only after mandated titration to the maximum combination dose. A recent report of a clinical trial in which hypertensive patients were exposed to initial therapy with maximum doses of a calcium channel blocker/angiotensin receptor blocker combination has provided further confirmation of safety.[14]

Safety concerns may be especially great in elderly populations with isolated systolic hypertension—a group with the lowest rates of blood pressure control and the greatest absolute benefit with effective blood pressure reduction.[1] Although lower initial medication doses may sometimes be indicated to minimize symptoms in elderly hypertensive patients, ultimately most will require and tolerate standard doses and multiple drugs to reach blood pressure targets. In the Hypertension in the Very Elderly Trial (HYVET) (≥80 years), combination therapy was used in almost 3 out of 4 participants because of the difficulty in achieving goal blood pressure even though the target systolic blood pressure was <150 mm Hg, and side effects were no more frequent than in the control group.[15] There are no randomized clinical trials to date supporting lowering systolic blood pressure below 140 mm Hg in elderly patients.[16]

Monotherapy with a diuretic, as recommended in past and present guidelines for initiation of therapy, may in fact create greater safety issues than

starting with a combination. Diuretics can produce hypovolemia, creating a risk of acute hypotension when blockers of the renin-angiotensin system are later added. Thiazides as single agents can also cause unwanted metabolic changes like hypokalemia or hyperglycemia, which are at least partly prevented by concomitant treatment with renin-angiotensin system blockers.[17]

FEASIBILITY OF ACHIEVING BLOOD PRESSURE CONTROL WITHIN 3 MONTHS

Results from early clinical trials may have misleadingly conveyed the impression that blood pressure control cannot be achieved despite years of therapy. In ALLHAT, control was achieved in 66% of patients after 5 years of follow-up.[8] However, control rates were only 50% at 6 months and 55% at 1 year. Moreover, even in the rigorous setting of this clinical trial, failures to intensify therapy despite inadequate control were frequent and it was judged "very likely that better blood pressure control rates could have been achieved if therapy were intensified more consistently for persistent systolic blood pressures $\geq$140 mm Hg."[8]

Higher rates of control in shorter time periods have been seen in more recent clinical trials. For example, a recent review of 9 clinical trials highlighted that among hypertensive patients with diastolic blood pressures between 95 and 110 mm Hg, control (<140/90 mm Hg) was achieved within 8 weeks for 74.6% of patients initiating valsartan 160 mg plus hydrochlorothiazide and in 84.8% starting valsartan 320 mg plus hydrochlorothiazide, without any additional titrations.[18] Among patients with uncontrolled hypertension on monotherapy in the Irbesartan/HCTZ Blood Pressure Reductions in Diverse Patient Populations (INCLUSIVE) trial, use of a combination angiotensin receptor blocker/thiazide diuretic with a single dose titration resulted in overall control rates of 69% in 18 weeks; control rates were considerably higher in the 70% of the study population without diabetes and its stricter definition of blood pressure control.[19] In the Avoiding Cardiovascular Events in Combination Therapy in Patients Living With Systolic Hypertension (ACCOMPLISH) trial, a comparison of the two drug combinations benazepril plus hydrochlorothiazide and benazepril plus amlodipine, with dose increases of the study medications after 1 and 2 months of therapy, control rates in excess of 70% were achieved by 3 months.[14] With additional medication increases after 3 months, control rates in the US cohort in ACCOMPLISH reached 78% by 6 months.

Common to these newer trials is the initiation of therapy with two antihypertensive drugs and mandated dose increases if control is not achieved within several weeks. The need for initial combination therapy is particularly important for grade 2 hypertension and in patients with diabetes and chronic renal disease, with its lower target goal of <130/80 mm Hg.[1] Even with combination therapy, achieving blood pressure control in 3 months or less may be difficult. It will require multiple visits, as often as every 2 weeks, in order to monitor blood pressure and the impact of therapy intensification. This becomes practical and safe as forced titration experience, such as the irbesartan/thiazide combination studies to rapidly control severe and moderate hypertension, have shown that approximately 60% of the blood pressure reduction can be obtained within 2 weeks of initiating therapy.[12,13]

IMPLICATIONS OF AN EXPLICIT EXPECTATION FOR RAPID BLOOD PRESSURE CONTROL

Care for hypertensive patients will need to be changed to meet this expectation. Along with the broader use of combinations, physician practices will need to be organized so as to allow the rescheduling of hypertensive patients on intervals as short as 2 weeks. Home self-measurement of blood pressure will be especially useful for assessing responses to antihypertensive medications, improving patient adherence, and helping to diagnose white-coat effects and masked hypertension[20,21]; the former requires restraint in medicating and the latter perhaps more aggressive therapy than indicated by office blood pressure readings.[22,23] A home blood pressure monitor with a graphic display of weekly control rates was associated in one study with more rapid blood pressure control than a standard monitor.[24]

An explicit expectation for blood pressure control within 3 months could have a number of beneficial effects on hypertensive patients. It would likely lead to more rapid and better blood pressure control with resulting reductions in cardiovascular morbidity and mortality. Achieving blood pressure control earlier may reduce the overall need for frequent office visits later, and hence, reduce overall costs. Such an expectation is easily measurable and could be readily incorporated into a national performance measure. Quality improvement efforts focusing on this measure would promote further improvements in care through the audit and feedback of clinicians' practices. However, there also could be detrimental effects. Patients with

hypertension could be overmedicated, although home blood pressure monitoring might minimize this problem. Inclusion as a quality measure may be associated with unintended consequences such as the diversion of resources away from other important aspects of care.[25] Holding clinicians accountable to a 3-month threshold could also penalize clinicians providing excellent care to very difficult to control patients.[26] Groups developing national quality measures will need to carefully balance the benefits and risks of incorporating this expectation into formal measures.

CONCLUSIONS

We believe that the balance of the evidence supports changing the paradigm of hypertension treatment and implementing an expectation that blood pressure control will be achieved within 3 months of starting medication therapy. Such an explicit expectation would help guide clinicians and provide a benchmark for which they could strive. *Start low, go slow* should no longer serve as the model guiding drug therapy of hypertension. To maximize reductions in cardiovascular events, care for patients with severe or complicated hypertension should, right from the start, anticipate the more forceful and frequent interventions now supported by clinical trial evidence. *Move fast, take control* should now guide clinicians' management of hypertension.

Can administrative data identify active diagnoses for long-term care resident assessment?

Dan R. Berlowitz, MD, MPH;[1*] Elaine C. Hickey, RN, MS;[1] Debra Saliba, MD, MPH[2]
[1]Center for Health Quality, Outcomes, and Economic Research, Edith Nourse Rogers Memorial Veterans Hospital, Bedford, MA; and Boston University School of Public Health, Boston, MA; [2]Greater Los Angeles Department of Veterans Affairs Geriatric Research, Education, and Clinical Center and Health Sciences Research and Development Center of Excellence, Los Angeles, CA; and University of California Los Angeles/Los Angeles Jewish Homes Borun Center, Los Angeles, CA

Abstract—Many veterans receive rehabilitation services in Department of Veterans Affairs (VA) nursing homes. Efficient methods for the identification of active diagnoses could facilitate care planning and outcomes assessment. We set out to determine whether diagnostic data from VA databases can be used to identify active diagnoses for Minimum Data Set (MDS) assessments. We evaluated diagnoses being considered for inclusion in MDS version 3.0 and present in at least 15% of a sample of VA nursing home residents. A research nurse following a standardized protocol identified active diagnoses from the medical records of 120 residents. A clinical nurse also identified active diagnoses in 58 of these patients. Inpatient and outpatient diagnoses from the VA National Patient Care Database were identified for the past year. We calculated kappa, sensitivity, and specificity values, considering the nurses' assessments the gold standard. We found that kappa values comparing research nurses and databases were generally poor, with only 8 of the 19 diagnoses having a value >0.60. Levels of agreement between the clinical nurse and administrative data were generally similar. We conclude that VA administrative data cannot be used to accurately identify active diagnoses for nursing home residents. How best to efficiently collect these important data remains uncertain.

Key words: active diagnosis, care planning, Community Living Centers, comorbidity, Minimum Data Set, nursing homes, outcomes data, rehabilitation, risk adjustment, veterans.

INTRODUCTION

Rehabilitation for patients with disabilities is increasingly being provided in skilled nursing facilities [1], now known in the Department of Veterans Affairs (VA) as Community Living Centers (CLCs). Critical to assessing and improving the quality of this rehabilitation care is a comprehensive understanding of resident outcomes [2]. Outcomes data may be used to profile CLCs on the quality of their care and to identify benchmarks for best practices within the entire VA. In the examination of outcomes, risk adjustment helps ensure that any observed variations reflect differences in care rather than differences in patient mix. Risk adjustment for rehabilitation outcomes should incorporate many different patient-mix factors, including sociodemographics, functional status,

cognitive ability, and sensory function [3–4]. A number of studies have also shown that comorbidities are an important patient risk factor to consider when adjusting on rehabilitation outcomes [5–7]. Capturing information on comorbidities will then be essential for the development of an outcomes tracking system for VA rehabilitation patients residing in CLCs.

Information on comorbidities is available on all nursing home residents, including those in VA CLCs, through the Minimum Data Set (MDS). This comprehensive resident assessment system was developed in response to the 1986 Institute of Medicine report on improving care in nursing homes [8] and includes information necessary for care planning. Specific sections address topics such as physical function, cognition, behavior, health conditions, and disease diagnoses. However, concerns have long been raised about the use of MDS data for purposes such as quality assessment and research [9–10]. In part, these concerns have been fueled by questions about the reliability of resident assessments, and studies have shown that the correlation among specially trained nurse assessors on various items may be low [11]. The Disease Diagnoses section of the MDS, which contains information on important comorbidities, has been viewed as especially difficult, in part because of the requirement that only active diagnoses be recorded. This requirement reflects the importance of the MDS in care planning, where knowledge of active diagnoses, as opposed to all diagnoses, is critical. Active diagnoses are defined as those that have a relationship to the resident's current functional status, cognitive status, mood or behavioral status, treatments, monitoring plan, or prognosis. The recently completed Data Assessment and Verification project, performed for the Centers for Medicare and Medicaid Services, identified Disease Diagnoses as one of the most common sections for discrepancies, mostly because of diagnoses that were no longer active being recorded in the MDS.

VA has a wealth of diagnostic data in its National Patient Care Database. Because these data are generated from recent hospital, outpatient, or long-term care encounters between patients and clinicians, they may be an alternate source of information on active diagnoses for use on the MDS. Therefore, as part of a validation of the proposed MDS version 3.0, we examined the correlation between VA administrative data and diagnostic data recorded in the MDS. Specifically, for the MDS data, we used MDS assessments performed by both specially trained research nurses and clinical nurses as part of routine care. These results could help inform the accuracy of VA administrative data and whether it may replace assessments currently performed by clinical nurses.

METHODS

Study Setting and Sample

This study was a part of the larger VA MDS 3.0 pilot testing and validation study funded by the Health Services Research and Development Service. Among the many goals of this study was to improve the accuracy of the diagnostic data collected during MDS assessments. Study participants were from four VA CLCs located in the northeast. At each CLC, residents were selected based on their being scheduled for their routine MDS 2.0 assessment, which is typically done on admission, quarterly, and with significant changes in health status. As an additional exclusion criterion, residents could not be comatose.

Minimum Data Set Assessments

Within 48 hours of the required MDS 2.0 assessment, either of two research nurses completed an additional pilot MDS 3.0 assessment. We used this pilot version of MDS 3.0 to collect information on active diagnoses. The Disease Diagnoses section of the pilot MDS 3.0 is similar to that of the currently used MDS 2.0 in terms of the specific diseases captured. However, a major change is the development of more detailed protocols to describe when a disease is active, where in the medical record this information should be sought, and the time frame to be considered for activity. Thus, it stresses first determining whether the condition is present and then whether it is active. As an example, for heart failure, active disease requires a physician-documented diagnosis of heart failure plus one or more of the following: a physician note indicating active disease; a positive test, such as a chest X-ray, within the past 30 days indicating heart failure; signs or symptoms, such as dyspnea, attributed to heart failure; current medication treatment; or hospitalization for heart failure within the past 30 days. Specific International Classification of Diseases-9th Revision-Clinical Modification (ICD-9-CM) codes were assigned to each MDS 3.0 diagnosis to facilitate comparisons with administrative data.

The trained research nurses conducted a detailed review of medical records to identify active diagnoses. These two research nurses had received extensive training in the use of MDS 3.0 and, in the case of the Disease Diagnoses section, had helped in the development of the criteria used to determine disease activity. Thus, the research nurses may be considered as the "gold standard" assessment. A total of 120 patients were evaluated by the research nurses.

Fifty-eight of these patients also had a pilot MDS 3.0 assessment completed by the clinical team. Typically, these assessments were performed by the MDS coordinator on the unit and were based on the assessor's knowledge of the resident, discussions at team meeting, and review of the medical records. These nurse-assessors had received more limited training in the use of the instrument and could be considered to represent how the assessment would typically be completed in actual clinical practice.

Department of Veterans Affairs Administrative Data

We used the VA National Patient Care Database to collect all ICD-9-CM codes from the year before the MDS 2.0 assessment for the 120 patients. We used ICD-9-CM codes from hospital, outpatient, and long-term care settings. However, we excluded codes from nonclinician visits, such as laboratory or radiology. No diagnostic data were collected from non-VA sources such as Medicare.

Analyses

Separate analyses were performed for the research and clinical nurses. We examined those MDS 3.0 diagnoses present in at least 15 percent of the patients when assessed by any source, whether research nurse, clinical nurse, or administrative data. Two-by-two tables were constructed for the presence or absence of each diagnosis in the nurse assessment and in the VA administrative data. Overall level of agreement between the two data sources was calculated for each diagnosis with use of the kappa statistic. Sensitivity and specificity were then calculated, with the nursing assessment as the gold standard. Thus, sensitivity described what proportion of patients identified by the nurse as having the disease was also identified as having the disease in the administrative data and specificity described what proportion of patients identified by the nurse as not having the disease was also identified as not having the disease in the administrative data.

RESULTS

Nineteen diagnoses were evaluated. For most diagnoses, limited agreement existed between the research nurses and the administrative data (**Table**). In only eight diagnoses did the kappa value equal or exceed 0.60: uncomplicated diabetes mellitus, stroke/transient ischemic attack (TIA), coronary artery disease, chronic heart failure, thyroid disorder, hemiplegia/paraplegia/quadriplegia, asthma/chronic obstructive pulmonary disease, and schizophrenia. For other diagnoses, the level of agreement was generally poor, with a kappa level as low as 0.18 for depression. Results were very similar when clinical nurses were compared with administrative data (**Table**), again with only eight of the diagnoses having kappa values exceeding 0.60. Research and clinical nurses were also similar in terms of which diagnoses they had high and low levels of agreement on with administrative data. The eight diagnoses with the highest kappa values (>0.60) for the research nurses included six diagnoses with the highest kappa values for the clinical nurses. The six diagnoses with low kappa values for the research nurses (<0.40) included the four with the lowest kappa values for the clinical nurses. No clear pattern was evident as to which diagnoses had high or low levels of agreement. Mental health disorders included the diagnoses with the highest kappa value, schizophrenia, and the lowest kappa value, depression.

Sensitivity of administrative data compared with the research nurses varied considerably, ranging from 30 percent for depression to 100 percent for both stroke/TIA and hemiplegia/paraplegia/quadriplegia. Low sensitivity indicates that diagnoses identified by the research nurse as present may not be listed in the administrative data. Specificity, in most cases, was better than sensitivity and varied less, with a range from 77 to 100 percent. High specificity indicates that the administrative data rarely listed diagnoses as present within the past year when the nurses indicated it was absent. Results from the clinical nurses were generally similar to the research nurses.

DISCUSSION

Accurate information on diagnoses is essential in care planning and tracking of outcomes of nursing home residents receiving rehabilitation. Numerous studies have confirmed the validity of the diagnostic data contained in

Table.
Comparisons between administrative data and research and clinical nurses' identification of nursing home residents' active diagnoses. In calculating sensitivity and specificity, we considered nurses as "gold standard."

Diagnosis in Administrative Data	Research Nurse			Clinical Nurse		
	Kappa	Sensitivity (%)	Specificity (%)	Kappa	Sensitivity (%)	Specificity (%)
Arrhythmias (nonatrial fibrillation)	0.31	57	90	0.38	100	86
Coronary Artery Disease	0.65	68	94	0.72	80	91
Chronic Heart Failure	0.60	68	93	0.56	78	88
Hypertension	0.47	74	77	0.46	89	55
GERD/Peptic Ulcer	0.48	54	91	0.68	65	100
Benign-Prostatic Hypertrophy	0.52	57	93	0.59	64	94
Anemia	0.36	48	87	0.38	45	93
Uncomplicated Diabetes Mellitus	0.69	78	91	0.65	100	80
Arthritis	0.36	53	87	0.53	60	91
Stroke/TIA	0.77	100	93	0.90	92	98
Hemiplegia/Paraplegia/Quadriplegia	0.91	100	97	0.71	89	92
Dementia: Alzheimer Disease	0.47	57	96	0.62	100	91
Dementia: Non-Alzheimer Disease	0.37	34	97	0.31	36	92
Asthma/COPD	0.63	68	94	0.63	59	98
Cancer	0.35	80	83	0.59	80	84
Thyroid Disorder	0.67	55	100	0.46	50	96
Anxiety Disorder	0.50	55	95	0.48	50	94
Depression	0.18	30	87	0.20	33	85
Schizophrenia	0.94	94	99	0.85	100	96

COPD = chronic obstructive pulmonary disease, GERD = gastroesophageal reflux disease, TIA = transient ischemic attack.

VA administrative records [12–14]. However, for nursing homes, the MDS requires that the diagnosis be not only present but active. This added requirement has not been previously examined in the VA. Given the difficulties clinical staff have in identifying active diagnoses, we hypothesized that VA administrative data might serve as a useful substitute in the completion of MDS for CLC residents.

Our results did not support this hypothesis. We found that the level of agreement, as reflected by kappa values, was generally low when we compared administrative data and research nurses. Kappa values were greater than or equal to 0.60 for only 8 of the 19 conditions. Tremendous variability was also found in sensitivity and specificity of administrative data, although specificities were generally higher. This suggests that when diagnoses are listed in VA administrative data within the past year, they do reflect conditions that are active. Using a time frame longer than 1 year would be expected to increase the sensitivity and reduce this specificity.

Results were not substantially different when we compared clinical nurses and administrative data. Levels of agreement were often poor, and for only eight conditions was the kappa greater than 0.60. However, perhaps reflecting the fact that information in administrative databases is generally derived from clinicians, specificity remained high.

Relatively few studies have examined whether administrative databases could replace clinicians' assessments on the MDS. In one study of Ontario nursing homes, the MDS often did not include many important diagnoses that had been present in the discharge diagnosis database from the preceding hospitalization [15]. Reasons for these discrepancies were unclear but thought to possibly reflect the incomplete transfer of diagnostic information upon resident transfer between settings. Other studies have either compared different research nurses [11] or compared clinicians' MDS assessments with trained assessors and standard protocols [16–17].

VA administrative data are generally felt to be more comprehensive than databases from other healthcare settings. Thus, it is difficult to imagine that other databases would be better able to identify active diagnoses. Results from this study, then, would be applicable to MDS assessments outside the VA. However, our study did not use the additional diagnostic data available in Medicare

files. Studies have shown that incorporation of Medicare data improves the capture of comorbidity burden in veterans who are dual users. The addition of this diagnostic data contained in Medicare files would be expected to increase sensitivity but reduce specificity; the effect on kappa values would be uncertain. Further studies would be required to determine whether additional diagnoses from Medicare would assist in the accurate identification of active diagnoses within the VA.

Several additional limitations of this study should be noted. We only examined four nursing homes located in the northeast. Results could differ in other locations. Our sample size was also relatively small, so the number of patients per diagnosis was low. Furthermore, several diagnoses from MDS 3.0 were excluded because they were present in less than 15 percent of the sample. We do not know whether administrative data would be better at coding these rare conditions.

While study results highlight that administrative data should not be used for the identification of active diagnoses on the MDS, our results do not suggest how the identification of active diagnoses may be improved. Our assumption is that the research nurses most accurately identified active diagnoses because of their reliance on strict protocols of medical record reviews. Additional training of clinical nurses on completion of the MDS would then be required to ensure the most accurate information on active diagnoses in nursing home residents. However, research nurses could miss important diagnoses because of poor documentation. The Ontario study suggests that improved transfer of data from hospital stays could help improve the identification of MDS diagnoses [15]. Given VA's electronic medical records, we believe a lack of data on transfer is a less likely explanation for our results. Additional studies are clearly indicated.

CONCLUSIONS

The MDS is a valuable tool for VA clinicians, managers, and researchers working with rehabilitation patients in CLC settings. An important aspect of the MDS is the Disease Diagnoses section that provides information essential in care planning and outcomes measurement. Despite the importance of these data, studies have shown that clinical staff poorly identify active diagnoses when completing the MDS [16]. Our results suggest that administrative data cannot substitute for the assessments currently performed by VA clinicians.

Risk Adjustment in Rehabilitation Quality Improvement

Dan R. Berlowitz, MD, MPH,[1,2] and Margaret Stineman, MD[3]

[1]Center for Health Quality, Outcomes and Economic Research, Bedford VA Hospital, Bedford, Massachusetts; [2]Boston University Schools of Public Health and Medicine, Boston, Massachusetts; [3]Department of Physical Medicine and Rehabilitation and the Center for Epidemiology and Biostatistics, University of Pennsylvania, Philadelphia, Pennsylvania

Risk adjustment is an important tool for examining quality and outcomes of care. Considerable work has been accomplished in developing and applying risk adjustment to a variety of health care settings. The knowledge gained from these experiences is increasingly available to help guide clinicians, managers, and policy makers in the area of stroke rehabilitation. Key issues include understanding the purpose of risk adjustment, the unique population being examined, and the specific outcomes of interest. Risk adjustment should also be based on models that have good statistical properties and also make sense to clinicians working in the field. Risk-adjustment systems such as the FIM™- function-related groups (FIM-FRGs) are now being used to monitor the quality of stroke rehabilitation. A specific application of this risk-adjustment system is demonstrated. **Key words:** *quality improvement, quality of health care, risk adjustment, stroke rehabilitation*

Clinicians, managers, and policy makers working in the area of stroke rehabilitation increasingly must address problems that require a comprehensive understanding of patient outcomes. Clinicians are interested in knowing about the quality of their care and whether observed outcomes are better than expected. Managers need to develop quality improvement initiatives and ensure that there are sufficient resources to care for their patients. Policy makers seek new methods to reduce costs and reward clinicians who provide optimal care. To achieve all these things, the characteristics, or case mix, of the population of interest needs to be defined. Without this information, it is often difficult to know whether poor outcomes in a group of patients are due to poor care or to a sicker population.

In the past 30 years, there have been tremendous advances in the knowledge of risk adjustment, the process by which the case mix of patients is described and the information used for predicting or understanding diverse outcomes. The central element of risk adjustment is determining expected outcomes based on intrinsic patient characteristics. To accomplish this, a risk-adjustment model is used that was developed for a specified large group or population, such as all patients in the country with a stroke. The model is then used to determine expected outcomes in a smaller population of interest, such as stroke patients at a particular hospital. Actual outcomes at the hospital may then be compared to these expected outcomes. The outcomes themselves may be clinical outcomes such as mortality or functional recovery. Alternatively, the outcomes may be measures of resource utilization such as expected costs or need for hospitalization. The process by which risk adjustment is performed has been well-defined, and numerous systems have been developed for use in specific circumstances. This large body of knowledge is now available to guide those working in the area of stroke rehabilitation.

What Is Risk Adjustment?

At its simplest, risk adjustment is a process that allows us to compare "apples and oranges." To make fair comparisons of different providers, treatments, or populations on an outcome of interest, we must take into account that some groups will have sicker patients than others. As outcomes studies rarely rely on randomizing subjects to different interventions, risk adjustment is a way to reduce the affects of these confounding factors that may influence the outcome of interest. It is the means of accounting for those patient factors that are

Top Stroke Rehabil 2010;17(4):252–261

doi: 10.1310/tsr1704-252

likely to vary among providers and also affect the outcome of interest. Many different terms are used to describe these patient factors including case mix, patient mix, disease severity, comorbidity, health status, and complexity. Although there are subtle differences in the definitions of many of these terms, they all are similar in conveying a level of risk for a certain outcome.

In considering risk-adjustment approaches for stroke rehabilitation, or any other purpose, Iezzoni[1] has emphasized a series of questions that should be addressed. First is "risk for what?" Approaches to risk adjustment will vary depending on the outcome of interest. Typically, risk adjustment has focused on outcomes such as mortality, cost, or hospitalizations. However, in stroke rehabilitation, functional outcomes such as physical and cognitive performance may be especially important. Thus, the outcome of interest should be explicitly specified.

A second question is "over what time frame?" Outcomes of interest and their predictors are likely to vary dramatically depending on the length of time people are being followed. A simple change, such as looking at 30-day mortality rather than hospital mortality, can alter what is found.[2]

The third question is "for what population?" Different groups will have very different risks for certain outcomes. In looking at mortality, children are obviously very different than adults, whereas the risks of developing many diseases are very different for women and men. In the area of stroke rehabilitation, it may be extremely important to differentiate between ischemic and hemorrhagic strokes, and outcomes, as well as their predictors, will vary in these 2 subpopulations.

The final question is "for what purpose?" When risk adjustment is used to evaluate individual clinicians, especially if important decisions such as credentialing or performance payments are at stake, it is critical that the risk adjustment be credible both from a clinical and statistical perspective. If important dimensions of risk are not captured, clinicians can excuse their poor outcomes by saying that their patients are sicker. In contrast, for outcomes such as capitated payments for health plans, risk-adjustment approaches with only limited statistical performance will often be sufficient.

Risk adjustment should strive to account for all important dimensions of risk. These dimensions of risk could include a wide range of patient-specific characteristics that are associated with an increased (or decreased) risk for the outcome of interest.[1,3] Demographics such as age, sex, and race/ethnicity may be included. Clinical factors might include the principal diagnosis, comorbidities, disease-specific severity, and physiologic derangements. In examining rehabilitation outcomes, baseline functional status is likely to be particularly important. Socioeconomic status, health-related behaviors, and specific attitudes may also be important dimensions of risk. Which of these factors are included in risk adjustment will often depend on the outcome of interest, the range of factors that are clinically believed to be important predictors of that outcome, and the availability of the data of interest. Factors such as age, gender, and comorbidities are often easily available in existing administrative databases, but other dimensions of risk may be more difficult to capture.

A clear clinical conceptualization of the association between individual risk factors and the outcome of interest should always guide risk adjustment. For example, outcomes often vary between different racial/ethnicity groups. Before including race/ethnicity as a risk factor, though, it must be clear as to whether the difference in outcomes is potentially due to inherent genetic factors in different racial/ethnic groups or to external factors such as bias in the health care system. In the later case, inclusion of race/ethnicity during risk adjustment would essentially excuse those providing poor care to certain racial/ethnic groups.[1] Risk adjustment prevents providers from being penalized for worse outcomes among patients with the selected dimensions of risk.

How Is Risk Adjustment Performed?

The simplest approach to risk adjustment would be a stratification in which patients are divided into 2 groups based on a single patient characteristic. The characteristic may be age or type of stroke and would be known to have a large impact on the outcome of interest. Within each stratum, patients would be compared on their outcomes. Although simple, the problem with this approach lies in the multidimensional nature of

risk. There are many different factors that need to be considered when predicting risk for a particular outcome. With stratification, only a single factor is being considered and all others are ignored.

Consequently, multivariate regression models that consider the independent effects of many different risk factors on the outcome are typically used in risk adjustment. These models are developed in very large groups of patients through a process that involves a close collaboration between clinicians and statisticians. Clinicians initially identify potential risk factors based on general medical knowledge and literature reviews. Both bivariate and multivariate statistical techniques are then used to test the associations of the potential risk factors with the outcome. Ideally, the results of this highly iterative process will be a risk-adjustment model that is both clinically credible and has good statistical properties. Based on the model coefficients, an expected rate of the outcome is calculated for each patient.

While the ideal approach to any risk-adjustment project may be to develop a model that is unique to the exact population and outcome being examined, the reality is that this is a very difficult and time-consuming process.[4,5] Consequently, for most purposes, it is not feasible to develop a new model. Instead, it is better to rely on an existing risk-adjustment approach that has been developed for a similar outcome. These "off-the-shelf" systems are often easy to apply and are a much better alternative than the option of not doing risk adjustment. It must be recognized that because they were developed in a different population, these systems are not likely to perform as well in the new setting of interest.[6] Any off-the-shelf system that is being considered for use should be carefully reviewed for purpose of development, variety of previous applications, and its ability to capture important dimensions of risk. Simple fixes to existing systems, such as adding a few variables or recalibrating the model, can often dramatically improve their performance in a new setting.

Examples of Existing Risk-Adjustment Systems

A wide variety of risk-adjustment systems have been developed for many different purposes. Perhaps the most widely used system is diagnosis-related groups (DRGs) that aims to predict hospital costs based on relatively few predictors including the primary diagnosis and age.[7] In predicting cost for nursing homes, resource utilization groups (RUGs) consider a broader group of predictors including functional status.[8] For clinical outcomes, the Acute Physiology and Chronic Health Evaluation (APACHE) has been widely used to predict mortality in intensive care unit patients based on both specific conditions present as well as the extent to which physiologic markers such as blood pressure, pulse, and electrolytes are abnormal.[9]

Some of the most extensive work has been the development of risk-adjustment systems that take advantage of information on comorbidity burden. The Charlson Index has been particularly widely used; it considers 16 different serious comorbidities and assigns weights based on the presence and, in a few situations, the severity of the condition.[10] Although originally developed for predicting 1-year mortality among women with breast cancer, it has been used for a variety of purposes including as a risk adjustor when length of stay and discharge destination for stroke rehabilitation patients have been examined.[11] Increasingly, health services research studies have relied on the Elixhauser measure that provides a method for grouping clinically similar diagnoses into 30 distinct categories, each of which can be examined for associations with the outcome of interest.[12] Several systems are also being used that were originally developed to predict resource utilization and costs among outpatients. These include adjusted clinical groups (ACGs), which group conditions similar on characteristics that include persistence of the condition, likelihood of requiring hospitalization, and need for specialty referral, and diagnosis cost groups (DCGs), which group conditions into clinical hierarchical clusters.[13,14] One study found that both ACGs and DCGs were better at predicting change in functional status, rehospitalization, and death among stroke rehabilitation patients than models that relied only on age and gender or the Charlson Index.[15]

In the area of stroke rehabilitation, the FIM™* function-related groups (FIM-FRGs) is the most widely used risk adjustment system.[16] Analogous

*FIM™ is a trademark of Uniform Data System for Medical Rehabilitation, a division of UB Foundation Activities, Inc.

to the DRGs and RUGs, the FIM-FRGs were initially designed specifically to characterize patients undergoing inpatient rehabilitation for reimbursements. FRGs include specific measures for 21 primary diagnostic reasons for rehabilitation, 1 of which is stroke. Within each impairment category, the system divides patients into groups according to the severity of their physical and cognitive disabilities as well as age at the time of admission to rehabilitation. The severity of initial physical and cognitive disability is expressed by the FIM™ motor and cognitive subscales.[17] The motor FIM™ includes patients' clinician-rated levels of performance on 13 physical activities, whereas the cognitive FIM™ accounts for 5 communication and social cognition activities. Higher motor and cognitive FIM™ scores are associated with less severe physical and cognitive disabilities, respectively.

Lessons Learned From Nonrehabilitation Settings

The extensive work done with risk adjustment in nonrehabilitation settings has highlighted many important lessons. Risk adjustment must be clinically credible. Clinicians must be able to look at what patient characteristics are being adjusted for and agree that they make sense. To accomplish this, clinically detailed information is often required. Such clinical detail needs to be tailored to the setting of interest. In long-term care, functional status may be key; whereas in the intensive care unit, physiologic derangements are often more important than specific diagnoses. The use of such clinically detailed information in risk adjustment will often be difficult as it is rarely available in databases. Studies have demonstrated, though, that risk-adjustment models incorporating only a limited number of clinically detailed variables can perform almost as well as models with more complete information. For example, the addition of laboratory results to a risk-adjustment model for in-hospital mortality led to substantial improvements in model performance.[18] Subsequent addition of vital signs and other key clinical findings resulted in only modest further improvements. Increasingly, the availability of electronic medical records will likely solve the need to easily obtain detailed clinic information on large numbers of patients.

Not only are unadjusted outcomes data not clinically credible, they are also unlikely to provide accurate assessments of performance. Studies from many settings have shown that providers' performance rates may vary dramatically depending on whether unadjusted or risk-adjusted rates are used.[5,19–21] Furthermore, which providers are identified as outliers will also change considerably. Thus, using unadjusted data in quality improvement initiatives may convey false assessments.

Use of off-the-shelf risk-adjustment systems also can be problematic. Even though they all purport to be measuring severity, different risk-adjustment systems will often come up with very different conclusions.[21,22] For individual patients, the predicted probability of the outcome of interest may vary considerably depending on the system used. In one study of in-hospital mortality among 9,407 stroke patients at 94 hospitals, 5 risk-adjustment systems were compared.[22] Expected probability of death was calculated in every patient using each system. When one system was compared to another one, they could differ considerably in over 60% of patients on the expected probability of death. When applied to individual providers, these systems would often identify different hospitals as outliers. In fact, in identifying outliers, any individual system is often more likely to agree with unadjusted performance than with another risk-adjustment system. Considerable care is required in deciding which off-the-shelf system should be used.

Lessons Learned From the Rehabilitation Setting

The extensive work done with risk adjustment in the rehabilitation setting leads to important lessons that parallel those from nonrehabilitation settings, but it also highlights the distinct qualities of the rehabilitation process. Risk adjustment must be clinically credible, reflecting differences in the unique philosophies and objectives of rehabilitation when compared to the acute and long-term care phases of care as well as clear differences in the population served.[1] Rehabilitation

professionals need to be assured that the patient characteristics being adjusted for make sense to their therapeutic objectives and will reflect expected patient differences in essential outcomes such as functional outcomes and discharge to the least restrictive environment. As in other settings, to accomplish this, clinically detailed and particular types of information will be required. Patients' initial functional status is a key measure of severity and need for resources, as in long-term care, but so is diagnostic information about the specific condition for which rehabilitation services are being provided and comorbidities, variables more seminal to case-mix measurement in acute care. Certainly, the amount of therapy needed and the outcomes expected will differ for stroke patients who are older, with more physical and cognitive disabilities, than for those who are younger and less disabled. Clearly, rehabilitation targeted to persons with stroke differs from that targeted to those with spinal cord injury or some other condition, and the need for medical management during rehabilitation will be greater among persons with major comorbidities such as end-stage renal disease than among those who are otherwise healthy. Finally, with outcomes such as home discharge, the qualities of patients' home environments including architecture, and the availability of caregivers are essential determinants. Such ecological information is rarely captured in medical approaches to case-mix measurement. Obtaining the breadth of this clinically detailed information in risk adjustment is difficult. It is rarely available in administrative records, and the analysis of all pertinent dimensions would depend on multivariable regression models that require statistical and analytic expertise, which is not easily available to most clinicians. As in other settings, studies in rehabilitation demonstrate that risk-adjustment models incorporating only a few of the most essential clinical variables can perform almost as well as models with more complete information.

Risk-adjustment systems such as FIM-FRGs,[15] which were initially established to scale reimbursement to case-mix complexity, have been shown to be useful in large and sustained quality improvement projects on stroke rehabilitation in the United States and in other nations. For one US example, the Veteran's Health Administration (VHA) embedded FIM-FRGs in its national treatment algorithm for monitoring stroke rehabilitation across its continuum of postacute rehabilitation services.[23] The algorithm, developed by a national expert panel within the VHA, was intended to promote access to care by advocating for the functional assessment of stroke patients across all severity groups and to encourage the early initiation of treatment and smooth transitions across levels of rehabilitative care. Within that algorithm, FRGs accounted for differences in patient characteristics across alternative levels of rehabilitation and were used to monitor and project resource use and outcomes. Expectations for functional outcome and total treatment costs were found to be similar within FRG groups regardless of whether patients underwent rehabilitation in medical or surgical units, inpatient rehabilitation units, or outpatient settings.

The FRG system also was effective in addressing differences in rehabilitation outcomes and resource use associated with structural variation. In Canada, where people have universal access to publically funded programs for stroke rehabilitation, the Canadian Institute for Health Improvement established FRG-specific benchmarks for stroke rehabilitation and applied an ongoing outcome pattern analytic approach.[24] Pattern analytic approaches work by comparing outcomes and resource use distributions across clinically similar groups of people in ways that make it possible to compare the outcomes of alternative health care systems or approaches.[25] FRGs proved to be a way to define clinically similar groups. For example, over a 6-year period, when examined within FRGs, more than 75% of patients in Canada had longer rehabilitation stays than what was considered a typical stay in the United States. The 75th percentile FIM™ discharge score ratings were higher for all and the 25th percentile FIM™ score ratings were higher for most FRGs in Canada than in the United States. The authors suggested that stroke patients may be discharged in the United States before they achieve optimal functional recovery. Comparisons of VHA to non-VHA resource use and outcomes within the United States showed similar pattern differences with VA average length of stays 30% to 200% longer

by FRG and average functional recoveries better in most FRGs. We now illustrate a simple pencil and paper approach to case-mix adjusted quality improvement applying a FIM-FRG algorithm that provides the means to adjust for patient complexity using 4 of the most essential clinical variables as noted previously.

A Case-Mix Adjustment Strategy Using a Clinical Vignette

For this example, we selected the vignette, Maintaining Functional Outcomes in Times of Change, from the introductory article by Strasser. To show the nuts and bolts of case-mix–adjusted continuous quality improvement (CQI), we selected the patient's motor FIM™ score achieved at rehabilitation discharge as the outcome of interest. The technique applies an outcome pattern analysis approach that looks at expected outcomes as falling within lower, middle, and higher ranges according to high gold standard FRG-adjusted benchmarks. The benchmarks reflect expected values calculated from a risk-adjustment model derived in over 55,000 patient discharges in 1995 from 467 rehabilitation facilities in the United States. They are considered to represent optimal patterns of functional recovery, because they were calibrated to reflect a time before the potentially distorting effects of the current rehabilitation prospective payment system. Stability of the benchmarks is further supported by the demonstration of remarkable consistency with FRG-adjusted values obtained from earlier years (1990 and 1992). Because of changes in the health care system and cost-containment pressures, these benchmarks might not be reasonably achieved today. They are intended to represent a high or optimal standard of outcome achievement, goals to shoot for in efforts to help patients achieve the highest possible functional outcomes after stroke.

The FIM-FRGs classification includes a series of separate modular measures calibrated to establish expected resource use and outcomes. The particular FRG module used here was designed to group patients according to their expected motor FIM™ outcome achievements at discharge from rehabilitation. Compared to the length of stay (LOS) and cost-predicting modules, the discharge motor outcome tool (DMF-FRG) requires more patient groups to adequately distinguish patients by expected functional outcomes.[26] **Figure 1** displays the DMF-FRG functional outcome benchmarks for stroke rehabilitation. The median expected discharge motor FIM™ score for each DMF-FRG is indicated by the middle horizontal line. The gold standard benchmark is a range of scores from the 25th to the 75th percentile. The lower horizontal line represents the 25th percentile lower limit of the motor FIM™ score benchmark and the upper horizontal line forms the 75th percentile upper limit of the benchmark. Half of all patients would be expected to have scores within the benchmark, that is, between the lower and upper lines according to the 1995 gold standard.

Comparison of the FRG definitions in **Table 1** to the pattern of plotted benchmarks in **Figure 1** graphically depicts how a patient's admission motor FIM™, cognitive FIM™, and age interact to adjust risk. Admission motor FIM™ score is the dominant variable in determining functional outcome as represented by the upward diagonal pattern of 25th and 75th percentile benchmarks. The expected discharge motor FIM™ score increases directly with the patient's admission score such that higher admission motor FIM™ scores are associated with the achievement of higher motor FIM™ discharge scores. Comparison of outcome expectations across the FRGs shows the degree to which it would be invalid to compare FIM™ motor discharge scores across populations of stroke patients presenting with different levels of functional severity. The downward trends from the dominant diagonal line, for example, in the benchmarks associated with FRGs 4, 5, and 6, show the negative prognostic effects of advanced age on functional achievements holding initial physical disability constant. The negative effects of advanced age appear most prominent among persons presenting with the most severe physical disabilities (lowest motor FIM™ scores). Among those with milder physical disabilities, cognitive dysfunction has a negative impact on prognosis interacting with both physical and cognitive disability at FRG 14 and 15. Because this article focuses on case-mix

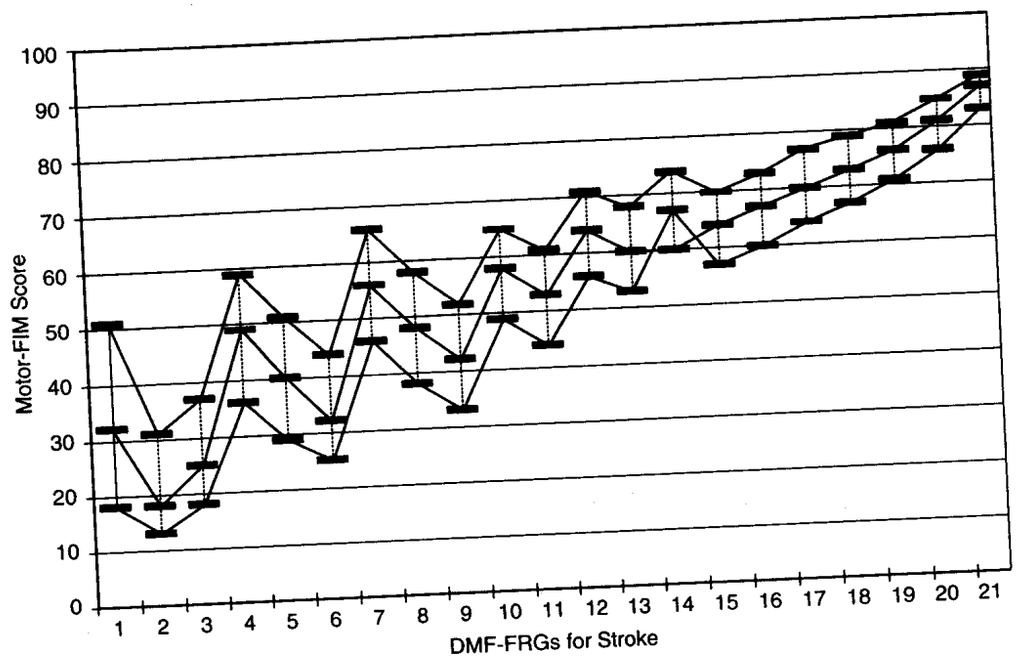

Figure 1. Discharge motor FIM™ benchmark gold standard. The figure describes discharge motor FIM™ function-related groups (DMF-FRG) (x-axis) and functional outcome benchmarks (y-axis) for stroke rehabilitation. These can be used in case-mix–adjusted continuous quality improvement (CQI) once all patients discharged over a specified period are assigned to DMF-FRGs. Each DMF-FRG–specific set of benchmarks defines a range of discharge motor FIM™ scores spanning the 25th through the 75th percentile. The lower horizontal line represents the 25th percentile lower limit of the benchmark and the upper horizontal line forms the 75th percentile upper limit of the benchmark. Percentiles were calculated from the actual outcomes achieved by over 34,000 patients treated across the United States in 1995 whose stroke rehabilitation occurred prior to implementation of Medicare's inpatient rehabilitation facility prospective payment system. To perform case-mix–adjusted CQI determine the proportion of patients each cycle whose functional outcomes are below, within, and above the DMF-FRG–specific benchmark in a particular cycle. Changes in proportions can be tracked over time through subsequent CQI cycles in efforts to address the impact of specific strategies designed to enhance patients' functional gains. Reproduced, with permission, from Stineman MG, Granger CV. Outcome, efficiency, and time-trend pattern analyses for stroke rehabilitation. *Am J Phys Med Rehabil.* 1998;77:193–201. Copyright © 1998 by Lippincott Williams & Wilkins.

adjustment, we use the vignette to illustrate how to case-mix adjust functional outcomes during the evaluate phase of the quality improvement cycle (see vignette, Maintaining Funtional Outcomes in Times of Change, from the introductory article by Strasser). A more detailed example of case-mix adjusted quality improvement applying this same vignette will be given in a separate article (see Stineman et al in this issue). That article is intended to illustrate implementation of a more complicated multidimensional case-mix adjustment strategy within the engage, educate, and execute phases of the full Quality Improvement/Knowledge Translation model as established by Pronovost and coworkers[27] and detailed by Needham and Korupolu in this issue.

This quality improvement initiative is intended to track and test ongoing therapeutic strategies to maintain motor FIM™ outcomes in the overall stroke population as structural changes imposed on this health system in this vignette are shifting stroke patients from higher intensity to lower intensity rehabilitation services. The FIM-FRG case-mix adjustment allows fairer comparisons across the functionally heterogeneous population of stroke patients seen in treatment and provides a way to compare the functional outcomes achieved in the inpatient rehabilitation facility (IRF) and

Table 1. Assigning the patient's stroke-specific DMF-FRG

Discharge FRG	Admission motor FIM™ score range	Admission cognitive FIM™ score range	Age range
1	18–16	-	13–63

Note: This table can be used for classifying stroke patients into their discharge motor FIM-FRG (DMF-FRG) on the basis of therapist observed admission motor FIM™ score, cognitive FIM™ score, and age.

those in the skilled nursing facility (SNF) to each other and both to the gold standard. The following steps are applied to achieve case-mix adjustment.

1. Use **Table 1** to classify patients into their FRG based on one or more of the following bits of information: admission motor FIM™ score, admission cognitive FIM™ score, and age. The patient's motor FIM™ score is determined by summing observed 1–7 rated performances on the 13 motor FIM™ items and 5 cognitive items into separate subscales.
2. Use **Figure 1** to find the patient's FRG on the x axis. Find the patient's motor FIM™ discharge score on the y axis.
3. Mark above the patient's assigned DMF-FRG where the patient's motor FIM™ discharge status falls according to expected values on the y axis.
4. Determine if the patient's actual motor FIM™ score at discharge is below the 25 percentile (lower than the gold standard), between the 25th and 75th percentile (within the expected gold standard range), or above the 75th percentile (higher than the expected gold standard). The lower limit of the vertical bar represents the 25th and the upper limit the 75th percentile.
5. Count the number of patients over the CQI cycle (perhaps a quarter year) whose discharge motor FIM™ scores are below, within, and above the benchmarks.
6. Calculate the proportions of patients below, within, and above the ranges for their case-mix adjusted functional outcome benchmarks. Determine the proportions for the entire stroke population seen and stratified into persons being treated in the SNF and IRF. If the SNF and IRF are achieving comparable outcomes, the proportions of patients below, within, and above their DMF-FRG benchmarks would be comparable.

As noted previously, with constraints related to the prospective payer system (PPS), cost-containment efforts, and the shifting of care away from IRFs into less costly venues as illustrated by the vignette, the benchmarks represent

high targets. When this approach to case-mix–adjusted quality improvement is applied, it is important to recognize that comparison to the national high gold standard would be less important than internal comparisons over time within your health system. Repeat the analysis steps 1–6 through subsequent cycles of quality improvement. Compare the proportions of patients in your health care system below, within, and above their FRG-specific benchmark over time. The goal would be to develop clinical programs that will improve the quality and efficiency of care provided as evidenced by shifting increasing proportions of patients from the lower into the expected benchmark range and even higher relative to the high gold standard.

This approach is powerful but limited. Additional clinical factors such as degree of paralysis, visual impairments, aphasias, and comorbidity, while clinically important determinants of outcome, will in part be captured by patients' initial functioning. However, such factors may explain variation in outcomes over and above the FRGs. For other outcomes of interest, such as risks of nosocomial infection, other sets of factors will be important. Ultimately, multivariate regression models that consider the independent effects of many different risk factors on the outcome will lead to the best risk adjustment for obtaining expected values. The development of such models depends on careful review of the literature targeted to the particular outcome and the empirical derivation of the models applying large populations of patients.

Conclusions

Risk adjustment is an essential tool for monitoring and improving stroke rehabilitation care. Many aspects of risk adjustment are complex, but the basic principles can be used by clinicians and managers to ensure that achieved outcomes for stroke patients mirror those expected based on patient complexity. Appropriate case-mix adjustment could contribute to our capacity to measure interventions and program changes associated with meaningful improvements in outcomes for complex patients with diverse rehabilitation needs. The simple case-mix adjustment illustrated is appropriate to addressing functional outcomes. Functional outcomes are only one of many essential outcomes appropriate to CQI. Different risk-adjustment strategies would be necessary to address other types of outcomes or processes of care. Moreover, optimal approaches to CQI are generally multifactorial, addressing multiple indicators simultaneously and their associations as illustrated elsewhere in this article series.

BACKGROUND: Prevalence of unhealthy alcohol use among medical inpatients is high.
OBJECTIVE: To characterize the course and outcomes of unhealthy alcohol use, and factors associated with these outcomes.
DESIGN: Prospective cohort study.
PARTICIPANTS: A total of 287 medical inpatients with unhealthy alcohol use.
MAIN MEASURES: At baseline and 12 months later, consumption and alcohol-related consequences were assessed. The outcome of interest was a favorable drinking outcome at 12 months (abstinence or drinking "moderate" amounts without consequences). The independent variables evaluated included demographics, physical/sexual abuse, drug use, depressive symptoms, alcohol dependence, commitment to change (Taking Action), spending time with heavy-drinking friends and receipt of alcohol treatment (after hospitalization). Adjusted regression models were used to evaluate factors associated with a favorable outcome.
KEY RESULTS: Thirty-three percent had a favorable drinking outcome 1 year later. Not spending time with heavy-drinking friends [adjusted odds ratio (AOR) 2.14, 95% CI: 1.14–4.00] and receipt of alcohol treatment [AOR (95% CI): 2.16(1.20–3.87)] were associated with a favorable outcome. Compared to the first quartile (lowest level) of Taking Action, subjects in the second, third and highest quartiles had higher odds of a favorable outcome [AOR (95% CI): 3.65 (1.47, 9.02), 3.39 (1.38, 8.31) and 6.76 (2.74, 16.67)].
CONCLUSIONS: Although most medical inpatients with unhealthy alcohol use continue drinking at-risk amounts and/or have alcohol-related consequences, one third are abstinent or drink "moderate" amounts without consequences 1 year later. Not spending time with heavy-drinking friends, receipt of alcohol treatment and commitment to change are associated with this favorable outcome. This can inform efforts to address unhealthy alcohol use among patients who often do not seek specialty treatment.

KEY WORDS: unhealthy alcohol use; medical inpatients; factors associated with drinking and consequences.

INTRODUCTION

Unhealthy alcohol use (alcohol consumption that increases the risk of health consequences and includes abuse and dependence) is a major public health concern[1,2]. In primary care settings the prevalence of unhealthy alcohol use is 7 to 20% or more, with most people not suffering from alcohol dependence[3]. However, in medical hospital settings, the proportion of patients with unhealthy alcohol use who meet the criteria for alcohol dependence is high[4]. For example, in four general hospitals in Germany, Freyer-Adam et al. found that 61% of inpatients with unhealthy alcohol use had alcohol dependence[5]. In a large urban safety-net hospital in the US (the sample for the current study), the proportion was 77%[4,6]. As such, the problem of unhealthy alcohol use in inpatient medical settings is likely to differ from that in other (particularly outpatient) health care settings.

In general populations, the natural history of drinking among those with dependence has been well studied, and social and personal factors have been identified as predictors of natural recovery. Epidemiologic studies indicate that there is a substantial proportion of individuals with alcohol dependence who will be in recovery 12 months later[7]. Age and participation in self-help or treatment affect the course of substance dependence and male gender, depression, heroin and cocaine use, divorce and low level of education are related to worse outcome[8]. "Resolution" (abstinence for more than 2 years) has been linked to heavier drinking practices and negative life events during the year before the onset of abstinence[9].

Nevertheless, the course of drinking and predictors of favorable drinking outcome among medical inpatients are not

well known. Describing both consumption and consequence outcomes allows assessment of a range of outcomes among diverse patients. It is of clinical interest among inpatients, especially because some may choose a "moderate" drinking goal during brief counseling sessions, and may do so without negative consequences even if previously diagnosed with dependence. Moderate drinking may be an appropriate goal if patients can do so without consequences.

Understanding the course of unhealthy alcohol use and predictors of favorable consumption and consequence outcomes may help clinicians to tailor advice and treatment planning, and to develop interventions for medical inpatients. The latter is important given the lack of robust evidence for the efficacy of brief interventions in this setting[5,10,11].

Therefore, we studied a prospective cohort of medical inpatients with unhealthy alcohol use to determine the course of alcohol use and consequences, and factors associated with favorable drinking outcomes, 1 year after hospitalization. We hypothesized that factors such as male gender, low socioeconomic status, depression, physical or sexual abuse, illegal drug use, presence of alcohol dependence and social pressure to drink would be associated with unfavorable outcome, and factors such as readiness to change and receipt of specialized alcohol treatment (including self-help) would be associated with favorable outcome.

METHODS

Data were collected by interview with medical inpatients at an urban academic hospital who were drinking risky amounts of alcohol [>14 standard drinks (14 g of pure alcohol)/week or ≥5 drinks on an occasion for men, >11 drinks/week or ≥4 drinks on an occasion for women and persons aged over 65 years]. This cohort was prospectively followed for 1 year. Subjects were participants in a randomized trial of a single brief motivational interviewing counseling session (compared with no brief motivational counseling); the intervention had no significant effect on drinking or alcohol consequences[6].

Research associates approached all patients aged ≥18 whose physicians did not decline the contact. Individuals fluent in English or Spanish who gave consent were asked to complete a screening interview. Eligibility criteria were: currently drinking risky amounts (as above), two contacts to assist follow-up, no plans to move from the area for the next year and a Mini-Mental State Examination score of ≥21. During the screening interview, subjects completed a 1–10 visual analog scale for readiness to change ("How ready are you to change your drinking habits"). Subjects who refused participation were more likely to be Black (45% vs 31%) and to drink greater amounts of alcohol (median 24 vs 18 drinks per week) compared to eligible subjects who enrolled, but were similar regarding readiness to change measured on a 1–10 visual analog scale.

At study entry we assessed demographics, principal admitting and alcohol-attributable medical diagnoses (by medical record review), alcohol use disorder diagnosis [assessed using the Composite International Diagnostic Interview (CIDI) Alcohol Module][12,13], education, homelessness, heroin use, cocaine use, physical or sexual abuse before the age of 18, and whether or not the subject spent time with heavy or problem drinkers (reflecting social pressure to drink). Not spending time with heavy-drinking friends was assessed with the question "How many of the people you spend time with are heavy or problem drinkers?" and later dichotomized into none vs. any. Baseline measures of health-related quality-of-life (QOL) [Short-Form Health Survey, Physical Component Summary (PCS) score][14], depressive symptoms, and readiness to change alcohol use [problem recognition and commitment to change drinking with the "Perception of Problem" (range 10–50) and "Taking Action" (range 6–30) scales, respectively] were also used. These latter two scales were determined based on a factor analysis of the Stages of Change Readiness Treatment and Eagerness Scale (SOCRATES) in this sample[15]. The Taking Action scale questions assess both actions to facilitate change that already occurred and commitment to change, with a higher score indicating a higher level of having taken action and commitment to change[16]. At 12 months, receipt of treatment since study entry was assessed by self-report [hospital detoxification, any treatment for alcohol problems (including counseling or therapy), Alcoholics Anonymous meetings, self-help, mutual help or other 12-step programs for alcohol problems or medication prescribed by a physician to prevent them from drinking]. At study entry and 12 months later, we assessed alcohol consumption with a validated 30-day calendar method (Timeline Followback)[17] and alcohol-related consequences with the Short Inventory of Problems (SIP)[18]. The outcome of interest was favorable drinking at 12 months, defined as abstinence or drinking "moderate" amounts [i.e., less than at-risk amounts, defined above except >7 (not 11) drinks per week was the cutoff for women and the elderly] without consequences. The outcome definition was based on a procedure described and validated by Cisler and Zweben[19–21] that classified drinkers according to two factors: whether they drank at-risk amounts and whether they experienced alcohol-related consequences. This composite outcome index was created to capture a broader range of clinically relevant outcomes, knowing that patients with unhealthy alcohol use may choose to keep on drinking but at lower levels and without suffering from alcohol-related consequences.

The following factors were tested: education, marital status, homelessness, physical or sexual abuse before the age of 18, heroin or cocaine use, elevated depressive symptoms, presence of alcohol dependence, readiness to change measure, spending time with heavy-drinking friends and receipt of alcohol treatment after hospitalization (evaluated at the 12-month assessment).

Confounders were defined a priori based on literature and clinical experience, and included: age, gender, race/ethnicity, randomization group, PCS and drinking (drinks per day, past 30 days) at study entry. We included a measure of drinking at study entry as a confounder because alcohol consumption level is known to be one of the strongest predictors of subsequent drinking.

Analyses

We used an iterative model-building procedure to identify factors associated with favorable drinking. Each factor of interest was entered in a separate model adjusted for potential confounders (i.e., in "minimally adjusted models"): age, gender, race/ethnicity, randomization group, physical health-related QOL (PCS score), presence of an alcohol-attributable principal diagnosis at hospital admission and drinks per day at study entry. The potential confounders were selected a priori based on literature and clinical experience.

Prior to regression modeling, we assessed bivariate correlations between all independent variables and covariates. To

avoid potential collinearity, no pair of variables with Spearman correlation coefficient >0.40 was included in the same model. Because it was correlated with other factors of interest (drinks per day, past 30 days, r=0.54; alcohol dependence, r=0.54; receipt of alcohol treatment, r=0.44; depressive symptoms, r=0.44), the Perception of Problem (PP) scale was excluded from further analyses. Since other work suggests that the PP scale and other variables reflecting perception of alcohol problems are markers of severity and since the PP scale was correlated with other better markers of severity, we excluded it from further multivariable analyses. We nevertheless report unadjusted models for PP, since measures of perception of alcohol problem are often used in the literature. No other pairs were correlated >0.40. In an unadjusted logistic regression model, subjects in the highest quartile (highest level) of PP had 2.21 (95% CI: 1.07, 4.56) times the odds of an *unfavorable* drinking outcome compared to the lowest quartile.

Factors significantly associated with the drinking outcome at an alpha level of 0.05 in these "minimally adjusted models" were included together in a single multivariable model along with confounders. Factors that were no longer significant at an alpha level of 0.05 in the multivariable model were removed one at a time to obtain the final model.

All analyses were adjusted for randomization group (i.e., assignment to brief intervention) at baseline. Analyses were performed using SAS software (version 9.1; SAS Institute, Cary, NC).

RESULTS

Of the 5,813 patients screened, 986 were drinking risky amounts. Of these, 462 were not eligible for entry into the cohort, and 183 were eligible but declined. Of the 341 subjects who were eligible and consented to be in the cohort, 287 (84%) had complete data at 12 months and were included in these analyses. The baseline characteristics of the 287 subjects are presented in Table 1. The five most prevalent principal diagnoses at hospital admission were: rule out myocardial infarction (n=50), pancreatitis (n=31), cellulitis (n=20), asthma (n=19) and pneumonia (n=19). Subjects who completed the 12-month follow-up did *not* differ significantly (alpha level 0.05) from those lost to follow-up with respect to the baseline characteristics presented in Table 1.

At 12 months, most subjects (63%) were drinking risky amounts, 29% were abstinent, and a few were drinking moderate amounts (with or without consequences) (8%). At 12 months, 33% had a favorable drinking outcome [i.e., they were abstinent (29%) or drinking moderate amounts without consequences (4%)] (Fig. 1).

Table 2 presents unadjusted logistic regression models for all factors of interest and confounders, and the final model developed from the iterative model building procedure. Elevated depressive symptoms, Taking Action, not spending time with heavy-drinking friends and receipt of alcohol treatment after hospital discharge were associated with a favorable drinking outcome in both unadjusted and "minimally adjusted models." These four variables were entered simultaneously with the a priori defined potential confounders in an adjusted logistic regression model. The depressive symptom variable was no longer significant in the multivariable model (p=0.2) and was therefore excluded from the final model. In the final model (Table 2), compared to the first quartile (lowest level) of Taking Action, subjects in the second, third and highest quartile had 3.65 (95% confidence interval, 1.47, 9.02), 3.39 (95% CI 1.38, 8.31) and 6.76 (95% CI 2.74, 16.67) times the odds of a favorable drinking outcome, respectively. Not spending time with heavy-drinking friends [adjusted odds ratio (AOR) 2.14; 95% CI 1.14, 4.00] and receipt of alcohol treatment after hospital discharge during the past year (from baseline to 12-month assessment; AOR 2.16, 95% CI 1.20, 3.87) were associated with a favorable drinking outcome. The Hosmer and Lemeshow chi-square test suggested acceptable model fit of the final logistic regression model (p=0.73).

Table 1. Characteristics at Study Entry of 287 Medical Inpatients Identified by Screening with Unhealthy Alcohol Use

Characteristics	
Age, mean (SD)	44.4 (10.6)
Female, n (%)	86 (30)
Currently married, n (%)	32 (11.2)
Education (years), mean (SD)	11.9 (2.5)
Homelessness, n (%)	73 (25)
Race/ethnicity	
African-American, n (%)	133 (46)
White, n (%)	108 (38)
Hispanic, n (%)	24 (8)
Other, n (%)	22 (8)
DSM IV Alcohol Diagnosis	
Alcohol dependence, n (%)	223 (78)
Alcohol abuse, n (%)	13 (4)
No alcohol use disorder diagnosis, n (%)	51 (18)
Alcohol consumption (drinks per day, past 30 days), mean (SD)	6.8 (8.9)
SOCRATES	
Perception of Problem, mean (SD)	35.5 (11.1)
Taking Action, mean (SD)	21.2 (5.8)
Depressive symptoms (CES-D score ≥16), n (%)	203 (71)
Heroin or cocaine use (past 30 days), n (%)	74 (26)
Physical abuse before age 18, n (%)	116 (41)
Sexual abuse before age 18, n (%)	66 (23)
Not spending time with heavy-drinking friends (less social pressure to drink), n (%)	84 (29)
Alcohol-attributable principal diagnosis at hospital admission, n (%)	42 (15)
Receipt of alcohol treatment including self-help	127 (44.6)

Homelessness was defined as more than 1 night spent on the streets or in a shelter over the past 3 months
SOCRATES: Stages of Change Readiness Treatment and Eagerness Scale
DSM IV: Diagnostic and Statistical Manual of Mental Disorders, 4th edn
CES-D: Center for Epidemiologic Studies Depression scale
Alcohol-attributable diagnosis includes any of the following: acute alcoholic cirrhosis of the liver, alcoholic cardiomyopathy, alcoholic gastritis, alcoholic hepatits, alcohol intoxication, alcoholic liver damage, alcoholic fatty liver, alcoholic pellagra, alcoholic polyneurpoathy, alcoholic withdrawal, alcoholic withdrawal convulsion, alcoholic withdrawal delirium, alcoholic withdrawal hallucinosis, other alcoholic psychosis, alcoholic amnestic syndrome, other alcoholic dementia, alcoholic pancreatitis or other diagnoses considered alcohol-attributable by the investigator (e.g., holiday heart, alcoholic ketoacidosis, alcohol-related rhabdomyolisis)

DISCUSSION

We investigated unhealthy alcohol use outcomes and factors associated with a favorable drinking outcome (abstinence or moderate drinking without consequences) at 12 months in opportunistically screened medical inpatients who were not

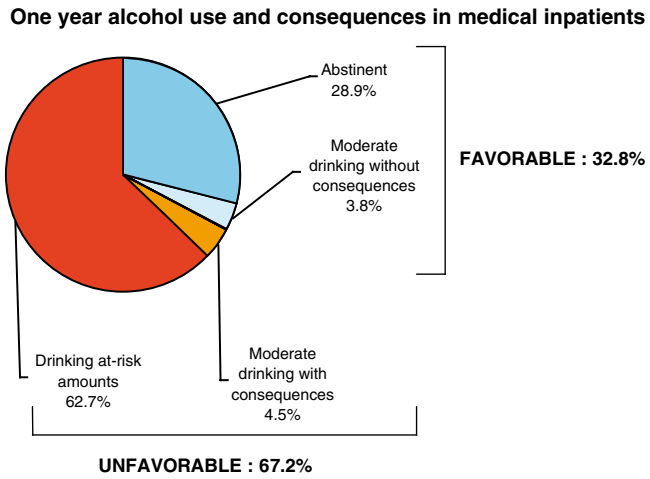

Figure 1. Note: Alcohol consumption was assessed with the 30-day Timeline Followback method. Alcohol consequences were assessed with the Short Inventory of Problems (SIP). The SIP is a 15-item questionnaire that assesses, over the past 3 months, the presence of alcohol-related consequences in various dimensions: physical, interpersonal, intrapersonal, impulse control and social responsibility.

necessarily seeking specialty alcohol treatment. Most continued to drink amounts that risk health consequences and/or have such consequences, but one third had a favorable drinking outcome. Abstinence was the most likely favorable drinking outcome. Few were drinking moderate amounts, with or without consequences.

In 1976, Imber et al. studied the natural history of drinking in male general hospital inpatients with alcohol dependence; 19% were abstinent 1 year later[22]. More than 30 years later, we found a similar though higher proportion of abstinence. The more favorable course might be due to a sample that consisted not only of subjects with alcohol dependence (though absence of alcohol dependence was not predictive of favorable drinking outcome in our sample). In the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), Dawson et al. showed that among individuals with alcohol dependence, a year later, 17.7% were drinking "low-risk" amounts, and 18.2% were abstainers; approximately half of those with a favorable consumption outcome were still drinking[7]. Similarly, Sobell et al., in two Canadian general population studies of individuals with alcohol dependence, found that low-risk drinking accounted for 40 and 60% of all cases of recovery[7,23]. Yet in our study, even though some subjects did not have alcohol dependence, favorable drinking outcome most often consisted of abstinence. Although reasons for the different observations are not clear, the setting and severity of the general hospital sample likely account for them in part.

In primary care, where the prevalence of alcohol dependence is lower, a similar proportion of screen-identified patients was not drinking risky amounts 6 months later[24]. Similarly, in a study of screening and brief intervention conducted among inpatients with unhealthy alcohol use (without dependence), 46% of the controls did not report any alcohol problems 12 months later. On average, they decreased their daily alcohol consumption by 24 g of alcohol (from 70 g). In most brief intervention studies, a substantial decrease in drinking has been observed in the groups that did not receive any interven-

Table 2. Associations with Favorable Drinking Outcome 1 Year After General Medical Hospitalization of 287 Patients with Unhealthy Alcohol Use: Unadjusted and Final Logistic Regression Models

	Unadjusted model		Final model	
	OR	95% CI	AOR	95% CI
Factors of interest				
Education (for a 1 year difference)	1.100	0.992, 1.219

tion[10,25–27]. The course of unhealthy alcohol use tends to involve self-change with or without formal help, with a substantial proportion of individuals either abstaining or drinking moderate amounts without consequences a year later. These changes take place for individuals in the general population and for individuals that have contacts with the health care system. These changes may be due to self-change, life events and experiences, notably the accumulation of negative events, as well as assessment effects—all things that happen regardless of interventions.

Few studies have investigated the course and factors associated with outcomes of unhealthy alcohol use in medical inpatients. Although people who enroll in trials differ from those who do not, and although assessment effects can affect outcomes, cohorts of subjects from randomized controlled trials can provide some relevant information. In addition, we identified factors associated with favorable drinking outcome: Taking Action (a measure of actions towards facilitation of change and commitment to change, which can be considered a specific subcategory of readiness to change), not spending time with heavy-drinking friends (which can be seen as a proxy measure for the social pressure to drink) and receipt of alcohol treatment over the past 12 months were positively associated with a favorable drinking outcome. Even though usually considered markers of severity or predictors of poor outcome, and contrary to our hypotheses, a diagnosis of alcohol dependence, drug use, low education level and homelessness were not associated with drinking outcome[8,28].

These results suggest the importance of commitment to change and action toward facilitation of change as valuable targets for interventions[29]. As shown in other studies, individuals who tend to have some intention or commitment to reduce their drinking when seen in a hospital will have a better prognosis[30]. Self-report of receipt of alcohol treatment between study entry and 12 months later was associated with favorable drinking outcome. This supports the current knowledge on treatment efficacy[2,31,32]. The observed positive predictive effect of not having heavy-drinking friends on favorable drinking outcome is also consistent with studies indicating the negative impact of the social environment on drinking, notably the impact of social pressure to drink and its negative impact on relapse risk[33]. Our results add to the evidence that the absence of a heavy-drinking social environment is associated with a better drinking prognosis for individuals with unhealthy alcohol use. Future research may explore relationships between alcohol use behaviors and social networks in order to determine if the same social network effects found in tobacco cessation can be identified for alcohol use[34].

The fact that factors usually considered predictors of poor outcome in outpatients (i.e., diagnosis of alcohol dependence, drug use, low education level, homelessness, childhood physical or sexual abuse) were not associated with drinking outcomes in our study is of interest. This may have been due to a lack of power, or alternatively to intrinsic differences in hospitalized patients and ambulatory patients with unhealthy alcohol use. Specifically, our study of hospitalized patients may have examined a more homogeneous and sicker population than usually enrolled in general population studies. Individuals with less severe social and health problems tend to access the health care system less and were therefore less likely to be included in our study. Notably, the present study showed a high prevalence of alcohol dependence among individuals with unhealthy alcohol use (i.e., most patients who screened positive had alcohol dependence). Even though the prevalence of dependence is usually high in screen-positive hospitalized patients, the fact that the study population was recruited at an urban safety net hospital may explain an even higher prevalence. Nevertheless, our findings suggest that these poor prognostic factors should not be seen as insurmountable obstacles when addressing unhealthy alcohol use among medical inpatients.

Study limitations should be considered when interpreting our findings. First, we evaluated the course of unhealthy alcohol use in a sample of subjects that was included in a randomized trial. It is unlikely that the intervention affected our results since we controlled for it in analyses and the trial had negative results. The subjects agreed to participate in a study in which they could receive alcohol counseling. This might have resulted in a selection of individuals more prone to behavior change or more motivated to change; however, it might also have led to selection of patients who were interested in counseling because they thought they could not change without it. Subjects who refused participation were similar to subjects who participated regarding readiness to change completed during the screening interview. Study subjects may also have had courses not representative of natural history due to assessment effects. If this is the case, then the course of unhealthy alcohol use in medical inpatients would be even worse than what we observed. Second, our study was able to identify associations over time but was not designed to study causation. This study is a secondary observational analysis, thus observed associations may not be causal and analyses may be underpowered. The latter may explain why some factors were not significantly associated with drinking outcome, though despite this possibility, other potentially useful and easily assessable clinical factors were associated with outcome. Third we grouped together various treatment modalities and are therefore not able to distinguish between them, though all are known to have efficacy[31]. The present cohort was followed for 12 months. This could be seen as short with regard to drinking outcomes. Our results should be replicated in cohorts with longer follow-up and with multiple assessment time points. Nevertheless, the literature suggests that 12-month outcomes are indicative of longer term functioning[35,36].

This study has notable strengths. We used a large prospective sample identified by screening patients in a general health care setting, with a high follow-up rate. Prospective observational studies are the ideal approach to studying the outcomes and their predictors. Our subjects were well-characterized using validated assessments. We also used a composite outcome of drinking and consequences that has been validated and that has clinical significance[20,21].

Our results bring additional information to clinicians treating medical inpatients, a population where unhealthy alcohol use is common. In this setting, one third of the patients will be abstinent a year later. Thus, some optimism regarding the natural history of alcohol use in this population is reasonable. Our results also suggest that homelessness, drug use and depressive symptoms, usually considered markers of severity or predictors of poor outcome, may not have a large negative impact on drinking outcome in medical inpatients. The presence of these markers should not prevent clinicians from addressing unhealthy alcohol use and should not lead them

(or their patients) to have a pessimistic view of the drinking prognosis.

The factors identified as being associated with favorable outcome could be useful for clinicians, since they are potentially amenable to change with clinician assistance. Clinicians should therefore be encouraged to target commitment to change in their discussions with patients and help them to take actions towards change. Similarly, linking medical inpatients with unhealthy alcohol use to alcohol treatment and encouraging changes in their social environment to decrease the social pressure to drink may increase the likelihood of a favorable outcome. Since abstinence was the most likely favorable outcome, clinicians should suggest to patients in this setting that abstinence should remain the preferred treatment goal. Clinicians should also keep in mind that factors usually seen as predictive of poor outcomes may not be obstacles among medical inpatients to the degree they may be in other populations of patients with unhealthy alcohol use.

Drinking patterns

ABSTRACT

Objective: To understand patterns of alcohol consumption and baseline factors associated with favorable drinking patterns among HIV-infected patients.
Methods: We studied drinking patterns among HIV-infected patients with current or past alcohol problems. We assessed drinking status in 6-month intervals. Based on National Institute on Alcohol Abuse and Alcoholism guidelines a favorable drinking pattern was defined as not drinking risky amounts at each assessment or decreased drinking over time. All other patterns were defined as unfavorable. Logistic regression models were used to identify baseline factors associated with a favorable pattern.
Results: Among 358 subjects, 54% had a favorable drinking pattern with 44% not drinking risky amounts at every assessment, and 11% decreasing consumption over time. Of the 46% with an unfavorable pattern, 4% drank risky amounts each time, 5% increased, and 37% both decreased and increased consumption over time. Current alcohol dependence and recent marijuana use were negatively associated with a favorable pattern, while older age and female gender, and having a primary HIV risk factor of injection drug use were positively associated with a favorable pattern.
Conclusion: Many HIV-infected adults with alcohol problems have favorable drinking patterns over time, and alcohol consumption patterns are not necessarily constant. Identifying HIV-infected adults with a pattern of risky drinking may require repeated assessments of alcohol consumption.

1. Introduction

Alcohol use is common among human immunodeficiency virus (HIV)-infected adults and has negative health consequences. Over a third of HIV-infected veterans drink amounts associated with health consequences (Samet et al., 2007a,b). In another study, almost half of HIV-infected patients initiating primary care reported a high probability of having an alcohol use disorder (had two of more positive answers to the CAGE screening tool) (Mayfield et al., 1974; Samet et al., 2004b). Unhealthy alcohol use (the spectrum from drinking risky amounts through alcohol dependence) is more prevalent among HIV-infected patients than it is in the general population (Lefevre et al., 1995; Conigliaro et al., 2003; Samet et al., 2004b; Chander et al., 2006). Drug and unhealthy alcohol use have been linked to HIV-disease progression, HIV risk behaviors, and decreased adherence to antiretroviral therapy (Samet et al., 2007a,b). In adults with alcohol use disorders, social and personal factors (e.g., male gender, major depression, heroin use, cocaine use, divorce, and less education) have been linked to a worse prognosis (Moss et al., 2007). The environment has an impact on the course of drinking too (e.g., social pressure to drink has been linked with relapse among individuals with alcohol dependence) (Zywiak et al., 2006a,b).

There is sufficient evidence to date (though not specifically among those with HIV infection) to conclude that brief counseling in the primary care setting for nondependent unhealthy alcohol use can lead to a decrease in drinking (Bertholet et al., 2005; Kaner et al., 2007), including among injection drug users (Stein et al., 2002). Nevertheless, alcohol use disorders are often chronic conditions characterized by recurrent episodes, and few prospective studies have explored alcohol consumption over time. Since the treatment of HIV infection requires longitudinal care, it gives clinicians repeated opportunities to address alcohol use. A greater understanding of consumption over time in HIV-infected individuals with alcohol use disorders could help clinicians and researchers

better address these problems. Therefore, in a prospective cohort of HIV-infected adults with current or past alcohol problems (HIV-Longitudinal Interrelationships of Viruses and Ethanol [HIV-LIVE]), we studied patterns of alcohol consumption and factors associated with those patterns.

2. Methods

Participants were recruited between August 2001 and July 2003 with follow-up every 6 months through 2005. Recruitment occurred from a previous cohort study (HIV-Alcohol Longitudinal Cohort), an intake clinic for HIV-infected patients, HIV primary care and specialty clinics, a homeless respite facility, a methadone program, study flyers, and referrals from physicians, other participants and social service agencies (Samet et al., 2004a). Individuals were eligible if they had a documented HIV antibody test by ELISA (confirmed by Western blot) and ≥2 positive answers to the CAGE alcohol screening questionnaire (Mayfield et al., 1974) or an alcohol use disorder diagnosis (lifetime) by a study physician clinical assessment. Participants were fluent in either English or Spanish. Exclusion criteria were cognitive impairment (score of <21 on the Mini-Mental State Examination) and inability to provide informed consent (Folstein et al., 1975; Smith et al., 2006). The study was approved by the Institutional Review Boards of Boston Medical Center and Beth Israel Deaconess Medical Center. Study participants who attended the baseline assessment and at least 2 follow-up visits (total of 3 or more assessments) were included in this analytic sample.

2.1. Outcome

The primary outcome of this study was having a favorable drinking pattern over time. At baseline and at each follow-up visit, alcohol consumption was assessed using a validated calendar method (30-day Timeline FollowBack) (Sobell and Sobell, 1995). Participants were classified at each assessment as abstinent, drinking below or drinking above risky amounts (as defined by the National Institute on Alcohol Abuse and Alcoholism [≥5 drinks/occasion or >14 drinks/week for men; 4 or 7 drinks, respectively, for women and persons aged 65 and over]). Longitudinal drinking patterns were summarized as favorable or unfavorable. A favorable drinking pattern was defined as not drinking risky amounts at every observed study visit (i.e., abstinent or consistently drinking below risky amounts) or a decrease in the observed drinking over time (e.g., from risky to not risky) with no observed increases. All other drinking patterns were defined as unfavorable (i.e. consistently drinking risky amounts, increase in drinking from not risky to risky amounts, or intermittent risky drinking).

In addition, since it is uncertain whether risky amounts as defined in the general population are appropriate definitions for HIV-infected adults, we evaluated the secondary outcome continuous abstinence, defined as reporting abstinence at every study visit.

2.2. Factors associated with drinking patterns

Factors of interest and potential confounders of these associations were assessed at baseline (defined a *priori* based on published literature and clinical experience). Marital status, homelessness (Kertesz et al., 2003), age, gender, race/ethnicity, primary HIV risk factor at the time of infection (injection drug use, men sex with men, heterosexual sex), recent heroin, cocaine and marijuana use (past 12 months), any attendance at Alcoholics Anonymous (AA) meetings (past 6 months), and whether or not the individual spent time with people who drink alcohol (a measure of social pressure to drink) were self-reported. Health-related quality of life was summarized using the Mental Component Summary (MCS) and Physical Component Summary (PCS) scores of the 12-item Short-Form Health Survey (Delate and Coons, 2000). Past 6-month and lifetime diagnosis of alcohol dependence were assessed using the Composite International Diagnostic Interview (World Health Organization, 1996).

We hypothesized that marital status, homelessness, AA attendance, and lack of social pressure to drink would be associated with more favorable drinking pattern; worse health-related quality of life and recent drug use would be associated with an unfavorable pattern. Other variables were considered potential confounders.

2.3. Analysis

We determined the frequency and proportion of each drinking pattern based on the observed data for each person. Multiple logistic regression models were fit to identify baseline factors associated with a favorable alcohol consumption pattern across time. The models adjusted for all factors of interest and potential confounders, none of which were highly correlated (Spearman $r > 0.40$). The Hosmer–Lemeshow test was used to assess model goodness-of-fit. All analyses were conducted using two-sided tests and a significance level of 0.05. Analyses were performed using SAS software (version 9.1; SAS Institute, Cary, NC).

Table 1
Baseline characteristics of a prospective cohort of adults with HIV-infection and current or past alcohol problems [$n = 358$].

Age, mean (SD)	41.6 (7.4)
Female, *n* (%)	89 (24.9)
Race/ethnicity, *n* (%)	
Black	157 (43.9)
White	119 (33.2)
Latino	63 (17.6)
Other	19 (5.3)
Homelessness, *n* (%)	84 (23.5)
Currently married, *n* (%)	22 (6.1)
Mental Component Summary score (MCS), mean (SD)	39.8 (11.4)
Physical Component Summary score (PCS), mean (SD)	43.5 (9.8)
Recent drug use (past 12 months), *n* (%)	
Heroin use	88 (24.6)
Cocaine use	163 (45.5)
Marijuana use	133 (37.2)
Drinks per day, last 30 days, mean (SD)	1.8 (5.5)
Attended AA meeting, past 6 months, *n* (%)	203 (56.7)
Alcohol dependence diagnosis (current), *n* (%)	35 (9.8)
Alcohol abuse diagnosis (lifetime), *n* (%)	61 (17.0)
Alcohol dependence diagnosis (lifetime), *n* (%)	245 (68.4)
Baseline drinking status, *n* (%)	
At risk drinking	114 (31.8)
"Moderate" drinking	41 (11.5)
Abstinent	203 (56.7)
Spending time with people who drink alcohol (Social pressure to drink alcohol), *n* (%)	219 (61.2)
Primary HIV risk factor, at the time of infection, *n* (%)	
Injection drug use	184 (51.5)
Men sex with men	82 (23.0)
Heterosexual sex	91 (25.5)

SD = Standard deviation. Homelessness was defined as at least one night on the street or in a shelter in the past 6 months. AA = Alcoholics Anonymous. Alcohol consumption (drinks per day) was assessed using the Timeline FollowBack method. The presence of a current (past 6 months) alcohol dependence, and a lifetime diagnosis of alcohol abuse or dependence was assessed using the Composite International Diagnostic Interview (CIDI). Risky drinking was defined as >14 drinks/week or ≥5 drinks on an occasion for men, >7 drinks/week or ≥4 drinks on an occasion for women and persons ≥ age 65 years. Moderate drinking was defined as drinking alcohol but below risky drinking limits. A drink was defined as 12–14 g of ethanol, as in the amount in the U.S. in one 12 ounce beer, one 5 ounce glass of wine, or 1.5 ounces of 80 proof liquor. Social pressure to drink alcohol: Subjects were asked how many of the people they spend time with currently drink alcohol (none, a few, about half, most, all). Answers were later dichotomized (none vs. other).

3. Results

Of the 400 participants in the HIV-LIVE prospective cohort study, 358 (90%) completed at least 3 study visits and were included in the present analyses. Median follow-up was 3.4 years. The baseline characteristics of the study sample are presented in Table 1. Over the course of follow-up, 54.5% had a favorable drinking pattern with 43.9% consistently drinking below risky limits at every assessment (70.7% of the latter group abstained), and 10.6% decreasing consumption over time. Of the 45.5% with an unfavorable drinking pattern, 3.6% drank risky amounts at each assessment, 4.7% increased their drinking to risky amounts and 37.2% had intermittent risky drinking.

In the logistic regression model (Table 2), among the factors of interest, recent marijuana use had a negative association with a favorable drinking pattern. Current alcohol dependence (past 6 months) was also negatively associated with an unfavorable pattern. Older age, female gender and having a primary HIV risk factor of injection drug use at the time of infection (compared to heterosexual sex) were associated with a favorable drinking pattern.

Older age and female gender were also associated with continuous abstinence while marijuana use, cocaine use, social pressure to

Table 2
Baseline factors associated with a favorable drinking pattern and continuous abstinence in multivariable logistic regression analyses among a prospective cohort of adults with HIV-infection and current or past alcohol problems [$n = 358$].

	Favorable drinking pattern Adjusted odds ratio (95% CI)	Continuous abstinence Adjusted odds ratio (95% CI)
Baseline factors of interest		
Homelessness	0.72 (0.41, 1.28)	0.61 (0.31, 1.20)
Currently married	0.64 (0.24, 1.70)	0.68 (0.23, 2.03)

AOR: Adjusted odds ratio from multiple logistic regression analysis. Homelessness was defined as at least one night on the street or in a shelter in the past 6 months. The presence of a current (past 6 months) diagnosis of alcohol dependence was assessed using the Composite International Diagnostic Interview (CIDI). Social pressure to drink alcohol: Subjects were asked how many of the people they spend time with currently drink alcohol (none, a few, about half, most, all). Answers were later dichotomized (none vs. other). The Hosmer and Lemeshow Chi-square test for the multivariable model suggests satisfactory model fit ($p = 0.7$ and $p = 0.9$ for favorable drinking pattern and continuous abstinence, respectively).
Bold values indicate statistically significant associations.

drink and current alcohol dependence were negatively associated with continuous abstinence.

4. Discussion

In a prospective cohort of HIV-infected adults with current or past alcohol problems, almost half of the subjects had an unfavorable drinking pattern over time, but most with an unfavorable pattern were not consistently drinking risky amounts; they varied their drinking between risky and less than risky amounts. Thus an unfavorable drinking pattern is not a fixed state. Most subjects with a favorable drinking pattern were consistently abstinent or consistently drinking less than risky amounts. Unlike the unfavorable drinking pattern, the favorable pattern appears to be far more stable, with consistent abstinence as the most common pattern over time.

Compared with other cohorts of subjects with alcohol use disorders, not specifically with HIV infection, the proportion of abstinent subjects among those with a favorable drinking pattern in this study (>70%) was higher. In general populations, people with alcohol dependence in recovery are evenly spread between abstinence and moderate drinking (Sobell et al., 1996; Dawson et al., 2005). Similar to non-HIV-infected populations, our study found abstinence to be the most stable form of remission (Dawson et al., 2007).

Adjusting for the severity of alcohol problems, we identified various factors independently associated with drinking pattern. Our results add to the evidence linking marijuana use to unfavorable drinking outcomes (both primary and secondary outcomes). Adolescent marijuana use is associated with heavy drinking in adulthood (Merline et al., 2008). Marijuana use is also a risk factor for alcohol dependence (Sartor et al., 2007). Our finding is consistent with studies showing an association between marijuana use and hazardous drinking among people in emergency departments (Woolard et al., 2003). Our findings of associations between age and female gender and favorable drinking patterns are also consistent with the results of general population studies (Dawson et al., 2005). Injection drug use as a risk factor at the time of HIV infection was associated with a lower odd of an unfavorable alcohol consumption outcome. We included this factor as a covariate to control for HIV risk. It was not identified as a predictor of interest as we did not have a hypothesis about its specific impact and thus would caution against over interpretation.

The effects of homelessness, heroin use, cocaine use, social pressure to drink, and AA attendance on the primary outcome were not statistically significant in this cohort although we may have had limited power to detect these associations. Nevertheless, even in the case of limited power, these factors appear to have weaker associations compared to factors of similar prevalence that were associated with drinking patterns. Of note, social pressure to drink and cocaine use was negatively associated with continuous abstinence.

This study has limitations. First, even though the study was prospective and analyses were adjusted for potential confounders, associations may or may not be causal. Second, the cut offs we used for risky drinking were defined for the general population and have not been specifically defined for HIV-infected patients. For a variety of reasons (e.g., susceptibility to hepatic toxicity, medication interactions, immunosuppression) it is likely that among HIV-infected patients, amounts of alcohol that risk health consequences may be lower than in the general population. As such, some participants classified in our study in the favorable drinking pattern group may have been at risk for harm from drinking. However, this misclassification is likely not a major issue in this analysis since most participants with favorable drinking were abstinent. In addition, findings for continuous abstinence were similar with marijuana use, age, gender, cocaine use and social pressure to drink associated with abstinence. Prior literature also suggests an impact of other drug use and environmental factors (e.g., social pressure to drink) on the course of alcohol use disorders (Zywiak et al., 2006a; Moss et al., 2007). Lastly, generalizability of our findings may not extend beyond urban U.S. HIV-infected populations of adults with alcohol problems.

This study also has notable strengths. The most important strength is that we were able to define drinking patterns that reflected changes in alcohol consumption over time, therefore providing a more accurate picture of the drinking patterns in this population compared to cross-sectional studies. Since intermittent risky drinking is common, future research should focus on drinking and consequences over time in HIV-infected adults. To more accurately assess the impact of drinking on clinical outcomes, repeated assessments of drinking over time will be preferable to one-time measures that are unable to capture temporal variability.

Our finding that half of the cohort had a favorable drinking pattern suggests that a favorable evolution of drinking amounts among HIV-infected patients with alcohol problems is common. Clinicians and patients alike should have reason for optimism. Patients should be supported in their efforts to reduce drinking, and success should be acknowledged when it occurs. Although larger studies may identify other factors associated with drinking patterns, those we identified make clinical sense and may be clinically useful for identifying and addressing risky drinking among HIV-infected patients with alcohol problems. Variations over time and the substantial risk of recurrent risky drinking suggest that repeated screening and brief intervention should be done for HIV-infected adults with past alcohol problems, even when patients have not recently exceeded safe drinking limits.

Role of funding source

Support for this study came from the following grants from the National Institute of Alcohol Abuse and Alcoholism (NIAAA) of the National Institutes of Health: R01-AA13216 (Clinical Impact of HCV and Alcohol in HIV-Infected Persons), R01-AA11785 (Medication Adherence in Alcohol Abusing HIV Patients), R01-AA10870 (Enhanced Linkage of Alcohol Abusers to Primary Care), and K24-AA015674 (Impact of Alcohol Use on HIV Infection in US and Russia). The NIAAA had no further role in study design; in the collection, analysis and interpretation of data; in the writing of the report; or in the decision to submit the paper for publication. This research was conducted in part at the General Clinical Research Center at Boston University School of Medicine (US Public Health Service [PHS] grant M01 RR00533) and at the Beth Israel Deaconess General Clinical Research Center (USPHS grant M01 RR01032).

ABSTRACT

Depression affects approximately 15% of the US population, and is recognized as an important risk factor for poor outcomes among patients with various illnesses. Automated health education and behavior change programs have the potential to help address many of the shortcomings in health care. However, the role of these systems in the care of patients with depression has been insufficiently examined. In the current study, we sought to evaluate how hospitalized medical patients would respond to a computer animated conversational agent that has been developed to provide information in an empathic fashion about a patient's hospital discharge plan. In particular, we sought to examine how patients who have a high level of depressive symptoms respond to this system. Therapeutic alliance – the trust and belief that a patient and provider have in working together to achieve a desired therapeutic outcome – was used as the primary outcome measure, since it has been shown to be important in predicting outcomes across a wide range of health problems, including depression. In an evaluation of 139 hospital patients who interacted with the agent at the time of discharge, all patients, regardless of depressive symptoms, rated the agent very high on measures of satisfaction and ease of use, and most preferred receiving their discharge information from the agent compared to their doctors or nurses in the hospital. In addition, we found that patients with symptoms indicative of major depression rated the agent significantly higher on therapeutic alliance compared to patients who did not have major depressive symptoms. We conclude that empathic agents represent a promising technology for patient assessment, education and counseling for those most in need of comfort and caring in the inpatient setting.

1. Introduction

Depression is a common, debilitating mental health disorder and is one of the leading causes of disability among men and women of all ages worldwide (World Health Organization, 2001). Although depression is treatable, stigma associated with mental health problems in general, and depression in particular, represents a significant barrier to treatment (Sirey et al., 2001). In addition, access to mental health care can also present a formidable barrier to depression treatment, particularly in rural areas of the country (US Department of Health and Human Services, 2004). Furthermore, once patients are in treatment for depression, relapses due to non-adherence are common.

Computerized systems hold the promise of increasing the reach and efficacy of depression screening and treatment interventions. Several of these systems have now been developed and successfully evaluated, demonstrating efficacy for the identification and treatment of depression (Fann et al., 2009; Marks et al., 2003; Wright et al., 2005). Central to the effective treatment of depression is the therapeutic alliance – the collaborative bond between patient and mental health provider (Krupnick et al., 2006), and we would expect that the therapeutic alliance is equally important to the efficacy of computerized depression treatment programs (Bickmore et al., 2005b). Yet, existing automated systems for detecting and treating depression have not focused on the development of therapeutic alliance.

Over the last 4 years we have been developing and evaluating a computer animated conversational agent, designed to provide information and counseling to hospital patients at the time of hospital discharge. The agent has been designed with many verbal and nonverbal behaviors intended to foster the development of a therapeutic alliance with patients, such as empathy and social dialogue. In the current study, we sought to explore how patients with major depressive symptoms would react to the agent. Specifically, we investigated whether they would find it more or less acceptable and usable, and whether they would form a stronger or weaker therapeutic alliance with the agent, compared to patients without major depressive symptoms. Positive findings would indicate that animated conversational agents with relational behavior could provide an effective medium for delivering automated depression screening and treatment.

1.1. Depression

Depression affects 13–16% of people in the US, and is an important risk factor for functional impairment and poor outcomes among patients with various chronic illnesses such as diabetes, coronary artery disease and multiple sclerosis (Hasin et al., 2005; Parashar et al., 2006; Scherer and Herrmann-Lingen, 2009). Depression is associated with both physiological and behavioral factors affecting health outcomes for chronic disease patients including poor self-care management, reduced treatment plan adherence, and certain medical conditions such as chronic inflammatory states and hypercoagulability.

Despite the availability of depression treatment, less than one third of depressed patients receive treatment (Pratt and Brody, 2008). While depressed patients often express interest in treatment they also report barriers including time constraints, stigma, childcare conflicts, lack of transportation, and poor access to mental health services particularly in rural areas (Goodman, 2009). Studies also show that when physicians face a burden of competing clinical priorities for a given medical encounter, depression often goes untreated. Other barriers cited by physicians include fragmented mental health systems, lack of insurance coverage, patient resistance and difficulty making the diagnosis of depression.

1.2. Health literacy and mental health

Health literacy is also a central interest of ours in developing agents for inpatient education and counseling, given the low levels of health literacy in our patient population (Paasche-Orlow et al., 2005). Health literacy is the ability to perform the basic reading and numerical tasks required to function in the healthcare environment (American Medical Association Ad Hoc Committee on Health Literacy for the Council on Scientific Affairs, 1999). Health literacy is not simply the ability to read; it also requires a complex set of analytical and decision-making skills, and the ability to apply these skills to health situations. Fully 36% of American adults have limited health literacy skills, with even greater prevalence among patients with chronic diseases, those who are older, and those who have lower levels of education (Paasche-Orlow et al., 2005). Among indigent and minority patients in urban areas this number rises to over 80% (Williams et al., 1995).

A handful of studies have evaluated the relationship between health literacy and mental illness (Francis et al., 2007; Gazmararian et al., 2000; Lincoln et al., 2006, 2008; Morris et al., 2006; Weiss et al., 2006). In most of these studies limited health literacy has been associated with higher rates of depressive symptoms. For example, one report demonstrated that health literacy has an important longitudinal relationship with the course of depressive symptoms among adults with addiction (Lincoln et al., 2006). Given this high degree of association between depression and health literacy, interventions targeted at assessing and treating depression must be designed to accommodate patients with limited health literacy.

1.3. Relational agents in mental health

Relational agents – animated conversational agents designed to establish trust and therapeutic alliance with users over time – represent a potentially powerful technology for delivering health care services to patients with mental illness. Fig. 1 shows the relational agent interface used in our work. These interfaces use the easy-to-understand format of face-to-face conversation, making them less intimidating and more accessible to patients with a wide range of computer, reading and health literacy skills, and a low-pressure environment where patients are free to take as much time as they need. In prior work, this interface has been found to be easily used by a wide range of participants, including those with no prior experience with computers (Bickmore et al., 2005a). In addition, these agents use many verbal and nonverbal behaviors designed to establish a therapeutic alliance with patients, including displays of empathy, close proximity, more frequent eye gaze and attentiveness, and social dialogue and humor (Bickmore et al., 2005b). Finally, many studies have shown that patients are more honest with a computer than a human clinician when disclosing potentially stigmatizing behaviors such as alcohol consumption and HIV risk behavior (Ahmad et al., 2009; Card and Lucas, 1981; Ghanem et al., 2005; Kissinger et al., 1999; Newman et al., 2002). Individuals with depression may thus find a relational agent more approachable than a clinician in many situations, making it more effective at depression screening and counseling.

1.4. Overview

The development of the relational agent followed work over the last decade on a new standardized hospital discharge protocol de-

Fig. 1. Relational agent interface for virtual hospital discharge nurse application.

signed to reduce re-hospitalizations. A key element of this protocol involves a human nurse spending half an hour with each patient, ensuring they understand their post-discharge self-care regimen before they leave the hospital. While this protocol was shown to be effective in a previous clinical trial (Jack et al., 2009), the additional nursing time required made it impractical to disseminate, motivating the development of the relational agent to perform this task. A more detailed description of the agent development methodology and pilot test results was presented in Bickmore et al. (2009).

In the rest of this paper we first review related work, then briefly review the design of our relational agent for hospital patient education. We then describe a new study assessing the acceptance of the agent by hospitalized medical patients with and without symptoms of depression, as part of a new, ongoing clinical trial.

2. Related work

2.1. Technology in mental health

Internet-based technology has been explored extensively for opportunities to expand access to mental health education and services. Mental health internet sites are now used to provide information, screen for mental health and mood disorders, assist in the delivery of treatment, and provide social and therapeutic support. Web-based interventions are effective for a range of mental health disorders including depression, panic, post-traumatic stress disorder, perceived stress in schizophrenia, stress, insomnia, and eating disorders. Overall, computer-based mental health services are well received by patients and clinically useful in feasibility trials, although an actively depressed mood can be a barrier to use.

2.2. Technologies for depression intervention and treatment

Investigators have reported mixed results from clinical trials of internet-based depression screening and treatment programs (Christensen et al., 2004; Clarke et al., 2002, 2005). In general, computer-based technology has been used to substitute or augment traditional face-to-face therapeutic contact and the delivery of self-help materials. Studies using internet technology for depression support groups have shown reduced social isolation among users and perceived benefit from participation (Hill et al., 2006; Weinert et al., 2008). However, some reports indicate that adolescents, who participated in internet support groups, had reduced interpersonal communication with family members. Screening for depression using internet-based self-assessment tools has proved successful, although minority and elderly persons are less likely to engage in web-based depression screening programs (Houston et al., 2001). Internet-based Cognitive Behavior Therapy and some self-help depression interventions are effective in relieving depression symptoms in mild to moderately depressed patients, and in some cases even more effective with severely depressed patients (Houston et al., 2001). Among factors positively correlated with computer use for mental health treatment are perceived usefulness of the treatment, preference for anonymity, ease of contact and ease of use (Lai et al., 2008). However, according to one study, when intervention programs are accessed outside the context of a randomized research trial, attrition rates are high. This suggests that contact with a mental health provider may be necessary.

While currently available internet-based depression treatment can improve access to care, new technologies that serve as third parties to therapeutic interventions are on the horizon to enhance patient engagement in mental health care. For example, Coyle and Doherty described a 3D computer game designed to enhance adolescent engagement in therapeutic discussion (Doherty and Coyle, 2009). In their study, therapists reported overall acceptance of the game therapy by patients, however no evidence on patient preference or attitudes toward the technology was available from the subjects themselves.

Lisetti used animated anthropomorphic conversational agents to address social phobias such as public speaking anxiety, panic disorder and agoraphobia, in which the patient interacts with the agent in the reenactment of a fear-inducing situation (Lisetti, 2008).

Patients participating in internet or computer-based depression interventions also face some challenges. Some of the barriers reported by users include time constraints, lack of motivation, technical or computer-access problems, physical illness, the lack of face-to-face contact, preference for taking medication, perceived lack of treatment effectiveness, and burden of the program (Christensen et al., 2009). One commonly encountered barrier to computer interaction for depression across trials is active depressive symptoms (Doherty and Coyle, 2009). For example, in the *T*ailored *I*nterventions for Management of *DE*pressive *S*ymptoms (TIDES) program, a computer-based education program on self-care strategies for depressive symptoms in persons living with HIV/AIDS, was rated as easy to use and useful, but computer anxiety and depressive symptoms were negatively correlated with intention to use. Klein et al. reported similar difficulties in a trial of cognitive behavior therapy for panic disordered patients (Klein et al., 2006).

2.3. Conversational agents in mental health

Some of the earliest dialogue systems developed in healthcare were designed for psychotherapy applications. The ELIZA system was developed in 1966 to simulate the behavior of a Rogerian psychotherapist, in which the patient and the computer exchanged typed text messages (Weizenbaum, 1966). Although ELIZA was not intended to be used for actual therapy, similar systems have been proven effective for therapy in which the system is essentially prompting a patient to think aloud and work through his or her own problems (Slack, 2000). In these applications, significant errors in understanding user input or in producing incoherent system output can often be tolerated, as the primary function of the system is just to keep the user engaged in the interaction.

Colby developed an ELIZA-like system that was designed to use Cognitive Behavioral Therapy to treat individuals with depression. In addition to providing typed text counseling with patients, the system provided text-based educational materials about depression (Colby, 1995). While Colby reported that the program was accepted by patients, evaluations by other researchers indicate the typed text medium confused some patients and the only comparative evaluation in the literature indicates that the system did not work as well as clinician-administered therapy (Wright, 2004).

2.4. Relational agents in mental health

Bickmore developed a relational agent to promote medication adherence among patients with schizophrenia. The agent tracks each patient's medication taking behavior for a single antipsychotic medication taken by mouth in pill or capsule form based on self-report, and also promotes physical activity (walking), and talking to the agent every day. For each of these three behaviors, the agent first asks for a self report of behavior, provides feedback on the behavior, and negotiates a behavioral goal. Intervention on each behavior is started and terminated according to a schedule for a 30-day intervention. Several elements were incorporated into the system to address the needs of individuals with schizophrenia, including extended orientation and termination of the therapeutic relationship, use of concrete language, and certain nonverbal behaviors. A 30-day quasi-experimental pilot study involving 20 patients indicated high levels of acceptance, usability, and self-reported adherence (Bickmore and Pfeifer, 2008).

3. Design of a relational agent for patient education at hospital discharge

We have developed an automated system that teaches hospital patients about their post-discharge self-care regimen, including medications, follow-up appointments, exercise and diet regimens, and pending lab tests. The system is designed to be used by patients while they are still in their hospital beds. In order to make the system as acceptable and effective as possible, we designed the interface to incorporate an animated virtual nurse agent who embodies best practices in health communication for patients with inadequate health literacy. The agent is deployed on a wheeled kiosk with a touch screen display attached to an articulated arm that can be positioned in front of patients while they are in bed (Fig. 1). The agent is designed to interact with patients once every day they are in the hospital, but the primary interaction is just prior to hospital discharge. At this time, the patient spends approximately half an hour using the system, reviewing the layout and contents of a personalized "After Hospital Care Plan" (AHCP) booklet that is produced for them and contains their post-discharge self-care instructions. The paper booklet is given to patients before their conversation with the agent, and the agent reviews a digital version of the booklet in the interface, so that patients can follow along with the agent's explanation in their paper booklets.

3.1. Development methodology

Our multi-disciplinary design team comprised HCI researchers, doctors and nurses, a health literacy expert, and programmers and animators. The design process, from project start to completion of the user studies, lasted 3 years.

We used a multi-faceted approach to designing a system that would effectively teach patients, including those with inadequate health literacy, about their hospital discharge instructions. We began our design process with an ethnographic study of a re-engineered hospital discharge intervention that was currently underway in the hospital. Members of the design team visited hospital rooms, attended rounds with the medical team, observed discharge sessions in which nurses taught patients about their AHCP booklets, and interviewed the nurses who were performing this task. From these activities we learned about the stakeholders and basic workflow requirements of the system.

In addition to these "big picture" activities, we investigated the micro-behavior of expert nurses during discharge consultations with patients. We videotaped several mock discharge interactions in which one of the nurses explained an AHCP booklet either to a member of the research staff or a participant recruited from the community. We conducted discourse analyses of the videotaped interactions to characterize the verbal and nonverbal behavior used by the nurses while explaining a booklet to a patient. We also conducted two rounds of user testing of an agent explaining discharge instructions to users in our HCI lab (Bickmore et al., 2008).

3.2. Implementation

The agent was developed using an existing framework for ECA-based health counseling (Bickmore and Picard, 2005), extended with a computational model for the explanation of documents (Bickmore et al., 2008). In this interface, the agent speaks, using a synthetic voice, and displays animated nonverbal behavior (hand gestures, posture shifts, facial expressions, etc.) in synchrony with the speech. User contributions to the conversation are made by touching utterance option buttons on a touch screen display that are dynamically updated for each user speaking turn (Fig. 1). We considered using speech recognition as the input modality rather than the touch screen, but the hospital room can be a very noisy environment, and a significant portion of the patient population speaks English as a second language with many accents that would be problematic for commercial speech recognition products.

Dialogues are scripted, using a custom hierarchical transition network-based scripting language, and a visual dialogue design tool. The final system contains 550 dialogue states including 322 unique medication scripts covering 2254 medicines, along with 48 scripts for diagnoses.

The importance of caring, empathy and good "bedside manner" is widely recognized in healthcare as a key factor in improving not only patient satisfaction, but treatment outcomes across a wide range of health care disciplines (Garrity, 1981), and particularly in nursing (Sourial, 1997). Given this, prior successful implementations of empathic computer agents (Bickmore and Picard, 2005), and the need for the agent to maintain patients' attention for the hour it may take to relate all of the information in their discharge plans, we augmented the agent's informational dialogue with relational dialogue. Following earlier work on relational agents, we integrated a range of relational behavior into the agent dialogue, including appropriate forms of address (calling the patient by name), social chat at the beginning of every interaction, meta-relational communication, appropriate humor, appropriate feedback at every empathic opportunity, and references to information discussed in past interactions to give a sense of continuity (Bickmore et al., 2005a). The agent also offers patients the opportunity to take breaks at several points during the interaction in order to sustain attention and engagement.

A fragment of a typical conversation is shown in Fig. 2. The agent proceeds through the AHCP booklet linearly, describing each section before moving onto the next. Conversations generally consist of: (1) a greeting and social chat (Fig. 3); (2) orientation to the virtual nurse and the discharge process; (3) introduction of the AHCP (Fig. 4); (4) review of medications, including comprehension tests (Fig. 5); review of appointments, including comprehension tests; review of recommended diet and physical activity; "patient activation", in which the patient is urged to keep track of any ques-

VN: Good afternoon. My name is Elizabeth and I am here to help you with the discharge process here at Boston Medical Center. You are Joe, is that right?

Patient: OK

VN: It is great to meet you Joe. As you might have noticed, hospitals are very busy places. My job is to make sure that before you leave, you feel that you have been given all the information you need to help make the transition from here to your home as smooth as possible.

VN: So, are you a Red Sox fan?

… several turns of social chat …

VN: It looks like you are going to be leaving the hospital soon. I know you must be looking forward to leaving the hospital, but before you go, I want to review some information with you.

Patient: OK

VN: *[displays AHCP cover page, gestures with whole hand]* This is a care plan that we created just for you. Remember to bring this booklet with you to all of your doctors appointments.

…

Fig. 2. Sample dialogue – relational aspects highlighted.

Fig. 3. Greeting and social chat with virtual nurse.

tions or issues they want to discuss with their primary care provider (Fig. 6); and their primary diagnosis (Fig. 7). Following the interaction with the system, typically lasting 30–40 min, a report is printed for the human nurse that describes issues raised by the program that require follow up, such as questions about medications that the virtual nurse could not answer.

3.3. Pilot studies

Two rounds of pilot studies were conducted to assess acceptance, usability and satisfaction with the system (Bickmore et al., 2009). Results indicate that patients found the system easy to use, reported high levels of satisfaction, and most said they preferred receiving the discharge information from the agent over their doctor or nurse. Patients also expressed appreciation for the time and attention provided by the virtual nurse, and felt that it provided an additional authoritative source for their medical information.

4. Acceptance of relational agent by patients with depressive symptoms

We sought to explore how hospital patients with major depressive symptoms would react to the relational agent, by investigating whether they would find it more or less acceptable and usable, and whether they would form a stronger or weaker therapeutic alliance with the agent, compared to patients without major depressive symptoms.

Fig. 4. Introduction of after hospital care plan by virtual nurse.

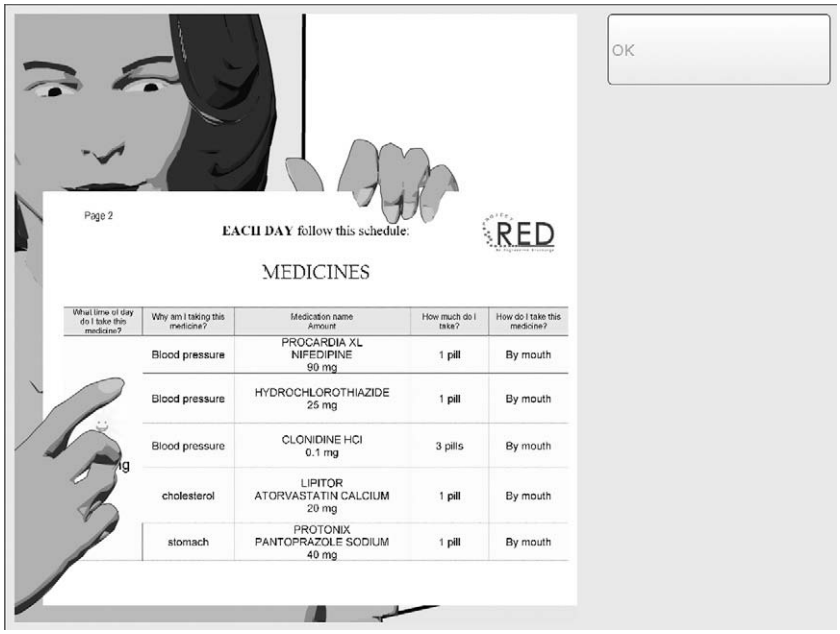

Fig. 5. Review of medications by virtual nurse.

4.1. Methods

A secondary analysis was performed using data from 139 English-speaking, hospitalized adults from an ongoing randomized controlled trial conducted at an urban academic safety-net hospital. The parent study, currently ongoing, is a two-armed evaluation study of the impact of the agent and other improvements to the hospital discharge process on 30-day hospital readmissions.

4.1.1. Study setting

The deployment site for the relational agent system is Boston Medical Center, a 547 bed safety-net hospital that serves an urban, 84% minority, traditionally underserved population. Approximately 58% of this population has inadequate health literacy (see Section 4.1.3 for the measure used).

4.1.2. Participants

Participants in the study were English-speaking adult patients, 18 years or older, admitted to the teaching service of Boston Medical Center, a large urban safety-net hospital with an ethnically diverse patient population. Three hundred and forty-seven subjects were enrolled and randomized between October 15, 2008 and June 20, 2009. Patients were required to have a telephone, be able to comprehend study details and the consent process in English, and have plans to be discharged to a US community. Patients were not enrolled if they were admitted from a skilled nursing facility or

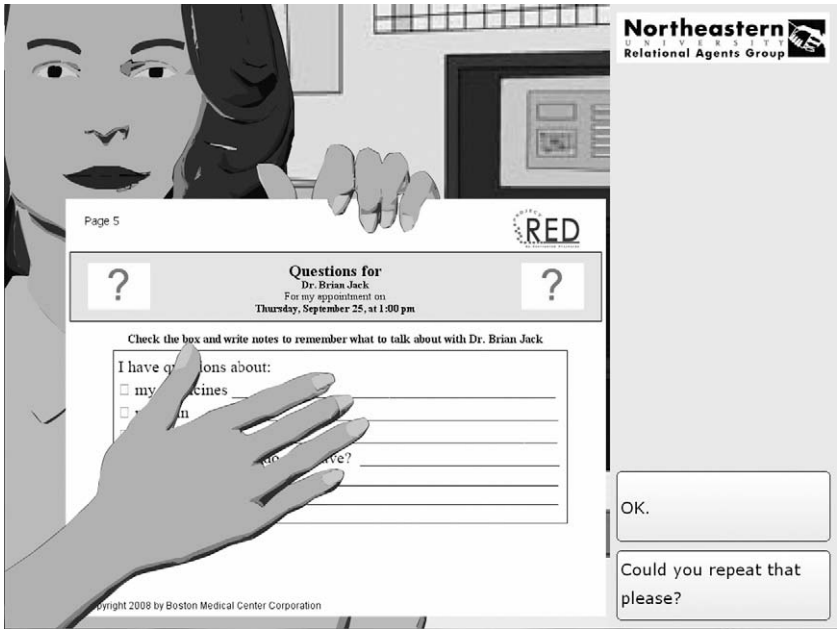

Fig. 6. Patient activation by virtual nurse.

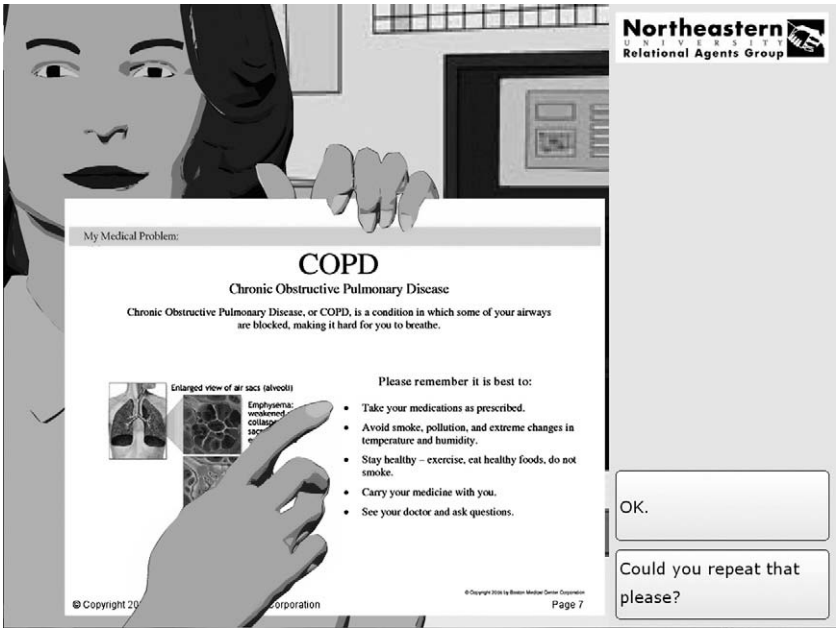

Fig. 7. Review of primary diagnosis by virtual nurse.

other hospital, transferred to a different hospital service prior to enrollment, admitted for a planned hospitalization, on hospital precautions, on suicide watch, deaf or blind.

Of the 347 subjects enrolled into the parent study, 173 were randomized into the relational agent intervention arm of the study. Of these, 131 completed all measures necessary for our analyses.

4.1.3. Measures

4.1.3.1. Depressive symptoms. The primary independent variable of interest was depressive symptoms, defined as a positive score for major depression on the validated PHQ-9 depression screening tool. A dichotomized variable was created using a standardized scoring system to determine the screening cut-off for major depressive symptoms (score $\geqslant$10 on a possible score range of 0–27) (Kroenke et al., 2001).

4.1.3.2. Therapeutic alliance. Patient perception of therapeutic alliance with the agent was assessed using the Bond subscale of the Working Alliance Inventory, a 12-item questionnaire assessing the emotional dimension of a patient's trust and belief that they can work together with their provider to achieve desired therapeutic outcomes (Horvath and Greenberg, 1989).

4.1.3.3. Health literacy. We assessed health literacy using the 66-word version of the Rapid Estimate of Adult Literacy in Medicine (REALM) (Davis et al., 1993). We defined limited health literacy as a reading level of 8th grade and below and adequate health literacy as 9th grade and above for our analyses, as prior authors have done (Lincoln et al., 2006; Lindau et al., 2006; Mancuso and Rincon, 2006; Sudore et al., 2006).

4.1.3.4. Attitudes towards the agent. In addition to therapeutic alliance, we assessed additional patient attitude towards and satisfaction with the agent using single item, scale response questions, shown in Table 1.

4.1.3.5. Questions asked. All patient interactions with the agent were logged for subsequent analysis. From these logs we counted the number of times each patient selected a response that provided additional information when offered as an option.

4.1.4. Procedure

Following enrollment, collection of background, demographic and depressive symptom information and randomization, intervention patients have their post-discharge self-care information entered into a workstation by a study nurse. This information is used to generate the AHCP booklet, and is also downloaded to a mobile kiosk that is then wheeled into the patient's room (Fig. 1). After the patient is given their paper booklet and provided with a brief training session on how to use the touch–screen interface, they are left to conduct their conversation with the agent. At the end of this interaction, any unresolved patient questions or issues are displayed for a human nurse to follow up with the patient, and results of the session are uploaded to a database. At this time, self-report measures covering attitudes towards the agent and therapeutic alliance are collected. All self-report measures are verbally collected to accommodate patients with limited literacy.

Table 1
Self-Report Measures of Attitudes Towards the Relational Agent.

Measure	Question	Anchor 1	Anchor 7
Satisfaction	How satisfied were you with Elizabeth?	Not at all	Very satisfied
Usability	How easy was talking to Elizabeth?	Easy	Difficult
Continue	How much would you like to continue working with Elizabeth?	Not at all	Very much
Relationship	How would you characterize your relationship with Elizabeth?	Complete stranger	Close friend
Preference	Would you rather have talked to your doctor or nurse than Elizabeth?	Definitely prefer doctor or nurse	Definitely prefer Elizabeth
Adherence	How likely is it that you will follow Elizabeth's advice?	Not at all likely	Very likely

Preference	4.16	2.03	4.73	1.67	0.29
Adherence	6.22	1.21	6.73	0.59	0.13

4.2. Results

All variables were tested for normality. Therapeutic alliance was found to have a significant negative skew and was logarithmically transformed (after reflection) to normalize the distribution. Questions Asked had a positive skew but was not transformed due a floor effect and the nature of the measure (non-parametric tests were used).

Of the 131 patients analyzed, 19 (14.5%) were classified as having major depressive symptoms according to the PHQ-9. Table 2 compares patient demographic and other characteristics by depression status. Patients with major depressive symptoms were similar to other patients on all characteristics except for computer literacy, with the depressive group scoring significantly lower.

Table 3 shows self-report ratings of the agent. Overall ratings of satisfaction and ease of use were very high, and only 24% of patients said they would have preferred receiving their discharge information from their doctor or nurse (40% were neutral, 36% said they definitely preferred the agent). Patients with major depressive symptoms stated a significantly greater desire to continue interacting with the agent, $p < 0.05$ by Mann–Whitney test (mean of 6.6 vs. 5.6).

Table 4 shows correlations among continuous measures. There are significant positive correlations between therapeutic alliance,

* $p < 0.05$ level.
** $p < 0.01$.

number of questions asks, satisfaction with the overall virtual nurse system, desire to continue using the system, preference for the virtual nurse over a human doctor or nurse, and stated expectation of following the agent's advice.

Patients with major depressive symptoms scored the agent significantly higher on therapeutic alliance compared to patients classified as not having major depressive symptoms (6.2 vs. 5.5, before transformation), $t(108) = 2.02$, $p < 0.05$, $d = 0.58$.

Patients classified as having inadequate health literacy scored significantly higher on therapeutic alliance compared to patients with adequate health literacy (5.9 vs. 5.4, before transformation), $t(116) = 2.56$, $p < 0.05$, $d = 0.47$. Patients with inadequate health literacy also asked the agent significantly more questions, compared to patients with adequate health literacy, $p < 0.05$ by Mann–Whitney test.

4.3. Discussion

Self-report ratings of satisfaction, ease of use, and attitudes towards the agent were high for all patients, with only 24% of patients indicating they would have preferred receiving their discharge information from their doctor or nurse. This result is similar to that found in our pilot studies, in which patients stated that they appreciated the amount of information given to them by the agent, the amount of time that the agent spent with them, and that the agent did not talk down to them as many providers do (Bickmore et al., 2009). As one patient reported:

> "It was just like a nurse, actually better, because sometimes a nurse just gives you the paper and says 'Here you go.' Elizabeth explains everything."

The primary finding of the study is that patients with symptoms indicative of major depression rated the agent significantly higher on therapeutic alliance compared to patients who did not have major depressive symptoms. In combination with their greater stated desire to continue working with the agent, this indicates that a relational agent is not only acceptable to patients with major depressive symptoms, but that these patients feel they have established a stronger emotional bond with the agent compared to patients without depressive symptoms.

Patients with inadequate health literacy also reported a significantly greater therapeutic alliance with the agent compared to patients with adequate health literacy. This effect was independent of depression. Given that both health literacy and depression represent barriers to healthcare, this indicates that automated patient education systems incorporating relational agent technology could help reduce disparities in access to care.

4.3.1. Limitations

There are several important limitations to our preliminary study. First, our results may not be generalizable to populations other than those served by urban safety-net hospitals or other populations excluded from the parent study. Second, our results are correlational, so we do not know the direction of the associations between major depressive symptoms and other measures reported. Finally, our results may be due to the fact that patients with depressive symptoms react more positively to computer-based interventions, or any novel intervention. This would be consistent with reports from evaluations of many other computer interventions for patients with mental health problems (Wright, 2004). Our observation that patients with inadequate health literacy also had higher therapeutic alliance may serve to partially mitigate this concern.

5. Conclusion and future work

Depressive symptoms are a risk factor for many adverse health conditions and early hospital readmission, thus the ability to identify hospitalized patients for depression is of great interest to the healthcare community. A relational agent that can screen and develop a therapeutic alliance may also enhance the likelihood of successful outpatient depression treatment following hospital discharge. Further, the deleterious effects of active depression on treatment response and disease severity may be ameliorated with prompt identification and initiation of treatment at the time of hospitalization for patients with depressive symptoms.

Low health literacy contributes to health disparities across diverse realms of healthcare, including access to care, medical decision-making, medication adherence, and preparation for a diagnostic test. The significantly greater therapeutic alliance reported by patients of low health literacy may be related to the agent's ability to deliver information in a nonjudgmental manner at a patient-centered pace of learning, alleviating the stigma felt by patients with low health literacy. Developing similar patient counseling applications in other healthcare settings where health literacy impacts disease outcomes could have a positive impact on health disparities.

Our future work in this area involves developing and evaluating relational agents for depression screening and treatment, to determine if the results found in this study do in fact imply the promise of the technology for reaching and treating depressed individuals in the inpatient setting.

Acknowledgements

This work was supported by grants from the NIH National Heart, Lung and Blood Institute and the Agency for Health care Research and Quality. Thanks to the many members of the Re-Engineered Discharge project team at Boston Medical Center and the Relational Agents Group at Northeastern University for their contributions to this work.

Embodied Conversational Agents (ECA) are computer-animated characters that simulate face-to-face conversation with patients. These agents can be programmed with best practices in human-human health communication and used for automated health education and behavior change counseling interventions. Evidence is presented from two ongoing clinical trials demonstrating that patients at different levels of health literacy find these agents acceptable and easy to use for automated health communication interventions. Innovative computer interface systems can be used to ensure that inadequate health literacy not serve as a barrier to interventions using health information technology.

Address correspondence to Timothy W. Bickmore, Northeastern University, Computer Science, WVH202, 360 Huntington Ave, Boston, MA 02115, USA. E-mail: bickmore@ccs.neu.edu

There has been an explosion of interest and creativity in the field of health information technology, driven not only by the tremendous advantages of electronic medical records, but also by the great prospect for this technology to directly support patients for self-care and health behavior change. Research in this area has accelerated over the course of the past 25 years; however, the potential health benefits of this technology have not been realized. Two of the chief reasons for this are related to accessibility and usability. If patients cannot acquire the technologies or use them correctly, there is little possibility that such advances could lead to improvement in clinical outcomes.

Indeed, it is likely that current advances in patient-facing health information technology will exacerbate health disparities, as the benefits of such technologies will disproportionately accrue to the wealthiest, most educated, and technologically advanced members of society (Norman & Skinner, 2006; Bodie & Dutta, 2008). In particular, patients with inadequate health literacy are likely to be particularly vulnerable in this regard. People with inadequate health literacy are much less likely to use computers and have difficulty processing health information (Kutner, Greenberg, Jin, & Paulsen, 2006). Addressing disparities in access and usability is thus an essential element of addressing health disparities in general.

We have developed a computer interface—called an Embodied Conversational Agent (ECA)—that is usable by people with inadequate health literacy (Bickmore, Pfeifer, & Paasche-Orlow, 2009). The interface uses the universal and familiar format of face-to-face conversation, not just as an interface metaphor, but as the actual model of interaction. This is accomplished through the use of an animated character that talks to patients using synthetic speech and synchronized conversational nonverbal behavior, such as hand gestures, head nods, and eyebrow raises (Figure 1) (Cassell, Sullivan, Prevost, & Churchill, 2000). Patients talk to the character using touch screen input.

Figure 1. Embodied conversational agent interface for walking promotion trial.

Motivation for Using Embodied Conversational Agents with Inadequate Health Literacy Patients

Evidence suggests that face-to-face encounters with a health provider—in conjunction with written instructions—remain one of the best methods for communicating health information to patients in general, but especially those with inadequate health literacy (Qualls, Harris, & Rogers, 2002; Colcher & Bass, 1972; Madden, 1973; Morris & Halperin, 1979; Clark & Brennan, 1991). Face-to-face consultation is effective because it requires that the provider focus on the most salient information to be conveyed and that the information be delivered in a simple, conversational speaking style (Qualls et al., 2002). Protocols for "grounding" in face-to-face conversation—the use of verbal and nonverbal cues such as head-nods, gaze and acknowledgment tokens ("uh-huh," "OK") to signal mutual understanding (Clark & Brennan, 1991)—allows providers to dynamically assess a patient's level of understanding and repeat or elaborate information as necessary. Face-to-face conversation also allows providers to make their communication more explicitly interactive by asking patients to do, write, say, or show something that demonstrates their understanding (Doak, Doak, & Root, 1996). Finally, face-to-face interaction allows providers to use verbal and nonverbal behaviors, such as empathy (Frankel, 1995) and immediacy (Argyle, 1988; Richmond & McCroskey, 1995) to elicit patient trust, enabling better communication and satisfaction.

Given the efficacy of face-to-face consultation, Embodied Conversational Agents (ECA) show particular promise for conveying health information to patients with inadequate health literacy by simulating face-to-face conversation with a provider. These systems can produce verbal and nonverbal conversational behaviors that signify understanding, mark significance, and convey information in redundant channels of information (including speech intonation, hand gesture, facial display, body

Figure 2. Embodied conversational agent interface in rehospitalization trial (photo Glenn Kulbako).

posture shift, and eye gaze), to maximize message comprehension. They can use the verbal and nonverbal communicative behaviors used by health providers to establish trust and rapport with their patients in order to increase satisfaction and adherence to treatment regimens (Bickmore, Gruber, & Picard, 2005). They can adapt their messages to the particular needs of patients and to the immediate context of the conversation, since each utterance by the agent is dynamically composed (not just pre-recorded). They can emulate clinicians' extensive use of pointing gestures when explaining written materials to patients in order to clarify references and describe the structure and layout of the text (as in Figure 2) (Bickmore, Pfeifer, & Yin, 2008). Finally, they can provide health information in a consistent manner and in a low-pressure environment in which patients are free to take as much time as they need to thoroughly understand it.

ECA-Based Health Intervention Clinical Trials

We are currently using the ECA interface in two randomized clinical trials that specifically examine the role of health literacy. In one of these trials, the ECA is being used to teach patients being discharged from the hospital about their after hospital care plan. In the other it is being used to promote walking in older adults. The goal of the current analysis is to evaluate data from these ongoing trials regarding the usability of the ECA system for people with inadequate health literacy.

The two clinical trials of ECA-based health interfaces are being conducted at Boston Medical Center, a large urban safety-net hospital and ambulatory care center with an ethnically diverse patient population. Both studies use an ECA-based computer interface to communicate health information to patients, modeling best practices in health communication for patients with inadequate health literacy.

In the current analysis we are focused on measures related to satisfaction, usability and other process measures (in both studies we are blinded to health outcomes until trial completion: 30-day hospital utilization in the rehospitalization study and walking steps and fitness in the walking study).

Rehospitalization Trial

The first trial, entitled, "A RCT to Reduce Cardiopulmonary Rehospitalization" (PI: Jack, R01HL081307) is a two-armed intervention trial to improve patient education and safety in the transition between hospital and home with a primary goal of reducing 30-day hospital readmission. The system is designed to be used by patients in their hospital beds. The agent is deployed on a wheeled kiosk with a touch screen display attached to an articulated arm that can be positioned in front of patients (Figure 2). The system is designed to interact with patients once each day they are in the hospital, but the primary interaction is just before hospital discharge (75% of patients only had this final, discharge interaction, due to short hospital stays or logistical constraints). The final interaction is performed after the final list of discharge medications are approved ("medication reconciliation"), and typically just before the patient leaves the hospital. In this interaction, patients spend approximately half an hour using the system, to review the layout and contents of a personalized "After Hospital Care Plan" booklet that is produced for them and contains their post-discharge self-care instructions. The paper booklet is given to patients before their conversation with the agent, and the agent displays and reviews a digital version of the patient's booklet in the interface, so that patients can follow along

with the agent's explanation in their paper booklets to review medications, exercise and diet recommendations, and follow-up appointments. The specific approach to discharge education used in this project was modeled on our prior intervention—the Re-Engineered Hospital Discharge (RED)—which was delivered by a nurse (Jack, Chetty, & Anthony, 2009).

Rehospitalization Trial Methods

Participants

Participants in the rehospitalization study were English-speaking patients, 18 years of age or older, admitted to the teaching service of Boston Medical Center between October, 2008 and August, 2009. Patients were required to have a telephone, be able to comprehend study details and the consent process in English, and have plans to be discharged to a U.S. community. Patients were not enrolled if they were admitted from a skilled nursing facility or other hospital, admitted for a planned hospitalization, on hospital precautions, on suicide watch, deaf, or blind. Of the 417 participants enrolled to date into the parent study (of a planned 750), 208 were randomized into the ECA intervention arm of the study. Of these, 143 completed all measures necessary for our analyses (there were no significant differences in demographic characteristics between those who completed all measures and those who left the hospital prior to completing the study protocol).

Measures

Health Literacy

Health literacy was assessed using the Rapid Estimate of Adult Literacy in Medicine (REALM) (Davis, Long, & Jackson, 1993). The sample was split into "adequate" and "inadequate" health literacy groups, using a REALM score of 9th grade and above, as other authors have done (Lindau, Basu, & Leitsch, 2006; Mancuso & Rincon, 2006; Sudore, Yaffe, & Satterfield, 2006; Lincoln, Paasche-Orlow, & Cheng, 2006).

Usability

Usability was assessed using single scale-measure self-report items to assess overall satisfaction with the ECA, ease of use, desire to continue working with the ECA, and preference for the ECA relative to human health providers, in addition to session duration.

Attitudes Towards the Agent—Therapeutic Alliance

Patient attitude towards the ECA was assessed using a measure of therapeutic alliance, specifically the affective bond subscale of the Working Alliance Inventory. This is a self-reported 12-item Likert scale questionnaire assessing the emotional dimension of a patient's trust and belief that they can work together with a provider to achieve desired therapeutic outcomes (Horvath & Greenburg, 1989).

Procedure

Participants were provided with brief training on how to "talk" to the ECA, in which the agent walks on the screen and greets the participant; participants are then told to

"touch what you want to say on the screen" (that is typically the extent of the training). At the conclusion of their interaction with the ECA they answered questions regarding usability and attitudes toward the gent just prior to leaving the hospital. All self-report measures were verbally collected by research staff to accommodate patients with limited literacy.

Rehospitalization Trial Results

Demographics and Health Literacy

Table 1 shows demographics of the study population. Participants with inadequate health literacy in the rehospitalization study were significantly older, less educated, and more likely to be non-White compared with participants in that study with adequate health literacy. Participants with inadequate health literacy also had significantly lower levels of computer literacy compared to participants with adequate health literacy.

Usability

Participants reported very high levels of overall satisfaction and ease of use, regardless of health literacy level: 78% of all participants scored satisfaction a 7 on a

Table 1. Subject demographics by health literacy level

Health literacy assessed via REALM for Rehospitalization Study and TOFHLA for Walking Study.

7-point Likert-type scale (with 7 = "very satisfied"), and 78% scored ease of use a 1 on a 7-point scale (with 1 = "very easy to use"). In addition, participants with inadequate health literacy showed a trend of greater satisfaction with the ECA compared to participants in that study with adequate health literacy.

None of the other usability measures were significantly different across health literacy levels.

Attitudes Toward the Agent

Participants scored well above the Likert scale midpoint on overall mean Working Alliance Bond subscale scores, regardless of health literacy level, and only 11% of participants scored below the midpoint of the composite measure. In addition, there were no significant differences between literacy groups on overall Working Alliance scores. However, differences on a few of the individual items in the scale reached significance, indicating a greater degree of personification of the agent (mutual respect, importance of relationship with the agent) by participants with inadequate health literacy.

Geriatrics Walking Promotion Trial

The second trial, entitled, "Computer Agents to Promote Walking in Older Adults with Low Health Literacy" (PI: Silliman, R01AG028668) is a two-armed intervention trial to promote walking in older adults with a primary goal of improving the number of steps per day at 12 months. Older adult ambulatory clinic patients at Boston Medical Center are given pedometers which link to tablet-PC computers. Intervention participants are given a tablet-PC to use at home for 2 months and are asked to interact with the ECA daily to set and discuss walking goals (Figure 1). In addition, participants can interact with the agent on a kiosk in the waiting room of their primary care provider.

Walking Trial Methods

Participants

Participants in the walking study were English-speaking patients, 65 years or older, who attend the geriatrics or internal medicine ambulatory care clinics at Boston Medical Center between April, 2009 and September, 2009. Patients were required to speak and read English at a level required to interact with the ECA (via a screening conversation with the agent) and to understand the study protocol, be inactive but medically able to begin a moderate intensity physical activity program, and free of cognitive impairment and significant depressive symptoms. Of the 88 participants enrolled to date into the parent study (of a planned 270), 44 were randomized into the ECA intervention arm of the study and 2-month study measures were obtained from 33 of these.

Measures

Health Literacy

Health literacy was assessed using the Test of Functional Health Literacy in Adults (TOFHLA) (Parker, Baker, Williams, & Nurss, 1995). A different measure was used relative to the rehospitialization trial due to the different patient populations and

study settings. Patients with subclinical dementia can often pronounce a word correctly but not know what the word means, invalidating REALM results. As this is more likely to occur in older cohorts, we chose to avoid the REALM in the walking study, and used the TOFHLA. However, as the TOFHLA takes more time to administer, it was not the best choice for rushed hospital environments, especially those with relatively younger adult populations. Both of these measures reflect print literacy and reading ability (Berkman, Pignone, Sheridan, & Lohr, 1994) and so may not be the most accurate assessments of ability to act on health information communicated verbally.

The sample was split into adequate and inadequate health literacy groups, using a TOFHLA score of 23 or above, as other authors have done (Lindau et al., 2006; Mancuso & Rincon, 2006; Sudore et al., 2006; Lincoln et al., 2006).

Usability

Usability was assessed through actual voluntary use of the system during the first two months in which patients had the tablet computer at home, based on the tablet log files. Measures included the number of sessions completed out of 60 possible daily conversations, the average duration of each session, and the percent of sessions in which participants plugged in their pedometer (the agent asked them to plug it in every session).

Attitudes Towards the Agent—Therapeutic Alliance

Attitude towards the agent was assessed using the affective bond subscale of the Working Alliance Inventory, as in the rehospitalization trial (Horvath & Greenberg, 1989).

Procedure

Participants were provided with the same brief ECA training as in the rehospitalization study, given at time of enrollment, before being sent home with a tablet computer for two months of home-based interactions with the agent. Assessments of attitudes toward the ECA were administered at an in-person research interview immediately following these 2 months. All self-report measures were verbally collected by research staff to accommodate patients with limited literacy.

Analysis

In order to examine the trends in participant use of the system over time, we analyzed the sessions data using mixed-effect modeling. All analysis was performed using R 2.9.0 (R Development Core Team, 2008) with the "nlme" package, fitting linear mixed-effect regression models to the sessions per week and literacy category data. Best fit results were for a model with random effects for intercept but not study week (slope).

Walking Trial Results

Demographics and Health Literacy

As in the rehospitalization study, participants with inadequate health literacy had lower levels of computer literacy compared to participants with adequate health literacy, although this difference was only trending towards significance, likely due to the smaller sample size (Table 1).

Table 2. Outcomes by health literacy level

Health literacy level	Inadequate	Adequate	*p* value
Rehospitalization Study			
Satisfaction (1 = not at all; 7 = very much)	6.57	6.45	.083

All t-tests except Satisfaction (Mann-Whitney due to ceiling effect).
*WAI: Working Alliance Inventory (all items Likert scale, 1 = disagree completely; 7 = agree completely).

Usability

Mixed effect regression indicates that participants with inadequate health literacy completed fewer home-based conversations with the ECA compared to participants with adequate health literacy ($p < .05$), Note that a simple *t*-test on total number of sessions also shows this result (approaching significance, Table 2). Regression results also indicate a significant decrease in home-based conversations with the ECA over time for all participants of -0.29 sessions/week ($p < .001$). There was no significant interaction between sessions per week and literacy category; participants had similar patterns of decreasing use over time, regardless of literacy category.

There were no significant differences in session durations between literacy categories, but there was a trend for participants with adequate health literacy to plug in their pedometers more frequently compared to participants with inadequate health literacy ($p = .058$, Table 2).

Attitudes Toward the Agent

As in the rehospitalization study, participants scored well above the Likert scale midpoint on overall mean Working Alliance Bond subscale scores, regardless of health literacy level, and only 9% of participants scored below the midpoint of the composite measure. In addition, there were no significant differences between literacy groups on overall Working Alliance scores. However, differences on a few of the individual items in the scale reached significance, indicating a greater degree of personification of the agent (mutual understanding) and a lower level of understanding of the technology (thinking the agent would discontinue use if the participant said the wrong thing) by participants with inadequate health literacy.

Discussion

Overall, there were very few differences in measures of acceptance and usability between patients with adequate and inadequate health literacy, suggesting that ECAs are approachable and usable by patients regardless of health literacy level. In the few measures in which there were significant or near-significant differences on health literacy, these were mostly in favor of patients with inadequate health literacy,

indicating that ECAs may be even more acceptable to this population than to patients with adequate health literacy.

In addition to the theoretical reasons why ECAs may be ideal interfaces for patients with inadequate health literacy, described earlier, patients interviewed in the pilot studies that preceded the two trials provided a better understanding of their reasons for accepting the technology (Bickmore, Pfeifer, & Jack, 2009; Bickmore, Caruso, Clough-Gorr, & Heeren, 2005). Patients in both pilots indicated that the system was very easy to use, even if they had little or no experience with computers:

- "*I don't like computers but that was easy*." (rehospitalization pilot)
- "*That is so easy. That is so good. Regular computers I don't do. But, that was so easy, even a baby could do that*." (walking pilot)

Patients in the rehospitalization pilot indicated that they liked being able to take as much time as they needed to understand everything, something they said that their doctors or nurses typically did not provide:

- "*Sometimes doctors just talk and assume you understand what they're saying. With a computer you can go slow, go over things again and she checks that you understand*."
- "*I prefer Louise [the name of the ECA character], she's better than a doctor, she explains more, and doctors are always in a hurry*."

Patients in both pilots were also mostly positive about the interventions:

- "*It was the best thing that happened to me, to have something that pushed me out and get me walking*." (walking pilot)
- "*She's nice. She's really good. Really good. She asks you the right questions. She tells if you if you're not doing up to par, you know, and all that. And if you're doing good, she'll tell you. If you're not she'll tell you. And it's honest. And it works. It really does. I like it. I like talking to her*." (walking pilot)
- "*She treated me like a real person! She's not like a computer. This is awesome work! This is really excellent*." (rehospitalization pilot)
- "*I've had problems with, not this hospital, but other hospitals. I wasn't given the quality time that this lady gave me*." (rehospitalization pilot)

One area of possible concern is that patients with adequate health literacy in the walking trial completed more sessions with the ECA compared to patients with inadequate health literacy. This may indicate that, despite having similar attitudes towards and satisfaction with the agent and despite finding the system easy to use, there may be other important factors such as patient activation that dictate the amount of use. However, the relationship between intervention dose and health outcomes in behavioral studies can be complex, and it could even be that fewer sessions result in better outcomes. The ECA provides an accessible and usable communication channel for patients irrespective of health literacy, but more research is required to ascertain contexts in which dose is important and then to tailor information and counseling dialogue content to ensure that a given intervention is effective for patients with inadequate health literacy.

Patients with inadequate health literacy appear to anthropomorphize ECAs more than patients with adequate health literacy, as reflected by specific items related to mutual understanding and respect, and belief that the agent may decide to stop working with them if they say something wrong. Although this indicates a

general lack of understanding of the underlying technology, it may ultimately prove beneficial for these patients if the increased personification leads to a greater sense of working alliance and increased adherence to the ECA's recommendations. Some patients may actually confuse the agent with a real person (e.g., if delirious in the hospital), which could be partially addressed by having both the humans administering the agent and the agent itself periodically remind users that it is just a computer. Another concern is that the results may indicate that patients with adequate health literacy do not like the social aspects of the interactions, feeling that they are unnecessary, slow, or even disingenuous. Future systems may allow patients to choose more conventional graphical user interfaces that let them work through the information in a session more efficiently.

Future Work

Our immediate future plans are to complete the rehospitalization and walking trials in order to demonstrate efficacy—in terms of clinically important health outcomes—regardless of health literacy level.

Now that we have established that ECAs can provide an acceptable and usable health communication channel for patients with inadequate health literacy, the opportunities for developing patient and consumer education and counseling interventions are limitless. Specific areas that we are investigating include:

- Automated explanation of written medical information to patients with varying levels of health literacy (Bickmore, Pfeifer, & Paasche-Orlow, 2009).
- Linguistically and culturally tailored health interventions, such as exercise promotion for older bilingual Latino adults (Yin, Bickmore, Byron, & Cortes, 2010).
- Longitudinal health behavior change interventions, in which alliance with the ECA is used to promote retention in the intervention as well as adherence (Bickmore, Schulman, & Yin, 2010).
- Deployment on other computer platforms, including mobile devices (Bickmore & Mauer, 2009).

A final important area of ongoing research is the automatic adaptation of the computer interface in response to patient characteristics and needs. Our finding that patients with high levels of computer literacy are less satisfied with the ECA may indicate that such patients should be given the option of using a more traditional computer interface to more efficiently access the information they need, while patients with low computer and/or health literacy would use the ECA. In addition, in some of our studies we have found that nurses provide different information to patients depending on their level of health literacy—providing more technical detail to patients with adequate health literacy, but providing more scaffolding (information about document structure) to patients with inadequate health literacy (Bickmore, Pfeifer, & Yin, 2008)—and this difference in presentation could also be emulated by an ECA that dynamically adjusts its dialogue based on patient needs.

Performance of mixed effects models in the analysis of mediated longitudinal data

Emily A Blood[1,2*], Howard Cabral[1], Timothy Heeren[1], Debbie M Cheng[1]

Abstract

Background: Linear mixed effects models (LMMs) are a common approach for analyzing longitudinal data in a variety of settings. Although LMMs may be applied to complex data structures, such as settings where mediators are present, it is unclear whether they perform well relative to methods for mediational analyses such as structural equation models (SEMs), which have obvious appeal in such settings. For some researchers, SEMs may be more difficult than LMMs to implement, e.g. due to lack of training in the methodology or the need for specialized SEM software. It therefore is of interest to evaluate whether the LMM performs sufficiently in a scenario particularly suitable for SEMs. We focus on evaluation of the total effect (i.e. direct and indirect) of an exposure on an outcome of interest when a mediating factor is present. Our aim is to explore whether the LMM performs as well as the SEM in a setting that is conducive to using the SEM.

Methods: We simulated mediated longitudinal data from an SEM where a binary, main independent variable has both direct and indirect effects on a continuous outcome. We conducted analyses with both the LMM and SEM to evaluate the performance of the LMM in a setting where the SEM is expected to be preferable. Models were evaluated with respect to bias, coverage probability and power. Sample size, effect size and error distribution of the simulated data were varied.

Results: Both models performed well in a range of settings. Marginal increases in power estimates were observed for the SEM, although generally there were no major differences in performance. Power for both models was good with a sample of size of 250 and a small to medium effect size. Bias did not substantially increase for either model when data were generated from distributions that were both skewed and kurtotic.

Conclusions: In settings where the goal is to evaluate the overall effects, the LMM excluding mediating variables appears to have good performance with respect to power, bias and coverage probability relative to the SEM. The major benefit of SEMs is that it simultaneously and efficiently models both the direct and indirect effects of the mediation process.

Background

A common method of handling longitudinal data is through linear mixed effects models (LMMs) [1]. These models account for the correlation of observations and allow estimation of the effect of predictor variables on repeated outcomes. They are relatively easy to implement and their regression parameters have a clear interpretability.

Complex relationships often exist among the variables studied, however, and it may be of interest to explicitly model the hypothesized causal pathways between independent variables and outcomes. Although multiple mixed effects models can be fit to evaluate mediation (see e.g. Krull and MacKinnon [2] and Baron and Kenny [3]), methods for mediational analyses, such as Structural Equation Models (SEMs), are necessary to simultaneously model mediated relationships. However, when the primary aim of an analysis is to determine the total effect (i.e. direct and indirect) of an exposure on an outcome of interest, it is unclear what the impact of explicit modeling of the mediated relationship is on power, bias, and on coverage probability for the main research aim.

SEMs are a well known and commonly used data analysis technique in the social sciences, and is becoming increasingly popular in many clinical research areas. The

SEM framework is a general modeling framework and allows the modeling of potentially complex relationships among observed and latent variables and can be applied in the longitudinal data setting.

There has been much previous work in applying SEMs to longitudinal data analyses [4-9], and the equivalence of LMMs and special cases of SEMs in settings without mediating variables has been well documented in the SEM literature [5,7,10-15]. The major advantages of SEMs are that they have the capability to incorporate measurement error on the variables in the model [5,8,13], allow explicit modeling of relationships involving mediating variables [16] and are able to decompose direct and indirect effects [11]. Disadvantages of SEMs that have been previously noted include potentially large sample size requirements and potential problems with skewed data. It is also essential for SEMs that investigators have clear hypotheses on the causal pathways between variables [9]. In addition, SEMs may be more difficult than LMM to implement, e.g. due to a lack of training in the methodology or the need for specialized SEM software. Given these potential limitations, it is of interest to explore whether a LMM performs well relative to an SEM in settings where mediation is present.

The purpose of this paper is to conduct a simulation study in a mediated longitudinal setting to evaluate whether a LMM performs sufficiently with respect to power, bias and coverage in a scenario that is conducive to using an SEM.

Methods

Setting

We consider a longitudinal setting similar to a study by Samet et al [17] evaluating the impact of heavy alcohol consumption on HIV disease progression. The data arise from a prospective cohort study in which the primary outcome, CD4 cell count, is assessed every 6 months for three years (i.e. 6 measures of CD4 count across time for each subject) and heavy alcohol consumption, the main independent variable, is assessed only at baseline. A potential mediator of the relationship between heavy alcohol consumption and HIV disease progression is adherence to antiretroviral therapy (ART) as it has been demonstrated that alcohol consumption may worsen a patient's ability to adhere to ART thereby leading to worse disease progression. In the current setting we assume that ART is assessed only at baseline. In addition to an indirect effect mediated by ART, alcohol consumption could also have a direct biological effect on CD4 cell count. The primary objective of the analysis is to evaluate the overall impact (direct plus indirect effect) of heavy alcohol use on CD4 cell count. Figure 1 shows a simple diagram illustrating the relationship between heavy alcohol consumption, ART adherence and the outcome CD4 cell count.

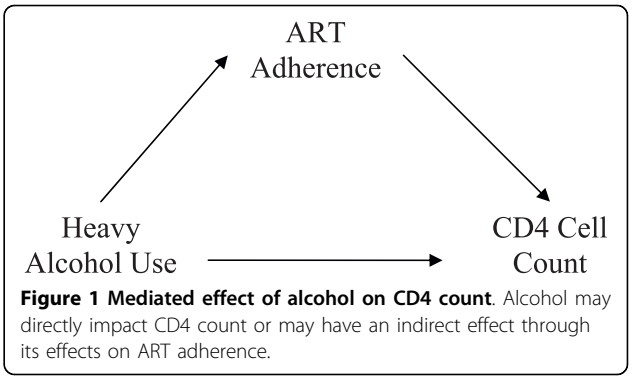

Figure 1 Mediated effect of alcohol on CD4 count. Alcohol may directly impact CD4 count or may have an indirect effect through its effects on ART adherence.

A standard analytic approach for analyzing these data would be to fit a LMM, which can account for correlation due to repeated assessments of CD4 cell count from the same subject and adjust for potential confounders. Alternatively, an SEM could be fit to the data which would explicitly model the hypothesized pathways between heavy alcohol consumption and CD4 count.

In this setting, where the main objective is to determine the total effect of heavy alcohol use on CD4 cell count, it is unclear whether a LMM can perform as well as an SEM, a method often preferred for analyzing mediated longitudinal data.

General SEM Formulation

There are two components to an SEM, the measurement model and the structural model. The measurement model relates unobserved latent variables and covariates to outcomes and exposure indicators. This model attempts to capture measurement error in observed variables. The structural model relates covariates and latent variables to latent variables. This model attempts to capture individual variation in the latent variables.

Using the same notation as Sanchez [15], the general model is expressed as:

Measurement Model

$$\begin{pmatrix} \mathbf{X_i} \\ \mathbf{Y_i} \end{pmatrix} = \nu + \Lambda \mathbf{U_i} + \mathbf{K} \mathbf{Z_i} + \epsilon_\mathbf{i} \quad (1)$$

Structural Model

$$\mathbf{U_i} = \alpha + \mathbf{B} \mathbf{U_i} + \mathbf{\Gamma} \mathbf{Z_i} + \zeta_\mathbf{i} \quad (2)$$

In the above equations, i indexes the individual, with $i = 1,..., N$ where N is the number of individuals. For the ith individual, $\mathbf{Y_i}$ is a vector of observed outcomes, $\mathbf{X_i}$ is a vector observed exposure indicators. $\mathbf{U_i}$ is a vector of latent variables and $\mathbf{Z_i}$ is a vector of observed, fixed

covariates. Although $\mathbf{U_i}$ appears on both sides of the matrix equation, the diagonal elements of **B** are zeros so that the same element of $\mathbf{U_i}$ would not appear on both the left- and right-hand side of a given equation. is a matrix of coefficients associated with $\mathbf{U_i}$, **K** is a matrix of coefficients associated with $\mathbf{Z_i}$ and ε_i is a vector of random residual errors for the measurement model. In the structural model, **B** is a matrix of coefficients (where the diagonal elements are zeros) associated with $\mathbf{U_i}$, Γ is a matrix of coefficients associated with $\mathbf{Z_i}$ and ζ_i is a vector of random residual errors for the structural part of the model. The mean of random residual errors for both the measurement and structural models are assumed to be zero. **Σ** is the covariance matrix of the residual errors of the measurement model (ε_i), and **Ψ** is the covariance matrix of the residual errors of the structural model (ζ_i). The $\mathbf{X_i}$ and $\mathbf{Y_i}$ are assumed to be multivariate normal (MVN). The errors in Equations 1 and 2 are assumed to be independent. Parameters are usually estimated via maximum likelihood, with the objective of minimizing the distance between the observed and model-based mean and covariance structure [16].

SEM Simulation Model

The SEM framework was used to generate the mediated longitudinal data for the simulation studies since the aim is to evaluate whether a LMM performs sufficiently in the setting where an SEM is presumed to be optimal. The scenario in which we simulated data is an extension of a specific SEM often referred to as a latent growth curve model or latent curve model [4,18]. In the latent growth curve model, the outcome variables are influenced by random intercept and slope variables. These variables are latent and can be influenced by predictors and other covariates. Let i index the individual (i = 1,..., N) and j index the time-point (j = 1,..., T), where T is the number of measurement times. In the current study, we considered a setting with a single continuous covariate (z_{1i}), such as age, and a single binary independent variable (z_{2i}) of primary interest, heavy alcohol consumption, predicting repeated observations of the outcome (Y_{ij}), CD4 cell count. Heavy alcohol use influences the outcome CD4 cell count through the random intercept and slope variables. In addition, ART adherence is a mediating variable (x_i) which influences CD4 count through the random intercept and slope variables. The variable ART adherence is said to be a mediator because the primary independent variable, heavy alcohol use, may affect CD4 count not only directly but also indirectly through ART adherence. We considered a setting with 6 time-points (T = 6) and illustrate the SEM model with the path diagram in Figure 2. Using the notation we have described above for SEMs and eliminating the subject index i for simplicity, our measurement and structural model for the scenario illustrated in Figure 2 can be written as:

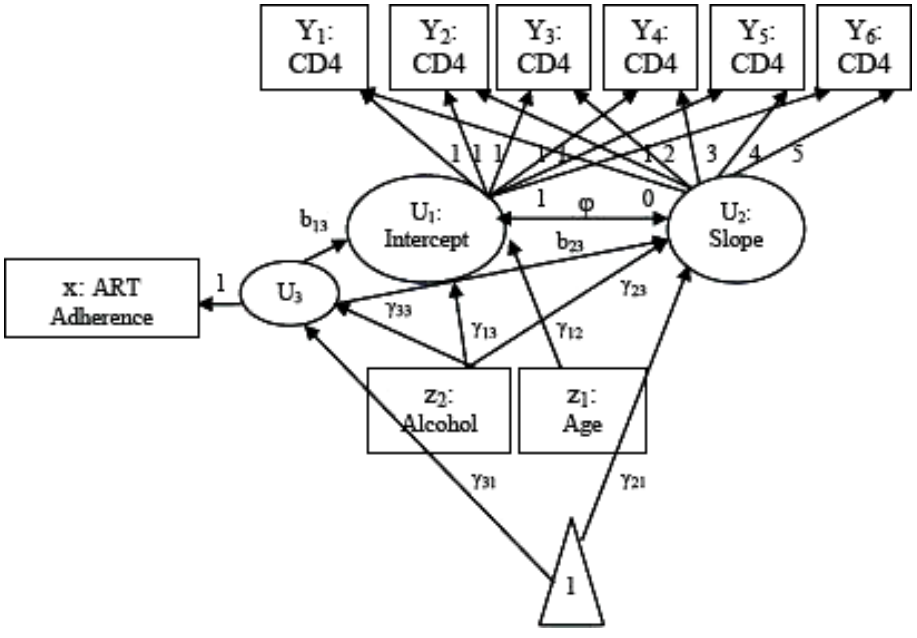

Figure 2 Path diagram for mediated longitudinal data. path diagram for mediated longitudinal data with the outcome (Y) measured at six occasions, a continuous covariate (z_1) measured once, a dichotomous main independent predictor (z_2) measured once variable and a continuous mediator (x) measured once.

Measurement Model

$$\begin{aligned} Y_j &= U_1 + t_j U_2 + \epsilon_j \\ x &= U_3 \end{aligned} \tag{3}$$

Structural Model

$$\begin{aligned} U_1 &= \gamma_{11} + \gamma_{12} z_1 + \gamma_{13} z_2 + b_{13} U_3 + \zeta_1 \\ U_2 &= \gamma_{21} + \gamma_{23} z_2 + b_{23} U_3 + \zeta_2 \\ U_3 &= \gamma_{31} + \gamma_{33} z_2 + \zeta_3 \end{aligned} \tag{4}$$

or in matrix notation as:

Measurement Model

$$\begin{aligned} \mathbf{Y_i} &= \Lambda \mathbf{U_i} + \epsilon_\mathbf{i} \\ x &= U_3 \end{aligned}$$

Structural Model

$$\mathbf{U_i} = \mathbf{B U_i} + \mathbf{\Gamma Z_i} + \zeta_\mathbf{i}$$

The latent intercept and slope are represented by U_1 and U_2, respectively. The continuous covariate (age) and main independent variable (heavy alcohol use) are represented by z_1 and z_2, respectively. Based on the model formulation presented in Equations 1 and 2, ART adherence (x) is considered both an outcome (as it is influenced by the main independent variable) and a predictor (as it influences the random intercept and slope), and therefore appears on the right- and left-hand side of the above equations. However, using the above formulation, only latent variables can be both outcomes and predictors. Thus to incorporate x as a mediator and stay within the framework defined by Sanchez [15], we must add an additional latent variable (U_3) to the model that is exactly equal to x; x can then be viewed as an indicator of this latent variable. Time is incorporated into the model by populating the Λ matrix from Equation 1 with the fixed times of measurements (t_j).

It can be shown that for a given outcome, Y_j, at time t_j, the predictive formula is:

$$\begin{aligned} Y_j &= b_{13}\gamma_{31} + b_{13}\gamma_{33} z_2 + \gamma_{12} z_1 + \gamma_{13} z_2 + \\ & b_{23}\gamma_{31} t_j + b_{23}\gamma_{33} z_2 t_j + \gamma_{23} z_2 t_j \\ & + (\zeta_1 + b_{13}\zeta_3) + (\zeta_2 + b_{23}\zeta_3) t_j + \epsilon_j \end{aligned} \tag{5}$$

The interpretation of the key model parameters of interest are as follows:

1. b_{13} is the effect of the mediating variable on the latent intercept.
2. b_{23} is the effect of the mediating variable on the latent slope.
3. γ_{33} is the effect of the main independent variable on the mediating variable.
4. γ_{23} is the effect of the main independent variable on the latent slope.
5. γ_{13} is the effect of the main independent variable on the latent intercept.

Under the assumption of MVN errors in both the measurement and structural model, the distribution of $\mathbf{Y}$ is MVN as well. The mean for any given Y_j is:

$$\begin{aligned} \mathrm{E}(Y_j) = (b_{13}\gamma_{31}) + \gamma_{12} z_1 + (\gamma_{13} + b_{13}\gamma_{33}) z_2 + \\ (b_{23}\gamma_{31}) t_j + (\gamma_{23} + b_{23}\gamma_{33}) z_2 t_j \end{aligned}$$

and the covariance matrix for the vector of Y_j's is:

$$\mathrm{Cov}(\mathbf{Y}) = \mathbf{W \Psi W}^{\mathrm{T}} + \mathbf{\Sigma}$$

where

$$\mathbf{W} = \begin{bmatrix} 1 & t_1 & b_{13} + t_1 b_{23} \\ 1 & t_2 & b_{13} + t_2 b_{23} \\ \vdots & \vdots & \vdots \\ 1 & t_6 & b_{13} + t_6 b_{23} \end{bmatrix}.$$

The primary setting we considered in our simulations assumed a constant effect of heavy alcohol use (the main independent variable of interest) over time. If there is no alcohol by time interaction (i.e. $\gamma_{23} = 0$ and $b_{23} = 0$), the total effect of heavy alcohol use on CD4 count is represented by $\gamma_{13} + b_{13}\gamma_{33}$, which is the sum of its direct (γ_{13}) and indirect ($b_{13}\gamma_{33}$) effect through ART adherence.

Secondary analyses assuming the effect of heavy alcohol use changes over time were also performed. In this setting, the interaction between alcohol and time is the primary interest. The total effect of alcohol use on the change of CD4 count over time is represented by coefficients corresponding to the interaction between alcohol use and time, $\gamma_{23} + b_{23}\gamma_{33}$, the sum of the direct and indirect effects, respectively.

Linear Mixed Effects Models

The LMM can be used to evaluate the total effect of heavy alcohol consumption on CD4 cell count, however, the mediated relationship is not explicitly modeled with

a single LMM. Two mixed models were considered for comparison to the SEM. The first model, which we will refer to as LMM1, includes the mediator (x) as a covariate in the model. In the formula below we have again eliminated the subject index (i) for simplicity and let j = 1,..., 6 index time-point. The first model is:

$$Y_j = \beta_0 + \beta_1 z_1 + \beta_2 z_2 + \beta_3 t_j + \beta_4 x + \beta_5 z_2 t_j + r_1 + r_2 t_j + e_j \quad (6)$$

where β_j's are unknown regression coefficients relating covariates to the mean of Y_j, r_1 and r_2 denote the random intercept and random slope, respectively and e_j is the random error with zero mean representing deviation of responses from the corresponding predicted means. In matrix form $\mathbf{e} = (e_1, e_2,..., e_6)^T$ is the vector of unknown random errors with E($\mathbf{e}$) = $\mathbf{0}$ and Cov($\mathbf{e}$) = $\mathbf{E}$; $\mathbf{r} = (r_1, r_2)^T$ is the vector of the random intercept and slope coefficients with E($\mathbf{r}$) = $\mathbf{0}$ and Cov($\mathbf{r}$) = $\mathbf{G}$. In the primary setting we explore, where the effect of alcohol is assumed constant and therefore the alcohol by time interaction in (6) is excluded, the effect of the main independent variable on the outcome is represented by β_2. In the secondary setting explored where there is an alcohol by time interaction, the parameter of interest is β_5. Variables in the causal pathway are often omitted as they otherwise artificially attenuate the effect of the main independent variable of interest. Thus, we also considered a second mixed model, which we refer to as LMM2, where we refit the model given in Equation 6 excluding the term for ART adherence ($\beta_4 x$).

The LMM assumes MVN errors, therefore the distribution of $\mathbf{Y}$ is MVN as well. For the LMM1 in Equation (6), the mean for any given Y_j is:

$$\mathrm{E}(Y_j) = \beta_0 + \beta_1 z_1 + \beta_2 z_2 + \beta_3 t_j + \beta_4 x + \beta_5 z_2 t_j$$

and the covariance matrix of the vector of Y_j's is:

$$\mathrm{Cov}(\mathbf{Y}) = \mathbf{Z}\,\mathbf{G}\,\mathbf{Z}^{\mathrm{T}} + \mathbf{E}$$

where

$$\mathbf{Z} = \begin{bmatrix} 1 & t_1 \\ 1 & t_2 \\ \vdots & \vdots \\ 1 & t_6 \end{bmatrix}.$$

In a comparison of the means of the SEM and LMM under the assumption of multivariate normality, there are two notable differences. First, the mean for the SEM is explicitly modeled as a function of both the direct and indirect effects of the main independent variable z_2 (i.e. $\gamma_{13} + b_{13}\,\gamma_{33}$) whereas in the LMM it is simply a function of its total effect (i.e. β_2). Second, in a LMM that includes the mediating variable (LMM1), the mean of the outcome is a function of the mediating variable itself, but this is not the case for the SEM where the mean depends instead on the effect of the mediating variable on the latent intercept and slope (i.e., b_{13} and b_{23}). With regard to covariance matrices, in the LMM the covariance depends on the values of time and the covariance matrix of the latent intercept and slope. In contrast, the covariance from the SEM depends explicitly on the mediating variable and its effects. That is, it is a function of the values of time, the parameters associated with the effect of the mediating variable on the random intercept and random slope, as well as the covariance matrix of the latent intercept, slope, and the mediating variable. Thus, the magnitude of the mediated effect and the covariance of the mediator and latent variables influence the covariance of Y in the SEM but this is not the case in the LMMs.

We simulated data under the mediated SEM and then fit the data with both the LMM1 and LMM2 models. The SEM model was also fit as a reference standard to compare with the LMM results. The goal was to identify advantages and disadvantages of using the LMM relative to the SEM in a longitudinal data setting where a mediator was present. In evaluating model performance, we focused on the parameters representing the total effect of heavy alcohol use on CD4 cell count.

Data Characteristics to be Varied in Simulated Data

We simulated datasets assuming the mediated longitudinal relationship described in the path diagram (Figure 2). The data were generated under the SEM model as the objective was to evaluate the performance of the mixed model when the SEM is expected to be preferable. The factors we evaluated were sample size, effect size and distributional assumptions.

Sample Size

A range of sample sizes was evaluated. We considered sample sizes as small as 25 and increased values up to 500 at which point both the SEM and LMM performed well.

Effect Size and Total Effect Distribution

When the effect of heavy alcohol use is constant over time, the total effect of the main independent variable on the latent intercept is given by $\gamma_{13} + b_{13}\,\gamma_{33}$. We defined the effect size by scaling this quantity by the total standard deviation of the latent intercept:

$$\text{Effect Size : Intercept} = \frac{\gamma_{13} + b_{13}\,\gamma_{33}}{\sqrt{\mathrm{var}(\mathrm{U_{1i}})}} \quad (7)$$

where

$$\text{var}(U_{1i}) = \gamma_{12}^2 \text{var}(z_{1i}) + \gamma_{13}^2 \text{var}(z_{2i}) + b_{13}^2 \gamma_{33}^2 \text{var}(z_{2i}) + \text{var}(\zeta_{1i}) + b_{13}^2 \text{var}(\zeta_{3i}) + b_{13} \text{cov}(\zeta_{1i}, \zeta_{3i}).$$

When the effect of heavy alcohol use changes over time, the direct effect of the main independent variable on the latent intercept is set to zero, and thus the effect size on the latent slope was defined as:

$$\text{Effect Size : Slope} = \frac{\gamma_{23} + b_{23}\,\gamma_{33}}{\sqrt{\text{var}(U_{2i})}} \quad (8)$$

where

$$\text{var}(U_{2i}) = \gamma_{22}^2 \text{var}(z_{1i}) + \gamma_{23}^2 \text{var}(z_{2i}) + b_{23}^2 \gamma_{33}^2 \text{var}(z_{2i}) + \text{var}(\zeta_{2i}) + b_{23}^2 \text{var}(\zeta_{3i}) + b_{23} \text{cov}(\zeta_{2i}, \zeta_{3i}).$$

We examined a range of effect sizes including small (approximately 0.2), medium (approximately 0.5) and large (approximately 0.8), as defined by Cohen [19]. In addition, within each effect size we varied the distribution of the direct and indirect effects and explored the following three scenarios: equally distributed direct and indirect effects; primarily direct effect; primarily indirect effect.

Distribution of the Outcome Variable

Both SEMs and LMMs assume normally distributed errors of the outcome variables. We compared the performance of each type of model when this assumption was not met. For each distribution evaluated we considered two scenarios: i) only the errors from the measurement model were non-normal and ii) errors of both the measurement and structural models were non-normal. The following distributions were evaluated:

1. Uniform($-\sqrt{3}, \sqrt{3}$) distribution- the parameters of the uniform distribution were chosen to obtain a mean of zero and a variance of one to be comparable to the standard normal setting.
2. Lognormal(0, $\sqrt{0.4812}$) distribution- the lognormal parameters were chosen such that the mean of the residual errors was equal to zero and the variance was equal to one. To achieve a mean of zero, exp(0.4812/2) was subtracted from all generated lognormal values.
3. Contaminated normal(0.4, 10) distribution- a mixture of a standard normal and normal with variance of 10, where 40% of the data were from the latter distribution [20].
4. Fleishman/Mattson method. The Fleishman [21] method describes a way to generate non-normal random variates with known skewness and kurtosis. The Mattson [22] method provides a way to generate non-normal random variates with specified correlation from non-normal random variates with known skewness and kurtosis. The method also provides a formula for the skewness and kurtosis of the randomly generated correlated values. The combined method [23] allowed us to change only the distribution of the errors while keeping the overall variance and correlation the same. We used two Fleishman/Mattson distributions. The first had a moderate level of skewness and low level of kurtosis. The second was highly skewed and highly kurtotic. The first results in a variance of 1, a skewness of 0.75 and kurtosis of 0 for the residual errors of the measurement model and skewness of (0.53, 0.5 and 0.75) and kurtosis of (-1.5, -1.9 and -3) for the three residual errors of the structural model, respectively. The second Fleishman/Mattson distribution we used results in a variance of 1, skewness of 1.75 and kurtosis of 3.75 of the residual errors of the measurement model and skewness of (1.2, 1.4 and 1.8) and kurtosis of (0.4, 0.5 and 0.8) for the three residual errors of the structural model, respectively.

Data Simulation

To generate a dataset under the mediated SEM data structure, the following steps were taken.

1. Two multivariate normal random variates were generated, one to be the residual error of the latent intercept and one to be the residual error of the latent slope. When evaluating the impact of distributional assumptions, the non-normal distributions defined in the previous section replaced the multivariate normal distribution in this step. The Mattson method [22] was used to keep the covariance between the random intercept and random slope at the same level as was used for the normal simulations.
2. The value of the latent intercept and latent slope were computed according to the structural model given in Equation 4.
3. Independent normal errors were created to be the residual errors for each of the repeated measures of outcome. When evaluating the impact of distributional assumptions, the non-normal distributions defined in the previous section replaced the multivariate normal distribution in this step.
4. The values of the longitudinal outcome variables were computed according to the measurement model given in Equation 3.
5. Steps 1 through 4 were repeated 1000 times to create 1000 datasets.

6. Each generated dataset was fit with the SEM, the LMM1 (i.e. with the mediator as a covariate), and the LMM2 (i.e. without the mediator as a covariate).
7. Model performance was assessed with the following: i.) Bias- the difference between the true parameter value and the mean observed parameter value divided by the true parameter value. ii.) Coverage probability - the percentage of the 1000 95% confidence intervals that contained the true parameter value. iii.) Power - the percentage of the 1000 datasets in which a hypothesis test of the parameter of interest was statistically significant. With a sample size of 1000, and a true power of 80%, the width of a 95% confidence interval around a power estimate based on the simulations would be approximately 5.0 percentage points. For a true 95% coverage probability, the width of a 95% confidence interval around a coverage probability estimate would be approximately 2.7 percentage points.

Results

The results from the mixed effects models focus primarily on the models that do not adjust for the mediator (i.e., LMM2) because these models capture the total effect of the main independent variable. Results from the mixed model adjusting for the mediator (LMM1) appear to capture the direct rather than total effect of the primary independent variable and are therefore only included in the sample size results to demonstrate this result. However, since the primary objective of the analysis was to evaluate the total effect of the main independent variable, we present only the comparison of the SEM and the mixed model that excludes the mediator in the remainder of the results. Typically, variables associated with the outcome are included in a model, including independent predictors and confounders. However, because mediators are in the causal pathway, it is recommended that such variables be excluded from a model to avoid attenuating the true association between an exposure and outcome [24]. Thus the LMM2 model is consistent with the general practice of excluding as a covariate variables thought to be in the causal pathway.

Sample Size

The results from the sample size variation are displayed in Table 1. With sample sizes of 25, 50 and 100, the estimated power to detect the total effect for all models was quite low (14%-65%). We note that for the SEM, with a sample size of 100, the power for the total effect was 65%, while the power to detect the direct and indirect effects were 26% and 71% (data not shown), respectively. With a sample size of 200, the power for the SEM and LMM2 were both high and similar in magnitude (91% and 89%, respectively), although the power for the LMM1 remained low at 41%. The estimated power of the LMM1 for a sample size of 500 was less than 80%. With a sample size of 500 the power for the SEM and LMM2 models were 99%, therefore we did not evaluate larger sample sizes.

The estimated coverage probabilities for the total effect for all sample sizes for the SEM were high, ranging from 92% to 96%. For the LMM2, these coverage probabilities range from 91% to 95%. For the LMM1, the coverage probabilities were much lower than either the SEM or the LMM2 and decreased with increasing sample size. This trend is likely due to the large bias of the estimate for the LMM1 and resulting confidence intervals that are not centered at the true value. Thus the wider confidence intervals from smaller sample sizes are more likely to include the true value.

Because the model performance was good for the SEM and LMM2 with a sample size of 250 subsequent simulations evaluating effect sizes and distributional assumptions were conducted using this sample size.

Table 1 Impact of sample size.

Simulated Data	Mediated SEM			LMM with Mediator as Covariate LMM1			LMM without Mediator LMM2		
Sample Size	Bias (%)	Coverage Probability (%)	Power (%)	Bias (%)	Coverage Probability (%)	Power (%)	Bias (%)	Coverage Probability (%)	Power (%)
25	1.5	92	26	-48	85	14	2.1	91	26
50	1.5	93	41	-49	84	16	2.0	93	42
100	1.2	94	65	-49	75	26	1.7	94	65
200	-1.2	96	91	-51	56	41	-1.1	95	89
250	-1.6	94	95	-52	48	47	-1.6	93	94
500	-1.0	95	100	-51	21	78	-1.0	95	100

Impact of sample size on model performance in evaluating the total effect of the main independent variable on random intercept.
Based on 1000 simulated datasets with medium effect size equally distributed between direct and indirect effects.

Effect Size and Total Effect Distribution

The results from the set of simulation studies varying the effect of the main independent variable on the random intercept are displayed in Table 2.

In evaluating the effect of the main independent variable on the random intercept, the power for the SEM and the LMM2 (i.e. LMM without the mediating variable) was > 99% when the effect size was large, regardless of whether the effect was primarily direct, primarily indirect or equally distributed between the direct and indirect paths. The coverage probabilities were also very similar between the SEM and LMM2 (≥ 93% in all cases).

For a medium effect, the point estimate of power was slightly higher for the SEM compared to the LMM2 regardless of how the effect was distributed. For example, when the effect was equally distributed the power was 94% for the LMM2 and 95% for the SEM. Although the power for all models was high (≥ 92%), the power for the SEM and the LMM2 appeared to increase as the proportion of the direct effect increased. When the effect was primarily indirect the power was 92% for the LMM2 and 93% for the SEM. The coverage probabilities for the total effect were again ≥ 93% for both the SEM and the LMM2. The higher point estimates of power in the SEM appeared to be due to the larger standard error of the effect estimate in the LMM2. Similar trends were observed with the medium-small and small effect sizes although the power for all models dropped markedly with the small effect size. For example, power was approximately 32% for both models in the case of a small effect size, equally distributed between direct and indirect effects.

Distributions

In simulations evaluating the effect of distributional assumptions, we used a sample size of 250 and a medium-small effect size that was equally distributed in direct and indirect effects (see Table 3). Results from the model with a normal distribution (and the same sample size and effect distribution as described above) had power of 80% and bias of -2.0% for both the SEM and the LMM2 and a coverage probability of 94% for the SEM and 93% for the LMM2. This is referred to below as the normal comparison model.

Assuming a uniform distribution on the residual errors of the measurement model the power to detect the total effect was estimated to be 82% for the SEM and 81% for the LMM2. Both of these models had similar estimates of power which were slightly greater than the power estimate of the comparison models with normal residual errors. This was likely due to an underestimation of the standard error of the parameters. For the model with normal residual errors, the mean of the standard errors of the total effect was 0.16 whereas the mean of the standard errors for the uniform was 0.15. The coverage probability was very similar for both the SEM and the LMM2 (96%). These estimates were slightly higher than those for the normal comparison models. The bias was small (< 1%) for both SEM and LMM2. The results were similar when a uniform distribution was used for the residual errors of both the measurement and structural models.

Model performance was good overall for both the SEM and LMM2 when errors followed a log-normal distribution (see Table 3), although not as good as under the uniform distribution.

Table 2 Impact of effect size and effect distribution.

Simulated Data			Mediated SEM			Mixed Model without Mediator		
Effect Size	Effect Distribution	Effect	Bias (%)	Coverage Probability (%)	Power (%)	Bias (%)	Coverage Probability (%)	Power (%)
Large	Equal	Total	-0.8	94	100	-0.8	94	100
	Direct	Total	-0.8	94	100	-0.8	93	100
	Indirect	Total	0.9	94	100	-0.6	94	100
Medium	Equal	Total	-1.5	94	95	-1.5	93	94

Medium-Small	Equal	Total	-2.0	94	80	-2.0	93	80
	Direct	Total	-0.9	94	84	-0.9	93	83
	Indirect	Total	-1.8	94	80	-1.8	93	79
Small	Equal	Total	-3.7	94	32	-3.7	93	32
	Direct	Total	-3.9	94	36	-4.0	93	35
	Indirect	Total	-3.7	94	34	-3.7	93	33

The impact of effect size and its distribution on model performance in evaluating the total effect of the main independent variable on the random intercept. Based on 1000 simulated datasets with a sample size of 250.

Table 3 Impact of distributional assumptions.

Simulated Data		Mediated SEM			Mixed Model without Mediator		
Distribution	Non-normal Residual Error	Bias (%)	Coverage Probability (%)	Power (%)	Bias (%)	Coverage Probability (%)	Power (%)
Uniform	Measurement	0.7	96	82	-0.8	96	81
	Measurement & Structural	1.4	97	87	1.6	96	85
Log-normal	Measurement	-1.3	94	82	-1.3	94	80
	Measurement & Structural	-0.7	95	82	-0.7	95	81
Contaminated Normal	Measurement	-0.2	95	18	0.07	95	17
	Measurement & Structural	9.5	96	8	11.1	95	8
Fleishman/Mattson 1	Measurement & Structural	-2.9	94	79	-3.0	94	78
Fleishman/Mattson 2	Measurement & Structural	-2.4	94	80	-2.6	94	78

The impact of distributional assumptions on model performance in evaluating the total effect of the main independent variable on the random intercept.
Based on 1000 simulated datasets with a medium-small effect size, equally distributed and a sample size of 250.
The Fleishman/Mattson 1 distribution is moderately skewed and slightly kurtotic.
The Fleishman/Mattson 2 distribution is highly skewed and kurtotic.

Power declined noticeably for both models when errors of the measurement model followed a contaminated normal distribution, however, the coverage probability and bias remained good (power ≤ 18%, coverage probability ≥ 95% and bias ≤ 0.2%). The coverage probability remained high likely due to the large standard error estimates yielding wide 95% confidence intervals. Similar trends were observed for the contaminated normal distribution on the residual errors of the measurement and structural models although model performance declined for both the SEM and LMM2. The lower power of both the SEM and the LMM2 fit to the contaminated normal data may be explained by the relatively large values of the residual variances created by the contaminated normal. For example, the estimated mean values for the residual variance was 40.6 in the SEM and the LMM2 compared to around 1 in the models based on a normal distribution. The effect of a large residual variances is a decrease in the true effect size of the main independent variable.

Both models performed well when measurement and structural errors followed Fleishman/Mattson distribution. The power was similar for the SEM and LMM2 (79% and 78%, respectively). Both models had the same coverage probabilities and bias, 94% and -3%, respectively. Similar values and trends were seen with the second Fleishman/Mattson distribution.

The results of an SEM are generally presented with at least two fit indices [25]. Commonly used fit statistics are the chi-square statistic, the AIC, the root mean square error of approximation (RMSEA) and the standardized root mean square residual (SRMR). LMM models are not usually presented with fit statistics, although during model specification, fit indices like the log-likelihood, AIC and BIC have been used for model selection [26]. The fit statistics for the SEM and LMM2 under different error distributions for both the measurement and structural models are given in Table 4.

Lower values suggest better model fit for each of the fit statistics presented. RMSEA values of < 0.05 and SRMR values of < 0.1 are considered good fit [25]. However, all of the fit statistics from the SEM with the exception of the AIC indicate that the log-normal, the most skewed distribution, had the worst fit followed by the second Fleishman/Mattson model which also has a skewed distribution. The AIC from the SEM and all of the fit statistics from the LMM2 were less affected by the skewness of the log-normal.

Results when Effects of the Main Independent Variable Change Over Time

The simulation results for the effect of the main independent variable on the random slope did not differ qualitatively from the results for the random intercept (data not shown). Overall, the point estimates of power were slightly higher for all models (SEM and LMM) likely due to the fact that no covariate by time interaction was included in the models. The lack of this additional interaction term results in higher true power for the effect of the main independent variable on the random slope. In general, the simulation results were similar to those observed in the primary setting where the main independent variable had a constant effect across time.

Discussion

Linear mixed effects models are often used to analyze longitudinal data. Although LMMs can be applied in settings where mediation is present, it is unclear whether they perform sufficiently well relative to SEMs which have a framework that explicitly allows for

Table 4 Goodness of fit.

		Distribution			
Model	Fit Statistic	Uniform	Lognormal	Fleishman/Mattson 1	Fleishman/Mattson 2
SEM	Chi-square	36.6	58.0	38.4	43.7
	RMSEA	0.010	0.040	0.023	0.021
	SRMR	0.039	0.043	0.041	0.041
	AIC	7309	7288	7307	7307
Mixed Model without Mediator	-2LogLikelihood	5550	5537	5549	5547
	AIC	5566	5553	5565	5563
	BIC	5594	5581	5593	5591

Assessing goodness of fit of SEMs and LMMs with datasets with non-normal error distributions.

Normal comparison model has SEM values of Chi-square = 38.2, RMSEA = 0.012, SRMR = 0.040, AIC = 7306 and LMM values of Negative 2Loglikelihood = 5548, AIC = 5564 and BIC = 5592.

mediational analyses. The objective of this paper was to evaluate the performance of the LMM in the analysis of longitudinal data with a single mediating variable, a setting conducive to the use of SEMs.

The simulation studies were conducted to assess whether the mixed effects model adequately modeled the mediated longitudinal relationships or if employing SEMs was necessary. The LMM and SEM were compared under a range of settings evaluating sample size, effect size and distributional assumptions. The results of our simulation study suggest that the mixed effects model performs comparably to the SEM with respect to power, bias and coverage probability in the analysis when the objective is to estimate the total effect of a primary independent variable. In addition, we demonstrated that mixed effects models used for the purpose of estimating total effects should not include mediating variables as covariates, since resulting coefficients represent the direct effect of the main independent variable on the outcome and erroneous conclusions could be drawn if these effects were interpreted as the total effect.

Both the LMM and SEM were robust to violations of the normality assumption. For the SEM, lack of normality had a larger impact on the model fit statistics than on power, coverage probability and bias. The uniform distribution, an example of a kurtotic, but not skewed distributions, had little effect on the SEM fit statistics compared to the negative impact observed for the lognormal and Fleishman/Mattson distributions, which were both skewed and kurtotic. Generally, the highest levels of skewness had the worst fit. For this reason, caution should be used in applying the SEM when the normality of the data is in question, particularly if the distribution of the data is skewed.

There are several considerations in deciding whether to use an SEM or a mixed model to analyze longitudinal data when a mediating factor is present. The SEM may provide a marginal increase in power, although the difference may not be statistically significant. More importantly, it efficiently evaluates the mechanism of the total effect, decomposing direct and indirect pathways, in a single model. However, larger sample sizes are required to make inferences about the specific direct and indirect effects. If the sample size is limited and the goal is to evaluate only the total effect of a primary independent variable, rather than delineating direct versus indirect effects, then the mixed model provides similar power and coverage probability to the SEM. Although direct and indirect effects could be evaluated by fitting additional mixed models (e.g. models with and without mediating factors), it is a less efficient approach compared to the SEM. In addition, there are broader issues that may influence choice of model such as clinical context, study design and sample size.

Complex SEMs may be difficult to implement without specialized software. Although common software packages such as SAS and R have the capability to run SEMs, software designed specifically for SEMs (e.g. Mplus, LISREL and AMOS) may be more intuitive and user-friendly in model specification, particularly in the development of highly complex models.

The current study examines one specific setting of mediated longitudinal data. Other situations with different data structures where mediation is present could also be explored, e.g. situations where the mediator and the primary independent variable as well as the outcome are repeatedly measured, categorical outcomes, and settings with more complex pathways between variables. In addition, we specifically explored the question of whether the LMM performs sufficiently in a setting favorable to the SEM. Future studies examining broader settings where the data arise from non-SEMs would provide further insight into the use of the LMM and SEM in mediated longitudinal settings.

Conclusions

In general, both SEMs and LMMs were robust methods with similar power in a variety of scenarios. The main

advantage of the SEM is the ability to estimate the direct and indirect pathways of the effect of the primary independent variable on the outcome, given sufficient sample sizes. Despite not directly modeling the mediated pathways, LMMs excluding mediating variables performed well with respect to power, bias and coverage probability in modeling the total effect of the primary independent variable on the outcome.

Comparison of In-Hospital Versus 30-Day Mortality Assessments for Selected Medical Conditions

Ann M. Borzecki, MD, MPH,†‡ Cindy L. Christiansen, PhD,*† Priscilla Chew, MPH,* Susan Loveland, MAT,†§ and Amy K. Rosen, PhD†§¶*

Background: In-hospital mortality measures such as the Agency for Healthcare Research and Quality (AHRQ) Inpatient Quality Indicators (IQIs) are easily derived using hospital discharge abstracts and publicly available software. However, hospital assessments based on a 30-day postadmission interval might be more accurate given potential differences in facility discharge practices.

Objectives: To compare in-hospital and 30-day mortality rates for 6 medical conditions using the AHRQ IQI software.

Methods: We used IQI software (v3.1) and 2004–2007 Veterans Health Administration (VA) discharge and Vital Status files to derive 4-year facility-level in-hospital and 30-day observed mortality rates and observed/expected ratios (O/Es) for admissions with a principal diagnosis of acute myocardial infarction, congestive heart failure, stroke, gastrointestinal hemorrhage, hip fracture, and pneumonia. We standardized software-calculated O/Es to the VA population and compared O/Es and outlier status across sites using correlation, observed agreement, and kappas.

Results: Of 119 facilities, in-hospital versus 30-day mortality O/E correlations were generally high (median: $r = 0.78$; range: 0.31–0.86). Examining outlier status, observed agreement was high (median: 84.7%, 80.7%–89.1%). Kappas showed at least moderate agreement ($k > 0.40$) for all indicators except stroke and hip fracture ($k \leq 0.22$). Across indicators, few sites changed from a high to nonoutlier or low outlier, or vice versa (median: 10, range: 7–13).

Conclusions: The AHRQ IQI software can be easily adapted to generate 30-day mortality rates. Although 30-day mortality has better face validity as a hospital performance measure than in-hospital mortality, site assessments were similar despite the definition used. Thus, the measure selected for internal benchmarking should primarily depend on the healthcare system's data linkage capabilities.

Key Words: hospital mortality, quality indicators, quality improvement

(*Med Care* 2010;48: 1117–1121)

Both in-hospital and 30-day mortality rates from procedures or medical conditions are frequently used for assessing quality of hospital care. Although in-hospital measures are relatively straightforward to derive, requiring only hospital discharge abstracts, critics of such measures cite potential biases due to differences in facilities' lengths of stay and discharge practices.[1,2] Commonly used measures for quality improvement (QI) and public reporting include the Agency for Healthcare Research and Quality (AHRQ) mortality indicators, a subset of the Inpatient Quality Indicators (IQIs), and the Centers for Medicare and Medicaid (CMS) 30-day mortality measures for acute myocardial infarction (AMI), congestive heart failure (CHF), and pneumonia.[3–5]

The IQIs were developed in response to demand for reliable, easy to use quality measures that could be applied across healthcare systems and settings. IQI mortality rates for several procedures and conditions can be readily obtained using publicly available software.[6] However, they were developed on the Health Care Utilization Project (HCUP) dataset which lacks linkage to information occurring outside the index admission. Although use of 30-day mortality measures allows for standardization of follow-up time, additional data sources and linkage capabilities are required that many hospital/healthcare systems may lack. Thus, using the IQIs for local benchmarking and QI remains an attractive option. This option would be even more attractive if performance assessments using in-hospital mortality were comparable to those obtained using 30-day mortality.

The Veterans Health Administration (VA) is the nation's largest integrated healthcare system, offering care to almost 7 million veterans. Unlike much of the private sector, the VA has the ability to link multiple datasets which are used for administrative and research purposes. This capability represents a unique opportunity to apply the AHRQ IQIs to VA data to compare in-hospital and 30-day medical condition mortality rates, and to determine whether facility-based assessments of standardized mortality rates vary by method.

METHODS

Study Population

Our study population consisted of veterans discharged from VA inpatient care during fiscal year (FY) 2004 through 2007 with a principal diagnosis of AMI, CHF, stroke, gastrointestinal (GI) hemorrhage, hip fracture, and pneumonia.

Data Sources

Our main data source was the National Patient Care Database's Patient Treatment File (PTF) which contains information on all VA discharges.[7] It includes demographics, diagnoses (principal and secondary ICD-9-CM codes), procedures (ICD-9-CM codes), and discharge status. Additional vital status information was obtained from the VA's Vital Status files.[8]

Overview of the Inpatient Quality Indicators

IQI development is described in detail elsewhere.[3] The final IQI set resulted from a 4-step process including comprehensive literature review, structured clinical panel review, coding expert consultation, and empirical analyses of potential IQIs. It includes both procedure- and medical condition-related mortality indicators which are in-hospital mortality rates associated with specific procedures or conditions that have shown provider variation and where evidence exists that high mortality may be associated with poorer care.[3] Originally intended as screens and case-finding tools for local QI efforts, these indicators are being used increasingly for hospital profiling and public reporting. The National Quality Forum has endorsed several of the mortality IQIs as hospital performance measures and CMS are adding selected mortality IQIs to their hospital reporting initiative.[9,10]

Given we previously found relatively little facility variation for the procedure-related mortality IQIs, herein we focus on the medical condition-related IQIs.[11]

Analyses

Analyses were performed using AHRQ IQI software (v.3.1), All Patient Refined-Diagnostic Related Group (APR-DRG) software (3M, v.24; for risk adjustment), both downloadable from AHRQ's website, and the Statistical Analysis System (SAS, v.8.0).[6,12] Our unit of analysis was the individual hospitalization.

We applied the IQI and APR-DRG software to the PTF (FY04–07) to generate in-hospital observed and risk-adjusted mortality rates (ie, deaths per 100 discharges with the specified principal diagnosis) and ratios of observed to expected rates (O/Es) at the level specified (eg, VA-wide or hospital/facility-level). The IQI software calculates a patient's expected probability of death during the hospital admission using parameter estimates derived from logistic regression models run on the HCUP population that include age, sex, age-sex interactions and APR-DRG mortality risk score as covariates. These regression estimates are used as true parameter values for the admission-level covariates from the population of interest. (patient-level observations are assumed to be independent). The sum of the expected probability of death across all qualifying hospital admissions is the number of deaths expected (E) if care were similar to that in the HCUP system. The ratio of the observed number of deaths (O) to the expected number of deaths (E) is a standardized mortality ratio, indirectly standardized to the HCUP population (Appendix A, online only, available at: http://links.lww.com/MLR/A129, for further details on IQI models.).

We used IQI software-generated O/Es and calculated 95% confidence intervals (CIs). Because the IQIs use an expected rate based on the HCUP population, we standardized facility-level O/Es (and CIs) to the overall VA rate in the 4-year period by multiplying by a constant equal to the inverse of the VA's national O/E. Sites were considered outliers if the 95% CI did not include 1.0. We similarly determined 30-day mortality standardized O/Es after linking the PTF and Vital Status files. For a given indicator, subjects with more than 1 IQI-related admission within a 30-day period and who died within 30-days of the original admission were only counted once in the 30-day numerator.

We compared in-hospital and 30-day median observed rates using Wilcoxon rank sum tests and standardized mortality O/Es using correlation coefficients. We calculated agreement with respect to outlier status via observed agreement (concordance) and weighted kappas.[13] Facility-level O/E pairs were considered concordant if there was no difference in facility assessment by mortality method versus discordant if there was a change.

RESULTS

Table 1 shows facility-level sample characteristics. Overall, the mean age was 69.5 (s.d.: 12.2); the sample was predominantly male (98%) and white (64%). Comorbidities were relatively prevalent; 61% of discharges had hypertension; over a third had coronary artery disease, diabetes, or chronic lung disease.

All medical conditions had significantly higher observed 30-day mortality rates compared with in-hospital (Table 1). Correlations between in-hospital and 30-day mortality O/Es showed strong positive associations (ie, coefficients ≥ 0.70; $P < 0.05$) except for hip fracture ($r = 0.31$, $P < 0.05$). Measures of agreement using weighted kappa based on outlier status followed similar trends as correlations, being at least moderate ($k > 0.40$) for all IQIs except hip fracture and stroke which showed slight ($k = 0.12$) and fair agreement ($k = 0.22$), respectively (Fig. 1).

Simple observed agreement or concordance between paired data did not necessarily follow the same trends as kappas. Median observed agreement was high at 0.88, ranging from 0.81 for pneumonia to 0.89 for GI hemorrhage and hip fracture, despite it having the lowest kappa (Table 2). The median number of facilities across indicators that changed outlier status was 18 (range: 12–23); the number of sites changing status was highest for pneumonia.

Examining across indicators by discordant pairs, facilities were slightly more likely to change from a nonoutlier based on in-hospital mortality to a low or high outlier using 30-day mortality. A change in outlier status from high to low or vice versa was very rare. This occurred for only 1 facility

TABLE 1. Facility-Level Study Sample Characteristics*

Facility Level Variable	AMI† N = 30,893	CHF N = 88,874	Stroke N = 26,065	GI Hem N = 39,063	Hip Fracture N = 8855	PNA N = 75,049

Hypertension	60.2 (53.6, 66.2)	59.8 (50.4, 67.9)	71.4 (65.6, 75.3)	51.8 (45.5, 58.0)	48.5 (42.2, 56.0)	49.7 (45.1, 53.7)

All observed 30-d death rates are significantly higher than in-hospital rates ($P < 0.05$).

*Analysis done at hospitalization/admission level. Medical conditions are defined per AHRQ IQI indicator specifications.[14] (See Appendix B, online only, available at http://links.lww.com/MLR/A130).

†There are 2 AMI mortality IQIs. We found similar results for AMI mortality with and AMI without transfers, we therefore present data for AMI with transfers only.[14]

‡Comorbidities are based on secondary diagnoses from the index admission using the HCUP Comorbidity Software; codes for CAD and CVD are based on prior work.[15,16]

AMI indicates acute myocardial infarction; CHF, congestive heart failure; GI Hem, gastrointestinal hemorrhage; PNA, pneumonia; CAD, coronary artery disease; CVD, cerebrovascular disease.

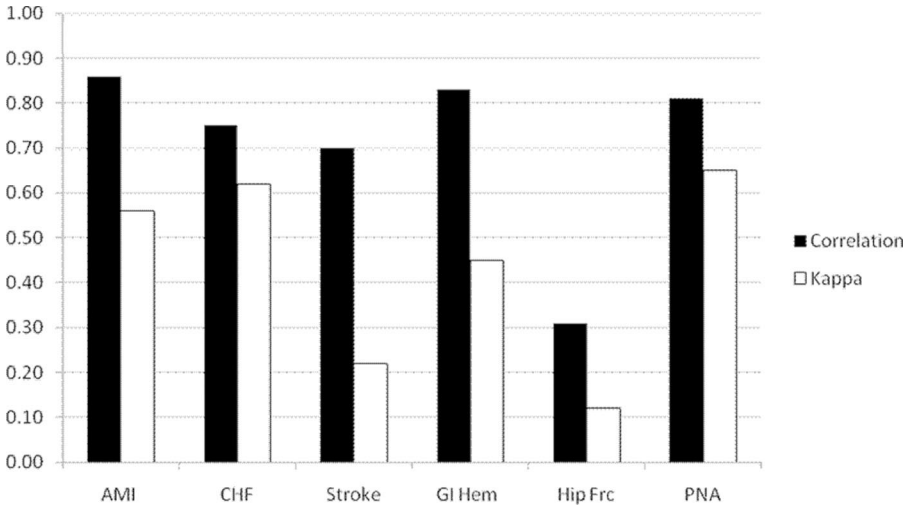

FIGURE 1. Facility-level correlations and kappas. Correlation coefficients for in-hospital versus 30-day standardized O/Es are shown. All correlations were significant ($P < 0.05$). Kappa measures of agreement are based on assessment of outlier status as low outlier, not an outlier or high outlier. Kappa interpretation: <0 = poor, 0 to 0.20 = slight, 0.21 to 0.40 = fair, 0.41 to 0.60 = moderate, 0.61 to 0.80 = substantial, 0.81 to 1.00 = almost perfect agreement. AMI indicates acute myocardial infarction; CHF, congestive heart failure; GI hem, gastrointestinal hemorrhage.

and 1 indicator, pneumonia; the site changed from a high to a low outlier (Table 2.) Facilities were more likely to change from a low or nonoutlier to a high outlier for 4 indicators (CHF, stroke, GI hemorrhage, hip fracture; Table 2). The median number of facilities across indicators that changed status from high to a nonoutlier or low outlier, or vice versa was 10 (range, 7–13); the number of sites changing status was highest for stroke.

DISCUSSION

This is the first study to use the IQIs to compare in-hospital and 30-day mortality across several medical con-

TABLE 2. In-Hospital Versus 30-d Mortality—Change in Outlier Status

Outlier Status (Site Pairs), n (%)	AMI N = 116	CHF N = 119	Stroke N = 119	GI Hem N = 119	Hip Fracture N = 110	PNA N = 119
Concordant pairs*	**102 (87.9)**	**97 (81.5)**	**97 (81.5)**	**106 (89.1)**	**98 (89.1)**	**96 (80.7)**
Not an outlier	92 (79.3)	74 (62.2)	93 (78.2)	100 (84.0)	97 (88.2)	67 (56.3)
Low-low	5 (4.3)	12 (10.1)	1 (0.8)	4 (3.4)	1 (0.9)	13 (10.9)
High-high	5 (4.3)	11 (9.2)	3 (2.5)	2 (1.7)	0 (0)	16 (13.4)
Discordant pairs	**14 (12.1)**	**22 (18.5)**	**22 (18.5)**	**12 (10.9)**	**12 (10.9)**	**23 (19.3)**
Low vs. not	2 (1.7)	3 (2.5)	7 (5.9)	1 (0.8)	1 (0.9)	9 (7.6)
Not vs. low	2 (1.7)	8 (6.7)	2 (1.7)	4 (3.4)	4 (3.6)	4 (3.4)
High vs. not	5 (4.3)	5 (4.2)	4 (3.4)	3 (2.5)	3 (2.7)	4 (3.4)
Not vs. high	5 (4.3)	6 (5.0)	9 (7.6)	5 (4.2)	4 (3.6)	5 (4.2)
High vs. low	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)	1 (0.8)
Low vs. high	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)	0 (0)

Concordant pairs are sites that have no change in their outlier status; discordant pairs do have a change in their outlier status based on the assessment method. Direction of change for discordant pairs is indicated starting from in-hospital to 30-d, eg, for "Low versus Not," for AMI, 2 sites changed from low outlier status based on in-hospital mortality O/Es to not being considered as outliers based on 30-d mortality O/Es.

*The percentage of concordant pairs is the same as observed agreement.

AMI indicates acute myocardial infarction; CHF, congestive heart failure; GI Hem, gastrointestinal hemorrhage; PNA, pneumonia.

ditions. Using a large national sample of VA admissions, we found that the AHRQ IQI software can be readily adapted to generate 30-day mortality rates. However, assessments of hospital outlier status comparing standardized in-hospital and 30-day mortality rates were similar regardless of the indicator. Whereas correlation coefficients and outlier status agreement based on kappas were lowest for stroke and hip fracture, based on observed agreement, the worst agreement was seen for pneumonia and best for hip fracture and GI hemorrhage. Although, at most 19% of facilities changed status on any indicator, with facilities more likely to change from a non-outlier using in-hospital rates to an outlier using 30-day rates. Potential mislabeling of sites as high outliers when they were low outliers or average, or as average or low outliers when they were high, was relatively uncommon, occurring in approximately 10% of facilities for any given indicator.

This is also the first study comparing mortality measurement methods to use relatively recent data that better reflect current discharge practices, and to use a VA population. The consistency of our findings with older studies in non-VA populations suggests our results are not dependent on the specific methodology used. Rosenthal et al compared in-hospital and 30-day standardized mortality ratios in Medicare discharges with CHF in 30 Ohio hospitals during 1992 to 1994.[17] Their correlation between mortality ratios was similar to ours at 0.78. Seven hospitals changed outlier status (ie, 77% observed agreement). On the basis of their findings, they concluded that in-hospital mortality is a "reasonably valid marker for 30-day mortality." Chassin et al also found generally high hospital-level correlations between in-hospital and 30-day mortality for 48 surgical and medical conditions (0.54 for all conditions), using 1984 Medicare data.[18] However, AMI and CHF correlations were highest (0.79 and 0.71, respectively).

As noted, the IQI software uses HCUP-based expected rates which likely differ from the VA population, given typical VA and non-VA population differences (eg, more males and comorbidities in veterans).[19] Other healthcare systems that differ from the HCUP population will face similar case-mix issues. Standardizing software-derived O/Es to the population of interest, as we have done, enables meaningful within system determination of outlier status among sites. Further, the IQI software uses parameter estimates from logistic models that do not account for patient clustering within hospitals. However, other investigators have found nearly identical results with respect to facility-level surgical morbidity and mortality outlier status when comparing hierarchical and logistic regression models.[20]

Although 30-day measures are generally considered more accurate measures of hospital performance than in-hospital mortality measures because they are less dependent on hospital discharge practices, the reviewed studies and our findings suggest that this is less of a concern except perhaps for stroke and hip fracture which had lower kappas and correlation coefficients. These conditions are both fairly dependent on inpatient rehabilitation services. Therefore, as found in non-VA settings, we presume that lengths of stay may be highly variable across facilities, depending on access to in-house versus out-of-house VA and non-VA rehabilitation facilities.[21–23] Thus, some patients may end up dying in-hospital because of relatively long stays, whereas others may die in a non-VA subacute care facility. This raises some concern over use of the hip fracture IQI by CMS for hospital reporting.[10]

Further, 30-day mortality measures like those used by CMS are also considered more accurate than in-hospital measures like the IQIs, because of more robust risk adjustment (they use diagnoses from the 12 months preceding the admission). CMS currently generates hospital-level assessments with respect to these measures using hospital-submitted Medicare claims and reports them on their Hospital Compare website.[24] Whereas CMS' methods may be replicated, software to generate these measures is not readily available and only 3 conditions are represented (AMI, CHF, and pneumonia).[4,5] Although the IQIs use the APR-DRGs and secondary diagnoses from the index admission for comor-

bidity risk adjustment, previous studies using alternative risk-adjustment methods based either on administrative data alone or more robust risk-adjustment with clinical data found similar results with respect to hospital mortality assessments.[17,18]

Thus, the AHRQ IQI software represents a useful option for calculating 30-day mortality across various medical conditions, especially for systems that have linkage to out-of-hospital death data. Although 30-day mortality is considered to have better face validity as a measure of hospital performance, for systems wanting to do internal benchmarking that do not have ready access to out-of-hospital death data, our findings suggest that similar results for selected conditions can be obtained by using in-hospital data alone.

Trends in the Inpatient Quality Indicators

The Veterans Health Administration Experience

Ann M. Borzecki, MD, MPH,†‡ Cindy L. Christiansen, PhD,*† Susan Loveland, MAT,†§ Priscilla Chew, MPH,* and Amy K. Rosen, PhD†§¶*

Background: The Agency for Healthcare Research and Quality Inpatient Quality Indicators (IQIs), which include in-hospital mortality and utilization rates, have received little attention in the Veterans Health Administration (VA), despite extensive private sector use for quality improvement.

Objectives: We examined the following: the feasibility of applying the IQIs to VA data; temporal trends in national VA IQI rates; temporal and regional IQI trends in geographic areas defined by Veterans Integrated Service Networks' (VISNs); and VA versus non-VA (Nationwide Inpatient Sample) temporal trends.

Methods: We derived VA- and VISN-level IQI observed rates, risk-adjusted rates, and observed to expected ratios (O/Es), using VA inpatient data (2004–2007). We examined the trends in VA- and VISN-level rates using weighted linear regression, variation in VISN-level O/Es, and compared VA to non-VA trends.

Results: VA in-hospital mortality rates from selected medical conditions (stroke, hip fracture, pneumonia) decreased significantly over time; procedure-related mortality rates were unchanged. Laparoscopic cholecystectomy rates increased significantly. A few VISNs were consistently high or low outliers for the medical-related mortality IQIs. Within any given year, utilization indicators, especially cardiac catheterization and cholecystectomy, showed the most inter-VISN variation. Compared with the non-VA, VA medical-related mortality rates for the above-mentioned conditions decreased more rapidly, whereas laparascopic cholecystectomy rates rose more steeply.

Conclusions: The IQIs are easily applied to VA administrative data. They can be useful to tracks rate trends over time, reveal variation between sites, and for trend comparisons with other healthcare systems. By identifying potential quality events related to mortality and utilization, they may complement existing VA quality improvement initiatives.

Key Words: quality of care, administrative data, quality improvement

(*Med Care* 2010;48: 694–702)

The Agency for Healthcare Research and Quality (AHRQ) Inpatient Quality Indicators (IQIs) were developed in response to demand for reliable, valid, easy to use quality measures that could be used across healthcare systems and settings.[1] They are evidence-based indicators derived from hospital discharge data. They include mortality, utilization, and volume indicators designed to screen for potential inpatient quality problems, highlighting areas in which quality of care should be further investigated.[2]

Originally intended for use as screens and case-finding tools for local quality improvement (QI) efforts, the IQIs are increasingly being used as performance measures for hospital profiling and public reporting.[3–7] Given their reliance on administrative data, AHRQ offers caution about such use.[3] Notwithstanding this, the National Quality Forum recently endorsed several of these indicators as hospital performance measures, and the Centers for Medicare and Medicaid Services are adding select individual and 2 composite mortality IQIs to their hospital reporting initiative.[7–9]

The IQIs were developed on Healthcare Cost and Utilization Project (HCUP) data, representing private sector hospitals from a subset of states. Thus, their validity and utility in systems, such as the Veterans Health Administration (VA), which may differ from HCUP with respect to patient case-mix or coding practices, is unknown. As the nation's largest integrated healthcare system the VA is a national leader in QI innovations and provision of high quality care. This has occurred through means such as development of a highly integrated, comprehensive electronic medical record, performance monitoring of certain chronic and acute conditions, programs aimed at improving surgical care, and more recently, the Quality Enhancement Research Initiative, intended to facilitate research translation into practice for selected patient populations.[10–12] Many of these initiatives, such as the National Surgical Quality Improvement Program (NSQIP), rely on chart abstraction and are thus labor-inten-

ISSN: 0025-7079/10/4808-0694

sive and expensive.[11] The IQIs, which have thus far received little VA attention, represent a potentially cost-efficient tool to complement these efforts.

Further, in the private sector there is evidence of decreasing rates of several of the mortality-related IQIs over time,[13] as well as geographic variation in IQI rates.[6,14] Whether similar trends exist in the VA is unknown. Although prior VA studies have found variation in longer-term survival for specific IQI-represented conditions, such as acute myocardial infarction (AMI), plus other measures of care,[15,16] the degree of variation across the VA has not been studied using the IQIs. Such variation, if found, will help improve care by focusing VA QI efforts on specific conditions or indicators.

This study's purpose was to examine: (1) the feasibility of applying the IQIs to VA data, (2) temporal trends in national VA IQI rates, (3) temporal trends and variation in rates across VA geographic regions, represented by Veterans Integrated Service Networks (VISNs), and (4) differences in VA versus non-VA temporal trends. Lessons learned from our experience may be applicable to other healthcare systems.

METHODS

Study Population

Our study population consisted of veterans discharged from VA inpatient care during fiscal year (FY) 2004 through 2007.

Data Collection

Our main data source was the National Patient Care Database's Patient Treatment File which contains information on all VA discharges.[17] It includes demographics, diagnoses (principal and secondary ICD-9-CM codes), surgical and nonsurgical procedures (ICD-9-CM coded), and discharge status. We obtained supplemental comorbidity information from the National Patient Care Database outpatient file[18] and facility information from the VA Support Service Center Occupancy Rate Reports (bed counts) and VA Office of Academic Affiliations (resident counts). National Inpatient Sample (NIS) IQI rates and standard errors were obtained from the HCUP-net site.[14]

Overview of the Inpatient Quality Indicators

IQI development followed a four-step process including comprehensive literature review, structured clinical panel review, coding expert consultation, and empirical analyses of potential IQIs.[19] They include 3 types of indicators: (1) Mortality indicators are in-hospital mortality rates associated with specific conditions or procedures that have shown provider variation and where evidence exists that high mortality may be associated with poorer care.[2,15,19–25] (2) Utilization indicators are rates of procedures where concerns exist about overuse, underuse, or misuse.[2,19,26–28] (3) Volume indicators are counts representing proxy quality measures based on evidence that hospitals performing more, highly complex procedures tend to have better outcomes, (eg, survival) for those procedures.[2,19,20,22] To provide more meaningful comparisons, we focused on indicators representing rates, rather than simple volume counts. We omitted 4 delivery-related utilization indicators because of low volume. (see Appendix 1, online only, Supplemental Digital Content 1, available at: http://links.lww.com/MLR/A86, for definitions of the 17 IQIs used in this study).

Applying the IQIs to VA Data: Required Data Elements

The IQIs algorithms link diagnoses and procedure codes with other information contained in standardized hospital discharge data to generate counts and rates.[2] Required data elements include age, sex, admission source, patient disposition, Diagnosis-Related Group (DRG), ICD-9-CM principal and secondary diagnosis codes, ICD-9-CM procedure codes, and All Patient Refined Diagnostic Related Group (APR-DRG) category, severity and mortality scores.[29] Because VA databases differ from HCUP's with respect to structure and specific data elements, we recoded certain variables based on previous work with AHRQ's Patient Safety Indicators.[30] For example, admission source has 19 possible VA values but only 5 in HCUP.

Analyses

Analyses were performed using AHRQ IQI software (v.3.1), APR-DRG software (3M, v.24), and the Statistical Analysis System (SAS, v.8.0).[29,31] Our unit of analysis was the individual hospitalization.

We applied the IQI and APR-DRG software to the Patient Treatment File to generate observed, risk-adjusted rates, and ratios of observed to expected rates (O/Es) for all IQIs at the level specified (ie, VA-wide, and VISN-level). The IQI software uses parameter estimates derived from logistic regression models (for mortality indicators) and linear regression models (for utilization indicators) run on the HCUP population that include age, sex, age-sex interactions, APR-DRG mortality risk score, and APR-DRG severity score as covariates. These regression estimates are used as true parameter values for the admission-level covariates from the population of interest. Patient-level observations are assumed to be independent). Risk-adjusted rates reflect the estimated performance on each IQI for a provider assuming that provider had the "average" case mix among all hospitals in the HCUP estimation sample.[29] Per AHRQ's recommendations, we excluded VISNs with fewer than 3 cases in the denominator for a given year.[29] Notably, higher rates for the utilization indicators potentially indicate poorer quality except for laparoscopic cholecystectomy.

We first examined FY04 through FY07 trends in national VA IQI risk-adjusted rates (software-produced), using weighted linear regression models and calculating *P*-values for their slope. The VA is geographically divided into 21 regional healthcare units known as VISNs. We chose this analysis level rather than the hospital level because many of the surgical procedures included in the mortality IQIs are performed at fewer than half of VA hospitals, whereas all are fully represented at the VISN level except for esophageal resection and pancreatic resection.

We examined VISN-level temporal trends in IQI risk-adjusted rates using similar methods to our VA-level models. We compared variation across VISNs over time (FY04–07)

and space, using software-generated O/Es and calculated 95% confidence intervals (CIs). Because the IQIs are risk-adjusted using an expected rate based on the HCUP population, we standardized the O/Es (and CIs) to the overall VA rate in each year by multiplying by a constant equal to the inverse of the VA's national O/E. VISNs were identified as outliers if the 95% CI did not include 1.0. The IQI software also generates composite scores for medical and procedure-related mortality which are output as risk ratios.[32] We generated composite scores using the default weighting of denominator weights, calculated 95% CIs, standardized scores to the VA population by considering the mean VA score as 1.0, and examined for outliers.

We next compared VA to non-VA trends using HCUP's posted NIS data.[14] Because we had access to FY03 VA data, and HCUP data were available for calendar years 2003 through 2007, to improve trend comparisons, we added an additional year of data to this analysis. Because of HCUP and VA data differences (eg, HCUP weights results to the total number of NIS discharges, VA data are not discharge-weighted) and differences in sample sizes and precision of estimates, we ran separate weighted linear regression models of the risk-adjusted IQI rates (one for NIS and one for VA), with weights calculated as 1/standard error.[2] We then compared slope estimates (FY03-FY07) using *t*-tests.

RESULTS

Table 1 shows sample characteristics. The total number of hospitalizations (FY04-FY07) was over 2 million; 18% of these met IQI definitions. Comparing all VA discharges to IQI-related discharges, the mean age was 63.0 (±13.6) years versus 68.3 (±11.8); both samples were predominantly male (96%) and white (>60%). IQI-related discharges had more diabetes (39% vs. 34%) and less severe mental illness (11% versus 17%) than the entire discharge population. Of the 123 facilities represented among the 21 VISNs, 83% were teaching hospitals.[33] The median facility bed-size was 126. Appendix 2 (online only, Supplemental Digital Content 2, available at: http://links.lww.com/MLR/A87) shows selected facility characteristics aggregated by VISN.

‡No. discharges of patients with a preceding diagnosis of schizophrenia, bipolar disorder or depression.

At the national level risk-adjusted rates of all the medical condition-related mortality IQIs decreased over time, although this was statistically significant only for acute stroke, hip fracture and pneumonia (from 10.5 to 8.8, 3.8 to 2.6, and 8.1 to 5.5 deaths per 100 relevant discharges, respectively; Fig. 1A). There were no significant temporal changes in procedure-related mortality IQI rates, despite a slight drop in coronary artery bypass grafting and percutaneous transluminal coronary angioplasty rates (Fig. 1B). Of the utilization indicators, laparascopic cholecystectomy rates increased significantly (from 6.3 to 7.0 per 100 cholecystectomies); the other indicators showed no changes (data not shown; available from authors).

At the VISN-level, most VISNs experienced temporal decreases in medical condition risk-adjusted mortality rates, although this trend was significant for at most 3 VISNs per indicator. No VISN rates increased significantly for any of the medical indicators; (data not shown, available from authors). Similar to overall VA findings, there were no significant trends for the procedure-related mortality IQI rates. For utilization indicators, we only found significant trends for cholecystectomy; whereas most VISNs increased over time, this was significant for just 3 sites.

Of the medical condition-related mortality indicators, pneumonia demonstrated the most inter-VISN variation. Two VISNs (b and n) were consistently high outliers over time (ie, lower 95% CI of the O/E was >1.0 in at least 3 of 4 years), whereas 4 VISNs (l, r, s, u) were consistently low outliers (ie, upper 95% CI was <1.0 in at least 3 of 4 years; Fig. 2A). Figure 3 shows outlier status aggregated across all medical conditions. Four VISNs were consistently high (b, f, i, and n) and 4 (l, r, s, and u) were consistently low outliers on one or more indicators (Fig. 3). By standardized composite scores, 2 VISNs were high (i and n), whereas one was a low outlier (l) in 3 or more years. Using US Census-Bureau area designations, high outlier VISNs tended to be from the South; low outliers were from the West and Midwest.[34]

Examining individual procedure-related mortality indicators, we found at most 2 VISN outliers per indicator per year; these varied by year. There were no outliers on standardized procedure-related composite scores in any years.

For the utilization indicators, cardiac catheterization showed the most variation (Fig. 2B), followed by laparoscopic cholecystectomy. All but 2 VISNs (d and o) were outliers in at least one study year. We found the highest bilateral cardiac catheterization rates in northeastern VISNs

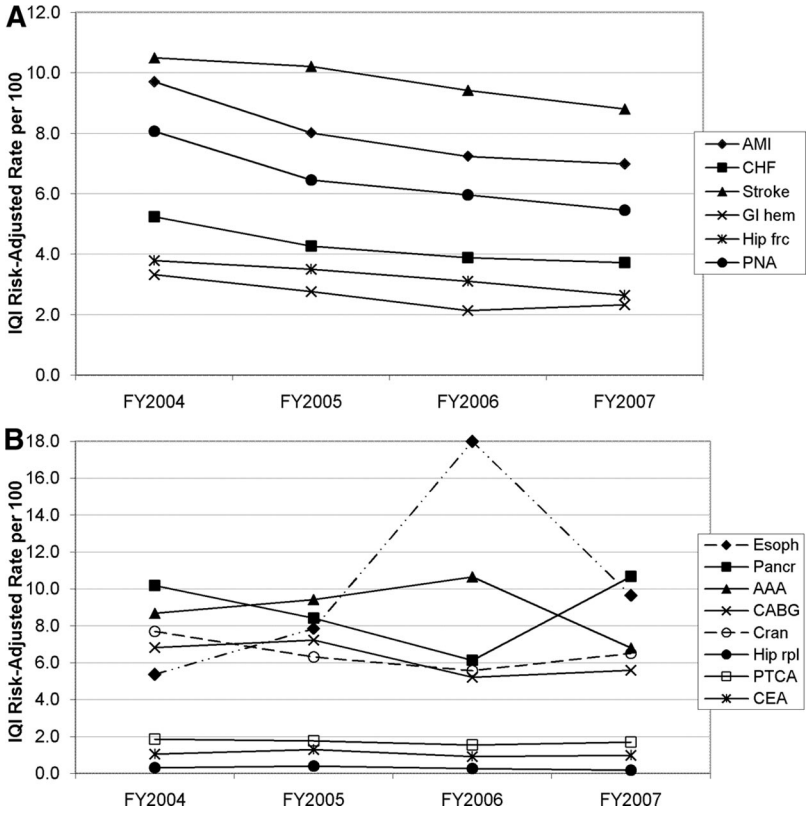

FIGURE 1. National VA Level IQI Mortality Trends. A, Medical Conditions; B, Procedures. Risk-adjusted rates per 100 discharges. Only stroke, hip fracture and pneumonia mortality rates decreased significantly over time; $P < 0.05$. AMI indicates acute myocardial infarction; CHF, congestive heart failure; GI hem, gastrointestinal hemorrhage; Hip frac, hip fracture; PNA, pneumonia; Esoph, esophageal cancer resection; Pancr, pancreatic cancer resection; AAA, abdominal aortic aneurysm repair; CABG, coronary artery bypass graft; Cran, craniotomy; Hip rpl, hip replacement; PTCA, percutaneous transluminal coronary angioplasty; CEA, carotid endarterectomy.

and highest laparascopic cholecystectomy rates in western VISNs.

Comparing VA and NIS risk-adjusted rates from 2003 through 2007, slope estimates differed significantly for AMI, acute stroke, hip fracture and pneumonia mortality, hip replacement, and all 3 utilization indicators (Table 2). AMI, stroke, hip fracture, pneumonia and hip replacement mortality rates, and incidental appendectomy utilization rates declined more rapidly in the VA. Laparascopic cholecystectomy rates rose more steeply, whereas bilateral catheterization rates decreased more slowly, in the VA compared with NIS.

DISCUSSION

This is the first study to apply the AHRQ IQI algorithms to VA data, provide information on VA IQI rates and geographic variation within and across years, and compare VA and non-VA trends. We found these algorithms are easily applied to VA administrative data with minor coding modifications. Our results also suggest that in the VA, the medical condition-related mortality and utilization indicators are more useful than the procedure-related mortality indicators for detecting temporal changes and discriminating between sites.

At the national level, mortality rates for several of the medical condition-related IQIs, (ie, acute stroke, hip fracture, and pneumonia) decreased significantly over time. Of the procedure-related indicators, including mortality and utilization indicators, only laparascopic cholecystectomy changed significantly with utilization rates increasing from FY04 through 07. We found similar trends with respect to improved medical condition survival in the non-VA (NIS) setting, but these changes were significantly greater in the VA. Comparing VISNs, individual utilization indicators showed the most variation, followed by the medical condition-related mortality IQIs; a few VISNs were consistently high or low outliers across years. The procedure-related mortality IQIs demonstrated little variation with respect to temporal trends or outlier status.

Our findings of improved survival from various medical conditions over time are consistent with published literature. An AHRQ-published report using NIS data found improved in-hospital survival between 1994 and 2004 for AMI, stroke, pneumonia, and hip fracture.[13] The authors also noted survival improvement from GI hemorrhage and CHF, plus some of the procedure-related IQIs, including hip replacement (although they sequentially compared rates from one year to the next, instead of using slope estimates). Earlier studies have suggested that in-hospital survival improvements from conditions such as pneumonia may be due to premature discharge and occur at the expense of worsened 30-day or longer term survival.[35,36] However, the Centers for Medicare and Medicaid Services' Medicare Quality Monitoring System reports also showed improved 30-day survival trends for AMI, stroke, and pneumonia (and CHF), between 1992 and 2001.[37]

Two recent studies examined 30-day survival trends following hospitalizations for medical conditions and surgical procedures. This was in the context of studying the impact of resident duty hour reform. They found similar trends of

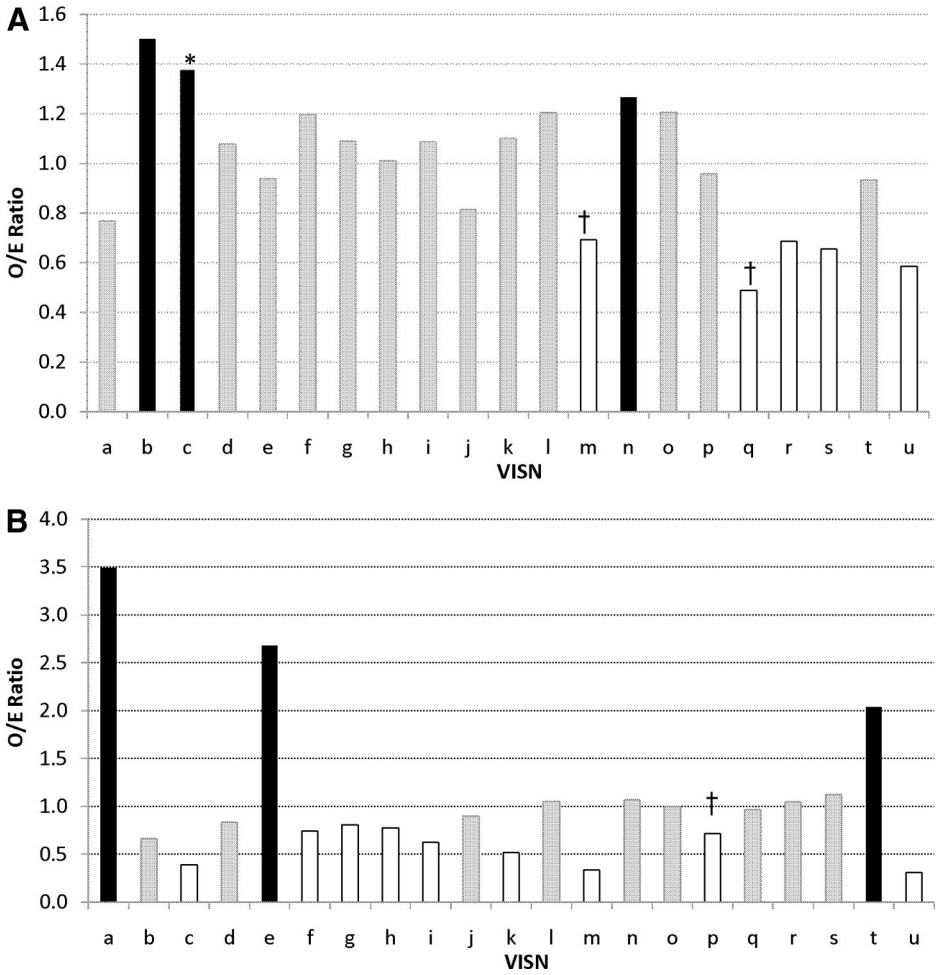

FIGURE 2. FY07 VISN-Level O/E Ratios with Outlier Status. A, Pneumonia; B, Bilateral Cardiac Catheterization. High outliers are indicated by black bars; low outliers by white bars. *High outlier in FY07, but not a consistent outlier. †Low outlier in FY07, but not a consistent outlier. VISN "l" was a low outlier in FY04–06 for pneumonia mortality. Only VISNs "d" and "o" were not outliers for bilateral cardiac catheterization utilization in any study years.

greater survival improvement for medical conditions versus surgical procedures, as well as greater improvement in the VA versus the non-VA (ie, Medicare) population, from July 2000 through June 2005.[38,39] The authors suggest the VA's greater mortality improvement might be because of more teaching hospitals in the VA compared with their non-VA sample; therefore, resident duty reform would be more likely to positively impact such outcomes.[39] Although the continued medical condition survival seen in our study through 2007 may be due to increasing medical service compliance with duty hour rules, this may also be owing to improvements in care resulting from ongoing national VA QI initiatives. Previous studies have found that other VA measures of quality substantially improved and exceeded non-VA settings after VA restructuring in the mid-90s with development of a comprehensive electronic medical record and increased accountability of local managers for performance on quality measures. Jha et al found the VA exceeded Medicare's performance during 1997 through 2000 on several Healthcare Effectiveness Data and Information Set measures that are tracked by the VA's External Peer Review Program (EPRP) including those pertaining to processes of care for patients admitted with AMIs.[10] Another study using a comprehensive assessment containing 294 processes of care, found better quality of care in the VA compared with private managed care patients during the same period.[40]

Our geographic trends are also relatively consistent with existing literature. For the medical mortality IQIs, we found lower outlier VISNs were from the West and Midwest, whereas higher outliers tended to be from the South. Posted HCUP data for calendar years 04 through 06 similarly shows lower death rates in the Mid-West or West; however, the Northeast had the highest death rates for the medical IQIs, not the South.[14] This discrepancy may reflect study population differences. Several geographic variation studies of Medicare patients (which may be more similar to VA patients) have findings similar to ours, with the highest mortality rates in the South for both stroke and AMI.[41,42] A study using 1990s VA data also found the South had the highest AMI mortality.[15] Our utilization findings of highest bilateral cardiac catheterization rates in the Northeast, and highest laparascopic cholecystectomy rates in the West are similar to posted HCUP data.[14]

Designed to be easy to apply, the IQI software uses parameter estimates from logistic and linear regression models based on the HCUP population that do not account for patient clustering within hospitals. Although this is a theoretical methodologic limitation, programs such as NSQIP

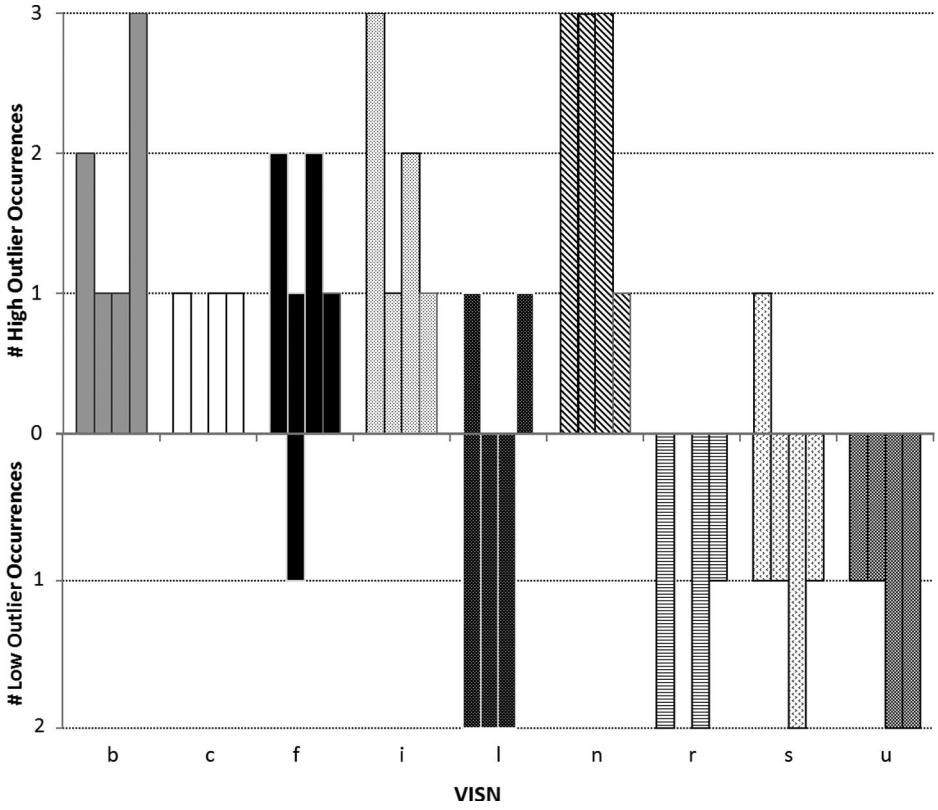

FIGURE 3. Inter-VISN Variation in Medical Condition Related Mortality Indicators. Figure depicts the number of occurrences per year and across years (FY04–FY07) for selected VISNs. Each bar represents one year. Each horizontal gridline represents one occurrence. For example, VISN "l" was a high outlier on one IQI in FY04 and FY07 and a low outlier on 2 IQIs in FY04 through FY06.

similarly use logistic models to generate facility-level surgical outcome O/Es. Hierarchical and logistic regression models using NSQIP data produced nearly identical results.[43]

HCUP-derived expected rates used to generate the risk-adjusted rates are likely to differ from the VA population, given typical VA and non-VA population differences, (eg, more males and more comorbidities in veterans).[44] Therefore, we standardized VISN-level O/Es to VA data to allow more meaningful site comparisons, and were able to identify consistent outlier sites. Other healthcare systems that differ from the HCUP population will face similar case-mix issues. Standardizing O/Es to the population of interest enables within system determination of outlier status among sites.

Similarly, it is difficult to directly compare VA risk-adjusted rates to those of non-VA systems. We intentionally avoided direct comparison to HCUP rates given differences including previously noted case-mix and weighting differences plus use of calendar years versus FY. Our methods enable valid trend comparisons between systems since they are not affected by case-mix differences. However, they do not account for different starting points between systems such that one may have more room to improve than another; further underlying case-mix may make changes more difficult to effect in one system versus another.

The relative insensitivity of the procedure-related mortality indicators to detect temporal changes or site differences in the VA may be due to the success of longstanding VA programs such as NSQIP, or because of inadequate sample sizes, (eg, esophageal cancer resection had only 0–12 cases in a given year). Other systems may face similar size sample issues in comparing procedure rates.

Other IQI-associated general limitations include the fact they measure outcomes, ie, mortality or utilization rates. As the end result of care, they are vitally important to measure, however, they are less immediately actionable than process measures. They also use administrative data. Whereas documentation of death and major procedures should be fairly complete,[45,46] accurate risk-adjustment requires accurate coding of comorbidities which may vary within and across sites.

Nevertheless, such indicators complement Healthcare Effectiveness Data and Information Set and Joint Commission measures already in place in most healthcare systems. In the VA, these indicators can supplement national QI programs, such as EPRP, which tracks various performance measures (primarily process measures and some intermediate outcomes), and NSQIP, which tracks major surgery outcomes,[12] thereby providing a more comprehensive picture of the quality of VA care. For example, EPRP tracks processes of care for patients admitted with AMIs such as percentage of patients prescribed aspirin within 24 hours of hospital arrival.[47] We would expect performance on this measure to be related to an IQI such as in-hospital AMI mortality rate.[48]

Although the IQIs are screens as opposed to definitive measures, successful QI methods used by NSQIP participants could be replicated using IQIs.[11] NSQIP distributes annual reports to each facility that show how they compare with other facilities. It includes mortality and aggregate morbidity

TABLE 2. Comparison of NIS Versus National VA Rates

Mortality Indicators*	System	Slope Estimate	Standard Error	Estimate Difference	*T*
Medical condition-related					
Acute myocardial infarction (without transfer) (IQI 15)†‡	NIS	−5.07	0.08	5.31	3.52§
	VA	−10.39	1.50

Pancreatic cancer resection (IQI 9)†	NIS	−6.67	1.20	6.87	0.50
	VA	−13.54	13.58		
Abdominal aortic aneurysm repair (IQI 11)†	NIS	−2.81	0.80	5.93	1.44
	VA	−8.74	4.03		
Coronary artery bypass graft (IQI 12)	NIS	−2.93	0.28	2.16	1.87
	VA	−5.09	1.12		
Craniotomy (IQI 13)	NIS	−4.11	0.59	0.01	0.00
	VA	−4.12	1.95		
Hip replacement (IQI 14)	NIS	−0.16	0.07	0.37	2.79§
	VA	−0.53	0.11		
PTCA (IQI 30)	NIS	−0.35	0.05	0.86	1.71
	VA	−1.21	0.50		
Carotid endarterectomy (IQI 31)	NIS	−0.60	0.06	−0.38	1.32
	VA	−0.22	0.28		
Utilization indicators					
Laparoscopic cholecystectomy (IQI 23)	NIS	13.49	1.17	−12.23	5.26§
	VA	25.72	2.01		
Incidental appendectomy (IQI 24)†	NIS	−0.57	0.16	0.79	3.03§
	VA	−1.36	0.21		
Bilateral cardiac catheterization (IQI 25)†	NIS	−7.25	0.96	−4.35	2.44§
	VA	−2.90	1.50		

*Rates are deaths per 100 discharges with the principal diagnosis or procedure unless otherwise specified. See online Appendix 1 for full definitions of indicators.

†Endorsed by the National Quality Forum.

‡Because we found similar results for AMI mortality with and without transfers (IQI 32), we present data for AMI with transfers only.

§$t > 1.96$ = significantly different slopes. A positive estimate difference indicates VA risk-adjusted rates are decreasing more rapidly than NIS rates.

NIS indicates National Inpatient Sample; CABG, coronary artery bypass grafting; PTCA, percutaneous transluminal coronary angioplasty; CEA, carotid endarterectomy; IQI, Inpatient Quality Indicators.

O/Es for all noncardiac surgery and separately for 8 subspecialities.[49] In 1996 the Salt Lake VA hospital was identified as a high outlier for general surgical morbidity.[50] After receiving this information, local clinicians reviewed charts of NSQIP-identified patients experiencing complications to determine practice patterns and identify possible provider issues. After finding that many wound complications resulted from contaminated wound closure, they developed and instituted wound infection and disruption prevention protocols which resulted in a clinically significant decrease in wound complications.[50]

With respect to the IQIs, we found considerable VISN-level variation in bilateral cardiac catheterization rates. One possible QI scenario would be as follows: management at a high outlier VISN examines rates within its facilities to determine whether any facility had higher than expected rates. If so, that facility's QI team would review charts of a sample of its cases to determine why patients underwent

bilateral rather than left heart catheterizations (eg, operator preference, patient characteristics). Literature review of best practices, and, although not used in the previous case, review of low outlier facilities systems and practices could be used to derive recommendations that would be implemented and their effect tested.

In summary, our findings suggest the AHRQ IQIs are useful for tracking and comparing outcomes representing potential quality of care issues within the VA. Such measurement, along with internal benchmarking, will help focus QI efforts on indicators showing the greatest intersite variation. Detailed case review of systems and processes at both high and low outlier sites, may identify failures amenable to improvement and successes that can be adopted by other sites respectively, with the ultimate goal of improving care across the system. Although population differences limit external benchmarking using current IQI risk-adjustment methods, trends over time may still be compared across populations and healthcare systems. Future research should entail improving risk adjustment to facilitate external benchmarking and identifying high risk populations to target for QI interventions.

Hypertension guidelines stress that patients with severe hypertension (systolic blood pressure (BP) ⩾180 or diastolic BP ⩾110 mm Hg) require multiple drugs to achieve control and should have close follow-up to prevent adverse outcomes. However, little is known about the epidemiology or actual management of these patients. We retrospectively studied 59 207 veterans with hypertension. Patients were categorized based on their highest average BP over an 18-month period (1 July 1999 to 31 December 2000) as controlled (<140/90 mm Hg), mild (140–159/90–99 mm Hg), moderate (160–179/100–109 mm Hg) and severe hypertension. We examined severe hypertension prevalence, pattern, duration, associated patient characteristics, time to subsequent visit, percentage of visits with a medication increase, and final BP control and antihypertensive medication adequacy. Twenty-three per cent had ⩾1 visit with severe hypertension, 42% of whom had at least two such visits; median day with severe hypertension was 80 (range 1–548). These subjects were significantly older, more likely black, and with more comorbidities than other hypertension subjects. Medication increases occurred at 20% of visits with mild hypertension compared to 40% with severe hypertension; $P<0.05$). At study end, 76% of patients with severe hypertension remained uncontrolled; severe hypertension subjects with uncontrolled BP were less likely to be on adequate therapy than those with controlled BP (43.7 vs 45.4%). Among hypertensive veterans, severe hypertension episodes are common. Many subjects had relatively prolonged elevations, with older, sicker subjects at highest risk. Although, follow-up times are shorter and antihypertensive medication use greater in severe hypertension subjects, they are still not being managed aggressively enough. Interventions to improve providers' management of these high-risk patients are needed.

Journal of Human Hypertension (2010) **24,** 9–18; doi:10.1038/jhh.2009.37; published online 14 May 2009

Keywords: epidemiology; chronic hypertension; therapy

Introduction

Hypertension is among the most prevalent chronic conditions worldwide; with rates as high as 70% among adults in developed countries such as Poland.[1] Although hypertension is usually asymptomatic, it may be associated with considerable morbidity and mortality. The higher the blood pressure (BP), the greater the risk for adverse outcomes including development of coronary artery disease, congestive heart failure, stroke and kidney disease.[2] Hypertension treatment has been clearly shown to reduce this risk.[2–4]

Accordingly, the current World Health Organization/International Society of Hypertension and the European Society of Hypertension guidelines and the prior Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC) guidelines classify BP into grades or stages based on the absolute BP level.[5–7] Although absolute cardiovascular risk is based not only on BP levels, but associated cardiovascular risk factors or target organ damage, individuals with the highest levels, grade/stage[3] or severe hypertension (that is, systolic BP ⩾180 mm Hg or diastolic BP ⩾110 mm Hg)[5,8] have a 20–30% 10-year risk of cardiovascular disease, that increases to very high risk, >30%, in the presence of any risk factors or target organ damage.[5] Further, these subjects are also at high short-term risk for serious cardiovascular events, the risk increasing with the degree and speed of elevation. Because of this, guidelines also stress that such patients should have close follow-up with reassessment at most within 1 week, and will require multiple drugs to achieve control.[5,9,10]

Although much has been written about the epidemiology and management of the general hypertension population, relatively little is known about these issues in those with severe hypertension. Limited cross-sectional data suggest a prevalence among those with hypertension in the

8–19% range.[10–13] How long such patients are exposed to high BPs, or how they are being managed in actual practice is relatively unknown, with existing data based on small samples and select populations.[12–14]

The purpose of the present study was to examine the following issues with respect to patients with severe hypertension: (1) what is the epidemiology of severe hypertension, in terms of prevalence, pattern of severe hypertension and duration of severe hypertension? (2) what patient characteristics are associated with severe hypertension? (3) how are patients with severe hypertension being managed in everyday practice, including time to next visit, percentage of visits with a medication increase and number of BP medications by final BP control?

Materials and methods

Study population

The study population is previously described.[15] Briefly, we identified individuals with hypertension who were receiving regular outpatient care at geographically diverse sites within the largest integrated health-care system in the United States, the Veterans Health Administration (VA), using the VA's National Patient Care Database (NCPD) through 2000, eligible subjects: (1) had at least two NPCD-listed hypertension diagnoses, ICD-9-CM code 401, between 1 July 1997 and 30 June 1999; and (2) were regular VA users (that is, $\geqslant 3$ NPCD-listed visits to a general medicine or subspecialty medical clinic between 1 July 1999 and 31 December 2000). Subjects were followed from 1 July 1999 through 31 December 2000. The study protocol was approved by the Bedford VA Hospital's institutional review board.

Data collection

Data sources were the Veterans Health Information Systems and Technology Architecture (VISTA), that is, the VA's electronic record system, the NPCD and Medicare files. VISTA, maintained at each site, contains multiple files including clinical data such as vital signs, laboratory results, pharmacy records and provider notes. (We previously found the vitals file very complete with provider notes contributing minimal additional BP information.)[16] VISTA also contains diagnoses and procedure information from all outpatient visits and inpatient stays, which is transferred to a central data repository and incorporated into the NPCD.[17]

Demographics and comorbidities were obtained from the NPCD (1998 to 2000 inclusive), supplemented by Medicare denominator, inpatient and outpatient files (MEDPAR, Carrier and Outpatient files). We used the Medicare denominator file as our primary race source because this is patient identified and supplemented this with VA race data. Baseline comorbidities were identified by the presence of specified ICD-9-CM codes in the 12 months preceding and including the index visit.[15] Height, weight and BP were obtained from VISTA vitals, and medications from VISTA pharmacy files (1 July 1999 to 31 December 2000).

Analyses

Available BPs were averaged at each visit. All visits during 1 July 1999 through 31 December 2000 were categorized according to the average systolic and diastolic BPs as follows: controlled ($<$140/90 mm Hg), mild (140–159/90–99 mm Hg), moderate (160–179/100–109 mm Hg) and severe ($\geqslant$180/110 mm Hg) hypertension. Patients were then grouped based on their visit with the highest average BP category unless otherwise specified. If systolic and diastolic BPs fell into different categories, the higher category was used. Among patients with more than one severe hypertension episode, patient level analyses considered only the first episode unless otherwise indicated.

Objective 1: examine the epidemiology of patients with severe hypertension. We first determined the prevalence of severe hypertension in our cohort based on the number of subjects who had at least one visit with severe hypertension divided by the total sample of hypertension patients. We also looked at the proportion of all visits with severe hypertension and the median number of visits with severe hypertension per patient. Next, we characterized the pattern of severe hypertension by determining the following proportions: (1) those who had a single visit with severe hypertension, with no severe hypertension at the next visit (that is, an isolated spike in their BP); (2) those who had severe hypertension at two or more consecutive visits (persistent severe hypertension); (3) those who had an intervening visit with a lower BP but then another visit with severe hypertension (recurrent severe hypertension). We further determined the median number of recurrences per patient. In addition, we examined time in days to a subsequent visit with a BP $<$180/110 mm Hg as a proxy for the duration of (that is, exposure to) severe hypertension, and compared among severe hypertension groups. We summed these time periods for patients with recurrent episodes. (This was examined first by censoring subjects with no visit after the severe hypertension visit at either the last day of the study period or death, and then by excluding them.)

Objective 2: patient characteristics associated with severe hypertension. We next compared patients with severe hypertension to subjects without severe hypertension, grouped by highest BP category, with respect to age, gender, race, baseline comorbidities (including cardiovascular risk factors and pre-existing cardiovascular conditions, and Charlson

index),[18,19] body mass index (BMI). We also compared severe hypertension subgroups with respect to these same characteristics.

We used χ^2-analysis for categorical variables, and *t*-tests, one-way analysis of variance (ANOVA) with Tukey's multiple comparison procedure, or Wilcoxon rank-sum tests as appropriate for continuous variables.

As part of a sensitivity analysis, we repeated objectives 1 and 2 assigning subjects to BP categories based on the first visit of the study period.

Objective 3: examine the management of patients with severe hypertension. We next examined actions potentially under clinician control. The following analyses were carried out at the visit level: (1) we determined the time in days to the next visit that included a BP assessment following a visit with severe hypertension. We used Wilcoxon rank-sum tests to compare the median interval to the next visit among severe hypertension subgroups, and between visits with severe hypertension to visits with moderate hypertension, mild hypertension or controlled BP. (2) We then examined the percentage of visits associated with a medication increase. To determine medication increases at a visit, we defined baseline medication use based on the 6-month period preceding study entry (that is, we examined medication data out to 1 January 1999); using methods we previously developed, a patient was considered to have an increase at a given visit if the dose of an existing medication was increased or a new medication was started.[20,21] We compared the proportion of visits with a medication increase among the severe hypertension subgroups then compared among visits with moderate, mild hypertension or controlled BP using χ^2-tests. We also looked at the impact of this increase on BP control at the subsequent visit for the severe hypertension group.

Although we lacked information on specialty referrals for BP management or to exclude secondary hypertension, as a proxy, we examined differences in proportions of patients seen in subspecialty clinics at which BP management might be addressed by χ^2-analysis and generating 95% confidence intervals. These clinics included hypertension, renal, cardiology and endocrinology clinics. We further looked at the frequency of these visits with a primary diagnoses related to hypertension (ICD-9-CM codes 401, 402, 403, 404 and 405 (secondary hypertension)) and the frequency of any 405 code at these visits.

To examine medication use and BP control at study end, we then categorized subjects based on their highest average BP at a visit before the last study visit. We compared the percentage of patients who achieved a BP $<140/90$ mm Hg at the last study visit by BP group. We next compared BP groups by mean number of prescribed antihypertensive medications (using ANOVA), percentage of subjects on each major class of antihypertensive medication and the percentage on adequate therapy defined as a regimen containing at least three different classes of drugs at least one of which had to be a loop or thiazide diuretic[9] at the last study visit using χ^2-tests. We then examined the mean number of prescribed antihypertensive medications at the time of the last visit by prior highest BP category and final BP control (that is, BP $<140/90$ mm Hg; yes/no) using linear regression models, comparing both within BP groups, and across groups for controlled vs uncontrolled. We also repeated analyses comparing among severe hypertension subgroups. Finally, we examined adequacy of antihypertensive therapy at the last study visit and final BP control. Within each BP group defined by the highest BP before the last study visit, we used χ^2-tests to examine likelihood of adequate therapy at study end by final BP control (yes/no); we also compared adequacy across BP categories. We performed similar comparisons among severe hypertension groups.

Results

Objective 1

Our total sample consisted of 59 207 subjects. The mean age was 65 years: 58% were white and 97% were men.[15] Twenty-three per cent ($N=13\,735$) had at least one visit with severe hypertension; among these subjects the median number of such visits was 1 (range 1–57). Six per cent of all visits (21 992/325 105) were associated with severe hypertension. Of note, 87% of visits with a BP of $\geqslant 180/110$ mm Hg had only one BP documented on the day of the visit.

Of the severe hypertension group, 18% had severe hypertension at two or more consecutive visits (persistent), 23% had one or more intervening visits with a lower BP but then another visit with severe hypertension (recurrent); 58% had a single visit with a BP $\geqslant 180/110$ mm Hg (isolated spike). In 17% of subjects with an isolated spike, there was no subsequent documented visit. The median number of recurrences among the severe hypertension group was 0, range 0–34 (interquartile range 0–1). The median number of days with severe hypertension overall was 80 (range 1–548; Table 1) and varied

Table 1 Total exposure to severe hypertension

BP category	*Exposure to severe hypertension Days, median (range)*[a]

Abbreviations: BMI, body mass index; s.d., standard deviation.
[a]$P<0.05$ for among-group comparisons and pair-wise comparisons; the severe hypertension group was significantly different than the three other hypertension groups with respect to all the characteristics listed. However, with respect to race, the prevalence of Hispanics in the severe hypertension group was only significantly different compared to the moderate hypertension group.

significantly by severe hypertension subgroup. (Overall exposure did not change significantly if we excluded subjects with a single visit.)

Categorizing subjects using the first study period visit, 7% of subjects had severe hypertension, of whom 27% had persistent, 28% had recurrent and 45% had an isolated spike. Exposure trends were similar.

Objective 2

Compared to subjects with lower BPs, severe hypertension subjects were older, ($67.0 + 10.8$ vs $64.6 + 11.2$ years; $P<0.05$), were more likely to be black (24 vs 16%; $P<0.05$) and women (3.3 vs 2.7%, $P<0.05$) compared to all other subjects combined ($N = 45\,472$). They also had more total comorbidities (for example, Charlson index $1.4 + 1.3$ vs $1.2 + 1.2$, $P<0.05$) and a higher prevalence of specific comorbidities such as diabetes, renal disease and peripheral vascular disease; although when further divided into BP categories, the controlled BP group had the highest prevalence of coronary artery disease, congestive heart failure and hyperlipidaemia. (See Table 2 for comparisons among BP categories.)

Among severe hypertension subgroups, the recurrent and persistent were similar with respect to age and race distribution, but the recurrent had the most comorbidities followed by the persistent then the isolated spike group. The isolated spike group was younger and more likely to be white (see Table 3). Similar trends were seen when subjects were categorized by the first study visit (data not shown; available from authors).

Objective 3

The median time to a subsequent visit after presentation was 42 days (range 1–503) for severe hypertension, 52 days (1–513) for controlled BP, 60 days (1–518) for mild and 55 (1–496) for moderate hypertension visits ($P<0.05$ for between-group differences).

Hypertension medication increases occurred at 40% of severe hypertension, 10% of controlled, 20% of mild and 32% of moderate hypertension visits ($P<0.05$). Among visits with severe hypertension, medications were increased at 41% of visits with severe hypertension among the persistent group, 36% of the recurrent group and 42% of the isolated spike group ($P<0.05$). If a medication was increased at a given visit with severe hypertension, BP was controlled 13.2% of the time at the next visit, versus 12.5% of next visits if there was no medication increase. (This difference was not significant (NS)).

The proportion of patients seen in a subspecialty clinic at which BP management might be addressed not surprisingly tended to increase with increasing BP category, and was significantly higher in the severe hypertension group (except for cardiology clinic visits) presumably in part driven by the higher prevalence of renal disease or diabetes in the more severe group (Table 4). The frequency of such visits associated with a primary diagnosis of hypertension ranged from 6.2% among the controlled group, 8.9% of the mild, 13.3% of the moderate, to 20.0% among the severe hypertension group. In severe hypertension subgroup, this ranged from 17.5% among the isolated spike group, 18.0% among the recurrent group and 29.8% among the persistent group ($P<0.5$

Abbreviations: BP, blood pressure; CI, confidence interval.
Non-overlapping of CIs indicates the proportions (percentages) are significantly different from each other.
[a]Clinics at which hypertension is likely to be treated.
[b]Any subspecialty clinic: hypertension, renal, cardiology or endocrinology.

for between-group differences). The frequency of a code for secondary hypertension ranged from 0% among endocrinology visits, 0.1% for cardiology, 0.9% for renal, to 2.8% of all hypertension clinic visits.

When categorized by the highest available BP before the last visit of the study, at the end of study 24% of the severe hypertension group had controlled BP, compared to 73% of the controlled, 51% of mild and 33% of the moderate group ($P<0.05$). For the severe hypertension subgroups, the isolated spike group was most likely to be controlled (27%), followed by the recurrent (21%) and the persistent groups (16%; $P<0.05$ for between-group differences). (Of note, 1390 subjects with only one visit with a BP were excluded from this analysis; 500 had controlled, 525 had mild, 243 had moderate and 122 (9%) had severe hypertension. We found similar results to those reported below if we included these subjects in analyses and assumed they had an additional visit and their BP category was stable (data not shown; available from authors).)

At the end of study, the mean number of BP medications increased significantly with increasing BP category (Table 5; Figure 1). In addition, severe hypertension patients were significantly more likely to be on all classes of antihypertensives compared to the other groups (Table 5). Among severe hypertension subgroups, the persistent and recurrent subgroups were on more medications at study end than

Abbreviations: ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; BMI, body mass index; CCBs, calcium channel blockers; s.d., standard deviation.
[a]$P<0.05$ for among-group and pair-wise comparisons; analyses were carried out separately for the BP groups and severe hypertension subgroups. In pair-wise comparisons, for BP groups, the mean number of medications and the percentage on each medication class or on adequate therapy increased with increasing BP group, except for β-blocker use where the controlled group was more likely to be on a β-blocker than the mild or moderate group. Also, the controlled and mild groups were not significantly different with respect to ACEI/ARB use, diuretic use, other vasodilators use and percentage on adequate therapy. For the severe hypertension subgroups, the mean number of medications, the percentage on each medication class or adequate therapy was significantly lower for the isolated spike group than the persistent or recurrent, except for ACEI/ARB use which was similar to the recurrent. The persistent and recurrent groups were similar in all comparisons except for ACEI/ARB use.
[b]Includes clonidine, hydralazine, methyldopa and minoxidil.
[c]Adequate therapy: a regimen containing at least 3 different classes of drugs at least one of which is diuretic.

the isolated spike subgroup (Table 5; $P<0.05$ for between-group differences). The proportion on each medication class was significantly lower for the isolated spike group than the persistent or recurrent group, except for ACEI/ARB use which was similar to the recurrent group (Table 5). Despite a trend towards higher use of each medication class among the persistent group compared to the recurrent, the differences were not significant.

Across all BP groups, those with controlled BP at study end (<140/90 mm Hg) were on more medications than those with uncontrolled BP (although this difference was not significant for the severe hypertension group; Figure 1). Within severe hypertension subgroups, the mean number of medications at study end was only significantly different between controlled and uncontrolled subjects for the isolated spike group (Figure 1).

Use of three or more medications including a diuretic at the last visit increased by increasing preceding highest BP category (although the difference between the controlled and mild groups was not significant) (see Table 5 and Figure 2). Among the severe hypertension subgroups, those with persistent or recurrent elevations were more likely to be on adequate multi-drug therapy compared to the isolated spike group (Table 5). Similar to the medication class analysis, the proportions on adequate therapy in the persistent and recurrent groups were not significantly different (Table 5).

When examining adequacy of therapy and final BP control, subjects with uncontrolled BP at the last visit were less likely to be on adequate multi-drug therapy than those with controlled BP within any given BP group or severe hypertension subgroup (Figure 2), although differences were not significant for the severe hypertension group (45.4 vs 43.7%, NS; Figure 2). In subgroups, differences were only significant among the isolated spike subgroup (Figure 2).

Discussion

This is the largest study to date examining the epidemiology and management of patients with severe hypertension. This is also the first to characterize the pattern of severe hypertension, to examine management of such patients and to compare among hypertension categories. We found that severe hypertension is relatively common, with almost one quarter of subjects having at least one visit with severe hypertension. Further, in many cases this represented more than a single isolated spike, with over 40% having persistent or recurrent severe elevations.

Factors associated with severe hypertension were similar to those found in previous studies of poor BP control. Subjects with severe hypertension were older, more likely to be black, women, and had more medical comorbidities than subjects with lower BPs.

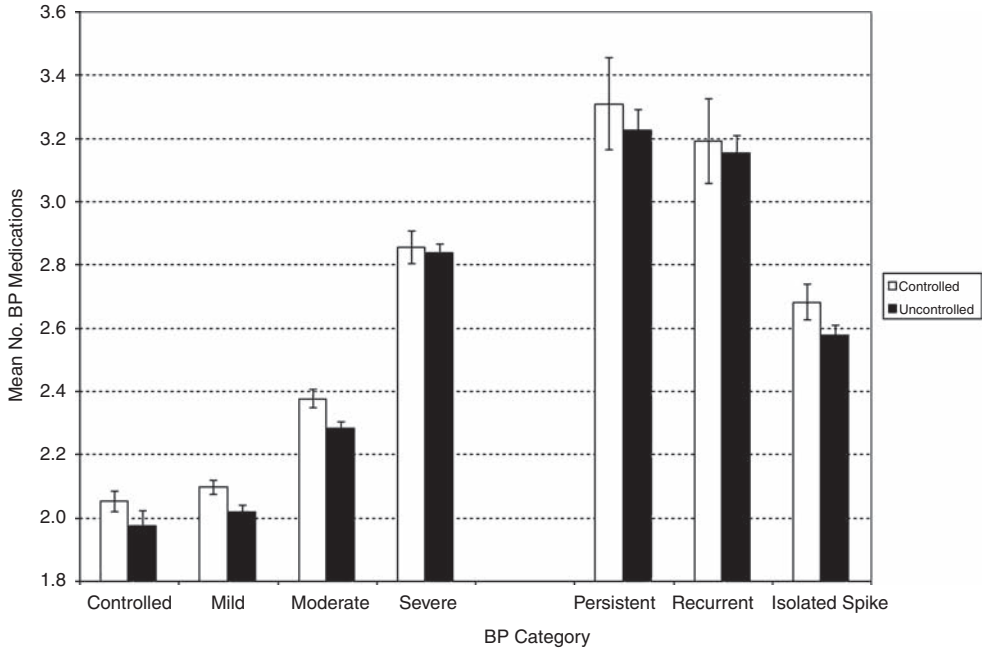

Figure 1 Mean number of antihypertensive medications at study end by highest preceding blood pressure (BP) category and final BP control. Means shown with surrounding bars representing 95% confidence intervals. (Error bars overlap for those in the controlled BP group with controlled vs uncontrolled BP at study end. However, by Student's *t*-test, the means of controlled vs uncontrolled are significantly different, $P<0.05$.)

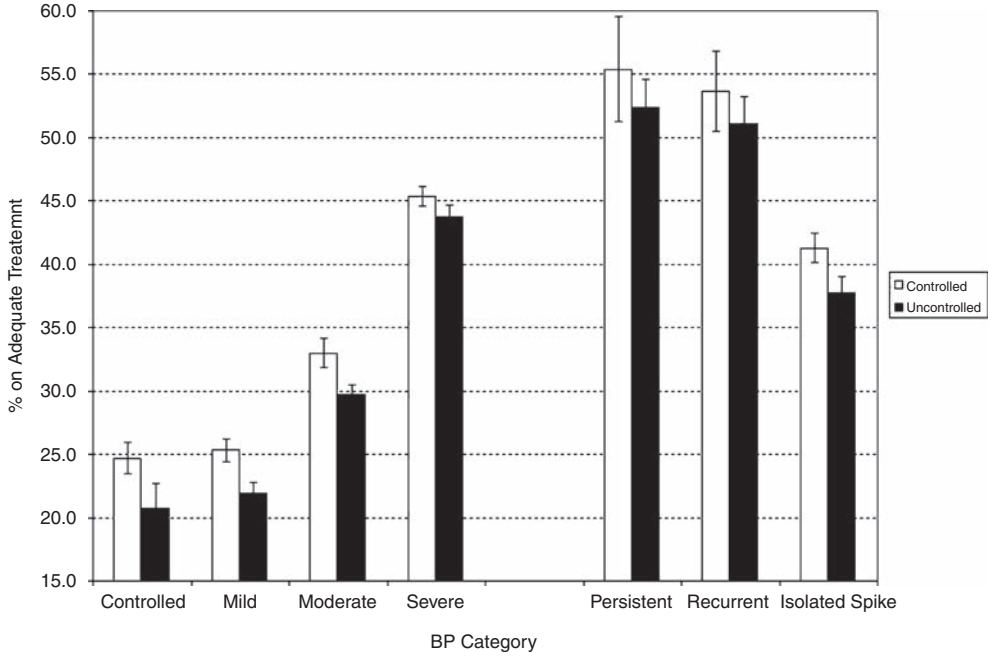

Figure 2 Adequacy of blood pressure (BP) treatment at study end by highest preceding BP category and final BP control. Bars represent 95% confidence intervals.

Similarly, among those with severe hypertension, those with recurrent or persistent elevations were older and women. The recurrent group had more medical comorbidities than those with persistent elevations or the isolated severe group. Analyses of National Health and Nutrition Examination Survey data likewise found age and being black were associated with poorer control.[22,23] An analysis of data from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial, additionally

found being woman, having diabetes and an elevated creatinine were associated with lack of control at follow-up.[24] We found similar associations in our previous examination of factors associated with poor BP control in this sample.[15]

We also found that patients with severe hypertension are often not treated aggressively enough. The median follow-up time after a visit with severe hypertension was 42 days, which is much longer than the guideline-recommended interval. Although medications were more likely to be increased as the severity of BP category increased, this still occurred at less than 50% of visits with severe hypertension and many subjects with severe hypertension remained uncontrolled at the end of the study. Although mean number of medications increased by BP category, within any category, including the severe hypertension group, subjects with uncontrolled BP at study end tended to be on fewer medications than controlled subjects. Further, a significant percentage of the severe hypertension group were not on adequate therapy at study end and continued to have poorly controlled BP. Among the severe hypertension subgroups, those on more medications tended to be better controlled at study end. Subjects with persistent severe hypertension were more likely to have their medications increased but were slightly less likely to be controlled compared to the recurrent group.

Existing data specifically examining severe hypertension epidemiology and management are very limited, being based on small populations and select samples. The largest observational study examined outcomes in 142 emergency room (ER) patients presenting with BPs $\geqslant$220 mm Hg systolic or $\geqslant$120 mm Hg diastolic.[12] Among those treated as urgencies and discharged from the ER, the mean time to a follow-up appointment was 21 days. Thirty percent of subjects returned to the ER with uncontrolled hypertension, 14% with hypertensive complications, within an average of 33 days. Drug management was also only examined in the acute ER setting. Longer-term use of drugs, BPs and clinical outcomes were not tracked. A cross-sectional Spanish study assessing cardiovascular risk and comorbidities in hypertension patients attending primary care practices found the following prevalences of BP categories among 1413 subjects: controlled 3%, mild 50%, moderate 39%, severe 8%.[13] The mean age of their sample was similar to ours at 65.3 (11.4) years. Among high-risk patients (based on comorbidities and absolute BP levels) there was no medication change in 30%. No information is given about the severe hypertension subjects as a distinct group. Only one study specifically examined subjects with severe hypertension.[12] Lalljie and Lalljie[12] studied management and BP outcomes in 48 subjects with severe hypertension of 252 (19%) patients presenting to a Jamaican hypertension specialty practice. Follow-up data were only reported on 31 of these subjects, of whom more than 50% achieved BP control during up to 2 years of follow-up with most requiring at least four drugs. Unlike our study, subjects were younger (62% were $<$65 of age), more likely to be women, with lower baseline comorbidity rates (31% had diabetes, 21% had heart failure and 15% had coronary artery disease).

This study has a few caveats. It was performed in a sample of predominantly male veterans with relatively high disease burden and good access to medical care and medications. Therefore, findings may not be generalizable to other settings. Our data predate VA quality performance data that show improvement in control rates over time, such that the current prevalence of severe hypertension is likely lower.[25] However, given the prevalence of hypertension in the VA population has increased from 37% in 1999 to 55–60% in 2006 (based on ICD-9 codes), in absolute numbers this still likely represents many patients with severe hypertension.[26] We lack data on some management aspects of severe hypertension subjects that may be of interest such as referrals to hypertension specialists (although we do know that less than 1.0% of these patients were seen in a hypertension clinic) or investigations to exclude secondary hypertension.

We have also demonstrated that the method used to define the BP group, for example, highest average BP at any visit vs the first visit of the 18-month study period produces dramatically different values with respect to severe hypertension prevalence. Further deviation from the true prevalence may result because BPs were obtained from the vitals file, with only one BP available for almost 90% of visits; we may be missing BPs present in provider notes. In addition, we cannot exclude white coat hypertension because we do not have access to home BP measures or 24 h ambulatory blood pressure monitoring. However, in a previous study, we found that provider notes contributed minimal additional BP information beyond the vitals file, including rare documentation of ambulatory or home BPs.[16]

Our examination of hypertension management was based on highest BP as opposed to the first study BP because we wanted to determine providers' responses to such high BPs. JNC 7, published after our study, emphasizes that most patients will require more than one antihypertensive drug to achieve control.[9] In our study using data through the end of 2000, the majority of patients across all BP groups were already on at least two medications, with many also on a diuretic. Thus, we would not expect substantially different findings with more current data other than slightly lower rates of severe hypertension as noted above. Our measure of treatment adequacy does not account for medication dosage and thus may be overestimating treatment adequacy. It is possible that this may in part explain

the lack of statistical difference between the proportions controlled and uncontrolled in the severe hypertension group at study end. However, this still does not account for the fact that many subjects in the severe hypertension group were not even on adequate therapy based on number of medications.

Although BP control, especially in severe hypertension subjects, may be improved by treatment intensification, specialist referral and investigation for and management of secondary causes of hypertension, we were unable to examine reasons for lack of treatment intensification and lacked data on referrals to hypertension specialists (although we do know that less than 1.0% of these patients were seen in a hypertension clinic) or on investigations to exclude secondary hypertension. Other investigators have found clinical uncertainty about true BP values to be a prominent reason for lack of treatment intensification.[27] Whether this has a role in patients with such high BPs is unclear.

In conclusion, among veterans with hypertension, severe BP elevations are relatively common with many patients having persistent or recurrent elevations with inadequate follow-up and intensification of therapy. This suggests that clinical inertia is not just an issue among those with mildly elevated BP. Given the increased cardiovascular risk associated with this degree of BP elevation, there is a need for better understanding of how these patients are being managed. In addition, interventions are needed to overcome clinical inertia and improve providers' management of hypertension, especially regarding severe hypertension.

What is known about the topic

- Little data on prevalence and management of patients with severe hypertension.
- Prevalence estimates of 8–19% based on small sample sizes ($N = 252$–1413) in select populations (for example, patients referred to hypertension clinics).
- No data on patterns of severe hypertension and how long patients are exposed to such high BPs.

What the study adds

- Largest study to date examining prevalence and management of patients with severe hypertension ($N = 59\,207$, of whom 13 735 had at least one visit with severe hypertension).
- First to characterize the pattern of severe hypertension, that is, isolated spike vs persistent or recurrent.
- First to compare management of patients with severe hypertension to patients with other categories of hypertension.

Conflict of interest

This project was funded in part by the Department of Veterans Affairs Health Services Research and Development service grant number SDR 99-300-1 and by Bristol-Myers Squibb. Dr Berlowitz has served as a consultant for Bristol-Myers Squib. All aspects of design, conduct and analysis were under sole authority of the authors without any restriction on publication.

ABSTRACT

BACKGROUND: Compared with those with health insurance, the uninsured receive less care for chronic conditions, such as hypertension and diabetes, and experience higher mortality.

METHODS: We investigated the relations of health insurance status to the prevalence, treatment, and control of major cardiovascular disease risk factors—hypertension and elevated low-density lipoprotein (LDL) cholesterol—among Framingham Heart Study (FHS) participants in gender-specific, age-adjusted analyses. Participants who attended the seventh Offspring cohort examination cycle (1998-2001) or the first Third Generation cohort examination cycle (2002-2005) were studied.

RESULTS: Among 6098 participants, 3.8% were uninsured at the time of the FHS clinic examination and ages ranged from 19 to 64 years. The prevalence of hypertension and elevated LDL cholesterol was similar for the insured and uninsured; however, the proportion of those who obtained treatment and achieved control of these risk factors was lower among the uninsured. Uninsured men and women were less likely to be treated for hypertension with odds ratios for treatment of 0.19 (95% confidence interval [CI], 0.07-0.56) for men and 0.31 (95% CI, 0.12-0.79) for women. Among men, the uninsured were less likely to receive treatment or achieve control of elevated LDL cholesterol than the insured, with odds ratios of 0.12 (95% CI, 0.04-0.38) for treatment and 0.17 (95% CI, 0.05-0.56) for control.

CONCLUSION: The treatment and control of hypertension and hypercholesterolemia are lower among uninsured adults. Increasing the proportion of insured individuals may be a means to improve the treatment and control of cardiovascular disease risk factors and to reduce health disparities.

KEYWORDS: Cardiovascular risk factors; Health disparities; Health insurance; Hypertension

The lack of health insurance is a large and growing problem in the United States. In 2008, 15.4% of the US population was uninsured, and the number of uninsured persons has increased over the past 2 decades.[1]

In the United States, adults without health insurance are less likely to receive screening for chronic medical conditions, such as hypertension and hypercholesterolemia.[2] Conversely, approximately 1 in 7 adults with diabetes or hypertension is without health insurance.[3] Compared with the insured near-elderly, the uninsured near-elderly have a higher mortality rate, which is mostly confined to those with diabetes, hypertension, and coronary heart disease.[4]

Of studies that have looked at the treatment and control of cardiovascular disease risk factors by health insurance status, the majority have relied on self-reported diagnoses,[5] only evaluated medication use without addressing the effectiveness of treatment,[6,7] or focused on hypertension alone.[7,8] The current investigation examined the prevalence, treatment, and control of hyper-

tension and elevated low-density lipoprotein (LDL) cholesterol in Framingham Heart Study (FHS) participants according to health insurance status. The majority of the FHS participants reside in Massachusetts, which has a highly insured population compared with the US average and has legislated mandatory health insurance effective July 2007.[9] The average percentage of the population that was uninsured from 2004 to 2006 was 10.3% for Massachusetts compared with 15.3% nationally.[10] Demonstrating differences in the treatment of cardiovascular disease risk factors in insured versus uninsured individuals in an area with high health insurance rates would underscore the public health implications of expanded insurance coverage.

CLINICAL SIGNIFICANCE

- The prevalence of hypertension and elevated low-density lipoprotein cholesterol is similar among the insured and uninsured.
- The treatment and control of hypertension and hyperlipidemia are significantly lower for uninsured than insured men.
- Hypertension treatment is significantly lower in uninsured than insured women.
- The lack of control of cardiovascular risk factors may explain poorer health and increased mortality in the uninsured compared with the insured.

MATERIALS AND METHODS

Study Population

The FHS is an observational study that began in 1948 when an original study cohort was enrolled. The children and spouses of children of the Original cohort were enrolled in the Offspring cohort, beginning in 1971.[11] The Third Generation cohort, composed of children of Offspring cohort participants, was enrolled starting in 2002.[12] Data from the 3539 participants in the Offspring cohort's seventh examination cycle (1998-2001) and 4095 participants in the first examination cycle for the Third Generation cohort (2002-2005) form the basis of this investigation. Participants who were aged 65 years or more and therefore eligible for Medicare (n = 1238) or had missing data on cardiovascular disease risk factors (n = 245) were excluded. An additional 53 participants with missing data on insurance status were excluded, resulting in a final sample size of 6098 participants.

Exposure Variable

Insurance status was sought as part of the sociodemographic questionnaire that participants completed during the clinic visit. Offspring cohort participants were asked, "Do you have health insurance?" Third Generation participants were asked about various types of insurance, including Medicare, Medicaid, Veterans Administration or military insurance, private or health maintenance organization insurance, or no insurance. Participants were classified as having no insurance if they did not respond affirmatively to any of the insurance categories but did answer at least 1 item of the insurance question.

Measurements and Definitions of Outcome Variables

The main outcome measures were blood pressure and LDL cholesterol. Blood pressure was determined by the average of 2 measurements performed by the examining physician during the clinic visit. Participants with systolic blood pressure of 140 mm Hg or greater or diastolic blood pressure of 90 mm Hg or greater, or those taking medication for a hypertension indication were defined as having hypertension. Medication use was by self-report. All participants had fasting blood work performed at the clinic visit. LDL cholesterol was calculated using the Friedewald equation.[13] A diagnosis of elevated LDL cholesterol was defined by National Cholesterol Education Program Adult Treatment Panel III guidelines and was LDL cholesterol 160 mg/dL or more for those with no or 1 cardiovascular disease risk factor, 130 mg/dL or more for those with 2 or more risk factors, and 100 mg/dL or more for those with coronary heart disease, diabetes or a coronary heart disease risk equivalent,[14] or current use of a lipid-lowering agent.

Participants were diagnosed with coronary heart disease if they had prevalent myocardial infarction, coronary insufficiency, or angina as determined by physician investigator review of FHS clinic visit and hospital records. Similarly, participants were diagnosed as having cardiovascular disease if they had a diagnosis of coronary heart disease, stroke (ischemic stroke or intracerebral hemorrhage), heart failure, or intermittent claudication as determined by physician review. For those without prevalent cardiovascular disease, a Framingham risk score was calculated predicting the 10-year risk of coronary heart disease.[15] The presence of metabolic syndrome was defined as 3 or more of the following: waist circumference of 102 cm or more for men or 88 cm or more for women, triglycerides of 150 mg/dL or more, high-density lipoprotein cholesterol less than 40 mg/dL for men or less than 50 mg/dL for women, fasting blood glucose of 100 mg/dL or more or use of insulin or an oral hypoglycemic agent, and blood pressure of 130/85 mm Hg or more or antihypertensive medication use.[16]

Participants provided detailed information on medical checkups, hospitalizations, emergency department visits, smoking, and alcohol use during the physician-administered examination. Heavy alcohol use was defined as 7 or more drinks per week for women and 14 or more drinks per week for men.[17] The Center for Epidemiologic Studies Depression Scale score was used to determine depressive symptomatology with a score of 16 or greater indicating a high degree of symptoms.[18] Participants also answered questionnaires providing detailed health and sociodemographic information, such as self-reported education and income lev-

els (both carried over from previous examinations) and health status.

Treatment and Control of Outcome Variables

Hypertension treatment was defined as currently taking antihypertensive medication. Control of hypertension was defined as blood pressure less than 140/90 mm Hg. Treatment for elevated LDL cholesterol was defined as currently taking prescription lipid-lowering medication. Control of LDL cholesterol was defined by Adult Treatment Panel III guidelines and depended on the number of cardiovascular disease risk factors each participant had at the time of the examination with levels being less than those described above.[14] Treatment for all conditions was defined by the proportion of participants being treated for a condition among those with the condition. Similarly, control was defined as the proportion of participants with adequate control of a given risk factor among those defined as having that risk factor.

Statistical Analysis

All analyses were gender-specific because of the presence of spouse couples within the study sample that were unlikely to be independent with respect to insurance status. For all continuous variables, generalized linear models, adjusted for age and cohort (Offspring vs Third Generation), were used to compare differences in mean risk factor levels between the insured and uninsured. For dichotomous variables, a logistic regression model, adjusting for age and cohort (Offspring vs Third Generation), was constructed to compare the proportion of clinical and psychosocial factors among those with and without health insurance. Multinomial logistic regression was used for polytomous variables. To assess the relations between health insurance status and cardiovascular disease risk factor prevalence, treatment, and control, odds ratios and 95% confidence intervals were calculated using generalized estimating equations and logistic regression to adjust for age and relatedness between study participants, because the FHS has a family-based design. All statistical analyses were performed using SAS, v. 8.2 (SAS Institute Inc, Cary, NC). A 2-sided P value of less than .05 was considered statistically significant.

RESULTS

Baseline Clinical Characteristics

Women comprised 53.5% of the study sample. Five percent of men and 3% of women were uninsured; 59% of the uninsured were men. Mean systolic and diastolic blood pressures for the insured and uninsured were 122/78 and 121/77 mm Hg for men and 116/73 and 118/73 mm Hg for women, respectively (Table 1). For men, total cholesterol and LDL cholesterol values were significantly higher among the uninsured at 200 and 126 mg/dL compared with 194 and 121 mg/dL for the insured, respectively ($P = .01$ and $P = .03$). In women, no differences were seen in lipid concentrations according to health insurance status with mean LDL cholesterol values of 110 and 114 mg/dL for insured and uninsured women, respectively. The prevalence of preexisting coronary heart disease or cardiovascular disease, the average Framingham coronary heart disease risk

**P* values are adjusted for age (years) and cohort (Offspring vs Third Generation).

score, and the prevalence of the metabolic syndrome did not vary by health insurance status for men or women. Uninsured women had a significantly higher mean BMI (28.0 vs 26.5; $P = .02$) and a higher prevalence of obesity (34% vs 23%; $P = .01$). In men, 46% of the uninsured smoked compared with 16% of insured men ($P < .001$); corresponding values for women were 33% and 16% ($P < .001$). Uninsured men were more likely to have heavy alcohol use than insured men (21% vs 15%; $P = .04$).

Baseline Psychosocial and Sociodemographic Characteristics

A comparison of categoric variables is presented in Table 2. There was a significant difference between the uninsured and insured in the percentage of persons defined as having a high level of depressive symptoms on the Center for Epidemiologic Studies Depression Scale, which was 24% versus 8% ($P < .001$) for men and 20% versus 12% ($P = .02$) for women. The rates of hospitalization were similar between uninsured and insured men; however, uninsured men were more likely to have been seen in the emergency department. Among women, the uninsured were less likely to have been hospitalized for any reason, including childbirth, 43% versus 58% ($P = .006$). The rates of routine physical examinations within the last 5 years were significantly lower among uninsured participants compared with insured participants in men (58% vs 88%; $P < .001$) and in women (76% vs 94%; $P < .001$). Only 53% of uninsured men obtained post high school education compared with 72% of insured men ($P < .001$). There were no significant differences in the percentage of women with post-high school education by health insurance status. The uninsured were more likely to have lower self-reported health status and had lower rates of family income $75,000 or greater than the insured.

Prevalence, Treatment, and Control of Cardiovascular Disease Risk Factors

Tables 3 (men) and 4 (women) report the gender-specific prevalence, treatment, and control of cardiovascular disease risk factors, adjusted for age and cohort. The mean systolic and diastolic blood pressures for men with a diagnosis of hypertension were 134/84 ± 16/10 mm Hg and 141/89 ±

*Odds ratios and *P* values are adjusted for age (years) and relatedness between family members.

14/8 mm Hg for those with and without insurance, respectively. The corresponding values for women with hypertension were 136/81 ± 18/10 mm Hg and 137/83 ± 22/11 mm Hg. Although the prevalence of hypertension was similar in uninsured versus insured men and women, the proportion of those treated for hypertension was lower for those without health insurance. The odds ratios for hypertension treatment were 0.19 in men (uninsured vs insured; $P = .003$) and 0.31 in women ($P = .01$). The proportion of those with controlled hypertension also was significantly lower in uninsured men at 8% compared with 42% in insured men (odds ratio of control of 0.17; $P = .01$).

Mean LDL cholesterol values among men with a diagnosis of elevated LDL cholesterol were 137 ± 37 mg/dL and 154 ± 35 mg/dL for the insured and uninsured, respectively. Corresponding values in women were 142 ± 39 mg/dL and 149 ± 38 mg/dL. The pattern for high LDL cholesterol among men was similar to that of hypertension. The proportion of those treated for high LDL cholesterol was 41% in insured men but only 7% in uninsured men (odds ratio of treatment 0.12; $P < .001$). Control of LDL cholesterol was achieved in only 7% of uninsured men with elevated LDL cholesterol versus 31% in insured men (odds ratio of control 0.17; $P = .004$). The percentage of women with elevated LDL cholesterol was marginally higher in the uninsured than the insured, but no differences in treatment or control were observed.

DISCUSSION

The proportions of those with treated and controlled major cardiovascular disease risk factors were considerably lower in uninsured compared with insured individuals. This was most notable for treatment and control of hypertension and elevated LDL cholesterol in men and for hypertension treatment in women. Whereas the lower rate of hypertension control in the uninsured has been demonstrated,[5] the finding that the proportion of controlled hypercholesterolemia also is significantly lower in uninsured men than insured men is new.

Our investigation demonstrated lower proportions of treatment and control of blood pressure among uninsured hypertensive individuals. The only randomized insurance study in the United States, the RAND Health Insurance Experiment, demonstrated that hypertensive individuals randomized to free health care had better blood pressure control than those who were randomized to insurance plans that required cost sharing.[19] Although the RAND study did not randomize people to uninsured versus insured health insurance status, and instead compared plans with a range in the amount of cost sharing for participants, their findings were consistent with the current results. In 2 quasi-experimental studies of insurance status investigating instances when Medi-Cal and Veterans Administration health insurance benefits were terminated, it was found that hypertensive patients whose benefits were cut experienced subsequent increases in blood pressure compared with those whose coverage was maintained.[20,21] Taken as a whole, these prior studies and our findings suggest that the lack of health insurance does have direct adverse effects on blood pressure for those with hypertension.

The prevalence of elevated LDL cholesterol did not differ between uninsured and insured men and was marginally higher in uninsured versus insured women in this study. Uninsured men were significantly less likely to have their LDL cholesterol levels treated or controlled than insured men. To assess hypercholesterolemia, we focused our investigation on LDL cholesterol because it is the focus of clear diagnostic and treatment guidelines.[14] Of the previous studies that have examined prevalence of hypercholesterolemia by insurance status, all have used total serum cholesterol and not LDL cholesterol as in this evaluation.[5,6,22] The difference in methodology may partially explain the new findings in this investigation. Our study also used contemporary data, from a time period when lipid-lowering treatment recommendations were more aggressive than in previous years.

Depressive Symptoms and Sociodemographic Factors

A notable finding was that the uninsured had significantly higher levels of depressive symptoms than the insured. It has been shown that the depressed uninsured are less likely to receive treatment than the depressed insured[23] and that depression is more severe in the uninsured than the insured.[24] Differences in psychosocial factors such as depression may not reflect an association with lack of insurance, but rather may reflect other common factors such as differences in education and socioeconomic status. However, the significance of depression and other psychiatric illnesses as comorbidities in the uninsured deserves further investigation. Consistent with previous work, our study demonstrated that the uninsured have lower rates of routine medical checkups, lower income and self-reported health status, and higher rates of smoking.[2,4,5]

Potential Mechanisms for These Findings

There are many possible mechanisms for why those without health insurance would have lower proportions of treated and controlled hypertension and hyperlipidemia. Although the prevalence of hypertension was similar between those with and without insurance, this does not mean that the rates of diagnosis also were similar between groups. Given that those without health insurance are less likely to have routine medical examinations than the insured, hypertension and hyperlipidemia are likely underdiagnosed among the uninsured. Indeed, the uninsured are less likely to be aware of personal diagnoses of hypertension or hyperlipidemia than the insured.[5] Even if the uninsured were diagnosed with these conditions, treatment is dependent on access to continued medical care and control of risk factors is dependent on obtaining treatment. Thus, decreased rates of routine medical examinations among the uninsured could have det-

rimental effects on rates of diagnosis, treatment, and control of cardiovascular disease risk factors. In addition, hypertension and hypercholesterolemia are asymptomatic conditions, and the uninsured may be less inclined to seek screening or care for these conditions. The costs of physician visits, blood chemistry tests, and prescription medication likely explain much of the observed lower proportions of treated and controlled cardiovascular disease risk factors among the uninsured compared with the insured. However, many other measured and unmeasured factors, such as lack of adherence to medical regimens because of depressive symptoms, poor understanding of health conditions because of lack of a regular health care provider, and cultural attitudes pertaining to the health care system, affect the interplay between health insurance and cardiovascular disease risk factor treatment and control. These complex interactions are beyond the scope of the present investigation but merit further elucidation.

Our study has a number of strengths. Data from the FHS are rigorously collected, 99% of participants had fasting blood glucose chemistry tests, and physician investigators review all cardiovascular disease end points. Notably, this study used physician-measured blood pressure and obtained fasting laboratory values to define the main risk factors and their treatment and did not rely on self-reported diagnoses as in a preceding study.[5]

Because of the cross-sectional nature of this investigation, we were unable to demonstrate that the lack of health insurance has a causal relation to uncontrolled risk factors or increased cardiovascular disease risk. Other limitations of this study include low numbers of uninsured participants, which limited our power to demonstrate differences in some outcomes by health insurance status. The participants in the FHS are almost entirely white and reside mainly in Massachusetts. Although the lack of geographic and racial diversity of the study participants does limit the ability to generalize the results of the current investigation, it also eliminates race as a confounder. Also, FHS participants undergo periodic examinations that can result in referrals back to their personal physician. Thus, FHS participants may have more contact with the health care system, greater health literacy, and increased awareness of personal diagnoses of conditions, such as hypertension and hyperlipidemia, than the general population. Unfortunately, we were not able to assess whether participants were underinsured. Including the underinsured, such as those with catastrophic insurance coverage only, among those with health insurance in this study might alter the observed association between health insurance status and rates of treatment and control of hypertension and hyperlipidemia.

CONCLUSIONS

Our investigation emphasizes the relations between insurance status and cardiovascular disease risk factor prevalence, treatment, and control. Although we studied a highly insured population—less than 5% of FHS participants were uninsured compared with more than 15% in the general population[1]—multiple noteworthy differences were identified. More research is needed to determine whether the associations we observed are replicated in different samples with a greater proportion of uninsured participants. Improved management of these common and modifiable risk factors may be one way to reduce disparities in health care for the uninsured.

Comparing a Self-Administered Measure of Empathy with Observed Behavior Among Medical Students

Daniel C. R. Chen, MD, MSc[1], M. Elaine Pahilan, MPH[2], and Jay D. Orlander, MD, MPH[1,3]

[1]Section of General Internal Medicine, Evans Department of Medicine, Boston University School of Medicine, Boston, MA, USA; [2]Office of Medical Education, Boston University School of Medicine, Boston, MA, USA; [3]Medical Service, VA Boston Healthcare System, Boston, MA, USA.

PURPOSE: Studies show that measures of physician and medical students' empathy decline with clinical training. Presently, there are limited data relating self-reported measures to observed behavior. This study explores a self-reported measure and observed empathy in medical students.

METHOD: Students in the Class of 2009, at a university-based medical school, were surveyed at the end of their 2nd and 3rd year. Students completed the Jefferson Scale of Physician Empathy-Student Version (JSPE-S), a self-administered scale, and were evaluated for demonstrated empathic behavior during Objective Structured Clinical Examinations (OSCEs).

RESULTS: 97.6% and 98.1% of eligible students participated in their 2nd and 3rd year, respectively. The overall correlation between the JSPE-S and OSCE empathy scores was 0.22, $p<0.0001$. Students had higher self-reported JSPE-S scores in their 2nd year compared to their 3rd year (118.63 vs. 116.08, $p<0.0001$), but had lower observed empathy scores (3.96 vs. 4.15, $p<0.0001$).

CONCLUSIONS: Empathy measured by a self-administered scale decreased, whereas observed empathy increased among medical students with more medical training.

KEY WORDS: empathy; JSPE; OSCE.

J Gen Intern Med 25(3):200–2
DOI: 10.1007/s11606-009-1193-4

Empathy in the physician-patient relationship is the physician's ability to recognize a patient's perspectives and experiences, and convey such an understanding back to the patient.[1,2] This understanding allows patients to feel respected and validated,[3] promotes patient and physician satisfaction, and may improve patient outcomes.[1,4–7] Empathy is one of the Association of American Medical Colleges' (AAMC) goals for the development and education of altruistic and compassionate physicians.[8]Studies of medical students and residents suggest that empathy decreases with increased medical training.[9–11] These studies used self-administered measures of empathy with an uncertain correlation with actual empathic behavior. One study by Hojat et al. showed a modest positive correlation between their self-administered measure of empathy at the beginning of the 3rd year of medical school and program directors' assessment of these students' empathy during the end of internship 3 years later.[12] While it is known that physician self-assessment does not compare favorably to observed measures of competence,[13] psychometrically sound scales are thought to do better if they are validated against observable behaviors.

This study explores the relationship between a self-administered measure of empathy, the *Jefferson Scale of Physician Empathy-Student Version* (JSPE-S), and observed empathy, as evaluated by standardized patients during end of year Objective Structured Clinical Examinations (OSCEs).

METHODS

Study Participants

All students in the Class of 2009 at Boston University School of Medicine (BUSM) were eligible to participate. The BUSM curriculum is a traditional 4-year medical school with 2 years of preclinical study, with limited patient contact in the form of weekly physician shadowing for 10 weeks and a weekly patient interviewing and examination course for 6 weeks, followed by 2 years of clinical clerkships and electives.

Study Design

Class of 2009 students in their 2nd and 3rd year of medical school were asked to participate in a voluntary online survey measuring "student attitudes toward medicine" during March-April 2007 and March-April 2008. The survey was administered during their end of year Objective Structured Clinical Examinations (OSCEs).

The *Jefferson Scale of Physician Empathy-Student Version* (JSPE-S), is a self-administered 20-item instrument measuring components of empathy among health professionals in patient-care situations.[2] Respondents indicate their level of agreement on a seven-point Likert scale. Scores range from 20 to 140, with higher values indicating a higher degree of empathy.

Participants also specified their gender, age, anticipated financial debt and likelihood of choosing various specialties.

Career specialty intentions were categorized into two groups, "People-oriented" specialties and "Technology-oriented" specialties.[11] Categorizations were based on categories determined in prior studies.[2,11]

Toward the end of the 2nd and 3rd year of medical school, students are required to take an Objective Structured Clinical Examinations (OSCEs) where they are assessed on clinical skills, including their doctor-patient interactions, by standardized patients. Second-year students complete three cases—two history taking and physical exam cases and one substance abuse case—while 3rd-year students complete six cases—specialty-oriented cases in Medicine, Pediatrics, Family Medicine, Psychiatry, Ob/Gyn, and Surgery (see online Appendix A for descriptions of student cases). Each student is rated on a five-point Likert scale for empathy for each case (see online Appendix B for descriptions of OSCE empathy question). All standardized patients were trained at the University of Massachusetts Medical School and were familiar with the examination material and empathy question, and many had several years experience in evaluating Boston University School of Medicine students.

Descriptive statistics and analyses of variance (ANOVA) were used to compare the JSPE-S scores among the different classes and categorized groups, while controlling for the effects of gender, age, anticipated financial indebtedness, and career preference. Post-hoc ANOVA pairwise comparisons were made using Tukey's HSD test. Correlations were made between JSPE-S and observed empathy scores. All computations were done with SAS statistical software version 9.1. This study was approved by the Boston University Medical Center Institutional Review Board.

RESULTS

The Class of 2009 had 167 students eligible in the 2nd year and 162 students eligible in the 3rd year to participate in the study; 97.6% and 98.1% of eligible students participated in their 2nd and 3rd years, respectively (Table 1).

The primary multivariate analysis of variance considered and adjusted for five factors: class, gender, anticipated financial debt, career preference, and age. The overall correlation between JSPE-S and OSCE observed empathy scores was 0.22 ($p<0.0001$).

Second-year students had higher JSPE-S scores compared to 3rd-year students (118.63 vs. 116.08, $p<0.0001$), but the average observed empathy score for 2nd-year students was lower than the observed empathy score for 3rd-year students (3.96 vs 4.15, $p<0.0001$) (Table 2).

Table 2. Results by OSCE[a]

	Second-year assessment (N=163)	Third-year assessment (N=159)	P-value
JSPE-S average[b]	118.63	116.08	<0.0001
OSCE empathy average per case[b]	3.96	4.15	<0.0001

[a]*Adjusted for gender, age, anticipated financial indebtedness, and career preference*
[b]*Possible JSPE-S scores range from 20 to 140*
[c]*Possible OSCE scores range from 1 to 5*

DISCUSSION

Self-administered tools are the most common method used to assess various educational interventions aimed at improving student empathy.[14–20] Nevertheless, the validity of such self-assessments is unknown.[13] Our study found a trend towards a decline in measured empathy with increased clinical training with a self-administered instrument, but an improvement in observed empathy among these more clinically experienced students. Our finding of empathy decline by the JSPE-S is similar to prior studies using this instrument to assess change from the pre-clinical and clinical years.[10,11] So why the discrepancy with simulated patient ratings?

We can suggest several explanations. The differences noted between the 2nd- and 3rd-year medical school classes on their self-assessment of empathy could be attributed to different training experiences and how these experiences shape student perception of illness, compassion, and empathy. The JSPE-S is designed to assess the empathy of health-care providers in patient-provider situations. In the first 2 years of medical school, students interact with patients mostly when shadowing practicing physicians and participating in clinical skills training courses. Third-year students continually interact with patients and may often share the experiences of patients and families coping with serious and sometimes fatal illness. Therefore, it is possible that with their limited clinical exposure 2nd-year students interpret the subjective anchors of JSPE-S questions differently from 3rd-year students who have a broader and more intense clinical experience. The student, in effect, has recalibrated his emotional understanding of illness through clinical experience and hence altered his score on paper without having impacted his nature.

An alternative explanation could be that student acculturation to critical illness and a true emotional recalibration within the student. Such a change could be protective in the professional development of a physician. Medical illness and patient suffering are real, intense, and frequently sad. It may be necessary for physicians to undergo a professional acculturation that is being captured by the self-assessment tool and

Table 1. Demographics and Characteristics of the Students in the Medical School Class of 2009

	Second year	Third year
Number of students eligible to participate	167	162
Number of completed surveys	163	159
Percentage of surveyed students who were female	54.0% (N=88)	56.6% (N=90)
Percentage of surveyed students preferring "people-oriented" specialties	51.0% (N=78)	58.3% (N=88)
Percentage of eligible students surveyed	97.6%	98.1%

that, to date, has been interpreted as a measured decline in empathy associated with early clinical training. Students in this case do become emotionally hardened and feel less empathy. The working hypothesis has been that clinical training lacks an element of humanity and that a "hidden curriculum" exposed by jaded, experienced practitioners undermines the idealism, humanism, and empathy young clinicians bring with them to clinical medicine.[11,14] This last argument has been the motivation for curricular innovations designed to enhance and support the maintenance of empathy. It would be difficult to discern the difference between these two hypotheses, but each would predict potentially lower scores on self-reported empathy as one traverses the early stages of clinical training.

So why did we observe more empathic behavior in more advanced students? The rating of empathy during an OSCE broadly includes verbal and non-verbal communication, as well as physical behavior, but cannot assess the internal emotion or motivation of the student. Third-year students had more opportunities to practice, observe, and get feedback on their empathic behaviors, independent of their internal emotional connection. From the perspective of clinical proficiency, one would anticipate that more experienced students would better demonstrate clinical behaviors, including empathic behaviors.

Thus, the apparent independence of the self-assessment measure and observer ratings suggests that the use of the JSPE as self-assessment tool may not sufficiently predict empathic behavior. Further confirmation of our findings is needed as this has implications for curriculum evaluation since a self-administered tool is easier and cheaper to use. These findings raise more challenging questions for educators: What are the important aspects of physician empathy to measure? Is assessment of empathic behavior adequate even if internal emotions are discrepant? Is the correct attitude acceptable if we cannot relate it to competent behavior?

There are several limitations of our study. The small number of OSCE cases, especially in the 2nd year, raises issues of score reliability and, though OSCE score differences were present, it is unclear how clinically significant a 0.2 point difference is at the physician-patient level. Since we had only a single empathy question for each case, we are unable to determine which observable behaviors were driving the rating. Our study is limited to one medical school, but we feel that our results are applicable to all schools with a similar traditional structure. Future studies should examine the subtleties of the physician-patient interaction by discriminating those elements that comprise empathic behavior, such as tone of voice, empathic language, and non-verbal communication.

The patients' need for an empathic physician will always be essential. Efforts to improve the empathic behaviors of trainees are important. More work is required so that curricular enhancements designed achieve these goals can be properly evaluated.

Hierarchy as a Barrier to Advancement for Women in Academic Medicine

Peter Conrad, Ph.D.,[1] Phyllis Carr, M.D.,[2] Sharon Knight, Ph.D., R.N.,[3] Megan R. Renfrew, M.A.,[4] Mary B. Dunn, Ph.D.,[5] and Linda Pololi, MBBS, MRCP[6]

Abstract

Background: Research on barriers to professional advancement for women in academic medicine has not adequately considered the role of environmental factors and how the structure of organizations affects professional advancement and work experiences. This article examines the impact of the hierarchy, including both the organization's hierarchical structure and professionals' perceptions of this structure, in medical school organization on faculty members' experience and advancement in academic medicine.
Methods: As part of an inductive qualitative study of faculty in five disparate U.S. medical schools, we interviewed 96 medical faculty at different career stages and in diverse specialties, using in-depth semistructured interviews, about their perceptions about and experiences in academic medicine. Data were coded and analysis was conducted in the grounded theory tradition.
Results: Our respondents saw the hierarchy of chairs, based on the indeterminate tenure of department chairs, as a central characteristic of the structure of academic medicine. Many faculty saw this hierarchy as affecting inclusion, reducing transparency in decision making, and impeding advancement. Indeterminate chair terms lessen turnover and may create a bottleneck for advancement. Both men and women faculty perceived this hierarchy, but women saw it as more consequential.
Conclusions: The hierarchical structure of academic medicine has a significant impact on faculty work experiences, including advancement, especially for women. We suggest that medical schools consider alternative models of leadership and managerial styles, including fixed terms for chairs with a greater emphasis on inclusion. This is a structural reform that could increase opportunities for advancement especially for women in academic medicine.

Introduction

The advancement of women in academic medicine has lagged relative to their increased presence in medicine. The percentage of women in medical school has increased steadily over the past 30 years,[1] with the result that women constitute approximately half of medical school graduates,[2] yet the gender distribution of faculty in leadership positions in academic medicine remains primarily unchanged. For example, in terms of academic rank distribution by gender, among clinical scientists, 29% of male faculty compared with 14% of female faculty achieve full professorship positions[3] (only 17% of full professorships are held by women).[4] Women are somewhat more represented at associate professor (15% men vs. 6% women) and assistant professor levels (24% men vs. 17% women).[5] This was virtually unchanged from 2003 to 2008. In 2007, the average department chair's per medical schools were 21 male to 3 female chairs, a 7-fold difference.[6] As of 2008, 14 women were deans or interim deans (11%) of the current 129 medical schools[7]; interim deans are not guaranteed to assume deanship.

In addition to inequalities in rank and leadership, women are also paid less than men at the same rank[8–10] and move through the ranks of leadership more slowly when they do

advance.[9,11–13] According to a recent study, women earned 11% less than men, after adjusting for rank, track, degree, specialty, years in rank, and administrative positions.[14] Several studies have shown that some women in academic medicine also report experiencing gender-based discrimination.[14–16] Gender-based inequalities in pay and difficulties in professional advancement are found in other professions as well.[17,18]

Sociologists have made major progress establishing that race and gender matter at work; however, there has been less success in explaining why workers' sex and race affect their employment outcomes.[19] Much research on women's advancement (or lack of it) in professions has focused on cultural and gendered values. Other studies have examined how the structure of the organization relates to professional advancement and work experiences. One area of organizational interest is the impact of hierarchy on advancement. Kanter, in "The Impact of Hierarchical Structures on the Work Behavior of Women and Men," emphasized the importance of understanding how structures of power and hierarchical arrangements relate to inequity in the workplace.[20] Kanter's study shifts perceived differences in men's and women's work orientations from individual-level factors connected with the culture and socialization of women (family and work roles) to the role of organizational structures (e.g., organization hierarchy) in shaping apparent sex differences in the workplace (e.g., low aspirations as a result of opportunity structure).

Sex composition is one aspect of social structure that can affect social inequality.[21–24] Kanter's theory of tokenism suggests that the relative number of women and underrepresented minorities (URMs) can affect employment outcomes.[21,22] The proportion of women in leadership positions can have an effect on women's hiring and promotion when they are present in large enough numbers to form coalitions and affect personnel decisions.[25] Institutional practices, such as leadership terms and policies for transparency in decision making, can also affect social inequality in the workplace. Policies that limit the effects of decision makers' biases on employment outcomes can limit discrimination based on gender and race. The potential for bias is greatest when decision makers have full discretion over their selections.[19,26,27] Because institutional practices can have serious consequences for hiring and promoting women and URMs, they necessitate further study.

The importance of hierarchy and institutional practices in understanding gender-based work inequalities in medicine is underexplored,[20] with a focus on coping strategies[16] and the impact of gender-based unconscious biases on women's advancement into leadership positions.[28] Few articles have specifically examined how the hierarchy of medicine and specific institutional practices impact women's professional advancement and work experiences.[16,28]

As part of a larger interview study on women and advancement in academic medicine, we have discovered several cultural factors that appear to affect potentials for women faculty advancement.[29,30] This article aims to fill a gap in existing literature on barriers to advancement of women in academic medicine by linking discussions of inequality to the institutional structural barriers. Specifically, we explore the perceived impact of one structural factor, hierarchy in medical school organization, on women faculty's experience and advancement in academic medicine.

Materials and Methods

The data were collected as part of a study on the advancement of women and URM faculty in academic medicine, C-Change (The National Initiative on Gender, Culture and Leadership in Medicine). Five medical schools were selected representing diverse characteristics of U.S. medical schools. The schools were drawn from different regions, including two public and three private schools. The demographics of women and URM faculty were nearly identical to national statistics. The study was IRB approved.

Participant criteria

Stratified purposeful and chain referral strategies were used to identify and select medical faculty from the five C-Change medical schools according to school, gender, race/ethnicity, department/discipline, and career stage. The principal investigator (L.P.) obtained a confidential list of faculty from each school and selected participants based on these criteria to produce a stratified sample based on demographics, positions, and career stages. Participants included medical and surgical subspecialist, generalist, and research scientist faculty, with 84% having an M.D. terminal degree and 16% a Ph.D. A total of 96 faculty were interviewed, divided into four career stages: (1) early career (2–5 years as faculty), (2) plateaued (those who had not advanced as expected in rank and responsibility and had been faculty members for $\geq$10 years, (3) leadership (senior) faculty, including deans, department chairs, and center directors, and (4) left (former faculty who had left academic medicine). Interviewees were divided almost equally among the four groups and the five schools, but we interviewed fewer participants in the early career stage because we reached data saturation in this category early in the study.

Sample selection

A total of 175 faculty were invited to participate, 8 refused primarily because of time constraints, 54 never responded, and 12 others responded but were unable to be scheduled. Male plateau faculty were more difficult to identify than similar stage female faculty. Women (55%) and URM faculty were oversampled (17% African American, 4% Hispanic/Latino, and 79% Caucasian/white), as were generalist physicians (20%). Details on the breakdowns of gender, race, and stage of sample are available elsewhere.[29]

Data collection and analysis

Four of the authors (P.C., P.C., L.P., S.K.) conducted in-depth, open-ended interviews with the selected respondents. All were experienced interviewers and used the same research protocol when interviewing respondents; 15% of the interviews were conducted in person, the rest by telephone. Interviews, typically 1 hour in length, were audiorecorded and transcribed verbatim. Interviewers used an interview guide with 20 open-ended questions and dozens of probes to supplement the major questions, including items related to choice of medicine as a career, faculty aspirations, energizing aspects of their careers, advancement and advancement barriers, collaboration, leadership, power, values alignment, and work-family integration. The interview guide included no specific questions on hierarchy, but respondents discussed

hierarchy-related issues when answering questions about belonging, frustrations, decision making, power and leadership, and aspirations. Hierarchy-related issues emerged as a major concern through the coding process of the data.

The data were coded, and all names and identifying information were removed. Multiple coders compared, verified, and refined coding categories. Data were analyzed by repeated readings of interview transcripts with an analytic focus on understanding and interpreting meaning. Over 4000 pages of transcribed narrative were stored, coded, and sorted using Atlas.ti software. Analysis involved data condensation to identify patterns and themes emergent from the coded data. The analysis was inductive and data driven, in line with the grounded theory tradition.[31,32] To verify data patterns and conclusions, we continuously reviewed transcripts and discussed findings among co-authors to achieve consensus. In this article, participants are identified by gender, degree, and faculty category.

Results

The hierarchal organization of the medical school emerged as an issue of concern in our interviews. Many of our respondents view the medical school as a hierarchical institution that strongly impacts their experience in academic medicine. Sometimes, the faculty members we interviewed felt they were treated more like underling employees than professionals or colleagues. Many thought they were informed about decisions that affected their work lives rather than being active participants in the decision-making process; they did not believe they had adequate input in some decisions that were directly consequential to their work. Respondents often noted that the medical school was a very bureaucratic organization and apparently becoming more so. Sometimes, the hierarchy and organization seemed convoluted when faculty had to wend their way to get some information or a decision. These bureaucratic layers can lead to frustration, resentment, or even apathy. As an early career female Ph.D. faculty noted, "It's such a heavily tiered administrative monster, the medical school tiers." A male former academic physician described the hierarchy well:

> Well, the leadership—it's a very small academic department—there's a hierarchy of a chairman of the department, supervising division chiefs, and to become a division chief, seniority is very important, but also the amount of grant money you bring to the institution. It's almost ironic because frequently I see the people who are the best researchers are often named division chiefs, and these are not always the people who have the best managerial skills, but they have brought in the most research dollars to the academic institution, and it's unfortunate that frequently they have to give up some of their research in order to take on the administrative duties of division chief.

Length of tenure of chairs

One issue that came up often was the power and extended length of service of the chairs. To respondents, department chairs seemed to be appointed for indefinite terms and serve at the dean's pleasure or until they chose to step down (or up). As one male faculty noted:

> You are chair for life. I mean, you don't serve at the pleasure of the clock; you serve at the pleasure of the dean. And if it pleasures him for you to remain as chair for the remainder of your mortal days, you will remain as chair for the remainder of your mortal days. . . . I could resign. [male, Ph.D., leader]

The extended duration of chair appointments seems to be a real issue in the accumulation of power and authority in the hierarchy. One plauteaued female physician faculty noted that her department had had only three chairs since it was founded in the 1960s! Another pointed out that "removing a chair is a rare thing." [male, Ph.D., leader]

Styles of chairs

Numerous faculty said that virtually all important decisions are made by the department chair. Faculty often feel excluded at this level of decision making, even about decisions that affect their work lives (e.g., when and where to move offices, strictures related to changes in clinical responsibilities). Although there does seem to be more participation in decision making at the local or division level, the department seems very hierarchical and even more so at the upper administrative level. For example, a male physician stated, ". . . it's very hierarchical [so] those at the lower levels have minimum input I think by and large. Certainly not into major strategic decisions at a departmental level. It's all held at a very high level. . . ." [male, physician, leader].

Chairs varied greatly in their style of inclusiveness. Some chairs are rather authoritarian, even dictatorial, in their style of running a department, allowing no opposing viewpoints. One plateaued female physician said: ". . . we work in a department where if my department chair got word of what I was saying to you, it would threaten my position." At least one person (male, Ph.D. left) called this "a feudal system where the lords reign." The chair seems to set the tone for leadership in the organization, and his or her particular management style affects the experience of being in the department. For example, one physician described how different managerial styles set the tone of expected interactions and decision-making processes: "One is I'm the boss, talk to me; the other is I'm the boss, don't hesitate to talk to somebody who's keeping me from ever having to talk to you" (male, M.D., leader). Some chairs do adopt a more collegial, or at least inclusive, style of management. The "I'm the boss, talk to me" does not necessarily mean that decisions are made democratically (male, physician, leader) but sets more of a collaborative tone that is appreciated by department members. So participation often results from the individual style of the chair.

There are consequences to the hierarchy. Some faculty members thought that upper administration "doesn't have a clue" of what is happening in their division. As a female physician noted:

> I think the upper administration does not appear to be aware of the problems we have, which I think is very strange because I think at one point they had to be where we are now. . . . It's like parents don't get teenagers anymore and they were once teenagers [female, physician, early career]

How people move in and out of leadership positions (including advancement and tenure) is often described as a mystery, something "done behind closed doors" (male, Ph.D., left) or in a "black box" (male, physician, leader).

Some faculty see the pitfalls of the hierarchy and believe a more collegial organization might be more productive. As one woman (female, former faculty, Ph.D.) noted:

> So if [the organization] were actually function driven . . . or if our purpose is to produce really excellent physicians and an inspired group of people who want to do research and biomedicine, what kind of structure would that . . . it would look a whole lot different . . . a whole lot less hierarchical, a whole lot more collaborative and it would be a little more welcoming to women and minorities.

In sum, hierarchy, length of chairship, styles of leadership, and probably communication all affect leadership in medical schools in complex but not incomprehensible ways.

Hierarchy and transparency

One of the major consequences of the hierarchal structure is its impact on decision making. For numerous decisions, faculty experienced a lack of transparency. Inclusion varied by the level of decision making. Overall, faculty feel more involved in decisions on a local level (e.g., the clinic or the division) or in the decision-making process closer to their own work. The amount of involvement in decision making was almost a continuum, from medical school to department to division to clinical or teaching situation, and as several respondents noted (e.g., male, physician, plauteaued), inclusion and usually transparency depended on what kinds of decisions were being made. Numerous respondents recognized that many institutional decisions were complex and difficult to judge "because you're not privy to the information" (male, physician, left). Although the same individual noted, as he moved up in the organization, that "it's unbelievable what's available to me, which I was never privy to . . ." This is mediated in part, however, by the style of the chair, chief, or director. If the chair is one who includes people's views and opinions in decisions, faculty are more likely to believe they are part of the decision-making process. If the chair is authoritarian or chooses only a small group to consult, others will feel excluded. For example: "[Decisions are made] behind the scenes. A few key people deciding how to make something happen . . ." (male, physician, leader) or "decisions were made by a group of privileged individuals behind closed doors" (female, physician, plauteaued). A well-placed male physician in a leadership role commented how his chair set the tone: "There's not a lot of democratic decision making going on in my department." On the other hand, sometimes a new chair can bring in a new style, as an early career female Ph.D. noted about the consensus oriented style of the current chair. Similarly, a former faculty male Ph.D. described how transparency has gotten better with the current head. He noted, "If the head happens to be a good communicator and if the head chooses to seek input, you can feel a little like you've got some say in the matter. Otherwise, it's essentially decisions are made behind closed doors and you're informed." A plauteaued female physician pointed out how a change in chair and style transformed a close-knit department to a place where decisions are no longer shared and are made behind closed doors. It felt to her like a "loss of family," but as a former faculty male Ph.D., commented, sometimes these decisions turn out well and are actually benevolent. People still didn't see the process as adequately transparent, however.

Lack of inclusion and transparency occurred on higher levels as well. For the most part, people did not feel much involved about decisions on the university level. A female faculty recalled:

> It used to be that . . . decisions were not talked about openly and that decisions were made by some group of privileged individuals behind closed doors . . . and you always got the feeling that you were getting [only] part of the story. [female, physician, plauteaued]

Another male leader physician noted that the chancellor ran an "efficient, crisp, and clean and military-like organization, but the faculty felt excluded." Another respondent observed, "In our faculty meetings, it's not a discussion about (an issue) . . . It's usually a reporting out about decisions that have already been made" (female, physician, plauteaued).

Sometimes respondents thought that a small group was making the decisions. Despite feeling involved on the local (division) level, more than one faculty expressed not feeling involved in the department because it was "a very authoritarianly run department" (female, physician, plauteaued). Another woman mentioned that at the institutional level, decisions often felt arbitrary, but she still felt part of the decision making "at the level of the clinic, not at the level of finances. . . ." (female, physician, early career). As an early woman faculty member stated, "There are too many things that are unspoken. There are too many things that are not transparent."

It seems that people are most resentful when decisions are made without them that affect their lifestyle (e.g., call schedule, patient responsibilities) or immediate work environment. This is likely significant because people believe it is important to maintain some measure of autonomy and control in their everyday work. As a female early career physician described, "I don't have any authority about some other things, like, right now we're in a position where we need to hire." This is clearly a major issue for some people. One faculty noted that all the medical director positions were eliminated without any consultation, and this led to a problem about who would pick up the medical directors' salaries. She said, "I felt betrayed" (female, physician, plauteaued). Another faculty noted that after a doctoral program was eliminated, the school just said, "Fine, we won't replace you, we'll just give those students to [name]" (female, PhD, leadership). She felt they dumped the students on her, knowing she was the kind of person who would not let the students flounder.

As faculty move up the ranks in the hierarchy (and a few do), there is some sense they are more involved in decision making. As one woman pointed out, "In my administrative position now, I feel that I am actually consulted more. . . ." (female, Ph.D., leader). A female administrator noted, "Because I'm department chairman, I'm part of the council of clinical chiefs . . . so I feel that my voice is heard" (female, physician, leader). A male faulty member reflected that as he moved up the ranks, he felt more included, to the point where he now felt the decision making was "collaborative and inclusive" (male, physician, leader).

Hierarchy and gender

Both men and women generally described hierarchy, especially the structure of chairs, as a strong feature of academic medicine, but men seemed to be more tolerant of the structure (e.g., "it's just a different management style") and seemed less bothered by it than women. Men typically described the hierarchy in a very matter-of-fact fashion. For example, a male faculty member described the structure of academic medicine

and the lack of democratic decision making but did not suggest it negatively impacts him:

> It's very hierarchical and those at the lower levels have minimal input, I think, by and large. Certainly not into major strategic decisions at a department level. It's all held at a very high level, really, and partially, that reflects the way the chairman operates, and he doesn't really broker a lot of discussion about decisions. There's not a lot of democratic decision making going on in my department. [male, physician, leader]

However, another male physician, despite his leadership status, described feeling "excluded" yet noted some ironic benefits of being able to work around this challenge: "The bad news is that I feel excluded. The good news is he doesn't speak to me so he doesn't tell me what to do. So I go about my business in my area of responsibility for the most part" (male, physician, leader).

When male faculty talked about hierarchy and top down decisions, they talked more about poor communications with underlings as a problem. As one man observed: "I think you have a few people who are administrators . . . and I think one of the most simple things they forget is just communication, good communication with people who really do the work and pay the bills. . . ." (male, physician, early career).

Women, on the other hand, perceived the hierarchical structure to be more burdensome. Female faculty described very specific and detailed accounts of how system-level hierarchical processes (e.g., appointment processes) and gendered-cultural values negatively impacted their career progress and advancement. For example, one female faculty member commented on how she believed a normal search process was altered to specifically detour her from being appointed.

> Historically, what happened at the institution is that there's a division that needs a director. If there are senior productive people . . . it is suggested that they apply. . . . When it was time for the director to step down they said . . . we're not appointing anybody, we're going to conduct a national search, which of course they had never done before . . . it had been unprecedented. . . . I think it was people being a bit uncomfortable with me being appointed division director.

Several women presented stories about how they felt marginalized and not taken seriously (with some exceptions, of course). For example, female faculty reported feeling as if they were treated like teenagers (female, physician, early career) or singled out as "disruptive" to the department when they spoke up (female, physician, left). Women, unlike men, discussed whether or not their voice was heard within the medical department. They state several reasons for this, including feeling inexperienced, self-doubt about knowledge of issues at hand, and perceived ramifications for speaking up. One female medical scientist (female, Ph.D., early career) spoke for a number when she said, "Many times I don't know how to make a contribution because I'm quite certain I don't know enough about the issue at hand." Another woman (female, physician, plauteaued) said, it was "too stressful and risky for her to participate" in department decisions, so she talked with the chair individually. This same woman believed her job might be threatened if she spoke up:

> The hardest thing . . . was to be in a department where you couldn't express yourself without getting—feeling that you were jeopardizing your career, and so my personal values . . . I was afraid earlier on that I would. . . . lose my . . . I would get kicked out of the department. . . . [female, physician, plauteaued]

One woman summarized this well, explaining how women have been socialized to think they need to be at a certain level of experience or meet certain qualifications, whereas men do not question their own level of knowledge or experience. "More likely [women] feel they need to be qualified to do something, where, men, in many ways, don't feel that need. . . . they assume they are qualified" (female, physician, plauteaued).

According to some female faculty, in order to be in a position of power and leadership in this authoritarian-style structure, one must dehumanize (female, physician, left) and "out-macho the guys" (female, Ph.D., left). In response, at one school, a group of women faculty met to give each other support. ". . . there is even a secret group of women faculty who met over a year or two to give support and to talk about what was going on, and [a] lot of paranoia that if somebody found out; namely, the chair . . . they'd be the next target. . . ." (female, physician, left).

Discussion

It seems clear that the hierarchy of chairs is a common and well-established structure in medical schools, and it has a significant impact on the faculty work experience and their perception of transparency. Although our research is based entirely on interviews, we heard nearly no comments negating our depiction of the hierarchy of chairs and what were perceived as "chairs for life." There are surely some excellent department chairs who run departments with inclusive and transparent decision making, but this seems largely based on the chair's personal orientation and leadership style. It is more difficult to control for individual chair style variations than it is to focus on a system that allows for little self-regulation. There is greater opportunity for biases and, thus, discrimination to play a role in decision making when there is little transparency.[19,27]

It is obvious that medical schools as bureaucratic organizations need some kind of hierarchy to operate. In such large organizations as academic medical centers, it is not surprising that many faculty feel remote from the upper levels of administration, but it is of much more concern that so many faculty see difficulties with the department chairpersons' managerial styles. The perceived problem with upper administration is that it is "out of touch" with what goes on in the academic trenches, making decisions without adequate transparency, and supporting the power of chairs.

We found that both men and women recognized the hierarchy, but it seemed to have a greater impact on women, creating what may be a real barrier to women's advancement in academic medicine within the hierarchy. Bickel et al. stated that "most women are accustomed to thinking of relationships in terms of support affiliation, whereas men are accustomed to competition and hierarchy."[33] To the extent this is true, this may provide insight into why men discuss the hierarchy in a matter-of-fact tone and experience this as less of an obstacle to advancement. Although we have no direct evidence to connect the hierarchy to women's advancement (that would take a different kind of study), there is little question that women faculty see the hierarchy of chairs with

its open-ended term policy and the reliance on individual chairs' personal orientation for inclusion as both affecting their work lives and their chances for advancement. It may also be that women do not see others like themselves at the top of the hierarchy, which may make it more threatening. Many women see this as "where the lords reign." Although it is not clear how much of the problem with hierarchy is the structure and how much is the incumbent, the indeterminate length of chair appointments creates a calcified structure that is difficult to change (or avoid). As W.I. Thomas' famous sociological dictum states, "Anything that is perceived as real is real in all of its consequences."[34] Here, the insight translates to if women perceive the hierarchy of chairs as a barrier to advancement, it becomes a barrier.

The hierarchy of chairs and the attendant perceived indeterminate term chair policy are not inevitable aspects of academic structure. Some medical schools have performance reviews for chairs, but these do not necessarily affect the length of time a chair serves. University Arts and Science departments typically have a rotating chair, where the chair is appointed or elected to a fixed term (often 3–5 years). In such a system, a chair can be reappointed or reelected, and every few years there is a review to see if this person should or desires to continue as chair. Adopting such a system would go a long way toward reduce the impact of the hierarchy of chairs and make for a more collegial structure. It would also create more openings where women, URM, and younger faculty could advance in academic medicine. Such a policy change could contribute to advancement for women (and by extension, URM and younger faculty) in several ways: (1) women currently perceive hierarchy as a barrier, (2) there are aspects of hierarchy that actually affect women (and men) in ways that are detrimental to their advancement, and (3) the indeterminate length of a chair's tenure allows for less turnover of the chair and, thus, fewer openings.

Most women faculty and many men faculty clearly would prefer a less hierarchical and more collegially oriented organizational structure. The structured hierarchy affects both inclusion and the perception of transparency in decision making. This aligns with our findings that women seek more collaborative work relationships in academic medicine.[30] A flatter, less hierarchical, and more collaborative structure is preferred by most faculty members.

The structured hierarchy, limited inclusion, and lack of decision-making transparency are not the only factors affecting women's advancement in academic medicine. A study by Carr et al.[16] further supports this by showing that female faculty who have experienced gender discrimination in a hierarchical structure report feeling a sense of helplessness to affect change, suggesting that the structure of hierarchy can affect psychosocial feelings and behaviors. Others have found that the hierarchical structure also impeded effective negotiations.[35] A recent survey study in one medical school shows that the top reasons women leave faculty positions include chair/departmental leadership issues, professional advancement, low salary, and personal reasons.[13] The most common reasons men leave include career and professional advancement, low salary, and lack of faculty development/mentoring. Although men and women share some similarities in terms of professional advancement and salary, women in particular express difficulties with chair/departmental issues, which is also reflected in the findings from our study. The current hierarchical structure developed when medicine was populated overwhelmingly by men. The gender composition of medicine and medical schools has changed enormously in the past three decades, and it may be time to reconsider whether some of this structure is optimally functional for the current needs of academic medicine.

This study has limitations. Although we attempted to select representative medical schools, the sample is from only five schools. Moreover, although we endeavored to interview a stratified but widely representative group of faculty, we only interviewed 96 people out of the thousands of academic faculty in the five schools. As noted, we had difficulty locating plateaued men to interview. Finally, hierarchy is only one factor limiting the advancement of women and URMs in academic medicine. How much this factor impacts advancement compared with other factors is still unknown.

Conclusions

Based on interviews with 96 faculty members at five disparate medical schools, we have identified the hierarchy of chairs as a potential barrier for the advancement of women in academic medicine. The fact that chairs are appointed for what appears to be indeterminate tenure creates a number of obstacles for advancement, especially given the calcified academic structure, including problems with inclusion and transparency in decision making and, given the infrequent turnover in chairs, a bottleneck for advancement. Women faculty seem more affected by this hierarchical structure than men, and addressing this may help the advancement of women in academic medicine.

Acknowledgments

We gratefully acknowledge the critical funding support of the Josiah Macy, Jr. Foundation and the supplemental funds to support data analysis provided by Office of Public Health and Science, Office on Women's Health, and Office on Minority Health; National Institutes of Health, Office on Research on Women's Health; Agency for Healthcare Research and Quality; Centers of Disease Control and Prevention; and Health Resources and Services Administration.

Thanks as well to Marianne McPherson and Meg Lovejoy for assistance with data coding and to the reviewers for their helpful comments. We are indebted to the medical faculty who generously shared their experiences in the interviews.

CLINICAL TRIALS *RECRUITMENT AND RETENTION* *Clinical Trials* 2010; **7**: 90–99

Impact of supplemental site grants to increase African American accrual for the Selenium and Vitamin E Cancer Prevention Trial

Elise D Cook[a], Kathryn B Arnold[b], John A Hermos[c], Worta McCaskill-Stevens[d], Sarah Moody-Thomas[e], Jeffrey L Probstfield[f], Sandra J Hamilton[g], Russell D Campbell[h], Karen B Anderson[i] and Lori M Minasian[d]

Background African American accrual to prevention trials at rates representative of the disease burden experienced by this population requires additional resources and focused efforts.

Purpose To describe the rationale, context, and criteria for selection of sites that received Minority Recruitment Enhancement Grants (MREGs) to increase African American recruitment to the Selenium and Vitamin E Cancer Prevention Trial (SELECT). To determine if African American accrual was higher among the 15 MREG sites when compared with similar nonawarded sites.

Methods Changes in African American accrual at sites that received MREGs are compared with changes in a group of 15, frequency-matched, nonawarded sites using a quasi-experimental, *post hoc* analysis. Successful and unsuccessful recruitment strategies reported by the MREG sites are described.

Results The increased number of African American participants accrued per month at MREG sites post-funding was higher than the change at comparison sites by a factor of 3.38 ($p = 0.004$, 95% CI: 1.51–7.57). An estimated 602 additional African American participants were recruited at MREG sites due to MREG funding, contributing to the overall 14.9% African American recruitment. Successful recruitment strategies most reported by MREG sites included increasing staff, transportation resources, recruiting through the media, mailings, and prostate cancer screening clinics during off-hours.

Limitations Comparison sites were chosen retrospectively, not by randomization. Although comparison sites were selected to be similar to MREG sites with regard to potential confounding factors, it is possible that unknown factors could have biased results. Cost-effective analyses were not conducted.

Conclusions MREG sites increased African American accrual in the post-funding period more than comparison sites, indicating MREG funding enhanced the sites' abilities to accrue African American participants. Targeted grants early in the accrual period may be a useful multi-site intervention to increase African American accrual for a prevention study where adequate African American representation is essential. *Clinical Trials* 2010; **7**: 90–99. http://ctj.sagepub.com

Introduction and background

Prostate cancer is a major health problem, second only to nonmelanoma skin cancer as the most common cancer in men in the United States. Furthermore, the rate of prostate cancer is higher and the mean age-of-onset is younger in African Americans than in non-African Americans [1–3]. Prostate cancer prevention trials (PCPTs) provide an important opportunity to test interventions that might reduce the burden of the disease [4]. However, unambiguous application of the results of such trials to African Americans depends upon adequate participation by African American men.

The PCPT was the first large, cooperative group randomized trial for the prevention of prostate cancer in healthy men [5]. The randomized participant goal for African American men was set at 8% to mirror the estimate of African American men aged $\geq$55 years in the US population. Only 4% African American men were randomized to PCPT during the 3-year enrollment period. Efforts to enhance minority participation in PCPT were not initiated until 1 year after the study was activated. In addition, about two-thirds of the overall accrual goal was met in the first year of recruitment, so any enhanced African American enrollment after that time could have had only a modest overall effect.

The PCPT minority recruitment experience suggested that successful recruitment of African American men into a PCPT requires recruitment efforts to be initiated at trial activation, infrastructure provided to support minority recruitment and a long-term commitment from funding agencies [6–8]. Known barriers commonly cited to impede minority recruitment must also be addressed, such as the attitudes, knowledge, and beliefs of potential minority recruits and their referring clinicians, as well as trial designs and costs [9–17].

Minority recruitment lessons learned from PCPT were applied to Selenium and Vitamin E Cancer Prevention Trial (SELECT), the next large, cooperative group prostate cancer prevention study. SELECT was designed to evaluate the effect of selenium and vitamin E on the incidence of prostate cancer without changing the clinician's practice of prostate cancer screening. The SELECT overall randomization goal was 32,400 healthy men, with 6480 men enrolled every year for 5 years. The study had a pre-established goal of 24% overall minority representation: 20% African American, 3% Hispanic, and 1% Asian/Pacific Islander [18].

Prior to trial initiation, SELECT took several steps to enhance recruitment of African American and other racial/ethnic minorities. First, the eligibility criteria were expanded. Second, sites with prior success in minority recruitment were sought, and the Department of Veteran Affairs Cooperative Studies Program was included as a SELECT affiliate because of its strong track record in minority recruitment [19]. Third, SELECT developed a national infrastructure to support minority recruitment. Fourth, SELECT provided additional funds in the form of Minority Recruitment Enhancement Grants (MREGs) to sites with the potential to increase minority enrollment [20].

Five months after study activation, SELECT was enrolling participants at nearly twice the planned rate. Although Hispanic and Asian/Pacific Islander recruitment met or exceeded the targeted enrollment rates, while African American recruitment was much lower than anticipated, it appeared that the overall enrollment goal would be achieved in less than the planned 5 years. SELECT investigators had to respond quickly to boost African American participation. Due to the projected shortened recruitment period, a targeted yet flexible intervention was needed to increase African American participation.

Two MREG requests for applications were distributed during the accrual period. The MREG was a $50,000 site grant, provided by the National Cancer Institute and designed to increase minority enrollment by enhancing recruitment strategies at sites with the potential to increase minority recruitment. An additional purpose of the MREG was to document the success of recruitment strategies used by sites for the benefit of future studies. While all SELECT sites could apply for an MREG, applicant sites were required to demonstrate the ability to recruit minorities and/or provide evidence of access to large numbers of minority men. The MREG requests for applications focused on all minority recruitment, but applications were scored higher if African Americans were the targeted population. Sites were notified of awards within 1–3 months following receipt of their application.

The National Cancer Institute provided funding to SELECT for 11 MREGs that were awarded in mid-2002. Only 32 sites out of all 427 SELECT sites applied, fewer than, had been anticipated. At the time of this initial funding, total recruitment was 10,500 and African American participation was at 9.8%. One year later, when overall SELECT enrollment reached 20,000 and African American participation was 12.4%, the National Cancer Institute allocated additional funding to issue another request for applications. As a result of this second round of competition in mid-2003, seven existing MREG sites and four new sites were awarded MREGs. In summary, 15 SELECT sites received a combined $1.1 million in grants over 2 years to increase African American and other minority participation (Table 1).

Table 1 Summary of MREG awards to SELECT sites

	Funding dates		
Site #	1st MREG	2nd MREG	Total funds
1[a]	July 2002	July 2003	$100,000
2[a]	July 2002	July 2003	$100,000
3	July 2002	July 2003	$100,000
4	July 2002	July 2003	$100,000
5	July 2002	July 2003	$100,000
6	July 2002		$50,000
7[b]	July 2002		$50,000
8	July 2002		$50,000
9	August 2002	August 2003	$100,000
10	September 2002	September 2003	$100,000
11[a]	October 2002		$50,000
12		April 2003	$50,000
13		April 2003	$50,000
14		August 2003	$50,000
15[a]		August 2003	$50,000

[a]Site had a large percentage of African American recruits pre-funding. MREG was awarded to maintain already high African American recruitment. [b]Very large site with access to large numbers of Hispanic and African American recruits. MREG was awarded to enhance both African American and Hispanic recruits.

Recruitment for SELECT ended in June 2004, 9 months after the last site received notification of a 2003 MREG award. SELECT accrued 35,533 participants, of whom 14.9% were African American. Although African American enrollment was less than the 20% goal, it was three times that seen in PCPT and the largest percentage of African Americans ever accrued to a cancer prevention trial.

This article describes the rationale, context, and criteria for the selection of sites that received additional funding to enhance African American accrual in the SELECT, a prostate cancer prevention study. The changes in African American recruitment at these sites compared with similar, nonawarded sites were evaluated in a quasi-experimental, *post hoc* analysis. Descriptions of how sites used these funds and what benefits and limitations these sites reported are also presented.

Methods

Quantitative study design

To determine whether MREG funding impacted African American enrollment in SELECT, the change in African American accrual rates before and after sites received funding was evaluated by comparing MREG sites with similar non-MREG sites in a *post hoc* analysis. In this quasi-experimental study design, the intervention (MREG) was not randomly assigned. The number and percentage of African American participants accrued before and after MREG sites received funding was measured. Comparisons are presented as the change in accrual rates and odds ratios for African American versus non-African American recruitment. For the purposes of this analysis, a participant's race was determined by self-report at randomization and was recorded for SELECT in compliance with current National Cancer Institute standards. If a participant self-reported as African American, regardless of other race affiliations or ethnicity, he was considered African American.

MREG sites were frequency matched to a set of non-MREG sites with similar early enrollment patterns to obtain a comparison group of sites with similar potential for African American accrual. The matching process involved consideration of two factors. The rate at which the sites were already randomizing African American participants to SELECT early in the enrollment period (prior to receipt of any MREG funds) was a strong potential confounder. Therefore, the primary matching factor was based on the percentage of African American participants accrued as of May 31, 2002, prior to receipt of MREG funding at any site. The total number of recruits prior to May 31, 2002, was the second factor in choosing comparison sites. An exception is Site 15, which started randomizing participants after May 31, 2002; total and percentage African American accrual as of June 30, 2003, was used instead. Each comparison site was assigned a hypothetical funding date based on the date the similar, matched, MREG site received an MREG award. This site-specific date separated the pre- and post-funding periods for purposes of

[a]Type of site. *Academic Center*: Facility is also involved in higher education and research. *CCOP, Community Clinical Oncology Program*: A large network that allows community physicians to participate in NCI-sponsored clinical cancer trials.*Cancer Program*: Facility that has a cancer program, may or may not be an academic center, not an NCI-designated Cancer Center or Comprehensive Cancer Center. *VACSP, Department of Veteran Affairs Cooperative Studies Program*: Department of Veterans Affairs provides health care to eligible veterans; VACSP coordinates large multisite research projects. *Community Health Center:* Facility that provides public health services. *MBCCOP, Minority-Based Community Clinical Oncology Program*: allows racial and ethnic minority cancer patients to have access to quality medical care in their own communities. [b]For example, sites had established relationships in the minority community. [c]For example, sites participated in national SELECT minority recruitment initiatives.

the analyses. A summary of MREG and comparison site characteristics is shown in Table 2.

As a whole, the MREG and comparison sites had similar characteristics. Each group included Academic Centers, VA Cooperative Study sites, Community Clinical Oncology Program sites, and Cancer Programs. There were no Community Health Centers among the comparison sites and no private practices among the MREG sites. Most sites in both groups had pre-existing foundations for accruing African Americans and had never used non-MREG SELECT resources to recruit African American participants to SELECT (Table 2).

Quantitative analysis

The outcomes of interest are (1) the accrual rate of African Americans, that is, the number of African Americans enrolled per month and (2) the probability that a randomized participant is African American. Although the event of interest (whether the participant randomized is African American) occurs at the participant level within each site, MREG is an intervention applied at the site level, giving rise to clustered data. Mixed effects regression models were used with the individual as the primary unit of analysis and site-specific random

[a]Similar MREG and comparison sites are shown on the same line. [b]Pre-funding is the site-specific period starting from the month of the first randomization at the site through the month prior to the initiation of MREG funding at that site, as shown in Table 1. The pre-funding period for each comparison site ends at the same time as the similar MREG site; comparison sites may have initiated accrual in different months than the MREG sites. [c]Post-funding is the site-specific period starting from the first month of MREG funding at that site through the end of SELECT accrual on June 24, 2004. The post-funding period for each comparison site is the same as the similar MREG site. [d]To estimate the average effect size across sites, means were calculated as follows: mean ''*N*'' is the sum of the monthly number of participants accrued by each site divided by 15; mean ''%'' is the sum of the percentage African American participants accrued by each site divided by 15.

effects were used to account for the correlation between participants accrued to the same site.

For the tabular data presentation, the number of participants accrued per month was the total enrollment at a site for the time period, pre- or post-funding, divided by the number of months the site had been accruing participants within the specified time period (Table 3). Percentage African American accrual was determined by the number of African Americans accrued divided by the total number of participants accrued, for each time period per site. Mean number of participants was the sum of the monthly number of participants accrued by each site divided by 15. Mean percentage African American accrual was calculated in the same fashion, to give an approximate average effect size across sites by giving each site equal weight.

All analyses were performed using PROC NLMIXED in SAS 9.1 (SAS Institute Inc, Cary, North Carolina). To predict the number of African American participants accrued per month, the number of African Americans recruited during the entire pre- or post-funding period was used as the response and a mixed effects model assuming a Poisson distribution was fitted. The response was modeled employing a log link function and included an offset for number of months of enrollment. To estimate the odds of randomizing African American participants, a mixed effects model was used to predict the probability that a randomized participant was African American in the pre- or post-funding time periods, using a Bernoulli distribution with a logit link function. Both models included fixed effects for MREG status, time (pre- or post-funding), and an interaction term for time and MREG status. Although these were not matched analyses, the frequency matched factors were included in the models: the percentage of African American participants and number of participants accrued through May 2002. The models included random site effects for pre- and post-funding, assumed to be normally distributed with mean 0 with an unstructured covariance matrix. A test of the interaction term was conducted to determine if the change in African American accrual patterns from pre- to post-funding were different when comparing the MREG sites with the comparison sites.

The expected number of participants accrued to MREG sites in the absence of MREG funding during the post-funding period was estimated using parameters from the Poisson model by setting the

MREG term to 0. The difference between this estimate and the actual African American enrollment post-funding at MREG sites provides an approximation of the additional number of African American participants accrued due to MREG funding.

Qualitative analyses

All MREG sites were required to submit monthly status reports during the period covered by MREG funding. These reports included whether or not specified minority recruitment strategies were successful. A successful strategy was defined for the sites as one that resulted in at least one randomization at a site in a given month, and an unsuccessful strategy was defined as one that had been used by the site but resulted in no randomizations that month. Successful and unsuccessful strategies were ranked by the number of times sites reported them.

In an effort to assess the overall impact of the MREG on randomizations and how the process could be enhanced, the 11 sites receiving the second round of MREG funding were asked to complete a final MREG summary report. The survey was comprised of four open-ended questions and one Likert item. These items were designed to probe the sites' experience with the MREG process by identifying institutional barriers to efficient use of MREG funds; evaluating the effectiveness of time spent on MREG-related activities; capturing lessons learned from the MREG experience; and providing an opportunity to present any relevant but previously unsolicited information.

Results

Quantitative findings

In general, overall enrollment for the 15 MREG and 15 comparison sites was steady throughout most of the recruitment period. The MREG sites enrolled 4507 total participants including 1266 (28%) African Americans; the comparison sites accrued 4025 participants of which 911 (23%) were African Americans. The rate of African American accrual for the MREG sites increased more than the comparison sites near the end of recruitment (Figure 1).

Monthly accrual data for the MREG and comparison sites are presented in Table 3. To allow for an evaluation of the enrollment differences between MREG and comparison sites, monthly randomization data are presented for African American and all participants by site, using means to provide an estimate of the average effect size across sites. MREG and similar comparison sites are presented side-by-side to best demonstrate the similarity of their baseline African American recruitment percentages. Other than the matched comparison site for MREG Site 11, these percentages can be seen to compare quite closely. Mean monthly African American accrual for MREG sites increased from 2.4 to 2.9 African American participants per month, while the comparison sites experienced a decrease from 1.8 to 1.1 African American participants per month. Mean percentage African American accrual across MREG sites increased from 34% to 44%; the comparison sites increased only modestly, from 25% to 28%. The mean number of participants accrued by MREG sites increased slightly, from 8.8 to 9.1 participants per month, and the comparison sites showed a decrease, from 6.8 to 3.0 participants per month. Thus, despite a minimal increase in the percentage of African American recruits between pre- and post-funding periods among the comparison sites, the low overall recruitment at comparison sites resulted in a diminished rate of African American recruitment per month.

Based on the results from the Poisson regression model, there was no evidence of a change in the monthly number of African Americans accrued to MREG sites post-funding (rate ratio = 1.28 $p = 0.84$ 95% CI: 0.47–3.51). The number of African Americans randomized to the comparison sites per month decreased overall by a factor of 0.38 ($p = 0.003$ 95% CI: 0.21–0.69) in the post-funding time period. The change in monthly African American accrual rate for MREG sites is 3.38 times the monthly change in accrual rate for comparison sites ($p = 0.004$ 95% CI: 1.51–7.57). This ratio indicates that while the MREG sites maintained the same levels of African American enrollment, the comparison sites' rates of enrollment of African Americans declined.

Results from the Bernoulli regression model showed the proportion of African American participants at the MREG sites increased after the receipt of funding. The odds for African American enrollment post-funding was 1.99 ($p = 0.08$ 95% CI: 0.91–4.32) times the odds pre-funding. In contrast at the comparison sites, the proportion of African American accrued did not increase (OR = 1.07 $p = 0.77$ 95% CI: 0.68–1.69). Comparing changes for MREG to non-MREG sites, the relative odds ratio was 1.86 ($p = 0.048$ 95% CI: 1.01–3.43), demonstrating that the MREG sites increased their odds of accruing African American participants post- versus pre-funding while the comparison sites did not.

MREG sites accrued 850 African American participants after receiving MREG funding. Based on the Poisson model parameters, the expected number of

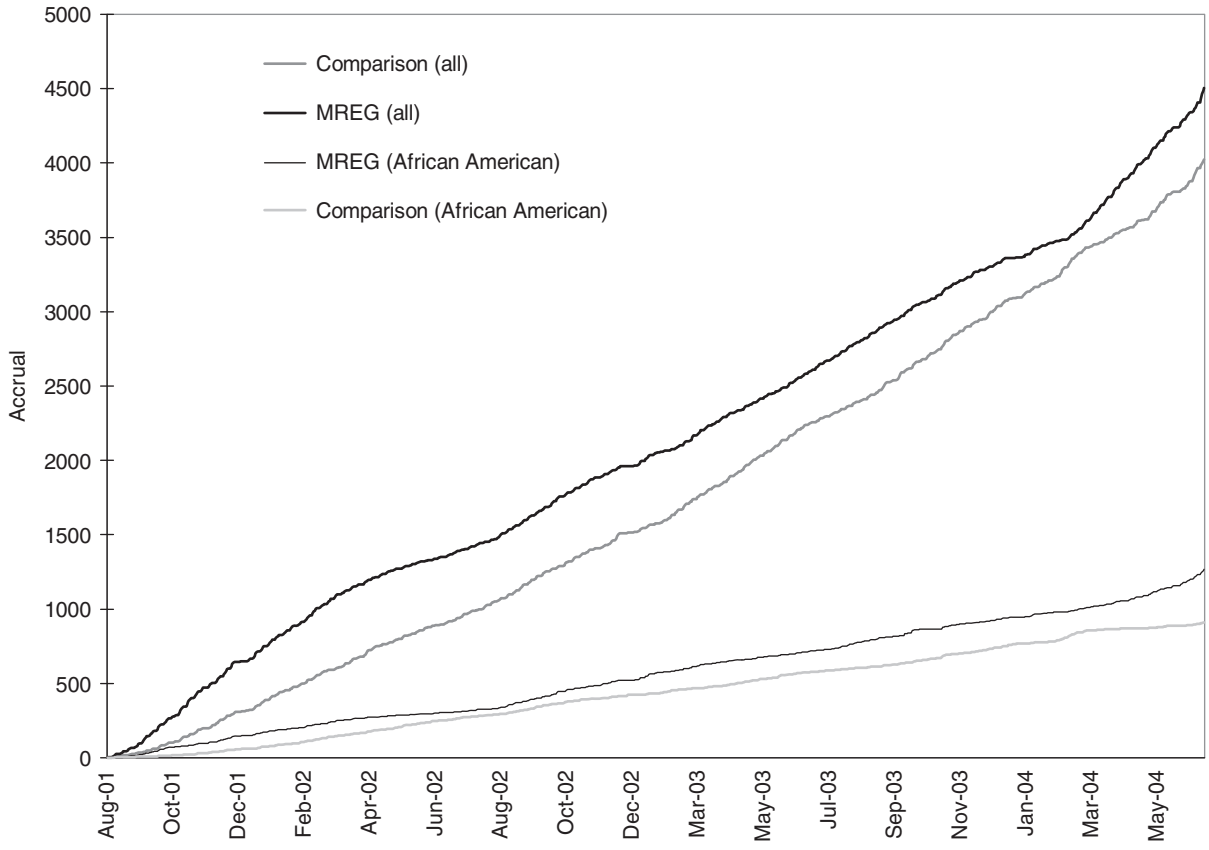

Figure 1 Cumulative accrual for sites awarded MREGs and non-MREG comparison sites for all participants and African Americans only. MREG sites ($n=15$) accrued 4507 participants with 1266 African Americans. Non-MREG comparison sites ($n=15$) accrued 4025 participants with 911 African Americans

African American participants these sites would have accrued in the absence of MREG funding is 248. The difference between these values, 602, is the approximate additional number of African American participants accrued at MREG sites due to MREG funding.

Qualitative findings

All MREG sites submitted monthly reports including minority recruitment strategies attempted during the funding period. Recruitment strategies that most frequently resulted in randomizations included: (1) additional staff time; (2) providing resources such as transportation and parking support, minority recruitment materials, and refreshments for recruitment meetings; (3) recruiting through the media; (4) mass mailings; and (5) prostate cancer screening clinics during off-hours. Strategies that were reported to result in very few randomizations and which some sites rated as unsuccessful included: (1) publicizing SELECT at health fairs, churches, barbershops, laundromats, and grocery stores; (2) local spokespersons; and (3) networking with clinics and community leaders. Some participants were recruited by affiliation with PCPT. The following three unsuccessful strategies included: (1) publicizing SELECT as a link on a local website, (2) targeting women's groups, and (3) publicizing the National Cancer Institute's website for cancer prevention information.

Eight of 11 eligible sites completed final MREG summary reports at the end of the second MREG funding cycle. Of these sites, 88% rated the time they spent on MREG-related activities as 'effective' or 'very effective'. Eighty-eight percentage of these sites also recommended that future studies provide additional funding to enhance African American recruitment before trial activation. The most common benefits listed by these sites included extra staff time (including evenings and weekends) to focus on African American recruitment and assist with planning, outreach, and hosting activities and funds for advertising and mass mailings. All sites reported hiring additional staff, usually a minority

outreach coordinator, and most sites increased existing staff time for minority recruitment. Other activities supported by the MREG included transportation and parking support, minority recruitment materials, recruitment advertisements in local media, food and supplies for recruitment meetings and postage for mass mailings.

MREG sites reported barriers that included funding and staffing delays, the absence of staff during summer vacation season when the first MREG became available, minority recruiter illness, and possible participant distrust of clinical trials. Some sites reported that it took additional staff time to recruit African American men. Sites also reported screening men who were not enrolled because they lived outside any SELECT study site area or they were African American men old enough for prostate screening but too young to qualify for SELECT.

Similar information on strategies used to enhance African American recruitment was not requested from the 15 comparison sites. Hence, it was not possible to determine whether the strategies reported by MREG sites, or their purported successes or failures, were similar or different from those possibly employed by comparison sites.

Discussion

We have presented qualitative and quantitative data that explore the impact of MREGs on African American recruitment in the SELECT, a large, multisite prostate cancer prevention study. Although SELECT did not meet the target of 20% for African American enrollment, the MREG sites contributed to an increase in African American randomizations. When compared to 15 sites that did not apply for or receive MREG funding, matched in a *post hoc*, quasi-experimental design, MREG sites had statistically significant increases in African Americans accrued per month and higher odds of accruing African American participants when comparing post- versus pre-funding periods. Both differences are statistically significant, indicating the MREG sites were successful in increasing African American randomizations after receiving the grants.

In this quasi-experimental analysis, the choice of comparison sites imparts an important limitation to these findings. The comparison sites had not applied for MREG funding, and there are no measures of their actual potential and motivation for either maintaining or expanding African American recruitment in the latter stages of SELECT recruitment. If a different mix of comparison sites had been chosen on a primary factor other than on pre-funding frequency of African American recruitment, differences in African American recruitment rates between MREG and non-MREG sites might have been more or less pronounced. Another limitation is that the amount of funding each site received was not considered, only the event of ever having received MREG funding.

A cost effectiveness analysis of this intervention was not conducted. However, it is estimated that MREG funding resulted in 602 additional African American participants. If the only outcome of importance from the MREG is African American enrollment, then the cost per additional African American participant accrued is approximately $1827, contrasted to the $1000 SELECT paid to the sites for each randomization. The intervention was expensive but effective.

Simply providing an additional $827 to SELECT sites for each African American man randomized may have increased the number of African American men enrolled to SELECT but probably would not have increased the overall recruitment of men to SELECT as seen with the MREG awards. Additionally, some sites would not have the access or resources to recruit from the African American population, regardless of the financial incentive to do so.

There were other potential benefits to the sites who received these grants that are unmeasured but important to the conduct of SELECT and future trials. These potential benefits could include: increasing overall randomizations by MREG sites; gaining a greater presence and support in the targeted communities; providing health education and clinical trials information to the community; and increasing a recruitment base for future studies.

The impact of the MREG on African American and total recruitment varied among the funded sites. Although these sites were chosen for their ability to recruit African American participants, not all MREG sites increased African American randomizations. For example, Site 12 was unable to hire a minority recruiter as planned, which contributed to their decrease in overall and African American enrollment after receipt of MREG funding. Some sites, such as Site 15, with high initial African American randomizations, used the funds to increase their overall enrollment rates while maintaining that of African Americans. Site 4 had a decline in overall enrollment rates just prior to receipt of MREG funding. They reported that their existing financial resources were being depleted, that the current staff was unable to handle additional volume, and that they were unable to continue their recruitment efforts at the same level in the absence of assistance. Had the MREG not been available, Site 4 would probably have made a reduced contribution to African American

participation. Additionally, Site 7, the largest MREG site, improved only Hispanic recruitment after receiving MREG funding, even though its stated intent was to increase both Hispanic and African American participation.

There are several potential sources of bias for this study. First, the intervention sites were not randomly selected, but were chosen via an application process where they had to demonstrate the potential and ability to recruit African American participants to SELECT. Some sites may have had existing minority recruitment programs in place; other sites may have been initiating African American recruitment efforts. Sites may have been experiencing a decrease in randomizations, such that MREG funding allowed them to continue African American enrollment at their preliminary rate, rather than increasing accrual; other sites may have been able to use funds to boost existing African American randomizations.

Varying degrees of success and failure were seen with some strategies, including publicizing SELECT at health fairs, networking with clinics, working with community leaders, and recruiting through churches. These variations speak to site and community differences and the intricacies of recruitment methodologies. Although we recommend the successful strategies used in SELECT, we realize that one size does not fit all, and sites need to have flexibility as to which strategies they pursue.

Although application for the first MREG award was open to all SELECT sites, only 32 SELECT sites ($< 10\%$) responded to the first request for applications. MREG funding was implemented after the trial was open and when sites were actively enrolling participants, overall at a higher than anticipated rate. This early success in overall accrual may have contributed to the fewer than expected number of sites applying for an MREG. Most sites would have established staff assignments to SELECT and budgeted funds and time commitments prior to the first MREG announcement. These site staff may have perceived that their site infrastructure and accrual goals could not accommodate the additional work involved in enhancing minority recruitment. Site staff may not have believed that they were able to increase minority enrollment to SELECT even with additional funding due to lack of access to the African American population or workload issues. A number of sites experienced delays in gaining access to MREG funds due to impediments within their own institutions. This resulted in further hiring and implementation delays. These factors lend further support for initiating minority recruitment strategies at trial inception and implementing them at the onset of randomization.

National African American minority recruitment strategies promoting prostate screening and SELECT may have augmented African American accrual for both MREG and non-MREG sites. For example, all sites were strongly encouraged to enroll African American men to SELECT, not just MREG sites. Three minority accrual workshops were conducted to increase African American enrollment to SELECT. The participating sites included both MREG and non-MREG sites with the potential to enhance African American recruitment. These workshops provided a forum for sites to exchange ideas form mentoring relationships and discuss strategies. Other nationwide minority recruitment strategies included 'SELECT Sunday', a faith-based strategy initiated in November 2003; African American media personalities participated in limited media spots promoting SELECT; and a barbershop initiative that preceded the release of the movie Barbershop 2, which opened February 6, 2004. Annual events surrounding Prostate Cancer Awareness Month, Minority Cancer Awareness Week, and Fathers Day also had the potential to boost enrollment to SELECT, and some sites tailored these events to enhance African American recruitment.

Future researchers considering the use of targeted funding to boost minority participation are recommended to make funds available and plan minority recruitment strategies prior to trial activation. A study should be ready to implement strategies before recruitment opens, choose recipient sites wisely, minimize delays incurred with hiring additional staff, and allow flexibility in the use of funds so sites can tailor interventions to their own needs. The information and strategies presented here should help guide future large-scale prevention and treatment studies, where recruitment of sufficient numbers of African American participants is necessary ethically and as a practical means to generalize results to this population.

BACKGROUND: Health care providers may be concerned that prescribing erectile dysfunction drugs (EDD) will contribute to risky sexual behavior.

OBJECTIVES: To identify characteristics of men who received EDD prescriptions, determine whether EDD receipt is associated with risky sexual behavior and sexually transmitted diseases (STDs), and determine whether these relationships vary for certain sub-groups.

DESIGN: Cross-sectional study.

PARTICIPANTS: Two thousand seven hundred and eighty-seven sexually-active, HIV-infected and HIV-uninfected men recruited from eight Veterans Health Affairs outpatient clinics. Data were obtained from participant surveys, electronic medical records, and administrative pharmacy data.

MEASURES: EDD receipt was defined as two or more prescriptions for an EDD, risky sex as having unprotected sex with a partner of serodiscordant or unknown HIV status, and STDs, according to self-report.

RESULTS: Overall, 28% of men received EDD in the previous year. Eleven percent of men reported unprotected sex with a serodiscordant/unknown partner in the past year (HIV-infected 15%, HIV-uninfected 6%, P< 0.001). Compared to men who did not receive EDD, men who received EDD were equally likely to report risky sexual behavior (11% vs. 10%, p=0.9) and STDs (7% vs 7%, p=0.7). In multivariate analyses, EDD receipt was not significantly associated with risky sexual behavior or STDs in the entire sample or in subgroups of substance users or men who had sex with men.

CONCLUSION: EDD receipt was common but not associated with risky sexual behavior or STDs in this sample of HIV-infected and uninfected men. However, risky sexual behaviors persist in a minority of HIV-infected men, indicating ongoing need for prevention interventions.

KEY WORDS: HIV infection; risky sexual behavior; STDs; men; phosphodiesterase inhibitors.

INTRODUCTION

Phosphodiesterase-5 enzyme inhibitors (sildenafil citrate, tadalafil, and vardenafil HCL) are approved pharmacotherapies to treat erectile dysfunction in men.[1] These erectile dysfunction drugs (EDDs) are commonly used in the United States,[2] marketed broadly, often requested by patients, and associated with improved quality of life.[3] EDDs have also been linked to high-risk sexual behavior in some groups of men at increased risk for HIV transmission, in particular men who have sex with men (MSM), men who use recreational or illicit drugs, and HIV-infected men.[4–16] Because of their association with risky behavior, some have argued that EDD medications should be classified as controlled substances.[5,17]

The source for obtaining EDD is an important issue to consider. Men may obtain EDD via prescription from a health care provider or from other sources, such as the Internet, friends, or the black market.[5,9,10,12] Health care providers must consider whether a prescription of an EDD could have adverse public health effects. Nearly all of the existing literature regarding EDD and risky sexual behavior has come from non-clinical samples of high-risk populations, in which prescribed EDD was rarely differentiated from EDD obtained from other sources. Thus, it is less clear whether prescribing EDD for erectile dysfunction in the context of routine health care is associated with risky sexual behavior or sexually transmitted disease (STD) transmission.

Health care providers caring for HIV-infected men must also consider whether an EDD prescription could facilitate sexual encounters that result in additional HIV transmission. The number of older, HIV-infected men has increased significantly in recent years, largely due to improved treatment but also due to new infections in this age group.[18] As the HIV-infected population ages, the demand for EDDs may increase in this group due to additional chronic diseases that are associated with erectile dysfunction. Thus, it is important to determine whether EDD obtained through routine healthcare is associated with risky sexual behavior in HIV-infected and HIV-uninfected men.

This study's objectives were to identify characteristics of men who received prescriptions for EDD though a network of Veterans Health Affairs (VHA) clinics throughout the United States, to determine whether EDD receipt was associated with risky sexual behavior and sexually transmitted diseases (STDs), and to determine whether these relationships varied based on HIV status, substance abuse, or having sex with men.

METHODS

The Veterans Aging Cohort Study (VACS) is an ongoing prospective cohort study involving HIV-infected and HIV-uninfected veterans receiving care at VHA clinics throughout the United States. The overarching aim of VACS is to study the role of alcohol consumption and comorbid medical and psychiatric disease on clinical outcomes in HIV infection.[19] VACS participants were recruited from infectious disease (HIV-infected) and general medicine (HIV-uninfected) clinics at eight sites (Atlanta, GA; Baltimore, MD; Bronx, NY, Houston, TX; Los Angeles, CA; New York City, NY; Pittsburgh, PA and Washington, DC).[19] Overall, 58% of HIV-infected men at the eight sites were enrolled, with only 9% of those approached refusing to participate.[19] HIV uninfected controls were targeted to match the demographics of the HIV-infected participants on 5-year age blocks, race and gender. Subjects completed a comprehensive baseline survey at enrollment and then at one year follow-up intervals. Further descriptions of the VACS sample and methodology are available online (www.vacohort.org).

The study sample for these analyses includes the subset of male VACS participants who completed a follow-up survey between September 2005 and January 2007 and who reported any sexual activity in the past year (n=2,787). Data were obtained from three linked sources: participant surveys, electronic medical records, and pharmacy data that are collected nationally through the Pharmacy Benefits Management (PBM) program (Hines, IL). The PBM program includes all outpatient prescriptions funded through the VHA healthcare system and are likely to be representative of the use of prescribed EDD in this population.

Measures. *EDD use* was defined as two or more prescriptions for sildenafil citrate, tadalafil, or vardenafil HCL, documented in the PBM database in the year prior to and up to the follow-up survey date. Thus, men who had received only one EDD prescription were not considered to be EDD users, because such men may have never used the medication, or simply tried it once. Although men were not asked about non-prescribed use of EDD at this assessment, a previous assessment in the same cohort demonstrated substantial agreement between self-reported EDD use and the PMB database, with fewer than 5% of men reporting EDD use exclusively from non-VA sources (unpublished data).

Risky sexual behavior was defined as "unprotected sex with a partner of serodiscordant or unknown HIV status". Specifically, men were asked, "During the past 12 months, did you ever, even once, have unprotected vaginal or anal sex (sex without a condom) with any of the following types of partners? Any partner who was HIV positive; Any partner who was HIV negative; Any partner whose HIV status was unknown." The following were the response options: Yes (unprotected sex at least once); or No (always used a condom). Those who reported unprotected sex with anyone of serodiscordant or unknown HIV status were classified as having risky sexual behavior.

STDs were identified by self report. Participants were asked, "In the past 12 months, have you been diagnosed with any of the following sexually transmitted diseases?" Persons were classified as having had a self-reported STD if they reported having genital warts, chlamydia, gonorrhea, syphilis, trichomonas, chancroid, or herpes.

Participant demographic characteristics, including gender, race/ethnicity, and marital status/living with partner were measured by self-report on the VACS baseline survey. Measures of alcohol and drug use and depression were included on the VACS follow-up surveys. Hazardous drinking (drinking associated with possible harm) was defined as a score of eight or more on the Alcohol Use Disorders Identification Test (AUDIT).[20] Participants were asked to report the frequency of use of marijuana, cocaine, stimulants, and heroin; current use for these drugs was defined as "at least monthly." Non-prescribed use of pain medications, defined as use of pain medications that were not prescribed, was based on self-reported use in the past year from a list of 20 specific narcotic pain medications. Depression, measured by the Patient Health Questionnaire (PHQ-9) at each follow-up assessment, was classified as present if the PHQ-9 score was 10 or more.[21] Comorbid medical conditions, including diagnoses of hypertension, diabetes, and coronary artery disease (CAD), were determined using International Classification of Diseases, Ninth Revision (ICD-9) codes from the electronic medical record. Persons were considered to have a comorbid diagnosis if at least one inpatient or two outpatient ICD-9 code diagnoses were recorded between one-year prior to and six months after the survey date. Persons were classified as having sex with men if they reported having "sex with males" or "sex with males and females" in the past year. Further details on variables and surveys can be found at www.vacohort.org.

Analysis

Demographic and behavioral characteristics were described and compared by HIV status using chi-square tests and t-tests, as appropriate. We used chi-square tests to determine whether EDD receipt varied by demographic and descriptive variables and to determine the bivariate associations of EDD receipt to risky sex and STDs.

Multivariable logistic regression models were used to identify independent factors associated with EDD receipt, risky sexual behavior, and STDs. Logistic regression models predicting EDD receipt were adjusted for demographic variables (age, race/ethnicity, married/living with partner, sex with

males in past 12 months), alcohol and drug use, and comorbidities identified as potential confounders (depression, diabetes, hypertension, and coronary artery disease). The logistic regression models predicting risky sexual behavior and STD included the same variables plus EDD receipt. There was significant collinearity between the sex with males and HIV status variables; therefore, we ran multivariate models stratified by HIV status. For each set of models, we first ran the multivariate logistic regression models including the variables described above. We then reran the models excluding variables with p>0.2 in both HIV-infected and uninfected models, and we present these models in the results. We also examined the relationship of EDD to risky sexual behavior or STDs in the following subgroups: those with hazardous drinking, cocaine use, and sex with men. All analyses were conducted using Stata 10.0 (College Station, TX).

Multiple imputation was used to address missing data.[22–24] For each of the following covariates, 1% or less were missing a response: married or living with partner, had sex with males, hazardous alcohol use, and depression. Pain medication use information was missing for 2%, and marijuana and cocaine use information was missing for 4%. Multiple imputation was conducted using the Stata v10.0 (Stata Corporation, College Station, Texas) ice command.[22–24] The imputation model included EDD receipt, risky sexual behavior, and all covariates included in the initial models (listed above), undertook ten switching procedures, and generated five datasets. The Stata v10.0 mim command was used to combine the results of the analyses from the multiply imputed data sets.[23] Analyses were also conducted on the complete case dataset (using categories to define missing data). Results from analyses of imputed data did not differ substantively from those using complete cases; therefore, the results from the imputation models are included here.

RESULTS

The study sample consists of 2,787 sexually-active men, of whom 1,469 (53%) were HIV-infected. Demographic and behavioral characteristics in both HIV-infected and HIV-uninfected men are shown in Table 1. Over 60% of the men were over age 50, over two-thirds were black, and one-third were married or living with a long-term partner. Many had comorbid health conditions, and substance use behavior was common; 18% reported hazardous alcohol consumption, and over 10%

P-value: comparison of HIV-infected vs. HIV-uninfected [a]Based on self-report; [b]Hazardous Alcohol Consumption: Alcohol Use Disorders Identification Test (AUDIT) score of ≥8; [c]Non-prescribed pain medications defined as any use in past year from list of 20 narcotic pain medications; [d]Score of 10 or more on the Patient Health Questionnaire (PHQ-9) (21); [e]Based on ICD-9 diagnosis; [f]defined as unprotected intercourse with a partner of serodiscordant or unknown HIV serostatus

reported marijuana, cocaine, or the non-prescribed use of pain medications. Compared to HIV-uninfected men, HIV-infected men were more likely to have reported having had sex with men, and the use of marijuana, non-prescribed pain medications, and stimulants (Table 1). HIV-uninfected men were more likely to be married or living with a partner, have hazardous alcohol consumption, and have other medical comorbidities.

Overall, 28% of these sexually active men received two or more prescriptions for EDD in the previous year (Table 1). HIV-infected men were slightly less likely to be prescribed EDD (26% vs. 31%, p=0.003). Regarding risky sexual behavior, 11% reported unprotected sex with a non-main partner in the past year. HIV-infected men were significantly more likely than HIV-uninfected men to engage in risky sexual behavior (15% vs. 6%, p<0.001). STDs were reported by 7% of the sample. HIV-infected men were significantly more likely to report a STD diagnosis in the previous year (10% vs. 4% p<0.001).

Individual Characteristics Associated with EDD Prescription

One-third of men age 50 years and over received two or more prescriptions for EDD in the previous year. Table 2 shows the relationship of demographic, behavioral, and clinical characteristics with EDD use overall, and among HIV-infected and HIV-uninfected men. Overall, EDD receipt was more common in older men, nonwhite men, non-MSM men, those with non-prescribed use of pain medications, and those with depression, hypertension, or diabetes (Table 2). Among HIV-infected men, EDD receipt was more common in older men, men who don't have sex with men, those with non-prescribed use of pain medications, and those with diabetes (Table 2). Among HIV-uninfected men, EDD receipt was more common in older men, nonwhite men, those not married or living with partner, and those with non-prescribed use of pain medications, cocaine use, depression, or hypertension (Table 2).

In both the HIV-infected and HIV-uninfected multivariate models, increasing age and use of unprescribed pain medications were associated with an increased likelihood of EDD receipt (Table 3). In the HIV-infected model, having sex with men was associated with a decreased likelihood of EDD receipt. In the HIV-uninfected model, non-white race/ethnicity and depression were associated with an increased likelihood of EDD receipt, while married/ living with partner was associated with a decreased likelihood of EDD receipt (Table 3).

Association of EDD Receipt with Risky Sexual Behavior and STDs

The percent of reported risky sexual behavior was similar between those who did and did not receive EDD (11% vs. 10%, p=0.6). This was true when the analysis was restricted to the HIV-infected men (16% vs. 15%, p=0.4) or the HIV-uninfected men (6% vs. 5%, p=0.6).

Table 2. Factors Associated with EDD Receipt Among Sexually Active Men Participating in VACS, 2005–2007, Overall and in HIV-infected and HIV-uninfected Men

Coronary artery disease[d] (ref=none)	0.8	0.4-1.5	0.5	0.7	0.4-1.0	0.06

[a]Based on self-report; [b]Non-prescribed pain medications defined as any use in past year from list of 20 narcotic pain medications; [c]Score of 10 or more on the Patient Health Questionnaire (PHQ-9) (21); [d]Based on ICD-9 diagnosis

In both the HIV-infected and HIV-uninfected models, being married/living with partner were associated with decreased likelihood of risky sex, whereas sex with males, hazardous alcohol consumption, and cocaine use were associated with increased likelihood of risky sex (Table 4). In the HIV-infected model only, unprescribed pain medication and marijuana use was associated with an increased likelihood of risky sex. For both HIV-infected and uninfected models, EDD receipt was not statistically significantly associated with risky sex (Table 4).

Overall, the percentage of reported STDs was similar between those who did not receive EDD (7% vs. 7%, p=0.7). This finding was similar among HIV-infected men (9% vs. 10%, p=0.5); although among HIV-uninfected men, those who received EDD were more likely to report an STD in bivariate analyses (6% vs. 3%, p=0.02). For both HIV-infected and uninfected models, EDD receipt was not statistically significantly associated with STDs (Table 5).In both the HIV-infected and HIV-uninfected multivariate models of STDs, unprescribed pain medication was associated with an increased likelihood of STDs. In the HIV-infected model, younger age and sex with men was associated with an increased likelihood of STDs.

There were no statistically significant relationships between EDD receipt and risky sexual behaviors or STDs in models limited to those with hazardous drinking, cocaine use, or men who reported having sex with men (data not shown).

DISCUSSION

In this sample of over 2,500 men attending VHA outpatient clinics, EDD receipt was not associated with risky sexual behavior or STDs, overall or within subgroups of HIV-infected men, substance users, or MSM. Thus, for men who obtain EDD via prescription from a healthcare provider, EDD appears to be prescribed responsibly and used responsibly. These findings differ from the majority of previous studies on this topic. One of the most plausible reasons for the varying conclusions is that the focus of our study is on men who received EDD as part of clinical practice, whereas nearly all of the previous reports linking EDD to risky sexual behavior were conducted in non-clinical samples in high risk groups, including MSM [4–12,16,25], substance abusers[11,26], and HIV-infected men outside of clinical settings.[13–15] In nearly all of these studies, the association of EDD and risky sexual behavior was consistently the strongest in men who also used stimulant drugs such as methamphetamines, ecstasy, or gamma-hydroxybutyrate (GHB), which were rare in our study sample.

The source of EDD may also influence its relationship with risky sexual behavior. In samples of younger MSMs, 40% or more report obtaining EDD without a prescription (e.g. via the internet or off the street).[5,9,10,12] Men obtaining EDD without a prescription appear to report higher-risk behaviors than those

[a]Based on self-report; [b]Hazardous Alcohol Consumption: Alcohol Use Disorders Identification Test (AUDIT) score of ≥8; [c]Non-prescribed pain medications defined as any use in past year from list of 20 narcotic pain medications; [d]Score of 10 or more on the Patient Health Questionnaire (PHQ-9) (21); [e]Based on ICD-9 diagnosis

obtaining it by prescription.[9] A study of EDD use in heterosexual drug users found that many men used the medications to "enhance sexual experience," rather than to treat erectile dysfunction, but 30% of that sample had obtained these medications without a prescription.[11] The current study only considered EDD that had been obtained by prescription, a source that is most relevant and under the control of the prescribing clinician.

In this study, the proportion of sexually active men who received prescriptions for EDD use was fairly high; one-third of men over age 50 received two or more prescriptions in the previous year, with receipt being equally likely among men aged 50 to 60 as in those aged 60 and above. EDD receipt was less common among MSM in this sample, which could reflect either less erectile dysfunction, or decreased use of physicians as a source of EDDs**,** or a reluctance by physicians to prescribe EDD to these patients. The association of EDD receipt with non-prescribed use of pain medications had not been reported previously. Possible explanations include an association of chronic pain with erectile dysfunction, side effects of the specific medications, or other characteristics of men that are more likely to use pain medications without a prescription. Similarly, the finding linking depression with EDD receipt could reflect either depression as a cause of erectile dysfunction, erectile dysfunction as a cause of depression, or side effects of medications used to treat depression.[27,28] Other studies have also found an association of depression with EDD use in HIV-infected men.[29]

The proportion of sexually active men who engaged in risky sex or reported STDs was fairly high, especially among HIV-infected men. This is consistent with a previous analysis in VACS in which men were more likely to engage in risky sex if they were younger, reported hazardous alcohol or drug use, were not married, or were MSM.[30] Persons with these risk factors may benefit from additional attention regarding HIV/STD prevention counseling regardless of their EDD use; an opportune time to address sexual health risks would be when an EDD is being prescribed.

Several potential study limitations should be noted. As in any cross-sectional analysis, the cause-and-effect relationship between EDD receipt and risky sexual behaviors can be difficult to assess, especially when the associations are compared at general levels rather than event-specific analyses. Men attending VHA clinics may have sociodemographic or behavioral characteristics that are different from men recruited from non-VHA clinical settings, although veterans have not been the focus of prior research on this topic. Our definition of EDD receipt does not include EDD that was obtained from a non-VHA pharmacy, provided as a sample medication, or obtained without a prescription. However, the focus of this analysis is on EDD obtained from a healthcare provider. It is also possible that providers systematically declined to provide EDD to men that they knew or suspected were engaging in risky sexual behavior, but this was not measured in the current study. Finally, measures of risky sexual behavior and self-reported STDs have limitations and are likely to underestimate the true prevalence of these behaviors and infections. However, we have no reason to suspect that reporting of these conditions would vary according to EDD receipt.

In conclusion, the findings from this study provide some reassurance to healthcare providers who prescribe EDD, including those who provide care to HIV-infected men. Although it is clear that some men who receive EDD engage in risky sexual behavior, we found that HIV-infected and HIV-uninfected men who received EDD were no more likely to engage in risky sexual behavior or to report new STDs than men who did not receive EDD. Physicians should continue to counsel their patients about HIV/STD prevention at opportune moments such as discussion of EDD, general checkups, or when identifying other risk factors associated with risky sexual behavior.

Investigators have the responsibility to ensure that prospective participants are fully informed about a research protocol prior to consenting to participate, yet many researchers face challenges when obtaining consent, since the majority of the general population has limited or no familiarity with research studies. These challenges are further magnified when obtaining consent from individuals with low literacy levels and who speak languages other than English. In this article we present findings from a qualitative study conducted with Spanish-speaking individuals with low-literacy designed to refine the Agency for Healthcare Research and Quality's Informed Consent and Authorization Toolkit for Minimal Risk Research. Findings from this study indicate that familiarity with providing informed consent and authorization for research or the experience of being a research participant appear to play key roles in an individual's ability to understand the consent and authorization process. While the text of the consent and authorization documents can be simplified using plain language principles, comprehension of several fundamental ideas such as risk and privacy need to be safeguarded with a consent process that confirms comprehension. Recommendations are provided to address the informational needs of individuals with low literacy levels and limited or no experience with research participation.

Investigators have the responsibility to ensure that prospective participants are fully informed about a research protocol prior to consenting to participate. This responsibility is fulfilled by means of an informed consent and the Health Insurance

Portability and Accountability Act (HIPAA) authorization process [http://www.hhs.gov/ohrp/humansubjects/guidance/45cfr46.htm; http://www.hhs.gov/ocr/privacy/]. Barring special circumstances, this process is facilitated and documented by means of an informed consent and HIPAA authorization form. Further, federal regulations mandate that consent for human research participants be presented in a fashion that is 'understandable' by potential participants and that research authorization forms be written in 'plain language' [http://www.hhs.gov/ohrp/humansubjects/guidance/45cfr46.htm]; [http://www.hhs.gov/ocr/privacy/hipaa/administrative/privacyrule/adminsimpregtext.pdf].

Consequently, many Institutional Review Boards (IRBs) have established readability guidelines. Unfortunately, IRBs rarely meet their own guidelines in the template text that they require investigators to use and most research consent forms present information in a manner that is unnecessarily complex and unreadable by most people (Paasche-Orlow et al., 2003). As such, obtaining consent—using written consent forms—for research participation from individuals with low literacy poses great challenges (Davis et al., 1998).

Research participants have commonly been found to lack basic understanding regarding fundamental aspects of the studies in which they are participating (Flory and Emanuel, 2004; Jenkins et al., 2010; Raich et al., 2001; Sugarman et al., 1999). While most authors have found benefits from designing consent forms that are shorter and easier to read (Coyne et al., 2003; Flory and Emanuel, 2004; Kang et al., 2009; Paris et al., 2010) simply decreasing the reading level will not ensure that all potential participants give consent and authorization that have been substantively informed. For example, easy-to-read consent forms might not be enough for potential research participants who lack familiarity with *providing* informed consent or the activities of participating in research (Sudore et al., 2006).

In addition, making consent forms easier to read does not necessarily address the linguistic challenges that researchers face when obtaining consent from individuals who speak languages other than English and/or have limited English proficiency even when using a consent form that has been translated into the target language without determining whether the translation process rendered an easy-to-understand consent form. To address this situation, most IRBs overseeing research conducted with non-English speaking populations allow investigators either to use a short-form translated generic statement delivered by an interpreter along with a discussion of the research using the English consent form as a guide or require researchers to submit translated versions of the consent forms they intend to use [REF: http://www.hhs.gov/ohrp/humansubjects/guidance/ic-non-e.htm] frequently requiring the application of a back-translation method (i.e., the process of translating a document that has already been translated into another language back to the original language by an independent translator) as a mechanism to assess the translation's accuracy. Although these strategies represent significant improvements from past practices, they may not be enough.

To address many of these concerns, an Informed Consent and HIPAA Authorization Toolkit was developed by Agency for Healthcare Research and Quality (AHRQ) staff and modified with input from experts in health literacy, clinical research, Federal regulations, HIPAA authorization requirements, and ethics. The toolkit was also pre-tested by researchers at Boston University Medical Center (ACTION Network Field Partnerships for Applied Research, Principal Investigator: MP-O) with a diverse group of research participants, researchers, and IRB

professionals. To refine and validate the language of the sample consent documents in this toolkit, we recruited English- and Spanish-speaking research participants with different levels of literacy to participate in focus groups and individual interviews in five cities (Atlanta, GA; Baltimore, MD; Boston, MA; Tucson, AZ; and Waukegan, IL). These materials are not copyright protected (http://www.ahrq.gov/fund/informedconsent/) and have been reviewed to ensure that the guidance provided is consistent with the regulations for obtaining and documenting informed consent for participation in minimal risk research and authorization for use of protected health information as required under HIPAA (see Appendix for example text excerpt). In this article we present findings from the qualitative study conducted with Spanish-speaking individuals with low-literacy designed to assess comprehension of and refine the AHRQ Informed Consent and Authorization Toolkit for Minimal Risk Research.

Methods

To evaluate the comprehension of a Spanish version (translated from English) of an easy-to-read minimal risk consent form and HIPAA authorization among Spanish-speaking Latino/as, we conducted three focus groups and 12 individual interviews. Individuals were recruited at adult basic education (ABE) programs and health clinics. *Teachers* at the ABE programs and *clinical staff* from the health clinics identified Spanish-speakers with low and higher literacy and informed them about the study. If they agreed to participate, they were invited to be part of a focus group or participate in an individual interview with a Spanish-speaking PhD level researcher. A total of 37 individuals were recruited. Twelve participated in twelve qualitative individual interviews and 25 participated in focus groups. Participants provided oral consent prior to participation and they received $25.00 for participation following completion of the focus group or interview. The rationale for using focus groups and individual interviews as the two qualitative data collection methods was that both methods allowed conducting an in-depth assessment of participants' comprehension of the toolkit's content.

The goals of the focus groups and individual interviews were: (1) to assess how much participants understood the information included in a consent and authorization form about a hypothetical study for patients with diabetes; (2) to obtain participants' input about how to improve comprehension; and (3) to explore the effectiveness of communication strategies other than reading in order to make the process of obtaining consent to participate in a research project meaningful to potential research participants. Although the consent form referred to a hypothetical study for patients with diabetes, the document did not have clinical content, and participant selection criteria did not include having diabetes. We informed participants that the consent form referred to a hypothetical study, and thus asked them to pretend that they had diabetes, and were being invited to participate in a study designed for people with diabetes.

Upon obtaining verbal instead of oral consent—in order not to exclude individuals with low literacy—to participate in the study, we gave participants a binder that contained the consent form and HIPAA authorization typed in non-glossy, high contrast paper with large print to avoid excluding individuals with low vision or other visual impairments. During both the focus groups and individual interviews we asked participants to review the text included in the

consent form and HIPAA authorization using a semi-structured interview format combined with cognitive interviewing (i.e., think-aloud) techniques. First, we asked participants to read the consent form and HIPAA authorization. For the focus groups, the facilitator asked the group to complete that task by taking turns reading the documents aloud.

Once participants read the documents, each statement included in them was reviewed following four steps. For the *first step*, the facilitator asked participants to review a statement on the document, and then asked, 'What does this statement mean to you?' Participants' perceptions of the phrase and what it meant to them were recorded, and follow-up questions were asked to further clarify participants' responses as necessary. If participants reported not knowing the meaning of a word, this was recorded. For the *second step*, the facilitator read the same statement aloud, and then asked questions about the statement (e.g., 'tell me in your own words what this means') followed by questions for clarification, if needed. After discussion of their perceptions, the *third step* involved the facilitator explaining what the statement meant and asking participants to think about how the wording could be improved to make the statement easier to understand or clearer (e.g., 'Which words need to be changed?' 'How can we say this better?'). Any different wording participants suggested in order to better or more easily explain the concept was noted. During *step four*, the facilitator presented textual variants of the same item to determine if other wording would be more appropriate.

Although the goal was not to reach consensus, if there was one relatively clear choice among focus group participants, that choice was marked as preferred. If the group agreed on multiple good options, they were noted and rank ordered per the group's preferences. This four-step procedure was repeated for each element in the sample informed consent and HIPAA authorization forms in order to address each of the elements of informed consent and authorization. At the end of the interviews and focus groups, participants were asked, ''tell me in your own words about the research project described in these documents.'' Based on feedback from participants, the text was adapted in an iterative fashion.

Results

After each participant of the first focus group took turns reading each statement included in the consent form and HIPAA authorization form and followed the four review steps described above, five of the seven members of this group could not explain the purpose of the documents in their own words. In contrast with participants in the first focus group, those in the other two focus groups as well as those who completed the individual interviews were able to formulate the documents' intent and content in their own words.

Most participants reacted *unfavorably* to the length of the documents. Even though the documents were written in plain language and followed low literacy principles, some participants deemed them too long. One participant provided the following recommendation: ''say what you need to say not using so many words.'' Another participant recommended not to use fine print since that kind of font ''is not trustworthy.'' All participants expressed their preference to have someone (e.g., researcher) going over the consent form with them. They also expressed the need to be given time and ''space'' to carefully review the consent form before making a decision about participating in the research study. This quote

illustrates what some participants deemed the appropriate way to handle the process of obtaining consent:

> "When someone hands you this document and sits in front of you while you are reading, it's intimidating and makes you nervous and you can't really read it well. So, we need time, and a properly designated space where we can read and sign it. If they can take it home and read it with a family member, it would be better. This way they'll feel more comfortable in discussing the document with THEIR family, rather than with a stranger. You're giving them options. You can say to them, "I can help you. You can do it by yourself, or you can take it with you." [It's important to give them options] because you are not aware of my skills yet."

Another participant expressed a similar opinion: "I would need to feel assured, just like we're doing here today. I would like to read it slowly, with various people, like we are doing here, and go step by step, in order for me to feel sure."

Most participants (in both focus groups and individual interviews) reported that they had never signed a consent or authorization form for research participation before. As they were going through the documents, it was evident that these individuals had difficulties understanding what it takes to participate in a research study and the purpose of going through the process of consenting. For example, participants had difficulties understanding the goals of the study as well as the research activities involved in the study described in the consent form. They also expressed limited understanding of the process of withdrawing from the research study and the use of personal health information obtained prior to withdrawing from the study.

Issues related to translation were also evident in the study. For example, participants provided feedback that some sentences contained words that were grammatically correct, but read like literal translations with a syntactic structure that followed English language rules, and thus had an impact on participants' comprehension. This finding underscores the importance of incorporating a pilot test to assess comprehension of the translated test prior to completing the final version of the translated during consent form.

Notable Areas of Complexity

Risk

A significant number of participants had difficulties understanding the purpose and intent of the section that described risks from participating in the research study. For example, many of them could not comprehend why the possibility that other people would learn about their participation in the study could be harmful. For other participants, the risk section explanation of mandatory reporting of crimes committed by participants instilled distrust among some participants, and made them consider not consenting to participate in the study described in the forms. In this regard, one participant said:

> "That is forewarning you that you're better off not opening your mouth.... And to tell lies, if you have any problem. Well, this part

> frightened me when I read it and it was the first thing I contested. The money part or the questions part was nothing. But this part tells me that I'm protected, but once I sign the document, I'm no longer protected. But, not only I am not protected for what I may say, but I can also end up in jail.''

Protected Health Information

After reading the documents some participants indicated that they would not provide consent to participate in the study described in the consent form and HIPAA authorization since they did not believe that their personal health information would be protected. The reason why they did not believe that their personal health information would be protected stemmed from what they described as confusing or contradictory information regarding the use this information. Participants who deemed this information confusing expressed a heightened level of distrust regarding the goals of the study and the need to sign a consent form. The following quotes illustrate the feelings participants expressed in this regard:

> ''I read in the document that my medical record is protected by a privacy law, but the minute I sign the consent, it is no longer protected. And it states that the information will be given to certain people. How am I going to be sure that people will not have access to that information? Besides, it states that I can stop the authorization at any moment, but that the information I have already provided will continue to be used. There really isn't any law that will protect me. In other words, what this is saying doesn't make sense.''

Another participant echoed the same feelings:

> ''Pardon me. It seems to me like this contradicts itself. It contradicts because first, it tells me that medical record information is protected under the Privacy Rule, and later on, it tells me that you are not responsible for protecting my information. It's not confusing. It's clear, but contradictory. We are no longer protected by the law because we are giving you authorization for other people to see it. They're going to be frightened. They [the research team] will use it for the study, for whatever they want. I repeat, it tells us, ''WE WILL DO OUR BEST . . .'' No one is giving me a written document or a guarantee. I'm not given a guarantee where it says, 'your information will be kept confidential with people of the study.'''

Other participants who felt that the documents felt short protecting their privacy, reported that since their participation in research could potentially produce knowledge that could benefit other people, they were willing to forgo full protection of their privacy in order to help others (see the Appendix for an example of toolkit's text). Finally, the study's results did not suggest that culturally-specific issues informed participants' willingness to participate in the hypothetical study described in the consent form.

Discussion

We undertook a series of cognitive interviews with iterative adaptation of consent and authorization documents to refine the template text for the AHRQ Informed Consent and HIPAA Authorization Toolkit. This activity was guided as well by a series of reviews conducted by a Delphi Panel of experts as well as by staff at the Office for Human Research Protections (OHRP) and the Office for Civil Rights (OCR). Findings from this study indicate that even when researchers follow recommendations designed to facilitate reading comprehension of consent forms—large font, plain language, shorter sentences, document written in respondent's preferred language, wide margins, and shorter paragraphs—comprehension is not guaranteed. While our experience provided evidence that improved readability is important, underlying conceptual complexity cannot be avoided in many instances. Some participants did not understand the content of the consent form even though they were able to read it. This appeared mostly for people with no prior experience with research and for those who have never seen a consent form. Indeed, lack of familiarity with the concepts appeared to be a more important barrier to comprehension than semantic or syntactic issues. Others understood most of the content, but were confused about the extent to which the consent form provided sufficient protections around the issues of confidentiality, risks and benefits. In addition to this, even though the documents had been edited to have fewer words than typically found in comparable documents, they were generally viewed as lengthy and wordy. It is clear that comprehension was not guaranteed through the application of technical document-focused strategies (e.g., large font, shorter sentences, etc.) designed to lower the document's reading level. This suggests that researchers should take additional steps to improve comprehension since it is not realistic to expect that reading a consent form will guarantee comprehension of the research project it describes (Sugarman & Paasche-Orlow, 2006).

Lack of familiarity with participation in a research study and lack of familiarity with providing informed consent and authorization appeared to play key roles in individuals' ability to understand what is being asked from them. Among those who understood both the process of participating in a research study and consenting to it via a written document, the language used in the consent form (even though it was considered written in ''plain language'') was deemed confusing and contradictory. Confusing and contradictory information in the HIPPA authorization form generated feelings of distrust among participants who demonstrated a high level comprehension of the document, and thus they felt that they did not have enough protections to be willing to sign the document.

The results of this study align with those of previous studies that have shown that comprehension of informed consent documents poses problems for many participants (Taub et al., 1986; Davis et al., 1998). Similar to the study described here, Davis and colleagues (2002) conducted a study to test whether the use of a simplified, illustrated consent document that followed low literacy recommendations would be easily understood by individuals with marginal-to-low reading skills. Although participants indicated that the simplified version was more conducive to participating in the study than a standard consent form, there was no difference in level of comprehension across the two consent form versions. They indicated that participants' reading levels appeared to be related to comprehension and thus questioned the use of written consent forms for low literacy individuals. Our results echo these earlier

findings, and demonstrate how basic research concepts can be challenging for people to comprehend even when they can read a document that describes those concepts. In addition to this, our study's findings regarding the absence of culturally informed bias towards consenting to participate in a research project compare with findings from another study conducted with Mexican Americans. That study focused on their recognition of the risks and ethical issues associated with enrollment in genetic family studies and explored how this recognition affects their informed and voluntary participation. The study found that participants did not recognize and tended to underestimate the social and cultural risks associated with their participation in genetic family studies (Arar et al., 2005).

The study provided the opportunity to further refine the Toolkit by improving the Spanish and shorten the text. Findings from this study also provide further evidence that energy needs to be put into the process of obtaining consent and authorization from potential research participants, since simply translating documents from one language into another is not enough to achieve comprehension. Institutional Review Boards, in their effort to protect human participants, need to provide specific guidelines to researchers who recruit individuals who speak languages other than English, have low literacy skills, and are unfamiliar with both research participation and informed consents. For those who speak languages other than English, Institutional Review Boards' requirement of conducting back-translation procedures to verify translation addresses the issue of content accuracy but not the issue of content comprehension. Back-translation is considered a rough and mechanistic assessment of translated text (Harkness et al., 2004), and thus falls short determining the translation's quality in terms of the level of comprehension on the part of the audience who will be using the translated text. In addition to that, a back-translation of a literal translation may simply replicate flaws present in the original text. In this sense, a back-translation could fall short as a tool to assess the adequacy of the translated text (Blais and Gidengil 1993). IRBs should provide templates of consent forms in languages other than English that are not only translated by professional translators but pilot tested for comprehension with individuals who speak those languages and who have different levels of literacy and familiarity with research and informed consent. Implementing these steps could lead to language-specific consent forms that successfully capture and clearly communicate the intended concepts to individuals with little or no familiarity with participation in research.

Since the data obtained from this research was communicated to AHRQ prior to the publication of this manuscript, the Toolkit—readily available to the research community—recommends that investigators obtaining consent from potential research participants implement interactive strategies to confirm participant's comprehension of the consent form. Our research design allowed us to do this, and it provided an opportunity to learn how participants interpreted the documents' content (i.e., confidentiality, risk) and further details of their decision-making process (e.g., forgoing privacy in order to help others through their participation in research). We recognize that, realistically, most researchers cannot spend unlimited amount of time obtaining consent from potential participants. However, in order to make comprehension of both the consent form and the research study in question a universal guideline or standard, Institutional Review Boards should also require that researchers complete training on interactive consent processes designed to address the informational needs of individuals with low literacy levels and limited or no

experience with research participation (Sudore, 2006). The training should include the use of prescreening protocols aimed at explaining the purpose of the research study to potential participants prior to obtaining consent as well as the use of probes and teach-back methods as tools to inform about consent and authorization and to verify comprehension. Such procedures are needed not only to conform to regulatory guidelines and ethical norms, but also, to improve access for a broad spectrum of potential participants to research protocols that they might otherwise avoid simply due to misunderstanding. The failure to enroll participants with low health literacy can threaten the validity of many research protocols. Finally, our findings suggest the need for IRBs and researchers alike to consider adding to consent forms a brief introductory statement explaining what participation in research is and why potential participants need to be informed about what is involved in the research study before they consent to join the study.

beneficial in terms of CV outcomes, but this was presumably confounded by the disadvantages of the atenolol-based regimen.

However, we did not focus on the variable predictability of HR because that was not the purpose of the study. We wanted to know whether having a higher baseline HR attenuated the superior effects on major CV events of the amlodipine-based compared with atenolol-based regimen. We could find no evidence of any such attenuation, and hence we believe that an increased baseline HR should not be an indication for preferential use of beta-blockade in hypertensive populations without coronary heart disease. Even if baseline HR had not predicted CV outcomes in the ASCOT study, we believe that the same conclusion should be drawn.

Bleeding Risk on Warfarin Among Elderly Patients With Atrial Fibrillation

Poli et al. (1) observed different rates of major hemorrhage between patients younger than 80 years of age and 80 years of age and older. As discussed by the authors, these rates differed considerably from the rates of major hemorrhage observed among similarly aged cohorts by Hylek et al. (2). We want to highlight an important methodological issue in the authors' calculation of event rates. The authors state, "the overall exposure to warfarin for each patient was calculated in relation to aging, before and after his/her 80th birthday." Thus, the authors allowed crossover of prevalent warfarin survivors from the younger cohort to the age ≥80 years inception cohort. At the time of enrollment, the baseline age ≥80 years cohort numbered 180 patients. Yet, in Table 1 of their article (1), the authors provide baseline characteristics for 327 patients in the age ≥80 years group. The 2 age inception cohorts are distinct and should contribute person-years exclusively to their baseline assignment. Given this methodological error, the rates of hemorrhage provided for the 2 inception cohorts are flawed. The reader is also unable to compare baseline characteristics between the younger and age ≥80 years inception cohorts because the authors permitted crossover of 157 patients. In addition, the observation period in the study by Hylek et al. (2) was intentionally truncated at 1 year to provide the first-year experience on warfarin. Calculation of adverse event rates over years tends to enrich the person-year denominator with "survivors" because bleeding rates are highest in the first 90 days of warfarin therapy. To accurately report rates of major hemorrhage among elderly individuals newly starting warfarin, the authors need to recalculate the bleeding rates according to baseline group assignment without crossover between the groups. To enable comparison of the 2 studies, events and person-years of observation would need to be restricted to the patients' first year of therapy. The anticipated results would be higher bleeding rates and deterioration of time "in-range" as reported.

Reply

We studied a cohort of atrial fibrillation patients on oral anticoagulant treatment for stroke prophylaxis (1). Our patients were routinely followed by the Anticoagulation Clinic of our institution with a median follow-up of 2.7 years, and some of them for as long as 13 years. At the beginning of warfarin treatment, the mean age of our cohort was 75 years; therefore, many patients reached the age of 80 years during follow-up. As stated in the article, we decided to analyze the occurrence of adverse events in relation to aging to evaluate whether aging itself could be correlated with an increase in bleeding risk that exceeds the advantages of stroke prevention. In reporting clinical characteristics of patients, we

Head and Neck Sequelae of Torture

Sondra S. Crosby, MD; Shaulnie Mohan, MD; Christina DiLoreto, MD; Jeffrey H. Spiegel, MD, FACS

Objectives/Hypothesis: To increase awareness of torture among otolaryngologists, and to describe methods and complications of head and neck torture.

Study Design: Retrospective review.

Methods: Five cases of survivors of torture were evaluated in an otolaryngology practice in an urban hospital setting.

Results: The subjects presented with widely variable symptoms and physical manifestations related to the head and neck as a result of torture, in addition to psychiatric disease. Documentation of head and neck findings were essential to the asylum claim.

Conclusions: Otolaryngologists serving immigrant and refugee populations must be familiar with methods and manifestations of torture involving the head and neck.

Key Words: Head and neck, torture, methods of torture, trauma.

***Laryngoscope,* 120:414–419, 2010**

INTRODUCTION

The UN Convention Against Torture defines torture as: "any act by which severe pain or suffering, whether physical or mental is intentionally inflicted on a person for such purposes as obtaining from him or her or a third person information or a confession, punishing him for an act he or a third person has committed, or intimidating or coercing him or a third person, or for any reason based on discrimination of any kind, when such suffering is inflicted by or at the instigation of or with the consent or acquiescence of a public official or other person acting in an official capacity. It does not include pain or suffering arising from, inherent in or incidental to lawful sanctions."[1]

In 2008, Amnesty International Report reported that torture and ill treatment occurred in 81 countries[2]; however, torture is commonly under-reported. At the end of 2007, there were 31.7 million people of concern to the UNHCR (refugees, asylum seekers, displaced persons, and others), 365,103 of whom reside in the United States.[3] The United States was the main receiving country for asylum applications, with 50,000 lodged in 2007.[3] A refugee is defined as an alien unwilling to return to his or her country of origin "because of persecution or a well-founded fear of persecution on account of race, religion, nationality, membership in a particular social group, or political opinion."[4] Asylum seekers meet the same criteria as refugees; however, they apply for asylum in the host country. This distinction is important because asylum seekers may be undocumented, and are an extremely vulnerable population. The prevalence of torture among refugee groups resettled in the United States varies with the population studied. For example, Jaranson et al. reported that the prevalence of torture in Somali and Oromo refugees in Minneapolis-St. Paul was 36% and 55%, respectively.[5] In a clinic-based survey of foreign-born patients presenting to an urban primary care clinic in Boston, 11% reported a history of torture.[6] Associated with a higher risk of torture were recent arrivals to the United States from the African and Asian continents.

When survivors of torture do seek medical care, it may be their first interaction with the healthcare system. Survivors may choose not to disclose their experiences due to fear of putting themselves and families in further danger, impairment of memory resulting from torture, cultural sanctions, or simply as a coping strategy.[7] Survivors of torture may have difficulty developing trust with healthcare providers, as one third to one half of survivors report that physicians oversaw their torture.[8] In one report, 6.6% (8/121) of foreign-born patients polled in a large urban clinic in the United States reported a history of torture, and none of these patients were recognized as torture survivors by the treating physicians.[9]

Torture is an assault of a person's mind, body, and sense of security, and may cause long-term physical and psychological effects. It is one of the most traumatizing of human experiences. Torture methods are often devised so that they leave minimal or no physical signs of torture after the fact, thus it is important for

providers to consider the possibility of torture in the appropriate clinical setting.[10]

Mechanisms of torture specific to the head and neck include, but are not limited to, beatings resulting in lacerations and facial fractures; cutting; burning (thermal and chemical); application of electric shocks to the tongue, lips, and ears; dental trauma; tympanic membrane rupture from deliberate hard slaps to the ears (known as teléfono); barotrauma from loud noises resulting in hearing loss; and near asphyxiation (e.g., waterboarding).[10] The physical symptoms and complications resulting from these forms of torture may require specialized evaluation and treatment by an otolaryngologist.

The objective of this report is to increase awareness of torture among otolaryngologists. This paper will specifically review prevalence of and methods of torture involving the head and neck. It will emphasize the importance of establishing rapport, obtaining a social history, and determining the method of torture to appropriately diagnose and adequately treat survivors of head and neck torture.

MATERIALS AND METHODS

A series of case reports of asylum seekers referred to the Boston Medical Center Department of Otolaryngology from the Boston Center for Refugee Health and Human Rights (BCRHHR) between May 2004 and December 2008 for evaluation and treatment of injuries to the head and neck as a result of torture in their home countries is presented. Cases included women and men $\geq$18 years of age who were survivors of torture by the United Nations definition. We describe the methods of torture, symptoms, physical exam, diagnosis, and treatment of these cases. Methods and manifestations of head and neck torture are reviewed. The institutional review board at Boston Medical Center approved the study.

RESULTS

Case 1

Patient 1 is a male in his mid-30s who fled from a Middle Eastern country after being persecuted for his religious affiliation. He was kidnapped and beaten for several hours, including sustaining blunt trauma to the head resulting in loss of consciousness. He was referred to the BCRHHR by his attorney for a forensic evaluation as part of his application for political asylum. Psychological manifestations of his torture included post-traumatic stress disorder (PTSD) and major depressive disorder. The patient complained of episodic dizziness lasting days to weeks, causing difficulty with ambulation and associated otalgia necessitating multiple visits to the emergency department. He did not relate the history of beating to his current symptoms, and was initially fearful of disclosing his symptoms. He worried that the gait imbalance that he experienced would cause people to suspect he was drinking alcohol, which was culturally taboo. The patient was referred by his primary care doctor to the otolaryngology clinic, where on physical examination, the patient was found to have normal cerebellar function, normal Romberg standard, and an abnormal Romberg tandem. With evaluation of gait, the patient was found to have normal gait with open eyes, but a slower, broad-based gait with closed eyes. Dix-Hallpike exam revealed right side down horizontal nystagmus for 10 seconds without latency, followed by rebound nystagmus on recovery of position. Otoscopic exam revealed normal external auditory canals and tympanic membranes bilaterally, however fistula test on the left was equivocal. Post-traumatic disequilibrium secondary to left oval window fistula was suspected, and vestibular and audiometric testing was ordered. Findings from the additional testing included left sensorineural hearing loss with otherwise negative electrocochleography (audiometric and vestibular). Because an oval window fistula was still suspected, the patient was taken to the operating room for exploratory tympanotomy, which revealed pooling of fluid around the oval window, confirming the diagnosis of an oval window fistula. Fat harvested from the pretragal tissue was used to repair the defect, and the graft was secured with Gelfoam. The patient is seen regularly for follow-up, and he has noted no return of the vertiginous symptoms since the repair. An affidavit in support of his asylum claim documenting his otolaryngolic injury was written by his primary care physician with input from the otolaryngologist, and the patient was granted asylum.

Case 2

Patient 2 is a female in her late 50s who fled from Central Africa after being beaten unconscious on two separate occasions for being a member of an opposition political party. Her primary complaint on presentation was excessive tearing, rhinorrhea, and a collapsed left nostril. She could not recall with what she was beaten, but she had significant scarring over her face and legs. She was referred to otolaryngology for further evaluation and treatment by her primary care physician at the BCRHHR. On physical exam, she had scarring of the left eyelid with retraction and mechanical lagophthalmos, multiple scars on her face with right medial canthus splitting, palpable old fractures at the left orbital rim, abnormal occlusion, thinned tissue over the right frontal bones, and decreased mobility of the right forehead. She was also noted to have nasal dorsum flattening, near total stenosis of the left nasal vestibule, and nasolabial fold scarring with displacement of the nasal spine. Neurological exam showed decreased mobility of the left frontalis muscle and paresthesias in the left ophthalmic and maxillary distributions. The patient was offered surgical repair of the nasal vestibular stenosis in addition to scar revision of the lower eyelid and right alar area. After discussing her options, the patient chose to defer treatment until the resolution of her legal issues. She has yet to return to clinic for follow-up. She suffers from cognitive impairment as a result of the head injury, in addition to PTSD and major depressive disorder, all of which complicate her medical care and her legal case. An affidavit documenting her head and neck injuries was presented to the court, and her case for political asylum was granted.

Case 3

Patient 3 is a male in his late 40s from Eastern Africa who was detained and tortured in his home country on multiple occasions because of his ethnicity. His people were persecuted, their villages pillaged, and the children abducted to serve in the army. He was arrested by the government and tortured (including beatings, electric shocks, and genital trauma). He sustained multiple injuries, including avulsion of his auricle with a sharp object and being forced to swallow it. He was seen by a primary care doctor in the BCRHHR, and referred to the otolaryngology clinic. He initially reported that his injuries resulted from a motor vehicle accident, but later admitted that his auricular injury actually occurred while confined in a torture camp. He was reluctant to disclose his torture history because of shame. His physical examination revealed a severed left ear with approximately two thirds of the superior helix and triangular fossa absent. The superior aspect of his external auditory canal was stenotic. The soft tissue was intact with a straight line laceration obliquely between the residual cartilage lobule and posterior auricular skin. The patient was felt to be a good candidate for reconstructive surgery. He underwent auricular reconstruction with a Medpor framework, temporalis fascia flaps, and a split thickness skin graft from the lower extremity. This patient suffers from PTSD and generalized anxiety disorder, requiring specialized psychiatric care. An affidavit documenting his head and neck injuries was submitted to the court, and he was granted political asylum.

Case 4

Patient 4 is a female in her mid-20s from a Middle Eastern country, who was strangled to unconsciousness and left in a bathtub where hot water scalded and burned her face and chest in a gender-based attack. It is not known whether chemicals were also used to enhance the extensive burn injury. When she awoke, she reported "there was no skin left on my face, it came off like soft cheese." She was hospitalized and did not regain consciousness for several months. She has undergone multiple reconstructive surgeries in several countries, and is seeking political asylum in the United States. Her examination revealed extensive scarring and contractures on her face, chest, and neck including extensive scarring of her eyelids. Prior surgeries including significant split thickness skin grafting to restore epithelial coverage to areas of debrided skin.

Case 5

Patient 5 is a male in his early 20s from Western Africa who was assaulted by a local government supported vigilante group that was heavily involved with theft, arson, and property damage. When he refused to join the organization, they retaliated by pouring acid on his face while he was sleeping.

He was seen by a primary care doctor in the BCRHHR and referred to the otolaryngology clinic for further examination of his injuries. He initially reported that his injuries had occurred as a result of a property dispute and that his brother had been responsible for the attack. Later, it was revealed his injuries were the result of vigilante violence. At the time the patient presented to the clinic, he had undergone partial auricular reconstruction at another institution. A Medpor graft had been placed to expand the right ear with a temporoparietal fascial flap 2 years earlier. He presented to us desiring to complete reconstruction. On physical exam, extensive burns were noted involving the right side of his face extending posteriorly to involve his scalp and inferiorly to involve the superior aspect of his lips. He had significant scarring and retraction of the upper and lower lids of his right eye, with opacification and injury to his cornea. He admitted to only being able to see shadows on the right side. There was a scar noted across the front of his scalp from a tissue expander. Examination of his right ear revealed cartilaginous structure under the scar and skin. No posterior sulcus or external auditory canal was visualized. After preliminary imaging was done, the patient was found to be a good candidate for completion of the reconstructive surgery. The patient underwent stage 3 reconstruction of his right ear with an otoplasty, lateralization of his auricle, and split thickness skin graft from his upper extremity. Postoperative follow-up revealed a patent right external auditory canal with an intact and mobile tympanic membrane. The patient was pleased with the outcome and reported improved hearing on his right side. His asylum claim is pending.

DISCUSSION

Head and neck trauma is frequently reported by torture survivors. Beating to the head is a common form of torture, with one report citing 73% of 200 survivors reported severe beatings to the head. In this series, vertigo was reported in 20%, of whom 87% had been beaten on the head.[11] Another study of 63 consecutive torture survivors in Denmark reported that 95% of the subjects had been beaten on the head and neck, and that 17% reported being subjected to teléfono. The most common presenting symptoms in this cohort were tinnitus, decreased hearing, impaired air passage through the nose, and dizziness. There was a significant relationship between teléfono torture and tinnitus.[12] Other common techniques of torture are listed in Table I.[13,14] The prevalence of torture survivors at our institution presenting with head and neck injuries requiring evaluation by an otolaryngologist is not known. The five cases in this report presented to care between May 2004 and December 2008; however, this sample does not include all survivors of torture with head and neck torture. Of 20 forensic evaluations completed by the first author (S.C.) in 2008, 12 (60%) had documented injuries involving the head and neck. These injuries included blunt trauma resulting in facial lacerations, loss of consciousness, a mandible injury requiring surgical repair, vertigo, dental avulsions; cutting wounds with a blade or knife to the face or lips; administration of electric shocks to the lips; extensive burns to the head and neck; and strangulation

TABLE I.
Most Common Types of Physical Torture[13]

The following is a list of the most common types of tortures experienced by survivors of torture:
Blunt trauma
Penetrating injuries
Suspension
Burns: chemical and thermal, cold and heat
Asphyxiation: wet, dry, chemical
Electric shocks
Forced human experimentation
Traumatic removal of tissue and appendages
Extreme physical conditions
Sexual trauma

injuries. Table II lists additional injuries and complications that can occur as a result of torture involving the head and neck.

Head and neck examination of the torture survivor should focus on the following findings:

Face

Fractures or soft tissue injuries can occur as a result of beatings to the head and neck. Scarring from lacerations, cutting wounds, or burns may be present after healing of the acute injury. Scars from trace electrical burns may be present on the ears, mouth, lips, or tongue. In addition, scars may be present on the lips or tongue from involuntary biting during the administration of electric shocks.

Nose/Paranasal Sinus

Examination of nasal structures and paranasal sinuses may reveal obvious pathology, such as a nasal fracture or a more subtle complication of torture, such as chronic sinusitis. Chronic sinusitis has been hypothesized to result following certain methods of torture. For example, Bangladeshi survivors who had been subjected to water treatments commonly reported complaints of chronic sinusitus.[15] Water treatment involves deluging a person's nasal cavity with hot or polluted water.[10,15] A torture technique known as submarino, which can be similar to water treatment, is a more common form of torture utilizing water. Wet submarino involves immersion of the head into fluids contaminated with urine and feces and drowning or near drowning a person. Aspiration of contaminated fluids leading to pneumonia is an immediate concern. With dry submarino, respiration is prevented by placing a plastic bag over the head, forcefully closing the oral and nasal passages, applying pressure over laryngeal structures, or forcing aspiration of various dusts, chemicals, or peppers.[10] Survivors may present with various complications ranging from facial edema/congestion, petechiae, bleeding, pneumonia, sinusitis, or other infection of the head and neck.[14]

Ears

Scarring on the tympanic membrane or any deformities to the external canal may be a significant finding related to a patient's history of torture. Teléfono, exercised in many regions, is a hard slap of the palm to the ears causing a rapid increase in pressure in the ear canal resulting in perforation of the tympanic membrane.[10] As small perforations heal quickly, these injuries may go unrecognized. Survivors may have been exposed to continuous loud music or noise at close range with resultant hearing loss. Survivors may also present with fluid in the middle ear, hearing loss, ossicular chain disruption, or fractures.

Oral Cavity, Pharynx, and Larynx

Dental torture, such as manual extraction of teeth and application of electrical current to the teeth, may cause a variety of complaints, including tooth avulsion or fracture. Survivors may present with mucosal swelling, bleeding, muscles spasms, and trismus or other limitations of jaw movement. Temporomandibular joint syndrome may develop as a result of beatings to the jaw.[10] Laryngeal damage may be the consequence of strangulation. Asphyxiation as a result of this pressure is another common method of torture that has a variable presentation, and may leave no physical sequelae. Laryngeal injuries may progress days later, leading to

TABLE III.
Questions When Inquiring About Experiences of Torture.

In what country were you born?
Can you tell me what made you leave your country?
Have you ever had problems because of your culture or tribe? Your political belief? Your religion? Your gender?
Have you ever been arrested or put in jail?
Have you ever been beaten or attacked by soldiers, police, or rebel groups?
Have you ever seen or heard others being beaten or attacked?
Have any members of your family been arrested or attacked because of their culture, tribe, political beliefs, or religion?
If a history of torture or trauma is elicited, what problems are you having now from being beaten or attacked?

airway obstruction or vocal cord dysfunction.[16] If cerebral anoxia is severe, the survivor may suffer loss of consciousness, seizures, and incontinence.[17] In addition, long-lasting cognitive dysfunction may result from anoxic brain injury.

Prior otolaryngolic injuries may go unrecognized if there are no obvious physical findings. Specific techniques are often utilized to limit long-term evidence of injury and thus, a detailed history of the injury, symptoms, and healing process becomes crucial for documentation.[10] Furthermore, survivors may be tortured early in their imprisonment, and by the time they are released from detainment and/or seek medical care in the country of asylum, physical signs of torture may have healed. Survivors may not be forthcoming about their history, and although many patients presenting to clinic will have visible or easily recognizable injuries, others will present with subtle complaints such as vertigo and sinus pain. Radiologic studies (plain films, computed tomography, magnetic resonance imaging, and scintigraphy) may be useful in the evaluation of torture survivors who have sustained head and neck torture, and results can be correlated with history and physical examination findings.[18] Scintigraphy can sometimes support a history of beatings even years after they occur.[19] Evaluation of survivors of torture will require both awareness and clinical judgment.

Several risk factors have been identified for torture including: refugee or asylee status, immigrant from a country where there has been civil war or a totalitarian or military regime, history of arrest or detention or prisoner of war, relative of a torture survivor, or leader of an opposition organization.[20] When treating members of these groups, otolaryngologists should consider that presenting symptoms may be the result of torture. This knowledge can inform the sensitivity with which the history and exam is conducted. As a result of the circumstances of the injuries, it may be necessary to proceed more slowly, and take breaks through the interview or examination. Table III lists questions that can be helpful when inquiring about experiences of torture.[21] In addition to the physical manifestations of torture, the prevalence of PTSD and depression are high among torture survivors.[22] These symptoms may include insomnia, nightmares, flashbacks, intrusive thoughts, and avoidance of triggers. Talking about one's history can potentially elicit an emotional response. Being vigilant in observing for signs of hyperarousal or re-experiencing (flashbacks, dissociation) is necessary so as to adjust the flow of the examination. Awareness of mental health issues, specifically PTSD, is an important preoperative consideration. One case report describes a torture survivor who had a postoperative course complicated by an emergence flashback. The patient was delirious, recapitulating her previous torture experience, and required relocation to a private room with a female nurse and implementation of grounding techniques.[23] Creation of a safe environment is an important consideration when caring for survivors of torture in the medical setting.

Providers should be aware that centers specializing in the care of survivors of torture exist and are available for referral, in addition to mental health providers who specialize in the care of trauma survivors. The BCRHHR works with survivors of torture and refugee trauma. The center is a member of the National Consortium of Torture Treatment Programs,[24] and operates as an interdisciplinary collaboration providing comprehensive medical, mental health, and dental care coordinated with legal and social services to individuals. A web course on caring for survivors of torture is available at www.bcrhhr.org.[25]

CONCLUSION

There are few reports in the literature that specifically address the topic of torture involving the head and neck. The manifestations are broad and depend on the torture method utilized. Otolaryngologists who see immigrant and refugee populations will see patients with sequelae of head and neck torture. Physicians may lack awareness of, or feel discomfort asking about torture. It is important that otolaryngologists are trained to recognize the signs and symptoms of torture, and make appropriate referrals to mental health specialists or specialized torture treatment programs. In addition, otolaryngologists may be asked to document injuries as part of the patient's application for asylum.

PEER REVIEWED

Abstract

Introduction

Better understanding of the health problems of refugees and people who are granted political asylum (asylees) in the United States may facilitate successful resettlement. We examined the prevalence of risk factors for and diagnoses of chronic disease among these groups in Massachusetts.

Methods

We retrospectively analyzed health screening data from 4,239 adult refugees and asylees who arrived in Massachusetts from January 1, 2001, through December 31, 2005. We determined prevalence of obesity/overweight, hypertension, coronary artery disease (CAD), diabetes, and anemia. Analyses included multivariate logistic regression to determine associations between CAD and diabetes with region of origin.

Results

Almost half of our sample (46.8%) was obese/overweight, and 22.6% had hypertension. CAD, diabetes, and anemia were documented in 3.7%, 3.1%, and 12.8%, respectively. People from the Europe and Central Asia region were more likely than those from other regions to have CAD (odds ratio, 5.55; 95% confidence interval, 2.95-10.47).

Conclusions

The prevalence of obesity/overweight and hypertension was high among refugees and asylees, but the prevalence of documented CAD and diabetes was low. We noted significant regional variations in prevalence of risk factors and chronic diseases. Future populations resettling in the United States should be linked to more resources to address their long-term health care needs and to receive culturally appropriate counseling on risk reduction.

Introduction

The United States has a longstanding humanitarian commitment to the resettlement of refugees from overseas. Each year, the number of people granted refugee and political-asylum status in the United States fluctuates based on variations in the stability of other countries, the global political climate, and domestic resettlement targets. The largest number of refugee admissions in 2008 was to the United States (68% of the 80,800 resettled refugees worldwide), but Australia, Canada, and Sweden had higher per capita admission rates (52.4, 32.5, and 24.3 refugees per 100,000 residents, respectively) than the United States (19.8 refugees per 100,000 residents) (1-3). In the 3 years from 2006 through 2008, the United States approved an average of 24,750 claims for asylum per year; the 3 leading countries of nationality (China, Colombia, and Haiti) together constituted 36.4% to 44.0% of all approvals (4).

Refugees and asylees (people who are granted asylum) are people outside of their country of origin who are unable

or unwilling to return to that country because they have experienced, or have a legitimate fear of, persecution on the grounds of race, religion, nationality, membership in a particular social group, or political affiliation (5). People who are granted refugee status and admission to the United States apply while overseas after having fled their home country or, for certain nationalities, while in-country. In contrast, people who seek political asylum do so either some time after entry into the United States or on arrival at a US port of entry. Historically, asylum applicants were in the United States for many years before being granted asylum because of delays in filing and processing asylum applications. Recently, this difference in time in the United States between refugees and asylees has lessened, in part because 1995 federal immigration legislation required potential asylees to file asylum applications within 1 year of arrival (6).

Because refugees and asylees differ in how long they have been in the United States, their countries of origin, and their socioeconomic circumstances, they likely have different health care needs. The Massachusetts Refugee Health Assessment Program (RHAP), a partnership between the Department of Public Health and contracted private, mostly federally qualified clinics, was established in 1995 to perform health screenings of refugees and other people who were eligible for refugee benefits. High rates of CAD in Russia include asylees, Cuban and Haitian entrants, certain Amerasians (mostly from Vietnam), and victims of human trafficking (7). Asylees were effectively denied access to RHAP services until 2000, when the starting date of time-limited eligibility for services was changed from the date of physical entry into the United States to the later date of asylum approval (8).

Domestic refugee health assessment programs, such as RHAP, have traditionally focused on identification and treatment of infectious diseases, although such programs also serve as a bridge to primary care. Few studies have focused on the screening of newly arrived refugees in the United States for chronic diseases, mental illness, or substance abuse, despite their relevance in these populations (9-14). Asylees may also be at risk of developing chronic diseases through acculturation while living as marginalized residents of low-income, urban neighborhoods in the United States before being granted asylum status.

The prevalence of chronic disease is high in many of the countries where refugees and asylees live before resettling in the United States. World Health Organization data show higher chronic-disease–related death rates in low- and middle-income countries compared with Canada or the United Kingdom (15). During the past 15 years, the largest group of refugees entering the United States has been from the nations that were formed from the former Soviet Union. Among this group, the Russian Federation in particular has seen growing mortality from preventable causes other than communicable disease, and cardiovascular disease is the leading cause of death (16). In the wake of the collapse of the Soviet Union, Russian life expectancy has declined as rates of nutritional deficiency and alcoholism have risen (17-19).

The changing demographics of both refugees and asylees entering the US health care system may result in greater health care needs for chronic, noninfectious diseases. However, programs designed to assess refugee health care needs are not generally structured to address chronic health problems. The objectives of this study were to determine the documented prevalence of risk factors for, and diagnoses of, chronic diseases among refugees and asylees who received RHAP health screening and to determine whether differences in prevalence of chronic disease and risk factors were associated with region of origin or visa category.

Methods

We performed a retrospective cross-sectional study using RHAP data from health screenings of asylees and refugees. For the purposes of this article, the term "refugees" includes people newly arrived in the United States from overseas (ie, true refugees), derivative asylees (ie, people arriving from overseas to reunite with immediate family members previously granted asylum in the United States), and Cuban, Haitian, and Amerasian special entrants. Eligible participants were aged 18 years or older, had entered the United States from January 1, 2001, through December 31, 2005, and had completed the RHAP screening (7). The institutional review board of Boston University Medical Center approved and monitored the conduct of this study, and the Massachusetts Department of Public Health approved the public release of this data analysis.

In the RHAP electronic database, the Massachusetts Department of Public Health maintains clinical and public health data on asylees and refugees, derived from official

government arrival notifications and RHAP reporting forms submitted by contracted health assessment clinical sites. Government arrival notifications are the source of basic demographic information (eg, patient age, sex, country of origin) and, in the case of refugees, medical diagnoses documented in reports from medical examinations performed overseas before arrival in the United States. RHAP reporting forms are the source of additional medical diagnoses and information obtained during refugee and asylee screening in the United States; they comprise a history and physical examination, immunizations, and a set of standard (eg, stool ova and parasites, complete blood counts, urinalyses) and optional tests based on individual health needs.

Risk factors for chronic disease included evidence of obesity (body mass index [BMI], ≥30 kg/m^2) or being overweight (BMI, 25.0-29.9 kg/m^2) and provider documentation of hypertension (including people with a single high blood pressure [systolic blood pressure ≥140 mm Hg] measurement) (20-22). Not all people with 1 elevated systolic blood pressure reading have true hypertension, but they require clinical follow-up because of their risk of hypertension. Chronic disease measures available for this study included provider documentation of CAD and diabetes (including evidence of glucosuria on urinalysis), and evidence of anemia (by hemoglobin values of <13 g/dL in men and <12 g/dL in women) (23).

In describing the population that used services, we first determined the number of refugees seen in RHAP from 2001 through 2005 by year of US entry and the number of asylees seen by year in which status was granted. We then described all people who completed RHAP screening by sex, visa category, age, and region of origin. The 5 regions of origin represented 92 countries.

For our main analyses, we determined the prevalence of obesity/overweight, hypertension, CAD, diabetes, and anemia, overall and by region of origin. We also determined the prevalence of obesity/overweight by age group. We used SAS version 9.1 (SAS Institute, Inc, Cary, North Carolina) to conduct multivariate logistic regression to examine associations of CAD and diabetes with being from the Europe and Central Asia region (including countries of the former Soviet Union and the former Yugloslavia), adjusting for age, sex, and BMI as covariates in the model. Visa category was not included in regression models because of the low numbers of asylees in the overall population and concerns about covariation of visa category with the more robust place-of-origin variable. Among refugees only, we also examined the proportion of documented diagnoses of CAD and diabetes that originated in reports from overseas medical examinations performed before US arrival and participation in RHAP screening.

Results

Of the 5,141 adult refugees and asylees with dates of entry from 2001 through 2005, RHAP documentation was available for 4,239 (82.5%) who completed health screening. Those who completed RHAP screening were similar to those who did not with respect to mean age (37.7 vs 36.5 years) and sex (49.8% vs 52.4% women). They differed in respect to country of origin (43.8% of completers vs 25.3% of noncompleters were from Europe and Central Asia) and visa category (11.2% of completers vs 13.5% of noncompleters were asylees).

The distribution of visa categories among people who received RHAP services varied by year of eligibility (Figure) and reflect the US allocations of visas each year (24). The reduced numbers of refugees from 2001 through 2005 reflect the government's limited processing of visa applications of refugees overseas after the September 11 terrorist attacks. The top 2 regions of origin of all people who completed RHAP screening were Europe and Central Asia and Africa (Table 1). Among the 3,765 refugees and the 474 asylees who completed RHAP screening, the top regions of origin respectively were Europe and Central Asia (47.8%) and Africa (52.7%). Compared with asylees, refugees had a higher mean (SD) age (38.8 [16.0] years vs 34.8 [10.5] years for asylees) and a slightly lower proportion of women (50.3% vs 52.7% of asylees).

We found differences in sex, visa category, and mean age by region of origin (Table 1). Women accounted for approximately half of asylees/refugees from all 5 regions. Asylees accounted for as little as 3.1% of people from Europe and Central Asia and as much as 28.5% of those from Latin America and the Caribbean. The mean age was highest for people from Europe and Central Asia and lowest for those from Africa.

Overall, almost one-fifth of this sample was obese, and more than one-fourth was overweight (Table 2). The largest proportions of obese and overweight people were

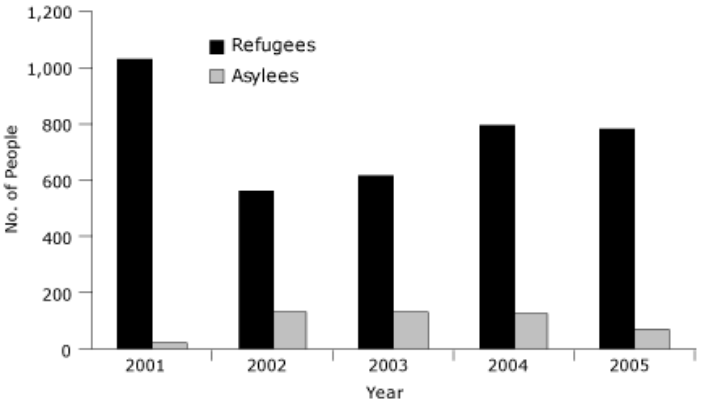

Figure. Distribution of refugees and asylees who received health assessment services in Massachusetts, 2001-2005 (N = 4,239).

from Europe and Central Asia. Among 18- to 49-year-olds, more than one-fourth were overweight and 15.9% were obese. Among 50- to 79-year-olds, 34.3% were overweight and 31.5% were obese. Almost one-fourth had hypertension diagnoses, again with documentation highest among people from Europe and Central Asia. Those from East and Southeast Asia had the lowest prevalence of obesity/overweight (3.6% and 21%, respectively) and the lowest prevalence of hypertension.

Documented chronic diseases varied by region of origin (Table 2). People from Europe and Central Asia contributed disproportionately to documented diagnoses of coronary artery disease (CAD). Anemia was highest among people from Africa and lowest among those from East and Southeast Asia.

In logistic regression models adjusting for age, sex, and BMI, people from Europe and Central Asia were significantly more likely than others to have CAD (adjusted odds ratio [AOR], 5.55; 95% confidence interval [CI], 2.95-10.47). Additionally, they were slightly less likely to have diabetes (AOR, 0.74; 95% CI, 0.49-1.13), but this latter finding was not significant.

Among the total of 157 diagnoses of CAD, 153 were among refugees rather than asylees. Most (81%) of these 153 refugee diagnoses had been entered in the RHAP database from overseas medical examination reports rather than from new findings during RHAP screening. Most (95%) of these 153 refugee diagnoses were among people from Europe and Central Asia. Among the total of 131 diagnoses of diabetes, 71 were among refugees. Almost half (49%) of these 71 diagnoses had been entered in the RHAP database from overseas medical examination reports. As with CAD, most (61%) of the 71 refugee diagnoses were among people from Europe and Central Asia.

Discussion

Region of origin was strongly associated with prevalence of risk factors for and presence of the chronic diseases assessed in this study, with the exception of diabetes. Associations with visa category were less consistent; however, because of their high concentration among people from Europe and Central Asia, refugees were significantly more likely than asylees to have certain risk factors or chronic diseases, particularly CAD. We found that almost one-fifth of our sample were obese, more than one-fourth were overweight, and almost one-fourth had hypertension. In comparison, the overall rates of documented CAD and diabetes were low. Refugees and asylees from the Europe and Central Asia region had the highest prevalence of obesity/overweight and hypertension and were more than 5 times more likely to have documented CAD compared with those from other regions. Regional differences in anemia prevalence in this young study sample were also apparent, suggesting other underlying chronic disease or nutritional deficiencies that varied by region.

Few studies of chronic disease among United States refugee populations exist, necessitating comparison of our findings with those of studies of immigrants as well as refugees. A recent study of 459 refugee psychiatric patients found the prevalence of hypertension and diabetes to be 42.0% and 15.5%, respectively (25). This was significantly higher than US norms and was especially pronounced in people younger than 65 years. Rates of obesity were also high, especially among Bosnians (54.5%), similar to our findings among people from Europe and Central Asia. In another study of Russian-speaking adult immigrants in New York, 53.8% had hypertension and 33.2% were obese, significantly higher prevalence rates than among other non-Hispanic whites after age adjustment (26). Lastly, in a nationally representative study of 6,421 adult immigrants with newly acquired legal permanent residence, the adjusted prevalence of obesity/overweight ranged from 36.5% to 65.9% for men and from 21.7% to 53.3% for women across all regions (27). The prevalence was lowest among men and women from Asia (similar to our study findings) and highest among men from the Latin America

and Caribbean region and women from the Middle East and North Africa region. Higher prevalence of risk factors and chronic diseases found in the studies above may be related to more acculturation to US lifestyle (28,29).

The low prevalence of CAD and diabetes found in our study may be accurate in this young population of primarily recently arrived refugees. It may also indicate inadequate time or resources for diagnosis of disease during either overseas or US health screening. Despite the overall low prevalence of CAD, the significantly increased likelihood of CAD among people from Europe and Central Asia compared with those from other regions may reflect the high burden of this disease in Russia, where cardiovascular disease is the leading cause of death (16). The latter may be due in part to high rates of smoking and hypertension in this region. One unexpected finding was the lower (but not significant) likelihood of diabetes in people from Europe and Central Asia compared with all other regions. This could be related to distinct differences in dietary patterns in Europe and Central Asia, including an increase in moderate alcohol consumption, which has been postulated in a meta-analysis of epidemiologic data on diabetes risk factors to reduce risk for development of type 2 diabetes (30).

One of this study's main strengths was the large sample size and demographic diversity of the refugees and asylees in Massachusetts. The large numbers of refugees and asylees in the RHAP database facilitated comparisons of the prevalence of risk factors and diagnoses of chronic diseases across regions of origin that could not have been done using a sample drawn from a single clinic. These comparisons are likely generalizable to other refugees and asylees resettling across the United States during the study period. However, they may be less generalizable to refugee/asylee populations entering the United States in other years because the regions of origin represented, as well as the diet and lifestyle patterns in a given region, may change over time.

The data available from the RHAP database were somewhat limited. Although refugees in the RHAP are typically seen within 90 days of arrival in the United States, it is likely that asylees had been in the United States for a longer time before RHAP screening, thus increasing chances of acculturation to US diet and lifestyle (7). However, data were not available to quantify these times more precisely. In addition, CAD, diabetes, and hypertension may have been underreported because these diagnoses were based on provider documentation either from overseas medical examinations or domestic health screening. On the other hand, we were able to extract more objective measures from the RHAP database to quantify obesity/overweight, elevated blood pressure, glucosuria, and anemia.

In summary, although rates of CAD and diabetes were low, this study found a high prevalence of risk factors for chronic disease such as obesity/overweight and hypertension. Findings suggest that refugees and asylees from Europe and Central Asia fall into a high-risk category. Future populations resettling in the United States should be linked to more resources to address their long-term health care needs and to receive culturally appropriate counseling on risk reduction. Further studies may shed more light on differences in risk among different subpopulations of refugees and asylees, but more programs are needed to help establish primary care after domestic health screening. Primary care will increase the overall health of these populations and the likelihood that they will be able to successfully integrate into United States society over time.

INNOVATION AND IMPROVEMENT

Tracking Abnormal Cervical Cancer Screening: Evaluation of an EMR-Based Intervention

INTRODUCTION: System level barriers have been associated with inadequate follow-up of abnormal cervical cytology.

OBJECTIVE: The aim of this study was to develop and evaluate an electronic tracking system to improve follow-up of abnormal Pap tests.

PROGRAM DESCRIPTION: We implemented an electronic medical record (EMR)-based Pap test tracking system at two clinical practices at an inner-city academic health center. The system generated a provider-specific monthly report of all abnormal Pap results, and provided a patient-specific Pap tracking table embedded in the EMR for each subject.

EVALUATION: We compared abnormal Pap test follow-up rates for the 24 months pre-intervention with rates 12 months following its implementation (post-intervention). The evaluation followed all subjects for 12 months from the date of their abnormal Pap test, looking for diagnostic resolution.

RESULTS: Subjects were young women (mean age = 30.5) of primarily white (42%) and African American (37%) descent, who spoke English (88%). Forty-eight percent were insured through publicly subsidized insurance. Controlling for type of abnormality and practice location, the adjusted mean time to resolution decreased significantly from 108 days (confidence interval, CI 105–112 days) in the pre-intervention period to 86 days (CI 81–91 days).

CONCLUSION: Our study cannot demonstrate that with follow up, we directly avoided cases of invasive cervical cancer. However, we show that in an at-risk urban population, an automated, EMR-based tracking system reduced the time to resolution, and increased the number of women who achieved diagnostic resolution.

INTRODUCTION

Screening for cervical cancer with a Pap test is only as successful as the follow-up rate for an abnormal result. If a patient has a Pap test, yet does not receive appropriate follow-up for an abnormal result, then the opportunity to prevent or treat pre cancerous lesions or cervical cancer is missed and the Pap test is ineffective. This is specifically an issue in lower income and minority populations who experience a higher risk of cervical cancer[1,2] and a higher rate of inadequate abnormal Pap test follow-up[3]. Multiple studies have documented the problem of inadequate follow-up of abnormal Pap tests[3–11].

AIM

With the advent of electronic medical record (EMR) systems, there is great potential to address inadequate follow-up from a systems point of view. We developed a tracking system for our internal EMR, and evaluated this tracking system as an intervention to improve adequate follow-up of abnormal Pap tests.

PROGRAM DESCRIPTION

We developed a tracking system that has two components:

1) A tracking report of abnormal Pap tests generated for the providers each month
2) A Pap test tracking table embedded in the EMR

The first component, the tracking report, identified potential cases by searching for Pap test orders placed by a provider in the EMR. An interface between the EMR and the pathology reports was developed and from these text fields created a document in the EMR. It was then possible to extract and track the cytology report corresponding to the day the order was placed. Pathology reports are provided in relatively standard text-only format which is scanned for specific phrases. Initially, work was done in coordination with the pathology department to determine standardized Pap test result language. In addition, all possible combinations of added spaces, added hyphens, and lower-case versus capitalized letters were accounted for so that abnormal test result would not be excluded. This process involved multiple iterations of comparing tracking reports directly from pathology, and adjusting the text parse filters to ensure capture of any missed results. Additionally, a hierarchy of abnormality severity was developed

Table 1. Field Provided in Monthly Provider Pap Test Tracking Reports

Demographic information:
• Practice location
• Provider name
• Subject medical record number (MRN)
• Subject name
Pap test information:
• Date of Pap test
• Result of Pap test
• HPV status (positive or negative, if tested)
• Result of LAST abnormal Pap test (if any)
• Date of LAST abnormal Pap test (if any)
Follow-up information:
• Date subject contacted of an abnormal result
• Method used to contact subject (eg. letter, phone call)
• Date of GYN follow-up appointment
• Status of GYN follow-up appointment (eg. future, arrived)
• Number of cancelled GYN appointments
• Practice location of GYN follow-up appointment

so that if a Pap result mentioned both ASCUS (atypical squamous cells of undetermined significance) and HGSIL (high grade squamous intraepithelial lesion), for example, then it would be labeled with the more severe abnormality (HGSIL).

Documented phone and letter contacts from standardized templates in the EMR were included with dates. Appointment data for this tracking report were extracted from another system that manages the outpatient clinic scheduling. Colposcopy appointment dates, location and status appeared on the report, including cancelled and no-show appointments. When a gynecologist performs a colposcopy, they use a standard colposcopy procedure template, which can therefore be tracked. A completed colposcopy was considered resolution of the screening Pap abnormality, and at this point the subject fell off the tracking report. The tracking reports were generated in spreadsheet format with the relevant provider and subject identifiers and results (Table 1). The report was cumulative, meaning that unresolved abnormal Pap test results remained on the report until resolved.

The second component of the tracking system was an individual Pap test tracking table within any individual subject record (see Fig. 1). This table showed the details of all past Pap test results, linked patient contacts, appointments and gynecology pathology results. The EMR tracking table gave providers efficient access to current Pap test status when seeing a patient in the office, and was another point of intervention during this visit.

The tracking reports were distributed to each provider monthly and included all of their patients who had had an unresolved Pap test abnormality (Fig. 2). We purposefully delayed the reporting of the abnormal Pap test results by one to two months to allow time for the subject to be contacted and for the colposcopy to be scheduled, and for the list to reflect patients with true delays. The standard manner for informing providers about their abnormal Pap tests did not change, where the Pap test result arrived directly in the ordering provider's EMR inbox for their review and action. Therefore, the paper tracking report serves as a second notice to providers of any abnormal Pap results, and highlighted patients who either did not keep or did not schedule a gynecology follow-up appointment, or who may never have

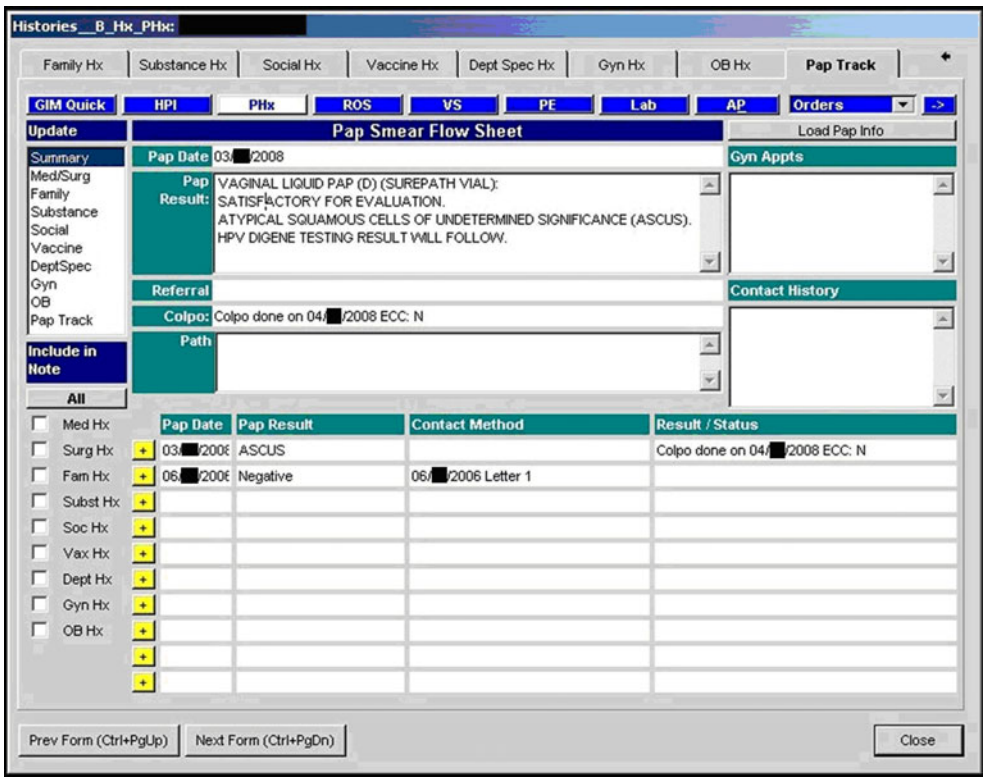

Figure 1. Example of an EMR Pap tracking table.

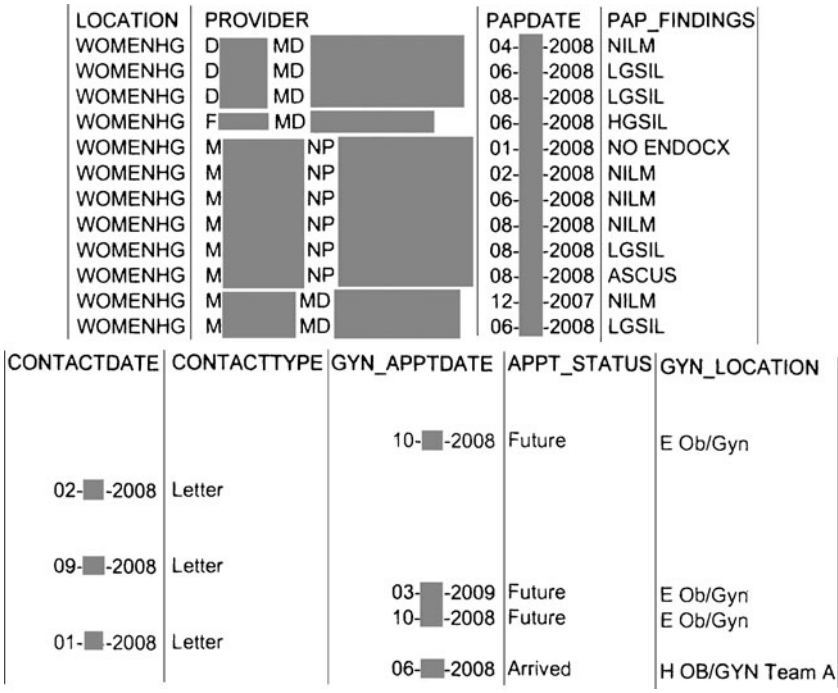

Figure 2. Example of a monthly abnormal Pap report.

been notified of their abnormal test results. Once the providers received copies of their individual Pap tracking reports there was no specific protocol about how they managed the information on these reports. No additional resources were given to providers to manage the information on the tracking reports.

EVALUATION

Study Design

We used a pre-test/post-test study design to evaluate whether implementation of a Pap tracking system 1) reduced the number of subjects with inadequate follow-up of abnormal Pap tests, and 2) reduced the time to follow-up. We compared inadequate Pap test follow-up rates prior to availability of the tracking system (pre-intervention) with inadequate follow-up rates following its implementation (post-intervention) at two clinical practices at an inner-city academic health center. The pre-intervention time period was December 2004 to December 2006. We allowed a 3-month implementation period for the tracking system, during which providers were trained and supported in its use. The tracking system was formally implemented on February 1, 2007 at one site, and April 1, 2007 at the second site. The post-intervention time period was therefore March 2007 to April 2008 for the first site, and May 2007 to June 2008 for the second site. All test results were followed for 12 months to determine if a diagnostic evaluation had been completed.

Study Subjects

Eligible subjects were 18 years of age or older, and had one of the following abnormal Pap test results:

1) Atypical squamous cells of undetermined significance with positive high-risk HPV serotype (ASCUS/HPV+)
2) Low-grade squamous intraepithelial lesion (LGSIL)
3) Atypical glandular cells of undetermined significance (AGC/AGUS)
4) Atypical squamous cells: cannot exclude high-grade squamous intraepithelial lesion (ASC-H)
5) High-grade squamous intraepithelial lesion (HGSIL)
6) Carcinoma in situ, or invasive cancer

Data Collection

We obtained an independent list from the pathology department of all abnormal Pap tests during the study time periods for each provider in the two clinical practices. Data were collected through retrospective electronic chart abstraction of all women with abnormal Pap tests, reviewed for 12 months following the abnormal test.

Independent Variables

Race/ethnicity was documented in the EMR as a single set of seven mutually exclusive responses, which we collapsed into "white," "black/African American" and "other." Primary language (nine categories) was collapsed into "English" and "non-English." Health insurance coverage was grouped into private, public and no insurance. The type of cervical abnormality was collapsed into ASCUS/HPV+, AGC/AGUS, LGSIL, HGSIL, and all others. We also included a dichotomous variable to indicate in which clinical practice the subject was seen.

Dependent Variables

The primary outcome for the study was timeliness of diagnostic resolution of the abnormal Pap test. Diagnostic resolution was defined as a definitive tissue diagnosis (biopsy with pathology), or a clinical evaluation determining that no further

[d] *HGSIL = high-grade squamous intraepithelial lesion*
[e] *ASC-H = atypical squamous cells: cannot exclude high-grade squamous intraepithelial lesion*

evaluation was necessary[12]. We evaluated the outcome both as a dichotomous and continuous variable. For the dichotomous variable, we categorized subjects as to whether they had received diagnostic resolution by 365 days. For the continuous variable, we defined follow-up as the number of days to diagnostic resolution, top coding those who did not resolve to 366 days.

Data Analysis

Our primary research question was whether there was a difference between the pre-intervention and post-intervention groups. We calculated and tested for the differences in median time-to-resolution using the one-way Wilcoxon test, differences in mean time-to-resolution using the t-test and differences in percentages using the chi-squared test. We used the Cox-proportional hazard method for univariate and multivariate hazard analyses of likelihood of resolving within 365 days. From the model we then calculated an adjusted mean time-to resolution and confidence intervals. Those predictors that were significant at the $p<0.10$ level in the bivariate analyses were included in the final multivariate models. All analyses were conducted using SAS v9.1 (SAS Institute, Cary NC).

RESULTS

Subject Demographics

Table 2 shows demographic and Pap abnormality characteristics for subjects in the pre-intervention period (n=137) and post-intervention period (n=69); 2.2% of the total 9164 Pap tests performed during the study time periods were abnormal. There were no statistically significant differences between the pre- and post-intervention groups in age, race/ethnicity, primary language, insurance status, or type of Pap abnormality (all $p>0.10$). Overall, subject characteristics reflected the low income and minority populations cared for at our institution, with 60% of subjects publicly insured or uninsured, and more than 50% from a racial or ethnic minority group.

Outcomes

Table 3 shows the pre- and post-intervention results for the two primary measures of diagnostic resolution. The bivariate comparisons did not show a statistically significant difference between the pre- and post-intervention period, although the direction of difference favored our hypothesis. In bivariate hazard analyses we found that the severity of cytologic abnormality and practice location were associated at the $p<0.10$ level and therefore included in the multivariable analysis. Age, race/ethnicity, language, and insurance status were not associated with the outcome. After multivariate adjustment for type of Pap abnormality and practice location, subjects in the post-intervention period were significantly more likely to ever

achieve diagnostic resolution (OR, 15.4; CI, 3.7–62) and more likely to achieve diagnostic resolution in a shorter period of time (HR, 1.40; CI, 1.03–1.9), relative to subjects in the pre-intervention period. The adjusted mean time to diagnostic resolution decreased from 108 days (CI 105–112 days) to 86 days (CI 81 to 91 days). Colposcopy results were similar between the two groups, (p=0.63) with 14% of women with CIN 2 or more severe lesions.

DISCUSSION

We developed and evaluated an EMR based tracking system for abnormal Pap tests, in order to assist providers in ensuring all abnormalities reached diagnostic resolution. We found that this tracking system significantly improved follow-up of abnormal Pap tests. Although many practices have developed electronic or paper tracking methods requiring manual entry, we report here on a novel method of incorporating the tracking within an electronic medical record that when initially developed had no intrinsic design features allowing this to happen.

Multiple studies have documented the problem of inadequate follow-up of abnormal Pap tests[3–11]. Leyden and colleagues looked at women diagnosed with cervical cancer from January 1995 to December 2000 in seven comprehensive health plans, and found that 13% of all cancers were attributed to inadequate follow-up of an abnormal Pap test[4]. Other studies have documented that 30–49% of women had either no follow up or delays beyond 3 to 7 months in abnormal Pap test follow-up in minority, uninsured or Medicaid-insured, or low income populations[3–11]. Systems specifically in safety net institutions that care for these communities are critical to improve follow-up rates and so improve effectiveness of cervical cancer screening. Our results are focused on resolution of abnormal Pap tests, and not in actual prevention of cervical cancer. Larger studies would be needed to demonstrate that such systems directly result in fewer women progressing to invasive cancer.

It is likely a combination of both systems and patient barriers that impede adequate abnormal Pap test follow-up. Patient barriers include difficulty in keeping follow-up appointments, limited understanding of the significance of the abnormality, and other life-issues taking priority. Systems barriers include failure of the provider to be aware of an abnormal result, and limited capability to systematically track patients who do not keep follow-up appointments. Our program addressed the systems barriers by giving providers tools to allow them to more easily track subjects after an abnormal Pap test. Our higher baseline follow up rates may already reflect some of the benefits of an EMR system; however, delays persisted without a tracking system.

Most of the EMRs used in outpatient medicine were developed with a focus on billing and require significant information technology development in data collection, synthesis and distribution to develop a tracking function. Our system required synthesis from multiple data sources, including scheduling, ordering, registration, and pathology. Data collection challenges included text-only fields in pathology reports; reports with standard result syntax or field based reports would avoid these pitfalls. Distribution of the reports was not automated, requiring that personnel adjust the programming and run the reports each month. Even during the intervention, changes to one part of the system resulted in difficulties and changes needed to access other parts of the system. Therefore, the system required some finite but constant resources to maintain, generate, and distribute the tracking reports. Despite these challenges, the system is in active use, and providers have reported satisfaction with the systems' ability to catch those cases that fall between the cracks. Most providers receive a monthly list of fewer than five patients. Of note, our work was supported through the medical center's risk management department, given the quality improvement benefits of the system. Given that many health care systems have adopted self insurance for malpractice, risk management funds might be a source to support other primary care initiatives for tracking and case management which improve quality of care and reduces risk[13].

One component of a medical home[14] is the ability to conduct population-based management of care, including tracking of abnormal screening test results. Our system serves as an example of the successful development and utilization of such a tracking system toward management of an entire practice. Our tracking system did not provide any additional assistance or personnel to the provider after they are given the monthly tracking report. Due to the relatively small number of abnormal Pap tests, providers were able to utilize existing staff personnel and their own efforts to ensure follow-up was achieved. This might be more of an issue if this tracking model was applied to a larger-volume abnormality, such as abnormal mammograms, cholesterol results, or glycosylated hemoglobin results in patients with diabetes. Additional resources, in terms of case management[15] or patient navigation[16], along with electronic tracking systems, have been employed to provide the additional follow through necessary when more frequent rates of an abnormality are expected, including phone or mail contact with patients, and rescheduling of missed appointments.

The Effectiveness of Tax Policy Interventions for Reducing Excessive Alcohol Consumption and Related Harms

Randy W. Elder, PhD, Briana Lawrence, MPH, Aneeqah Ferguson, MPA, Timothy S. Naimi, MD, MPH, Robert D. Brewer, MD, PhD, Sajal K. Chattopadhyay, PhD, Traci L. Toomey, PhD, Jonathan E. Fielding, MD, MPH, MBA, the Task Force on Community Preventive Services

Abstract: A systematic review of the literature to assess the effectiveness of alcohol tax policy interventions for reducing excessive alcohol consumption and related harms was conducted for the *Guide to Community Preventive Services* (*Community Guide*). Seventy-two papers or technical reports, which were published prior to July 2005, met specified quality criteria, and included evaluation outcomes relevant to public health (e.g., binge drinking, alcohol-related crash fatalities), were included in the final review. Nearly all studies, including those with different study designs, found that there was an inverse relationship between the tax or price of alcohol and indices of excessive drinking or alcohol-related health outcomes. Among studies restricted to underage populations, most found that increased taxes were also significantly associated with reduced consumption and alcohol-related harms. According to *Community Guide* rules of evidence, these results constitute strong evidence that raising alcohol excise taxes is an effective strategy for reducing excessive alcohol consumption and related harms. The impact of a potential tax increase is expected to be proportional to its magnitude and to be modified by such factors as disposable income and the demand elasticity for alcohol among various population groups.

Introduction

Excessive alcohol consumption is the third-leading actual cause of death in the U.S.,[1] and each year it accounts for approximately 79,000 deaths and 2.3 million years of potential life lost (about 29 years of life lost per death; apps.nccd.cdc.gov/ardi/Homepage.aspx). Excessive alcohol consumption contributes to a variety of health and social problems, including unintentional injuries (e.g., injuries due to motor vehicle crashes); suicide; homicide; liver cirrhosis; gastrointestinal cancers; vandalism; and lost productivity.[2] Alcohol consumption by underage drinkers also contributes to the three leading causes of death among adolescents (unintentional injuries, suicide, and homicide),[3] and any underage drinking is considered excessive.

One of the fundamental laws of economics is that quantity demanded of a product is inversely related to its price (Law of Demand).[4] Based on economic theory, therefore, increasing the price of alcohol would be expected to lower alcohol consumption. Alcohol taxes are promulgated primarily by federal and state governments, but can be instituted at the local or county level. Currently in the U.S., alcohol taxes are beverage-specific (i.e., they differ for beer, wine, and distilled spirits) and are usually "nominal" taxes, meaning they are based on a set rate per unit volume and are not adjusted for inflation (i.e., they generally remain stable as the cost of living increases). At the state and federal levels, inflation-adjusted alcohol taxes have declined considerably since the 1950s.[5] Concordant with this decrease in the real value of these taxes from substantially higher levels, the inflation-adjusted price of alcohol decreased dramatically,[6] reflecting the

fact that changes in taxes are efficiently passed on through changes in prices.[7] The goal of this systematic review is to assess the relationship between alcohol taxes or prices and public health outcomes related to excessive alcohol consumption to better inform decision makers about the potential utility of using tax policy as a means of improving those outcomes.

Healthy People 2010 Goals and Objectives

The intervention reviewed here is relevant to several objectives specified in *Healthy People 2010*, the disease prevention and health promotion agenda for the U.S. (Table 1).[8] The objectives most directly relevant to this review are those that aim to reduce excessive alcohol consumption (26-11); reduce average annual alcohol consumption (26-12); and reduce key adverse consequences of excessive alcohol consumption (26-1, 26-2, and 26-5 through 26-8). In addition to these specific objectives, *Healthy People 2010* notes that excessive alcohol consumption is also related to several other public health priorities such as cancer, educational achievement, injuries, risky sexual activity, and mental health; thus, a reduction in excessive alcohol consumption should help to meet some of the national goals in these areas as well.

Table 1. Selected *Healthy People 2010*[8] objectives related to excessive alcohol consumption

Adverse consequences of substance use and abuse
26-1 Reduce alcohol-related motor-vehicle fatalities[a]
26-2 Reduce cirrhosis deaths
26-5 Reduce alcohol-related hospital emergency department visits
26-6 Reduce the proportion of adolescents who ride with drinking drivers
26-7 Reduce intentional injuries resulting from alcohol-related violence[a]
26-8 Reduce cost of lost productivity due to alcohol use[a]
Substance use and abuse
26-10a Increase proportion of adolescents not using alcohol in past 30 days[a]
26-11 Reduce proportion of people[b] engaging in binge drinking
26-12 Reduce average annual alcohol consumption
26-13 Reduce proportion of adults who exceed guidelines for low-risk drinking

[a]Objective also relates to illicit drug use
[b]Aged ≥12 years

Recommendations from Other Advisory Groups

Several authors[9–12] have suggested that increasing alcohol prices by raising alcohol excise taxes is among the most effective means of reducing excessive drinking and alcohol-related harms. Increasing alcohol excise taxes has been specifically recommended as a public health intervention by the IOM, Partnership for Prevention, the WHO, and the expert panel convened for the Surgeon General's Workshop on Drunk Driving.[13–16] These recommendations are based on studies[14,17,18] showing that increased alcohol taxes are associated with decreased overall consumption, decreased youth consumption, decreased youth binge drinking, reduced alcohol-related motor-vehicle crashes, reduced mortality from liver cirrhosis, and reduced violence.

The Guide to Community Preventive Services

The current systematic review of the effects of alcohol taxes and prices on excessive alcohol consumption and related harms applies the stringent inclusion and assessment criteria of the *Guide to Community Preventive Services* (*Community Guide*).[19] It was conducted under the oversight of the independent, nonfederal Task Force on Community Preventive Services (Task Force), with the support of USDHHS in collaboration with public and private partners. The CDC provides staff support to the Task Force for development of the *Community Guide*.

To support efforts to address important public health priorities, such as reducing excessive alcohol consumption and its related harms, the Task Force makes recommendations for practice and policies based on the results of *Community Guide* reviews such as this one. These recommendations are based primarily on the effectiveness of an intervention in improving important outcomes as determined by the systematic literature review process. In making its recommendations, the Task Force balances information about effectiveness with information about other potential benefits and harms of the intervention itself. The Task Force also considers the applicability of the intervention to various settings and populations in determining the scope of the recommendation. Finally, the Task Force reviews economic analyses of effective interventions, where available. Economic information is provided to assist with decision making, but it generally does not affect Task Force recommendations. See the Task Force–authored paper in this issue for recommendations regarding the effects of alcohol taxes and prices on excessive alcohol consumption and related harms.[20]

Evidence Acquisition

Community Guide methods for conducting systematic reviews and linking evidence to effectiveness are described elsewhere[19] and on the *Community Guide* website (www.thecommunityguide.org/methods). In brief, for each *Community Guide* review topic, a systematic review development team representing diverse disciplines, backgrounds, and work settings conducts a review by (1) developing a conceptual approach to identify, organize, group, and select interventions for review; (2) developing a conceptual model depicting interrelationships among interventions, populations, and outcomes; (3) systematically searching for and retrieving evidence; (4) assessing and summarizing the quality and strength of the body of evidence of effectiveness; (5) translating evidence of effectiveness into recommendations; (6) summarizing data about applicability (i.e., the extent to which available effectiveness data might apply to diverse population segments and settings), economic impact, and barriers to implementation; and (7) identifying and summarizing research gaps.

Conceptual Model

The conceptual causal pathway by which increased alcohol taxes are expected to reduce excessive alcohol consumption and its related harms is depicted in Figure 1. The first step in this pathway posits that tax increases will be passed on to the consumer in the form of higher alcohol prices, as has been documented previously.[7] According to the Law of Demand,[4] an increased price would be expected to lead to a decrease in the quantity of alcoholic beverages demanded, resulting in decreases in excessive alcohol consumption and its harmful consequences. Details of the specific independent variables and outcome measures that reflect the concepts in this conceptual causal pathway are provided below.

One complicating factor in this conceptual model arises from the fact that different types of alcoholic beverages (e.g., beer, wine, and spirits) are taxed at different rates in the U.S. and several other countries. When tax increases affect one type of beverage only (designated as the "targeted" alcoholic beverage in Figure 1), one must consider the possibility of substitution effects, whereby alcoholic beverages that have not been affected by the tax increase may be consumed in greater quantities. To the extent that such substitution occurs, the overall rate of excessive drinking would not decrease as much as would otherwise be expected based on the decrease in quantity demanded for the beverage targeted by the tax increase. However, binge drinkers are known to prefer certain types of alcoholic beverages (e.g., most adult binge drinkers in the U.S. consume beer)[21] for reasons that may not be entirely related to price (e.g., availability, convenience, taste); thus, it is not clear whether and how large an effect beverage substitution would likely have on overall alcohol consumption, even when tax increases affect one beverage type only.

Conceptual model for the causal relationship between increased alcohol taxes and decreased excessive alcohol consumption and related harms (oval indicates intervention; rectangles with rounded corners indicate mediators or intermediate outcomes; and rectangles indicate outcomes directly related to improved health)

Review Inclusion Criteria

To be considered for inclusion in this review, candidate studies had to (1) meet minimum *Community Guide* standards for study design and quality[19]; (2) be published in an English-language journal, book chapter, or technical report; (3) be conducted in a high-income economy; and (4) evaluate independent variables and outcome measures of interest.

Independent variables of interest. In addition to the other criteria noted above, to be included in this review, a study had to evaluate either the effects of a

change in alcohol tax policy or the relationship between alcohol taxes or prices and outcomes of interest. Studies of the effects of alcoholic beverage prices were considered relevant to an evaluation of alcohol taxes because there is evidence that changes in alcohol taxes are passed on to the consumer in the form of higher or lower prices, with little or no lag time.[7] In fact, there is some evidence that tax increases may be magnified as they are passed on to the consumer. For example, when the federal excise tax on beer increased by $9 per barrel in 1991, it was estimated to have increased retail prices by $15 to $17.[7]

Outcome measures of interest. The outcome measures of interest in this review are direct measures or proxies relating to the two final boxes in Figure 1—that is, excessive alcohol consumption and the harmful consequences of such consumption. When excessive alcohol consumption is assessed directly, it is typically done through surveys assessing either the prevalence or frequency of binge drinking (four or more drinks per occasion for women, or five or more drinks per occasion for men); heavy drinking (more than seven drinks per week for women, or more than 14 drinks per week for men); or underage drinking (defined by state or national laws). Measures of societal levels of alcohol sales or consumption were also considered an acceptable proxy for excessive consumption for two primary reasons. First, there is an extremely strong relationship between per capita alcohol consumption and various measures of excessive drinking.[22,23] Furthermore, because people consuming greater quantities of alcohol may be more sensitive to price increases, reductions in societal levels of alcohol consumption subsequent to price increases may result in even larger declines in excessive consumption.[22]

In addition to studies directly or indirectly assessing excessive alcohol consumption, studies assessing health-related outcomes associated with excessive alcohol consumption (e.g., alcohol-related motor-vehicle crashes) were also included in this review. In some cases, a single paper reported multiple measures of a single general outcome (e.g., both single-vehicle nighttime crashes and total crashes reported as measures of alcohol-related crashes). In these instances, the measure that was most strongly associated with excessive alcohol consumption based on estimated alcohol-attributable fractions was chosen as the primary result reported for that outcome.

Search for Evidence

Conducting a thorough search for studies of the effects of alcohol taxes or alcohol prices is challenging because the effects of alcohol taxes or prices are often studied in conjunction with many other variables. As a result, a search that targets "tax" or "price" may fail to identify many relevant studies. To address this issue, a search was conducted for relevant studies as part of a broad database search for terms related to several alcohol policy interventions of interest to the current review group, covering the period from database inception through July 2005. Using MeSH terms and text words, the following databases were searched: MEDLINE, EMBASE, PsycINFO, the ETOH database of the National Institute on Alcohol Abuse and Alcoholism, Web of Science, Sociological Abstracts, and EconLit. Search strategies are available at www.thecommnityguide.org/alcohol/supportingmaterials/SSincreasingtaxes.html. The reference lists of prior literature reviews, as well as reference lists from studies included in this review, were used to identify additional relevant articles. The search produced 5320 potentially relevant papers, of which 78 met the inclusion criteria.

Data Extraction and Quality Assessment

For each candidate study, study characteristics and results were recorded, and the quality of study execution was assessed. The degree to which a study's basic design protected against threats to internal validity was rated using a three-level classification system ranging from least suitable (for designs with a cross-sectional analysis or a single observation before and after an intervention) to greatest suitability (for designs with concurrent comparison conditions).[19] Ratings of the quality of each study's execution provided further information on their utility for the purposes of the review. Quality of study execution was assessed using a standard 9-point scale, reflecting the total number of identified limitations to internal or external validity (viz. study population and intervention descriptions, sampling, exposure and outcome measurement, data analysis, interpretation of results, and other biases). Studies with zero or one limitation were categorized as having good execution, those with two to four limitations had fair execution, and those with five or more limitations were categorized as having limited execution.[19] Studies with limited execution were excluded from further analysis.

Effect Measurement and Synthesis of Results

The most common method for studying the effects of alcohol taxes on alcohol-related outcomes is to assess how they (or the prices they influence) relate to those outcomes over time, while controlling for potential confounding factors. For most of the studies in this review, the reported results were either directly reported as elasticities or were transformed into elasticities. These were then directly compared with elasticities calculated from other studies. An elasticity represents the percentage change in a dependent variable associated with a 1% increase in an independent variable (e.g., price or tax rate). For example, a price elasticity of −0.5 means that a 10% increase in price would be expected to result in a 5% decrease in the outcome of interest. Tax elasticities have a similar interpretation, but cannot be directly compared with price elasticities because taxes represent only a fraction of the total purchase price (resulting in smaller values for tax elasticities). In most cases for which

elasticities were not reported in the original studies, only the direction and significance of the reported effects could be evaluated in this review.

Because elasticities are measures of relative change, they provide a common metric for comparing and aggregating related, but not identical, outcomes (e.g., different measures of alcohol consumption; different types of motor-vehicle crashes). In general, measures of alcohol consumption fell into two broad categories: those that evaluate indices of consumption at the societal level (e.g., total alcohol sales) and those that evaluate consumption at the individual level (e.g., self-reported binge drinking). Measures of alcohol-related harms were grouped into broad categories of related outcomes, such as motor-vehicle crashes, liver cirrhosis, violence, alcohol dependence, and all-cause mortality.

For most of the outcomes of interest in this review, results were synthesized descriptively, without the use of any summary effect measures, due to a substantial amount of variation in the specific outcomes assessed and in the units used to measure the effects of changes in taxes or prices. The only outcome for which both enough studies and sufficiently similar results were found to allow a quantitative synthesis of the results was societal-level alcohol consumption. Data from these studies were summarized graphically and by using descriptive statistics, specifically medians and interquartile intervals. These results were also stratified on several variables considered by the review team to be potentially important effect modifiers (e.g., study design), allowing for an assessment of the robustness and generalizability of the results. This approach to synthesis was primarily chosen for the following two reasons. First, because many of the included studies had some overlap with respect to the locations and time periods covered in their analyses, their results were not completely independent. Second, many of these studies did not report results in a way that allowed for the calculation of CIs for their elasticities.

For studies that reported stratified results (e.g., separate price elasticities for beer, wine, and spirits), the median value across the relevant strata reported in that study was used for the calculation of summary statistics. This approach prevented studies that reported multiple outcomes from having undue influence on the summary statistics.

Evidence Synthesis

Description of Included Studies

A total of 78 papers[24–101] reported on studies that met the review inclusion criteria. Only some of the outcomes from one study[83] were included because not all of its analyses met quality of execution criteria. Five other studies[70,88–91] were excluded from the review because they failed to meet quality of execution criteria. Detailed descriptions of the included studies are available at www.thecommunityguide.org/alcohol/supportingmaterials/SETincreasingtaxes.html.

Most studies assessed total alcohol consumption at the societal level (i.e., per capita alcohol consumption). The design of these studies varied across countries. Most studies conducted outside the U.S. used interrupted time–series designs, because alcohol taxes in other countries tend to be set at the national level, and as such, it is generally not possible to do intra-country comparisons. In contrast, most of the U.S. studies used a panel study design, in which multiple states were assessed over time, allowing each to serve as a comparison for the others. These studies included both those that accounted for between-state differences using a fixed-effects approach (whereby stable between-state differences are controlled for by dummy coding) and those that used a random-effects approach (whereby between-state differences in variables other than tax or price are controlled for by including important predictors of alcohol consumption in the model). The remaining studies assessed measures related to excessive drinking (e.g., the prevalence of underage or binge drinking) or alcohol-related harms, the most common being outcomes related to motor-vehicle crashes.

Intervention Effectiveness

Alcohol price and overall consumption. Of the studies in the review, 50 assessed overall alcohol consumption; 38 (76%) of these reported price elasticities[25,27,33–38,40,43,45,47,48,52,53,57,63,65,67,71,73,74,77,78,80–82,84,92–95,97] (six of these studies came from one paper[80] that calculated elasticities for multiple countries). Almost all of these 38 studies (95%) reported negative price elasticities, indicating that higher prices were associated with lower consumption. These results were quite consistent across beverage type, with median elasticities ranging from −0.50 for beer to −0.79 for spirits (Figure 2). Similarly, interquartile intervals for beer, wine, and spirits were also consistent across beverage type, with the 25th percentile elasticity ranging from −0.91 to −1.03, and the 75th percentile ranging from −0.24 to −0.38. Results for studies of overall ethanol consumption across beverage types were somewhat more variable because of the presence of several outliers with very large elasticities; for this outcome, the 75th percentile was comparable to that for the other outcomes (−0.50), but the 25th percentile had a substantially larger absolute value (−2.00).

As indicated in Table 2, the price elasticities reported in the reviewed studies were also quite consistent when evaluated by study characteristics (i.e., design suitability, model type, time period, and location). Across all of the nine strata examined, median elasticities ranged from −0.51 to −0.90, the 25th percentile elasticities ranged

from −0.78 to −1.10, and the 75th percentile elasticities ranged from −0.32 to −0.50. The most notable differences in elasticities across strata were among panel studies that used fixed- versus random-effects regression models. In general, fixed-effects models tended to produce elasticities of slightly smaller magnitude than did random-effects models. This might be expected because the elasticities from fixed-effects models do not account for between-state differences in taxes that are stable over time (although these models have several other desirable qualities).

Of the 50 studies that assessed overall alcohol consumption, 12 studies[29,31,32,39,41,49,54,75,76,83,98,99] assessed the relationship between price and overall consumption, but these studies did not provide price elasticities or sufficient information to calculate them. Many of these studies reported the results of multiple analyses that produced separate results for different subpopulations, beverage types, or analytic models with different parameters. In eight of these studies,[29,31,32,39,41,54,76,83] all of the reported results indicated that higher prices were associated with lower alcohol consumption; in seven,[29,31,32,39,41,54,83] results were significant across all analyses, and one[76] had results of mixed significance across analyses. The other four studies[49,75,98,99] had mixed results across beverage types or analytic models, with some results in the expected direction and some in the opposite direction.

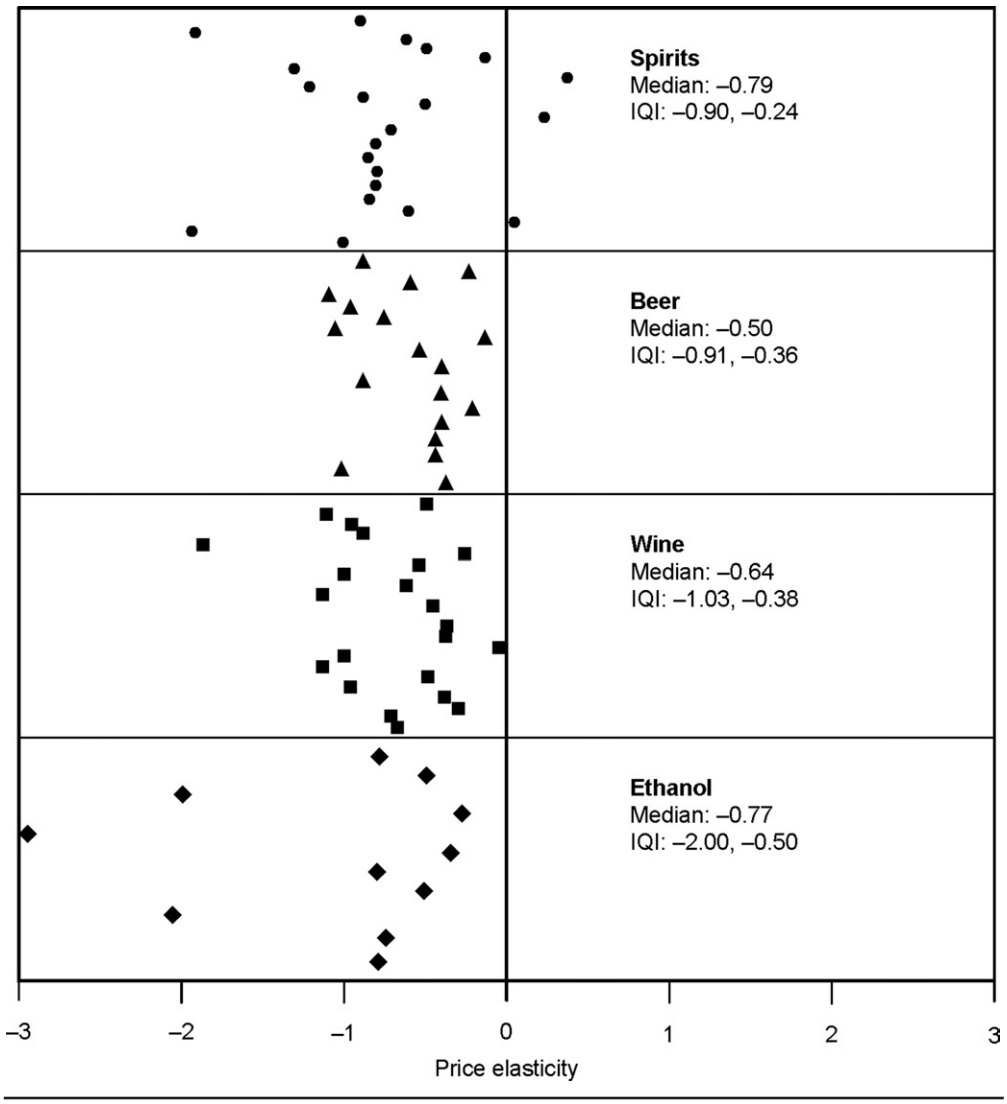

Figure 2. Scatterplot showing the association between alcohol price elasticities and excess consumption as measured by societal alcohol consumption. Each data point represents a single study's elasticity estimate for the given beverage type.
IQI, interquartile interval

Alcohol price or taxes and individual consumption patterns. Sixteen studies[24,46,53–56,58–62,64,68,72,96,102] in the review used survey data to evaluate the effects of alcohol prices or taxes on individual alcohol consumption patterns. Most of these studies assessed the prevalence of alcohol consumption among youth aged <25 years, primarily underage youth. Respondent groups included high school students, college students, young people in the general population, and adults in the general population. All but two of these studies[54,59] were conducted in the U.S.

Of the nine studies[24,46,56,58,60–62,64,68] that assessed the relationship between alcohol price or taxes and drinking prevalence among young people, six[46,56,58,60,61,68] consistently indicated that higher prices or taxes were associated with a lower prevalence of youth drinking (four with one or more significant findings). Three of these studies reported price elasticities: −0.29 for drinking among high school students;[46] −0.53 for heavy drinking among

Table 2. Medians and interquartile intervals for price elasticity of alcohol consumption, stratified by study characteristics

Characteristic (no. of studies)	Median elasticity	Interquartile interval
Design suitability		
Greatest suitability (16)	−0.76	−1.06 to −0.50
Moderate suitability (16)	−0.51	−0.85 to −0.39
Least suitable (6)	−0.68	−0.94 to −0.32
Model type		
Random effects (7)	−0.90	−1.10 to −0.50
Fixed effects (8)	−0.69	−0.78 to −0.40
Time period[a]		
Before 1963 (19)	−0.61	−0.90 to −0.38
1963 or later (19)	−0.76	−0.89 to −0.44
Location		
U.S. (21)	−0.63	−0.90 to −0.44
Non-U.S. (17)	−0.68	−0.88 to −0.37

[a]First data point in time–series

those aged 16–21 years[58]; and −0.95 and −3.54, respectively, for binge drinking among men and women aged 18–21 years.[61] The three remaining studies[24,62,64] reported mixed results across different analyses, with the majority of their effect estimates indicating an inverse relationship between tax or price and drinking observed in the studies above.

The nine studies that assessed the relationship between price or taxes and alcohol consumption patterns in adults or in the general population also generally found that increasing the prices or taxes on alcoholic beverages was associated with a lower prevalence of excessive alcohol consumption and related harms. Two of these studies assessed the relationship between alcohol price and the prevalence of binge drinking using data from the National Longitudinal Survey of Youth, which followed a group of people aged 14–22 years in 1979.[55,68] In a cohort of those aged 25–26 years from this survey, higher prices were associated with significant decreases in both overall alcohol consumption and frequent binge drinking (more than four episodes per month).[68] However, in a subsequent study of a cohort of those aged 29–33 years, higher prices were not significantly associated with the overall prevalence of binge drinking, and the direction of effects varied across beverage types.[55] Other studies based on surveys of the general adult population found that higher alcohol prices were associated with a lower overall prevalence of current drinking[72] and binge drinking,[53,72,102] and with a lower frequency of binge drinking.[53,72,96,102]

Three studies reported elasticities for the relationship between price and binge drinking; these ranged from −0.29 to −1.29, levels that are comparable to those for overall societal-level consumption.[53,61,96] Two additional studies evaluated a tax change in Switzerland that resulted in a 30% to 50% decrease in the price of imported spirits.[54,59] These studies found that the change was associated with a small (2.3%) increase in the prevalence of any drinking, and larger increases in measures of excessive alcohol consumption, specifically binge drinking (3.4%) and heavy drinking (9.3%). It is also noteworthy that the most marked increases in spirits consumption occurred among young men.

In summary, most studies that were included in this review found that higher taxes or prices were associated with reductions in alcohol consumption in general and excessive alcohol consumption in particular. Although these effects were not restricted to a particular demographic group, there is some evidence that they may be more pronounced among groups with a higher prevalence of excessive alcohol consumption (e.g., young men).

Alcohol price or taxes and alcohol-related harms. Twenty-two studies in the review evaluated the effects of changes in alcohol price[28,44,51,61,72,83,93,100] or taxes[24–26,29–31,66,69,85–87,98,101,103] on various alcohol-related harms. The most common outcomes evaluated were motor-vehicle crashes (including crash fatalities), various measures of violence, and liver cirrhosis. The studies were primarily conducted in the U.S., using state-level data.

Motor-vehicle crashes and alcohol-impaired driving. Eleven studies evaluated the effects of alcohol price[44,72,93,100] or taxes[24,26,29,30,86,98,103] on motor-vehicle crashes (Table 3). These studies found that the relationship between alcohol prices or taxes and injuries and deaths due to motor-vehicle crashes was generally significant and of a comparable magnitude to the relationship between these variables and alcohol consumption. The numeric values of the reported elasticities are substantially higher for studies that assessed the effects of alcohol prices than for those that assessed changes in alcohol taxes. This reflects the fact that taxes represent a relatively small proportion of the total purchase price of alcoholic beverages, so a larger proportional increase in taxes is necessary to achieve the same effect on the final purchase price of alcoholic beverages as a smaller proportional increase in the price itself. The reported elasticities were also generally higher for studies that assessed outcomes more directly attributable to alcohol consumption (e.g., alcohol-related crashes) than to those for which the relationship to alcohol consumption was less direct (e.g., all crash fatalities).

Three studies evaluated the relationship between alcohol prices[44,61] or taxes[66] and self-reported alcohol-impaired driving. These studies consistently found that alcohol-impaired driving was inversely related to the price of alcoholic beverages. The estimated price elasticities were similar for samples of Canadian[44] and U.S.[61] adults (range of −0.50 to −0.81; all $p<0.05$). The U.S. study stratified their sample by age in addition to gender, and reported price elasticities of −1.26 to −2.11 (both with $p<0.05$) for men and women aged 18–21 years, respectively.[61] The estimated tax elasticities from the remaining study were substantially larger for women than men (−0.29 vs −0.06), but neither estimate was significant.[66]

Table 3. Results of studies evaluating the relationship between alcohol prices or taxes and motor-vehicle crashes

Study	Independent variable	Dependent variable	Elasticity (*p*-value)
Price elasticity studies			
Cook (1981)[93]	Ethanol price[a]	Fatalities	−0.70 (NR)
Adrian (2001)[44]	Ethanol price[a]	Alcohol-related crashes	−1.20 (<0.05)
Sloan (1994)[72]	Ethanol price[a]	Fatalities	<0 (>0.05)
Whetten-Goldstein (2000)[100]	Ethanol price[a]	Alcohol-related fatalities	<0 (>0.05)
Tax elasticity studies			
Chaloupka (1993)[26]	Beer tax	Alcohol-related fatalities, all ages	−0.097 (<0.05)
	Beer tax	Alcohol-related fatalities, youth aged 18–20 years	−0.156 (<0.05)
Evans (1991)[86]	Beer tax	Single-vehicle nighttime fatalities	−0.12 (<0.05)
Ruhm (1996)[30]	Beer tax	Nighttime fatalities, youth aged 15–24 years (by age)	−0.18 (<0.05)
Saffer (1987)[42]	Beer tax	Fatalities, youth aged 15–24 years (by age)	−0.18 to –0.27 (all <0.05)
Ruhm (1995)[29]	Beer tax	Fatalities	<0 (<0.05)
Mast (1999)[98]	Beer tax	Fatalities	<0 (>0.05)
Dee (1999)[24]	Beer tax	Nighttime fatalities, youth aged 18–20 years	>0 (>0.05)

[a]Average price per ounce of ethanol across beer, wine, and spirits

Non–motor-vehicle mortality outcomes. Six studies evaluated the effects of alcohol price[25,28,72,83,93] or taxes[31] on nontraffic deaths. Despite substantial variability in their individual effect estimates, all six studies found that higher alcohol prices were associated with decreased mortality.

Five studies evaluated the relationship between alcohol prices and deaths from liver cirrhosis.[25,28,72,83,93] The two studies that reported results as elasticities produced substantially different elasticity estimates for this outcome, −0.90 ($p<0.05$)[93] and −0.01 ($p>0.05$).[28] Results of another study indicated that a $1 increase in the spirits tax would lead to a 5.4% decrease in cirrhosis ($p<0.05$).[25] Another found a nonsignificant effect in the expected direction.[72] The final study found a strong correlation of −0.87 between alcohol prices and cirrhosis deaths.[83] Although all of these studies indicate a consistent relationship between higher prices and lower cirrhosis mortality, there are substantial differences in the estimated strength of this relationship, which may be due to methodologic differences among studies.

One of the studies that evaluated cirrhosis mortality also assessed the relationship between alcohol price and several other causes of death.[72] The researchers found that there was a significant ($p<0.05$) inverse relationship between the price of alcoholic beverages and deaths from alcohol-related cancers (e.g., breast cancer) and suicide, and a nonsignificant ($p>0.05$) relationship between alcohol prices and deaths from homicides, falls, fires/ burns, and other injuries. Although these findings are surprising given the stronger relationship between alcohol consumption and intentional and unintentional injuries, the findings were robust across several regression models.

One study assessed all-cause mortality using a two-stage process.[31] In the first stage, the authors assessed the relationship between alcohol taxes and sales, and found that a one-cent increase in taxes per ounce of ethanol (a tax increase of approximately 10%) would be expected to result in a 2.1% decrease in sales. In the second stage, they found that a 1% decrease in alcohol sales was associated with a 0.23% decrease in all-cause mortality rates ($p<0.05$).

Violence outcomes. Three additional studies found that higher alcohol taxes are associated with decreased violence.[69,85,101] When the differences among tax and price elasticities are taken into account, the strength of the relationships reported in these studies were comparable to those found for alcohol consumption outcomes. The first

study estimated that beer tax elasticities on violent crime rates in the U.S. were −0.03 ($p>0.05$) for homicide; −0.03 ($p>0.05$) for assault; −0.13 ($p<0.05$) for rape; and −0.09 ($p<0.05$) for robbery.[101] The other two studies assessed the relationship between beer taxes and violence toward children, with different methods using overlapping samples. In the first analysis,[69] tax elasticities were −0.12 ($p<0.05$) for any violence toward children and −0.16 ($p<0.10$) for severe violence toward children. The subsequent analysis found that these results appeared to be due to an influence of taxes on violence by women but not by men.[85]

Other outcomes. Two studies evaluated the association between alcohol prices and two other health-related outcomes: alcohol dependence and sexually transmitted diseases. The first estimated an alcohol price elasticity for alcohol dependence of −1.49 ($p<0.05$).[51] The second used multiple methods of evaluating the effect of tax changes on sexually transmitted diseases, and found robust effects on rates of both gonorrhea and syphilis.[87]

Applicability

The Law of Demand[4] states that the inverse relationship between the price of a commodity and the quantity demanded is almost universal, and that only the strength of this relationship will vary across commodities or population groups. Consistent with these expectations, estimates of price elasticity for societal levels of alcohol consumption were robust across the various high-income economies in North America, Europe, and the Western Pacific Region evaluated in the studies in this review. Although results for harms related to excessive consumption came primarily from the U.S. and Canada, these findings are likely to be broadly applicable across high-income countries.

One important factor hypothesized to affect the strength of price elasticities for alcohol across different population groups is disposable income. Specifically, groups with less disposable income, such as underage drinkers, may be expected to be more sensitive to changes in alcohol prices than those with more disposable income.[104] Unfortunately, based on the studies in this review, it was not possible to determine whether alcohol price elasticities differ significantly on the basis of age or income. Furthermore, although the reviewed studies provided evidence that changes in alcohol prices affect excessive consumption (e.g., the prevalence and frequency of binge drinking), the available data were not adequate to assess potential differences in price elasticities based on drinking pattern (i.e., between excessive and nonexcessive drinkers).

Economic Efficiency

Our systematic economic review identified two studies that estimated the cost effectiveness of alcohol tax intervention based on modeling.[10,105] The first study[105] assessed the costs and outcomes of 84 injury prevention interventions for the U.S. and found that an alcohol tax of 20% of the pretax retail price offered net cost savings (i.e., the savings outweigh the costs) even after taking into account the adverse economic impact of reduced alcohol sales. The second study[10] analyzed the comparative cost effectiveness of alternative policies to reduce the burden of hazardous alcohol use for 12 WHO subregions and found that taxation was the most effective and cost-effective intervention in populations with a 5% or greater prevalence of heavy drinkers. The costs associated with this intervention included the cost of passing the legislation itself, and the cost of administering and enforcing the laws once they are passed. Effectiveness was assessed using disability-adjusted life-years (DALYs), a standard measure of global health impact that considers the impact of an intervention on healthy years of life lost as a result of either death or disability. For the Americas A region, consisting of the U.S., Canada, and Cuba, which is the region most relevant to this review, the intervention costs for current taxation were $482,956 (converted to 2007 dollars using the Consumer Price Index) per 1 million population per year, based on a 10-year implementation period and discounted at 3% per year to reflect the time value of money. The cost was assumed to stay the same when the tax was increased by 25% or 50%. Current taxes were estimated to prevent 1224 DALYs per 1 million population per year, yielding an average cost-effectiveness ratio for this intervention of approximately $395 per DALY averted. This is much less than the average annual income per capita in these three countries, a threshold for an intervention to be considered very cost effective that was proposed by the Commission on Macroeconomics and Health.[106] The DALYs averted increased to 1366 and 1489 per 1 million population per year when taxes were increased by 25% and 50%, respectively. Because these incremental DALYs averted could be achieved without any increase in costs, these increases in taxes improve cost-effectiveness estimates relative to the current tax scenario. To obtain country-specific estimates of the DALYs saved per country as a result of this intervention, the regional analysis needs to be adjusted using country-specific data. Such estimates are limited by the assumptions made and the data available.

Barriers to Implementation

The level of taxation of alcoholic beverages has economic effects on several groups, including federal,

state, and local governments; affected industry groups; and the general population of alcohol consumers. Whereas raising alcohol taxes may provide an important source of revenue for governments, such tax increases may be resisted by some industry groups and consumers. However, public support for increased alcohol taxes increases substantially when tax revenues are specifically directed to fund prevention and treatment programs instead of being used as an unrestricted source of general revenue.[107]

Other Benefits or Harms

In addition to the direct public health outcomes evaluated in this review, the primary benefit of increased alcohol excise taxes is that they can provide a source of revenue to support programs to prevent and treat alcohol problems. They also can provide some compensation for the societal costs associated with excessive alcohol consumption that are not borne by the drinker (i.e., "external" costs). Economic analyses suggest that alcohol taxes would need to be increased substantially to address adequately such external costs as crime, alcohol-related crashes, domestic violence, and productivity losses.[18,108]

A potential concern is that increases in alcohol taxes may have a greater proportional economic impact on people with lower incomes (i.e., alcohol taxes may be regressive). However, alcohol taxes constitute a minor proportion (i.e., <1%) of the tax burden of Americans, including those with low incomes. As such, concerns about the regressive nature of such taxes could be readily addressed by compensatory changes in other elements of the tax system. In addition, the amount of tax paid is directly related to the amount of alcohol consumed, and thus increases in alcohol excise taxes will be disproportionately paid by excessive drinkers, who also experience most of the alcohol-related harms and thus generate most alcohol-attributable economic costs. Furthermore, the beneficial economic results of reducing excessive alcohol consumption and related harms may also be disproportionately greater for people with low incomes. Lower-income people may be particularly vulnerable to the harmful consequences of excessive alcohol consumption—consumed by themselves or others—because of factors such as lower rates of health insurance coverage, which may result in lack of or incomplete treatment for alcohol-related illness or injuries. Increasing alcohol excise taxes could also directly benefit low-income populations if the revenue generated from these taxes is used to help improve the availability of healthcare services for uninsured and other vulnerable populations.

Summary

The reviewed studies provide consistent evidence that higher alcohol prices and alcohol taxes are associated with reductions in both excessive alcohol consumption and related, subsequent harms. Results were robust across different countries, time periods, study designs and analytic approaches, and outcomes. According to *Community Guide* rules of evidence,[19] these studies provide strong evidence that raising alcohol taxes is an effective strategy for reducing excessive alcohol consumption and related harms.

Most of the studies that were included in this review assessed the relationship between alcohol prices and the outcomes of interest using price elasticities. Alcohol-related harms that were well represented in the literature reviewed included alcohol-impaired driving, motor-vehicle crashes, various measures of violence, and liver cirrhosis. For the largest body of evidence in this review—that is, societal levels of alcohol consumption—the majority of estimates of price elasticity fell within the range of approximately −0.30 to −1.00, indicating that a 10% increase in alcohol prices would be expected to result in a 3% to 10% decrease in alcohol consumption. These results indicate that alcohol consumption is responsive to price, and suggest that the impact of a potential tax increase is likely to be proportional to its size. It would also be reasonable to expect that alcohol price elasticities may vary across population groups by age and disposable income, among other factors, but assessment of such group differences was not possible using results from the studies in this review.

Research Gaps

The volume and consistency of the evidence reviewed here suggests little need for additional research on the basic questions of whether changes in alcohol taxes and price affect excessive alcohol consumption and related harms. Nonetheless, studies published subsequent to the 2005 cutoff date for this review continue to indicate the public health benefits that accrue from increasing alcohol taxes. For example, a recent meta-analysis found very similar mean price elasticities for alcohol consumption as were found in this review.[109] Similarly, a recent study of alcohol-related disease mortality found that substantial alcohol tax increases in Alaska in 1983 and 2002 resulted in estimated reductions of 29% and 11%, respectively.[110]

However, additional research is needed to assess:

1. Whether changes in alcohol prices differentially affect drinking behavior and health outcomes for important subgroups of the population, such as underage young people.

2. The relative benefits of increasing taxes on all alcoholic beverages simultaneously, versus selectively increasing taxes on specific beverage types. This evaluation should be considered in light of known differences in the beverage preferences of binge drinkers, historic changes in tax rates across beverage types, and the effect of inflation on real tax rates by beverage type.
3. The impact of different approaches to taxing alcoholic beverages on excessive alcohol consumption and related harms. Specific emphasis should be placed on the impact of alcohol sales taxes, where taxes are calculated as a proportion of the total beverage price; the potential impact of standardizing alcohol taxes across beverage types based on alcohol content; and the potential impact of alcohol taxes levied by local governments on a per-drink basis in on-premise, retail alcohol outlets (i.e., tippler taxes).

nature genetics

Thirty new loci for age at menarche identified by a meta-analysis of genome-wide association studies

To identify loci for age at menarche, we performed a meta-analysis of 32 genome-wide association studies in 87,802 women of European descent, with replication in up to 14,731 women. In addition to the known loci at *LIN28B* ($P = 5.4 \times 10^{-60}$) and 9q31.2 ($P = 2.2 \times 10^{-33}$), we identified 30 new menarche loci (all $P < 5 \times 10^{-8}$) and found suggestive evidence for a further 10 loci ($P < 1.9 \times 10^{-6}$). The new loci included four previously associated with body mass index (in or near *FTO*, *SEC16B*, *TRA2B* and *TMEM18*), three in or near other genes implicated in energy homeostasis (*BSX*, *CRTC1* and *MCHR2*) and three in or near genes implicated in hormonal regulation (*INHBA*, *PCSK2* and *RXRG*). Ingenuity and gene-set enrichment pathway analyses identified coenzyme A and fatty acid biosynthesis as biological processes related to menarche timing.

Menarche, the onset of first menstruation in girls, indicates the attainment of reproductive capacity and is a widely used marker of pubertal timing. Age at menarche varies widely between girls and is highly dependent on nutritional status[1]. Early menarche is associated with several adverse health outcomes, including breast cancer[2], endometrial cancer[3], obesity[4], type 2 diabetes[5] and cardiovascular disease[6], as well as shorter adult stature[4]. Studies of twins and extended families, although largely performed in populations free of nutritional deprivation, estimate that around 50% of the variance in menarche timing is attributable to genetic factors in such settings[7].

Recently, common variants in *LIN28B* were associated with age at menarche in four independent genome-wide association studies (GWAS)[8–11]. *LIN28B* is a human homolog of *lin-28* in *Caenorhabditis elegans*, which controls the rate of progression from larval stages to adult cuticle formation, indicating the possible conservation of specific micro-RNA regulatory mechanisms involved in developmental timing[9]. A second menarche locus was identified in an intergenic region at 9q31.2[8,10]. These two loci together explained only 0.6% of the variance in age at menarche[8]. We anticipated that a much larger GWAS would substantially increase the yield of loci associated with age at menarche.

Here we report a much expanded meta-analysis of GWAS for age at menarche. By combining data from the previous studies[8–11], plus several further studies to form the ReproGen Consortium, we identified at least 30 previously unidentified loci associated with age at menarche at genome-wide significance levels. Our findings show a close link between the genetic regulation of energy homeostasis and pubertal timing and suggest the presence of other diverse pathways.

RESULTS

Genome-wide association for age at menarche

This expanded GWAS includes data from 32 cohorts of European ancestry ($N = 87{,}802$). In most studies, age at menarche was determined by self recall, and the mean age at menarche in individual studies ranged from 12.4 to 13.6 years, excluding individuals with menarche <9 years and >17 years (Online Methods, **Supplementary Table 1** and **Supplementary Note**). Genome-wide SNP genotyping was performed using a variety of different platforms (**Supplementary Table 2** and **Supplementary Note**). Therefore, after applying standard quality control measures, we imputed the genotypes for ~2.5 million autosomal SNPs in the HapMap European CEU sample using Build 35 or 36 to allow inverse variance meta-analysis of additive genetic association results from each study. We also meta-analyzed results from X-chromosome SNPs in studies which had this data available ($N = 52{,}781$). Test statistics from each cohort were adjusted using genomic control to avoid inflation of results due to population stratification.

There was strong deviation from the uniform distribution of *P* values expected under the null hypothesis (**Supplementary Fig. 1**). This deviation was attenuated, but persisted, following removal of those signals associated with the two previously identified loci. In total, 945 SNPs representing 45 loci ($r^2 < 0.05$ based on HapMap in a 750-kb region) were associated with age at menarche at genome-wide significance levels ($P < 5 \times 10^{-8}$) (**Fig. 1** and **Supplementary Fig. 2**). None of these loci were located on the X chromosome. These 45 loci included three apparent second signals (defined as two genome-wide significant SNPs in low linkage disequilibrium (LD) ($r^2 < 0.05$) in the same 750-kb region) at 2q33.1, 6q21 and 14q32.2. The second signal at 6q21 (rs314279) had a low minor allele frequency (MAF = 6%) and was not present in many studies. We therefore genotyped this SNP *de novo* in the InCHIANTI cohort and found it was in LD with the top chromosome 6 signal (rs7759938, $r^2 = 0.3$). In HapMap, the r^2 between the two chromosome 6 SNPs was 0.015, but the *D* was 1.0. To verify the independence of additional loci, we performed a conditional analysis and a meta-analysis of all 32 studies using the top SNPs at all the 42 genome-wide significant regions as covariates (in addition to birth year). In these conditional analyses, the possible second signals on chromosomes 2 and 14 showed strong but not genome-wide significant associations with age at menarche ($P < 7.1 \times 10^{-6}$), suggestive of, but not confirming, second independent signals in these two regions (**Fig. 1** and **Supplementary Table 3**).

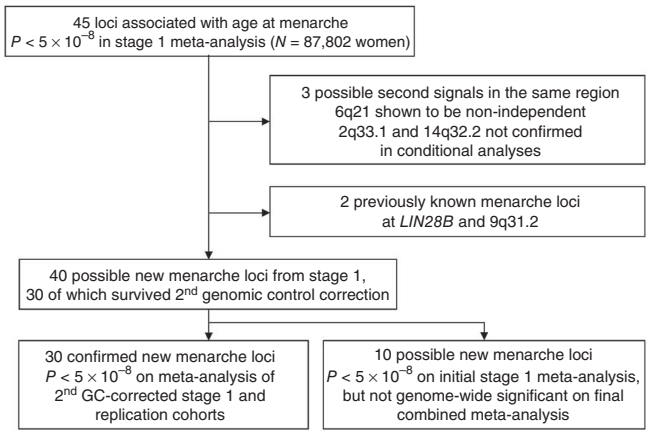

Figure 1 Flow diagram of the discovery and confirmation of new loci for age at menarche. GC, genomic control.

The two most significant loci for age at menarche confirmed the previously reported associations at *LIN28B* (rs7759938, $P = 1.6 \times 10^{-58}$) and 9q31.2 (rs2090409, $P = 4.4 \times 10^{-33}$) (**Table 1** and **Supplementary Fig. 3**). In addition, there were genome-wide significant signals for a further 40 possible previously unidentified loci, of which 30 survived a second more stringent correction for the overall genomic control in the stage 1 cohorts ($\lambda = 1.173$) (**Table 1**, **Fig. 1** and **Supplementary Fig. 3**).

Replication studies

We sought confirmation of the 40 possible new menarche loci in up to 14,731 women from 16 additional studies with *in silico* GWAS data and new genotyping data from one cohort (**Supplementary Tables 4** and **5**). This replication sample was substantially smaller than our stage 1 sample and was therefore underpowered to confirm individual SNP associations (**Supplementary Fig. 4**). Nonetheless, 37 of the 40 possible newly associated loci showed directionally consistent associations in both stages (**Table 1**; binomial sign test $P = 9.7 \times 10^{-9}$). A combined meta-analysis of the more stringent second genomic control–corrected stage 1 results and replication cohorts gave confirmatory evidence for 30 new menarche loci, leaving 10 unconfirmed possible menarche loci (**Table 1** and **Fig. 1**).

Based on the combined stage 1 and replication results, the estimated magnitudes of per-allele effects for the new menarche loci ranged from 4.5 to 2.1 weeks per allele (**Table 1**) and had an inverse relationship with MAF (**Supplementary Fig. 5**). Among the four largest *in silico* replication cohorts (each comprising >800 women), the variance in age at menarche explained by all 42 known, confirmed and possible new menarche loci ranged from 3.6% to 6.1% (**Supplementary Table 6**).

Candidate genes at new loci

The strongest new menarche signal was for rs1079866 (3.9 weeks per minor allele; 95% CI 2.9–5.0, $P = 5.5 \times 10^{-14}$) located approximately 250 kb downstream of *INHBA*, which encodes the protein subunit Inhibin beta A. Heterodimers of Inhibin beta A and the Inhibin alpha subunit form the female reproductive hormone Inhibin A[12]. Inhibin A, produced by granulosa cells in the ovary, increases dramatically during pubertal development in girls[13,14] and is involved in negative feedback regulation by inhibiting production of follicle stimulating hormone by the pituitary and secretion of gonadotrophin releasing hormone from the hypothalamus[15]. Conversely, homodimers of Inhibin beta A form the hormone Activin A, which stimulates pituitary follicle stimulating hormone production and also exhibits a wide range of biological activities, including the regulation of cellular proliferation and differentiation[16].

The second strongest new signal was for rs466639 ($P = 1.3 \times 10^{-13}$); this SNP is intronic in *RXRG*, which encodes retinoid X receptor gamma, a nuclear receptor that forms dimers with the receptors for retinoic acid, thyroid hormone and vitamin D, increasing both DNA binding and transcriptional function on their respective response elements[17].

Four new loci for menarche were previously identified by GWAS for adult body mass index (BMI)[18–20]: rs9939609 (in or near *FTO*, $P = 3.1 \times 10^{-8}$), rs633715 (*SEC16B*, $P = 2.1 \times 10^{-8}$), rs2002675 (*TRA2B* and *ETV5*, $P = 1.2 \times 10^{-9}$) and rs2947411 (*TMEM18*, $P = 1.7 \times 10^{-8}$). Apart from rs2002675, these menarche signals were either identical to or in tight LD ($r^2 > 0.9$) with those BMI loci, and in all cases, the BMI-increasing allele was associated with earlier menarche. Variants at these four loci have also been associated with childhood BMI[18–20], and these findings support a likely causal effect of childhood BMI on earlier pubertal timing.

Three new menarche loci were found in or near further genes implicated in the regulation of energy homeostasis and body weight in animal models: rs6589964 ($P = 1.9 \times 10^{-12}$) lies ~18 kb from *BSX*, rs10423674 ($P = 5.9 \times 10^{-9}$) is intronic in *CRTC1*, and rs4840046 ($P = 2.4 \times 10^{-8}$) lies ~160 kb from *MCHR2*. *BSX* encodes a DNA-binding protein and transcriptional activator. In mouse, *Bsx* is expressed specifically in the pineal gland, telencephalic septum, hypothalamic pre-mammillary body and arcuate nucleus and is necessary for postnatal growth, locomotory behavior, expression of the genes *Npy* and *Agrp*, and for the hyperphagic phenotype in leptin deficiency[21]. *CRTC1* encodes the CREB-regulated transcription coactivator 1, an activator of cellular gene expression. *Crtc1*$^{-/-}$ mice are hyperphagic, obese and infertile, and *Crtc1*$^{-/-}$ females have low circulating luteinizing hormone levels[22]. Leptin potentiates the effects of *Crtc1* transcriptional activity, and *Crtc1* overexpression in hypothalamic cells increases expression of Kisspeptin, which in turn activates secretion of the gonadotrophin releasing hormone. *MCHR2* encodes the melanin concentrating hormone receptor 2, an orphan G protein–coupled receptor which shows high affinity binding to the hypothalamic neuropeptide melanin-concentrating hormone (MCH), which regulates nutrient intake and energy homeostasis through *MCHR1*[23]. Furthermore, MCH directly inhibits gonadotrophin releasing hormone neurons and thereby links energy balance to reproduction[24].

rs852069 ($P = 3.3 \times 10^{-8}$) lies ~84 kb from *PCSK2*, which encodes proprotein convertase subtilisin/kexin type 2, an enzyme that cleaves latent precursor proteins, such as proinsulin and proopiomelanocortin, into their biologically active products. Although rare deleterious mutations and common variants in *PCSK1* are known to influence obesity risk, it is notable that *PCSK2* differs from *PCSK1* in that it additionally cleaves pro-luteinizing hormone-releasing hormone and could therefore have a more direct influence on the reproductive hormone axis.

Pathway analyses

Remaining new menarche loci were found in or near genes that are involved in a seemingly diverse range of biological functions (**Supplementary Table 7**). We used ingenuity pathway analysis (IPA) to identify potential biological pathways common to these identified loci. Based on direct interactions only, we identified two functional networks containing 16 and 11 genes, respectively, of those genes nearest to the new menarche loci (**Supplementary Fig. 6**). Network 1,

related to 'gene expression, cellular growth and proliferation, and cellular function and maintenance', covers a wide and nonspecific range of biological pathways. Functions in network 2 relate to 'lipid metabolism, small molecule biochemistry and molecular transport' (**Supplementary Table 8**). Central to network 2 are *RXRG* and several genes involved in fatty acid biosynthesis, including several fatty acid–binding proteins and *ACSL1*, which encodes an enzyme that converts free long-chain fatty acids into fatty acyl-CoA esters.

To identify potential further biological pathways that influence menarche timing, we used a gene set enrichment analysis (GSEA)

Table 1 Stage 1 and replication results for 42 known, confirmed or possible new loci for age at menarche

BMI, body mass index; WHR, waist-hip ratio.
[a]Selected SNPs at each locus are those published for association with BMI, WHR or obesity (rather than those with the strongest signal for age at menarche). SNPs listed are those with a significant association ($P < 0.05$) with age at menarche. A full version of this table including SNPs related to adiposity traits but not reaching significance for menarche can be found in **Supplementary Table 13**.

approach in meta-analysis gene-set enrichment of variant associations (MAGENTA), in which each gene in the genome is assigned an adjusted score that represents its association with age at menarche, and predefined pathways are tested for enrichment of multiple associations (Online Methods). The most significant pathway ($P = 4.9 \times 10^{-3}$) was the biosynthesis of coenzyme A, which is a carrier of acyl groups and is necessary for pyruvate oxidation and fatty acid synthesis and oxidation (**Supplementary Table 9**).

Functional SNP and structural assessment

We explored the potentially functional impacts of our new menarche loci in order to identify their likely genetic mechanisms. In addition, by particularly focusing on those groups of SNPs that have been identified as functional, we aimed to identify possible further menarche loci which did not reach genome-wide significance in our primary meta-analysis.

Copy number variation. Using data from a recent genomic map of copy number variation (CNV)[25], we established that none of the 42 known, confirmed or possible new menarche loci were related to CNVs. Next, we explored the 1,052 CNV-tagging SNPs for association with age at menarche in our GWAS sample. Only one tag SNP was associated with age at menarche after Bonferroni correction (rs3101336, $P = 3 \times 10^{-7}$; **Supplementary Fig. 7**). This SNP tags a CNV near the NEGR1 gene locus, which has been previously associated with body mass index[20].

Non-synonymous SNPs. None of the 42 known, confirmed or possible new menarche variants were amino acid changing. However, two were in strong LD ($r^2 \geq 0.8$) with non-synonymous variants. rs1862471 (intronic in OLFM2 at 19p13.2) is in LD ($r^2 = 0.8$) with rs2303100, which encodes an arginine to glutamine residue change in OLFM2. Second, rs4929923 (in the 3 untranslated region of TRIM66 at 11p15.4) is in LD ($r^2 = 0.92$) with rs11042023, which encodes a histidine to arginine residue change in TRIM66.

To identify possible further menarche loci, we then explored the set of 12,062 non-synonymous SNPs for association with age at menarche in our GWAS sample. Outside of the already associated regions, three non-synonymous SNPs were associated with age at menarche after correction for multiple testing (the Bonferroni threshold for 12,062 independent tests was $P < 4.1 \times 10^{-6}$). These non-synonymous SNPs were rs1254319 in *C14orf39* ($P = 1.9 \times 10^{-7}$), rs7653652 in *C3orf38* ($P = 1.4 \times 10^{-6}$) and rs913588 in *JMJD2C* ($P = 3.3 \times 10^{-6}$).

Expression QTLs. Three of the forty-two known, confirmed or possible new menarche variants were highly significantly cis associated with mRNA expression ($P < 1 \times 10^{-6}$ for mRNA transcript abundance) based on publicly available data from lymphoblastoid cell lines of 400 children (mRNA by SNP Browser). These transcripts were in GAB2 (associated with rs10899489), RBM6 (rs6762477) and NARG2 (rs3743266) (**Supplementary Table 10**). As these genomic loci included a number of genes (**Supplementary Fig. 3**), these specific transcript associations inform the likely functional gene at each locus.

Table 3 Associations between known height SNPs and age at menarche

Gene	SNP[a]	Chr.	Position	Menarche β (weeks per allele)	Menarche s.e.	Menarche *P*	Height-increasing allele	Menarche-increasing allele

$\chi^2 = 7.02$, $P = 0.008$ for 11 out of 44 height-associated SNPs also associated with age at menarche (at $P < 0.05$) compared to the 2.2 expected by chance. However, seven height-increasing SNPs are associated with earlier menarche and four are associated with later menarche. Menarche *P* values are derived from our stage 1 meta-analysis of 32 studies with genomic control applied to individual studies.
[a]Selected SNPs at each locus are those published for association with height (rather than those with the strongest signal for age at menarche). SNPs listed are those with a significant association ($P < 0.05$) with age at menarche. A full version of this table including SNPs associated with adult height but not reaching significance for menarche can be found in **Supplementary Table 14**.

Given the likely close biological interaction between the regulation of age at menarche and adiposity, we hypothesized that adipose tissue expressed SNPs (eSNPs) might show a preponderance of associations with age at menarche. Of the 5,184 adipose eSNPs identified in the Icelandic Family Adipose cohort[26], 23 were significantly associated with age at menarche after correction for multiple testing (using a $1/n$ P value threshold for 5,184 independent tests ($P < 1.9 \times 10^{-4}$)) (**Supplementary Table 11**). Of these adipose eSNPs, rs10835211 (menarche $P = 9.4 \times 10^{-6}$) is near *BDNF*, which is a BMI locus and is implicated in eating behavior and body weight regulation[27,28]. rs7160413 (menarche $P = 2.2 \times 10^{-5}$) is near *DLK1*, a gene implicated in early onset puberty[29]. rs133934508 (menarche $P = 3.6 \times 10^{-5}$) is associated with expression of *PITX1*, which encodes a pituitary transcriptional regulator[30].

Candidate gene assessment

Candidate gene studies for age at menarche have largely focused on genes involved in sex steroid-hormone biosynthesis and metabolism, highlighted through animal models or human cases with extreme delayed puberty or hypogonadotrophic hypogonadism[31]. We examined 8,770 SNPs in 16 candidate genes[31–33] and their surrounding regions (±300 kb) for association with age at menarche in our GWAS meta-analysis sample (**Supplementary Table 12**). SNPs in the regions of *TAC3R* (top hit, rs17034046, $P = 3.4 \times 10^{-7}$, ~19 kb upstream of *TAC3R*) and *ESR1* (top hit, rs9383922, $P = 2.2 \times 10^{-6}$, 110 kb upstream of *ESR1*) were significantly associated with age at menarche after correction for multiple testing (the Bonferroni threshold for 8,770 independent tests was $P < 5.7 \times 10^{-6}$). Rare deleterious mutations in *TAC3R*, encoding a receptor for Neurokinin B, and in its ligand *TAC3* have been found in families affected by hypogonadotropic hypogonadism and pubertal failure[31]. *ESR1* encodes an estrogen receptor that is essential for sexual development and reproductive function, and polymorphisms in *ESR1* have previously been nominally associated with age at menarche[33].

Overlapping heritability of body size and menarche timing

Family studies have suggested a substantial coinheritance of the timing of puberty and BMI[34], and this is supported by our finding of four established BMI variants among our new menarche loci. We therefore systematically assessed whether established loci for adiposity-related traits (BMI, waist-hip ratio (WHR) and obesity) and adult height were also associated with age at menarche. Nine of the twelve BMI loci and two of the four WHR loci tested were associated with age at menarche (**Table 2** and **Supplementary Table 13**). In all cases, the BMI- or WHR-increasing allele was associated with earlier menarche, which is consistent with the direction of association in epidemiological studies[35]. Eleven of the forty-four adult height loci were associated with age at menarche (**Table 3** and **Supplementary Table 14**). However, for seven of these loci, the adult height-increasing allele was associated with earlier menarche, which is in the opposite direction to the association in individual-level epidemiological studies[35].

We then assessed the relevance of our new menarche loci to adult BMI and height by exploring *in silico* data from the GIANT consortium. Nine of the forty-two menarche loci were associated with adult BMI (at $P < 0.05$; $N = 32,530$); in all cases, the allele associated with higher BMI was associated with earlier menarche (**Supplementary Table 15**). Eighteen of the menarche loci were associated with adult height (at $P < 0.05$; $N \sim 130,000$); although for three of these loci, the direction of effect was opposite to that predicted from epidemiological studies (**Supplementary Table 16**). Despite these joint associations with body size, in Avon Longitudinal Study of Parents and Children (ALSPAC) mothers, the combined influence of the menarche loci on age at menarche appeared to be completely unattenuated following adjustment for adult height and BMI (**Supplementary Table 17**), suggesting that in general, these menarche loci have direct effects on age at menarche. However, we acknowledge that further large studies with childhood growth data are needed to establish the causal directions of effect of these loci.

DISCUSSION

In a large GWAS meta-analysis comprising over 87,000 women, we identified 30 new loci for the timing of menarche and provide evidence for a further ten possible new loci. These loci were in or near genes associated with cellular development, body weight regulation, hormonal regulation and a wide variety of other biological functions. Previous studies comprising up to 17,510 women had detected only one or two genome-wide significant signals[8–11]. We now show that those earlier signals at *LIN28B* and 9q31.2 represented the 'low-hanging fruit' with particularly large effect sizes relative to their MAF (**Supplementary Fig. 5**). The list of functions of those genes nearest to the menarche loci (**Supplementary Table 7**) and the results of pathway analyses indicate a wide diversity of biological processes that regulate the timing of female pubertal maturation.

Among the confirmed new menarche loci were several loci implicated in body weight regulation, including four loci with established associations with BMI (in or near *FTO*, *SEC16B*, *TRA2B* and *TMEM18*). Furthermore, our systematic analysis of established BMI-related SNPs showed that the majority of alleles related to higher BMI and WHR also showed at least nominal associations with earlier menarche (**Table 2**). It is noteworthy that three new menarche loci are in or near genes implicated in energy homeostasis in animal models (*BSX*, *CRTC1* and *MCHR2*). In the GIANT consortium data, we did not detect any associations between these loci and adult BMI, however the *BSX* and *MCHR2* loci were nominally associated with adult height. In order to robustly investigate whether menarche loci have pleiotropic effects on growth or whether the association with menarche timing is driven through increased adiposity, measures of body fatness before menarche or even before the onset of puberty would be required but were unavailable in most studies. Further functional studies of these new menarche loci may also help to clarify the biological mechanisms linking these traits. In addition to influencing the timing of pubertal initiation, sufficient adiposity is also required for the maintenance of normal hypothalamic-pituitary-gonadal function through signaling by adipocytokines such as leptin[36]. Our pathway analyses highlighted coenzyme A and fatty acid biosynthesis as biological pathways related to menarche timing. Hypothalamic levels of long-chain fatty acyl coenzyme As have been shown to regulate rodent feeding behavior and glucose homeostasis[37], and genetic variants in this pathway could therefore potentially alter central nutrient sensing.

Earlier age at menarche is related to shorter adult stature in large epidemiological studies[35]. We found that several adult height-increasing alleles were also associated with age at menarche (**Table 3**), but at different loci, these alleles were associated with either earlier or later menarche. These paradoxical associations suggest a complex interplay between growth and pubertal timing. Earlier menarche is associated with taller, rather than shorter, childhood height, and there are likely separate causal effects of rapid linear growth on earlier puberty and of earlier pubertal maturation on earlier growth plate fusion and cessation of growth.

Although our pathway analyses strongly identified potential new biological pathways involved in pubertal timing, we acknowledge that the ability to assign putative functions to these menarche loci is substantially limited by the lack of identification of the causal variant at each locus. Many of the strongest associated SNPs were located

hundreds of kilobases distant to the nearest gene, and some menarche loci contained several plausible genes. Indeed, none of the top signals represented non-synonymous SNPs and only two SNPs were in LD with such variants (in *OLFM2* and *TRIM66*). Use of eQTLs helped to identify the likely causal genes (*GAB2*, *RBM6* and *NARG2*) at three menarche loci that spanned multiple genes. However, much future work will be required to identify the causal variants and implicated genes related to these menarche loci.

Despite the large size of our meta-analysis and the substantial increase in the number of menarche loci, these together explained between 3.6%–6.1% of the variance in age at menarche, equivalent to 7.2%–12.2% of its heritability. The majority of menarche loci had estimated effect sizes of between 2 and 3 weeks per allele. Assuming the presence of many true menarche SNPs with an effect size of 2 weeks per allele, even our large meta-analysis would only have had sufficient power to detect half of those SNPs with a MAF of 50% and only one in ten of those SNPs with MAF of 10% (**Supplementary Fig. 8**).

We corrected for population stratification by applying the genomic control method[38] to each of the individual study results. When we applied a more stringent second correction for the overall genomic control inflation factor across all 32 studies, 10 of the 40 possible new menarche variants fell below genome-wide significance (**Fig. 1** and **Table 1**). However, our subsequent finding of confirmatory evidence ($P < 0.05$) even in our limited replication studies for four of these ten variants (in or near *TRIM66*, *TMEM108*, *TMEM18* and *NFAT5*) suggests that the second correction for genomic control is likely to be overconservative.

Our identification of strong associations with SNPs near the candidate genes *TAC3R* and *ESR1* supports the likely presence of further menarche loci which did not meet the genome-wide significance threshold. Systematic assessment of functional genetic variants identified several further putative menarche loci. rs3101336, which tags a CNV near the BMI locus *NEGR1*, showed strong, but not genome-wide significant, association with age at menarche ($P = 3 \times 10^{-7}$). Exploration of adipose tissue eQTLs also identified further putative menarche loci related to genes implicated in eating behavior (*BDNF*), precocious puberty (*DLK1*) and pituitary function (*PITX1*). It has been suggested that lower levels of statistical significance may be applied to variants with prior biological candidacy, however this must be balanced against the desire to avoid false positives, and we suggest that these putative menarche loci require confirmation in further studies.

Notably all of the top menarche variants had MAF ≥ 7%. Although it has been suggested that low-frequency variants have larger effects than common variants[39], our study was clearly underpowered to detect low-frequency variants (MAF < 5%) with modest effect sizes. It is also possible that rare variants are not well captured using genome-wide chips. Future imputation using deep sequencing data from the 1000 Genomes Project may identify additional low frequency hits as well as refine the location of possible functional variants.

In the majority of studies contributing to this report, age at menarche was recalled several years later and often to the nearest completed whole year. Although recalled age at menarche is a valid measure[40] and is unlikely to show systematic bias by genotype, any nondifferential error would lead to reduced statistical power. Menarche indicates the completion of puberty in females, and it is unclear whether our new menarche loci also influence timing of other pubertal phenotypes. The known menarche locus in *LIN28B* was shown to also influence the onset of breast development in girls, the timing of pubic hair development and voice breaking in boys[9] and the timing of the pubertal growth spurt in both boys and girls[41]. Although our new menarche loci might also regulate such wider pubertal processes, it is plausible that some (for example, *INHBA*) might have sex-specific effects. Our study was restricted to cohorts of European ancestry and our results are therefore not generalized to other groups. African-American girls tend to show earlier pubertal maturation compared to girls of European ancestry[42], and genetic studies in such populations might reveal different menarche loci.

In summary, we identified at least 30 new loci for age at menarche. Our findings demonstrate the role of genes which regulate energy homeostasis and hormone pathways and illustrate the complexity of the regulation of the timing of puberty.

ONLINE METHODS

Stage 1 GWAS populations. Thirty-two studies contributed to the stage 1 GWAS meta-analysis, comprising 87,802 women of European ancestry. The consortium was made up of populations from the Age, Gene/Environment Susceptibility Study (AGES, $n = 1849$), the Amish population (Amish, $n = 557$), the Atherosclerosis Risk in Communities study (ARIC, $n = 4247$), the British 1958 Birth Cohort (B58C-T1DGC and B58C-WTCCC, $n = 1584$), CoLaus ($n = 2797$), deCODE ($n = 15,864$), the Danish National Birth Cohort (DNBC, $n = 1748$), the Estonian Genome Center, University of Tartu (EGCUT, $n = 987$), the European Prospective Investigation into Cancer and Nutrition (EPIC-obesity cases and cohort, $n = 1840$), the Erasmus Rucphen Family Study (ERF, $n = 1103$), the Framingham Heart Study (FHS, $n = 3801$), the Helsinki Birth Cohort (HBCS, $n = 976$), the Health 2000 study (Health 2000 cases and controls, $n = 922$), InCHIANTI ($n = 597$), the Indiana University premenopausal Caucasian women peak BMD study (Indiana, $n = 1497$), the Nurse's Heath Studies (NHS, $n = 5360$), the Northern Finland Birth cohort (NFBC, $n = 2648$), the Netherlands Twin Register (NTR, $n = 1051$), the Queensland Institute of Medical Research (QIMR, $n = 3528$), the Rotterdam studies (RS1, RS2 and RS3, $n = 5406$), the Study of Addiction: Genetics and Environment (SAGE, $n = 1376$), the SardiNIA study ($n = 2158$), Twins UK I, II and III ($n = 3962$), and the Women's Genome Health Study (WGHS, $n = 22,028$). Full details can be found in the **Supplementary Note**. All studies were approved by local ethics committees and all participants provided written informed consent.

Phenotype measurement and inclusion criteria. Age at menarche recalled by the participant was recorded in each study. Specific questions asked can be found in **Supplementary Table 1**. Only women of European ancestry with a valid age at menarche between 9 and 17 years were included in this analysis, as this represents the normal physiological range. Information on birth year was also collected in each study.

Genotyping. The 32 stage 1 studies were genotyped using a variety of Affymetrix (6.0, GeneChip 500K, 250K, MIP50K and 10K) and Illumina (HumanHap 550K, 318K, HumanHap 300K, HumanHap 370K CNV, HumanHap610 quad, Human660W-Quad BeadChip, 6K and Human 1Mv1_C) genotyping arrays. Genotyping call rate cutoffs were at least 90%, and SNPs were filtered for those with a minor allele frequency of greater than 1%. More details on the filtering criteria for genotypes in each individual study can be found in **Supplementary Table 2**.

Genotype imputation. In order to increase genomic coverage and allow the evaluation of the same SNPs across as many study populations as possible, each study imputed genotype data based on the HapMap CEU Build 35 or 36. Algorithms were used to infer unobserved genotypes in a probabilistic manner in either MACH, IMPUTE[43], or software that was developed by the researchers. As a quality control measure, we excluded non-genotyped SNPs with an imputation quality less than 0.3 (for observed versus expected variance in MACH) or 0.4 (for IMPUTE's proper info statistic) from the meta-analysis.

Association testing. Each study performed genome-wide association testing for age at menarche across approximately 2.5 million SNPs based on linear regression under an additive genetic model. Analyses were adjusted for birth year in order to remove the effect of the temporal decline in age at menarche. Studies used PLINK, ProABEL, MACH2QTL, SNPTEST, R packages or MERLIN-fastassoc for the association testing. The results from individual studies were corrected by their respective genomic inflation factors (λ) (**Supplementary Table 1**) according to the genomic control method to correct for population stratification[38].

Meta-analysis. We used an inverse-variance meta-analysis to test the effects of each genetic variant on age at menarche across the 32 studies. Fixed effects models were used, although in the absence of significant heterogeneity, choice of model has little impact on the results. In order to correct for potential relatedness between two Icelandic cohorts (AGES and deCODE), the corrected association results for these cohorts were first meta-analyzed and the genomic-control method was reapplied to the results of the combined sample. These results were then meta-analyzed with the remaining 30 studies. We also displayed further results following a second correction for genomic control using the overall genomic inflation factor calculated from the meta-analysis of all 32 studies. All meta-analyses were conducted using the METAL software package. We considered P values $< 5 \times 10^{-8}$ to indicate genome-wide significance.

We also meta-analyzed results from X-chromosome SNPs in a subset of studies with this data available. This included seven imputed datasets and one directly genotyped dataset. Total sample size was ~60% of the autosomal meta-analysis ($N = 52,781$) and the same statistical model was tested.

Conditional analysis. In order to establish whether genome-wide significant SNPs with low LD in the same chromosomal region (defined as $r^2 < 0.05$ in a 750-kb region) were independent loci, we carried out a conditional analysis. Each study performed a genome-wide analysis for age at menarche using linear regression adjusting for the top signal at each of the 42 associated regions to determine whether potential second signals remained significant even after adjusting for these variants. Birth year was also included as a covariate. Results from each individual study were meta-analyzed to determine whether these potential second signals were truly independent (that is, if $P < 5.0 \times 10^{-8}$).

Replication studies. In order to confirm our possible new menarche loci, we tested our 42 top hits for *in silico* association with age at menarche in 8,669 women from 16 studies with GWAS data and which were not included in the first stage meta-analysis (**Supplementary Table 4**). In addition, new genotype data was generated for 30 of the 42 menarche loci and tested for association with age at menarche in up to 6,118 women from the Avon Longitudinal Study of Parents and Children (ALSPAC). Genotyping was performed by KBiosciences (Hoddesdon, UK) using their own unique system of fluorescence-based competitive allele-specific PCR (KASPar). As in stage 1, analyses were restricted to women reporting age at menarche between 9 and 17 years and adjustment was made for birth year. Mean age at menarche ranged from 12.4 to 13.5 years, consistent with studies in the stage 1 meta-analysis. Linear regression was used to test the association between each variant and age at menarche in an additive genetic model. These results were then meta-analyzed with genomic control–adjusted statistics from our stage 1 meta-analysis using inverse-variance fixed effects models.

In order to calculate the overall variance explained by these menarche loci in each of the replication cohorts, we calculated the r^2 value from a model including all 42 known, confirmed and possible new menarche variants and birth year and compared this to a model including birth year alone. We only included cohorts with >800 women in their full model analyses, as sample sizes smaller than this may give spurious results.

Pathway analysis. Ingenuity pathway analysis (IPA) Knowledge Base 8.5 (Ingenuity Systems) was used to explore the functional relationship between proteins encoded by the 42 known, confirmed and possible new menarche loci. The IPA Knowledge Base contains millions of findings curated from the literature. Genes or nearest genes to the 42 loci (**Table 1**) were entered into the Ingenuity database. These 'focus genes' were analyzed for direct interactions only. Networks were generated with a maximum size of 35 genes and shown as graphical representations of the molecular relationships between genes and gene products. Proteins are depicted as nodes in various shapes representing the functional class of the protein. The biological relationships between nodes are depicted by lines. To determine the probability of the analyzed gene to be found together in a network from Ingenuity Pathways Knowledge Base due to random chance alone, IPA applies a Fisher's exact test. The network score or P value represents the significance of the focus gene enrichment. There are 25 diseases and disorders categories and 32 molecular and cellular function categories in the IPA Knowledge Base. Enrichment of focus genes to these diseases and functional categories was also evaluated. The P value, based on a right-tailed Fisher's exact test, considers the number of identified focus genes and the total number of molecules known to be associated with these categories in the IPA knowledge database.

MAGENTA was used to explore pathway-based associations in the full GWAS dataset. MAGENTA implements a GSEA-based approach, the methodology of which has been previously described[44]. Briefly, each gene in the genome is mapped to a single index SNP with the lowest P value within a 110 kb upstream, 40 kb downstream window. This P value, representing a gene score, is then corrected for confounding factors such as gene size, SNP density and

doi:10.1038/ng.714

LD-related properties in a regression model. Genes within the HLA region were excluded from analysis due to difficulties in accounting for gene density and LD patterns. Each mapped gene in the genome is then ranked by its adjusted gene score. At a given significance threshold (95th and 75th percentiles of all gene scores), the observed number of gene scores in a given pathway, with a ranked score above the specified threshold percentile, is calculated. This observed statistic is then compared to 1,000,000 randomly permuted pathways of identical size. This generates an empirical GSEA *P* value for each pathway. Significance was determined when an individual pathway reached a false discovery rate < 0.05 in either analysis (**Supplementary Table 9**). In total, 2,529 pathways from Gene Ontology, PANTHER, KEGG and Ingenuity were tested for enrichment of multiple modest associations with age at menarche.

eQTLs. We tested the association between 5,184 adipose tissue eSNPs identified in the Icelandic Family Adipose (IFA) cohort ($n = 673$) with age at menarche in our stage 1 meta-analysis sample. The IFA cohort dataset included the expression of 23,720 transcripts representing 84% of the 20,060 protein-coding genes annotated in the Ensembl database (v 33)[26].

Abstract

Background: Genome-wide association studies have found type 2 diabetes-associated variants in the *HNF1B* gene to exhibit reciprocal associations with prostate cancer risk. We aimed to identify whether these variants may have an effect on cancer risk in general versus a specific effect on prostate cancer only.

Methodology/Principal Findings: In a collaborative analysis, we collected data from GWAS of cancer phenotypes for the frequently reported variants of *HNF1B*, rs4430796 and rs7501939, which are in linkage disequilibrium ($r^2 = 0.76$, HapMap CEU). Overall, the analysis included 16 datasets on rs4430796 with 19,640 cancer cases and 21,929 controls; and 21 datasets on rs7501939 with 26,923 cases and 49,085 controls. Malignancies other than prostate cancer included colorectal, breast, lung and pancreatic cancers, and melanoma. Meta-analysis showed large between-dataset heterogeneity that was driven by different effects in prostate cancer and other cancers. The per-T2D-risk-allele odds ratios (95% confidence intervals) for rs4430796 were 0.79 (0.76, 0.83)] per G allele for prostate cancer ($p<10^{-15}$ for both); and 1.03 (0.99, 1.07) for all other cancers. Similarly for rs7501939 the per-T2D-risk-allele odds ratios (95% confidence intervals) were 0.80 (0.77, 0.83) per T allele for prostate cancer ($p<10^{-15}$ for both); and 1.00 (0.97, 1.04) for all other cancers. No malignancy other than prostate cancer had a nominally statistically significant association.

Conclusions/Significance: The examined *HNF1B* variants have a highly specific effect on prostate cancer risk with no apparent association with any of the other studied cancer types.

Introduction

A large number of epidemiological studies have suggested correlations between type 2 diabetes (T2D) and various cancers[1,2,3]. Most evidence suggests an inverse correlation between T2D and prostate cancer[4,5,6] although not all studies agree on this[7]. Several studies also suggest positive correlations between other cancers and T2D[1,2,3]. It is unclear whether these correlations, if true, represent casual relationships and whether they may also reflect some shared genetic background. Recently, with the advent of genome-wide association studies (GWAS), a large number of genetic variants have been identified that confer susceptibility to T2D or specific types of cancer[8]. An interesting observation has been that specific variants in the *HNF1B* gene (formerly *TCF2*) have been demonstrated to be associated both with the risk of prostate cancer[9,10,11] and the risk of T2D[9,12] with the effects being in the opposite direction for these two phenotypes.

HNF1B was previously known to be mutated in individuals with maturity-onset diabetes of the young type 5 (MODY 5)[13], but a biological explanation of the impact of the identified common variation on T2D and prostate cancer risk remains elusive. The identified genetic effects are small in magnitude even for prostate cancer and T2D, representing odds ratios [ORs] per allele in the range of 1.2 [9,11] and 0.9 [9,12], respectively. Therefore, small effects for other cancer types would not be readily detectable, unless very large studies were performed or data were combined from several studies.

A definitive answer on whether *HNF1B* variants modulate also the risk of other malignancies, or show specificity for prostate cancer, requires large sample sizes. Here we present the results of a large collaborative meta-analysis of *HNF1B*, rs4430796 and rs7501939, which have the most consistent associations with both prostate cancer and T2D. Relevant data were collected on the two variants from GWAS on cancer phenotypes in Caucasian populations in order to examine whether they have an effect on cancer risk in general, on few specific cancers, or only on prostate cancer.

Results

Database of contributed information

All the originally contacted investigators of cancer-related GWA studies agreed to participate in this collaborative analysis, with the exception of the investigators of 3 GWA studies [14,15,16] (1 on breast cancer, 1 on colorectal cancer and 1 on neuroblastoma), 1 of which had no data on the requested variants, as they had used a Affymetrix platform[15]. Investigators who agreed to participate in the collaborative analysis contributed data on 13 datasets for rs4430796 and 19 datasets for rs7501939 [11,17,18,19, 20,21,22,23,24,25,26,27,28,29,30,31,32,33]. For 5 datasets, data were available only for the latter polymorphism either because the polymorphism was not available on the platform used or the SNP failed quality control criteria.

The contributing teams and datasets are shown in Table 1 with data on the number of cases and controls for each polymorphism and for each type of cancer. Datasets from the Framingham cohort contained imputed data for both polymorphisms since an Affymetrix platform had been used, rs4430796 data from the M.D. Anderson Cancer Center was imputed since this SNP had not been directly genotyped, and melanoma data from AMFS and Q-MEGA contained counts from pooling experiments, otherwise all other datasets had direct genotyping on individual participants. Detailed demographic and other characteristics of the study populations can be found in the respective primary publications of these GWA studies [14,15,16,17,18,20,21,22,23,24,25,26,27,28, 29,30,31,32,34].

Overall, the collaborative analysis included data on rs4430796 for 19,640 cancer cases and 21,929 controls; for prostate cancer there were 11,145 cases and 9,650 controls, while for all other cancers there were 8,495 cases and 12,279 controls. The collected data on rs7501939 included 26,923 cases and 49,085 controls; for prostate cancer there were 12,898 cases and 40,371 controls, while for the other cancers there were 14,025 cases and 43,893 controls. Malignancies other than prostate cancer in these datasets included colorectal, breast, lung and pancreatic cancers, and melanoma (Table 1). deCODE contributed data on 4 different cancers and had a common population control group for all 4 of them. The Framingham Heart Study (FHS) contributed data on 4 different cancers and had a common population control group (subjects $\geq$65 years at the last contact who are not nuclear family member of the cancer cases) for all 4 studies with the exception of prostate and breast cancer which used male and female only controls respectively. The common control groups for deCODE and FHS are only counted once in the total sample sizes above.

The meta-analysis of all datasets (Table 2, Figure 1) showed a per T2D risk allele association with both rs4430796 (G allele OR 0.91 [95% CI: 0.88, 0.94] $p = 3\times10^{-10}$) and rs7501939 (T allele

doi:10.1371/journal.pone.0010858.t001

OR 0.91 [95% CI: 0.88, 0.94] $p = 5v10^{-10}$) according to fixed effects calculations, while by random effects calculations there was nominal significance (OR 0.94 [95% CI: 0.88, 1.00], $p = 0.033$ for rs4430796 and 0.93 [95% CI: 0.86, 1.01], $p = 0.07$ for rs7501939). The reason for this diversity is that there was very large between-study heterogeneity in the effect sizes (I^2 of 82% [95% CI: 73-89%] and 80% [95% CI: 70-86%], respectively, for the two polymorphisms; Q-test p-value <0.001 for both polymorphisms), and this makes the fixed effects calculations less reliable. Results were qualitatively similar when we increased the variance in deCODE, FHS, and IARC estimates to account for the overlapping control group (not shown).

The heterogeneity was largely driven by the diversity in the effect sizes between prostate cancer and all other cancers. A meta-analysis limited to prostate cancer datasets gave consistent associations with both rs4430796 (OR per copy of T2D risk allele (A) 0.79 [95% CI: 0.76, 0.83], $p<10^{-15}$ by fixed effects and 0.79 [95% CI: 0.74, 0.84] $p = 10^{-13}$ by random effects), and rs7501939 (OR per copy of T2D risk allele (T) 0.80 [95% CI: 0.77, 0.83] $p<10^{-15}$ by fixed effects and 0.79 [95% CI: 0.74, 0.85], $p = 2\times10^{-11}$ by random effects) (Table 2). There was some residual between-study heterogeneity even within the prostate cancer datasets (I^2 of 42% [95%CI: 0–79%] and 56% [95% CI: 0–82%], respectively, for the two polymorphisms; Q-test p-value 0.037 and 0.14, respectively), although the heterogeneity pertained only to the exact magnitude of the genetic effects and a nominally statistically significant association was seen in each of the datasets except for the Framingham study where the number of prostate cancer cases was more limited.

Conversely, the results for all other cancers suggested no significant association and results were consistent across studies. The summary OR was 1.03 and 1.00 for the two polymorphisms respectively ($p = 0.14$ and 0.81 by fixed effects) and the 95% CIs excluded ORs deviating more than 7% from the null (OR = 1.00) for rs4430796 and more than 4% from the null for rs7501939 (Table 2). The Q-test p-value was 0.99 and 0.45 for the two polymorphisms respectively and random effects estimates were thus identical to fixed effects estimates.

There was also no convincing evidence for an association between either of the two polymorphisms and any of the other cancers (besides prostate cancer), when each cancer type was evaluated separately. Point estimates were in the opposite direction (odds ratio 1.03–1.05) for pancreatic and lung cancer, but were not nominally statistically significant (Table 2). The difference between the prostate cancer and other cancers' effect estimates was beyond chance ($p<0.05$) for both polymorphisms.

Table 2. Summary of results for association between rs4430796 and rs7501939 and diverse cancer types.

	rs4430796	rs4430796	rs4430796	rs7501939	rs7501939	rs7501939

OR: odds ratio, CI: confidence interval, n/a: not applicable (heterogeneity I^2 confidence intervals are not calculated when there are only 2 studies). Odds ratios are based on fixed effects calculations. When point estimates or confidence intervals differ by over 1% in random effects calculations, random effects results are mentioned in the text. * the common control groups of deCODE and FHS are counted only once.

doi:10.1371/journal.pone.0010858.t002

Discussion

The current collaborative analysis documents that both rs4430796 and rs7501939 have robust support for association with prostate cancer, while we did not observe any convincing evidence for an association of any of the other cancers examined with either polymorphism. When data from all other cancers, excluding prostate cancer, were combined the summary effects had 95% CIs that excluded even subtle associations. Apart from prostate cancer, when other datasets for each individual cancer type was combined, the 95% CIs consistently excluded associations with modest effects. This would suggest that the effects mediated by these polymorphisms are specific to T2D and prostate cancer and they do not involve any other cancer types.

The *HNF1B* gene encodes a transcription factor and it was initially identified as a MODY gene[13]. Subsequent studies have suggested that mutations in this gene may also be related to renal disease[35] and chromophobe renal cell carcinoma[36]. No GWAS evaluating kidney cancer were included in our analysis, and no kidney cancer GWAS has been published to-date. The expression profile of the gene shows a tissue-specific pattern. It is essential for embryonic survival and is expressed in the gut, kidney, liver, lung, pancreas, prostate, thymus and genital tract [37,38]. It could be speculated that the lack of association with some cancers studied here may be due to the low or absent expression of this gene in those tissues (for example breast cancer). We did not have data on liver cancer, thymoma or genital tract cancer, but data on lung, pancreatic, and colorectal cancer showed no association, with point estimates very near to the null.

The two variants that we assessed are not necessarily the functional culprits. GWA studies typically derive markers of phenotypes that are probably linked with the functional genetic variation[39]. However, identifying the functional variants is difficult. Even if they could be identified, it is unlikely that substantially large genetic effects for other cancers would exist, if the tagging variants have so consistently null effects. Another caveat is that we only examined populations of Caucasian descent. This reduces the heterogeneity that could be due to different LD patterns in populations of different ancestry. However, it would be worthwhile to investigate the associations of the *HNF1B* variants for T2D, prostate cancer, and other cancers, also in non-Caucasian populations. Preliminary data suggest that both of the examined variants had consistent associations with T2D in Caucasian, Asian (Hong Kong), and West African ancestry participants[9], while the association of rs4430796 with prostate cancer risk was found to be even stronger in the Japanese than in Caucasian populations[40]. Moreover, it would be useful to dissect associations with specific disease subsets. Even within the analyzed Caucasian-descent populations, we observed some modest between-study heterogeneity in the strength of the association between the *HNF1B* variants and prostate cancer. This may be due to different associations in different sub-phenotypes. For example, some data suggest that the rs4430796 A allele may primarily increase the risk for early-onset (<50 years) prostate cancer rather than later-onset disease[41].

In conclusion, while the two examined *HNF1B* variants conclusively have pleiotropic effects on both T2D and prostate cancer, the pleiotropy apparently does not extend to other cancer types. Genetic effects may offer a way to dissect comorbidity between specific cancers and metabolic phenotypes. Besides *HNF1B*, other gene loci have started appearing where variants are identified that modulate susceptibility to both T2D and some malignancy, e.g. prostate cancer for the *JAZF1* locus gene [11,42] and melanoma for the *CDKN2A* locus [43], although different, unlinked variants are implicated in the susceptibility to the malignancy and T2D, respectively. The elucidation of correlated pleiotropic effects on diverse phenotypes will require very large studies, given the generally subtle effects involved. Collaborative efforts between multiple teams, as in the current study, may offer a suitable approach to answer such questions.

Methods

Eligible GWA investigations and data

We used the NHGRI catalogue of published GWA studies[44], a comprehensive database of GWA investigations to identify GWA studies on cancer phenotypes published as of May 20, 2008. We also performed additional PubMed searches to identify whether any additional GWA studies on cancer phenotypes had been published until then. We focused on solid cancers, excluding hematologic malignancies. Given that these GWAS did not include any studies on pancreatic cancer (of special interest, given the association with T2D), we also identified GWAS on pancreatic cancer that had not been published by that time, so as to ensure their inclusion.

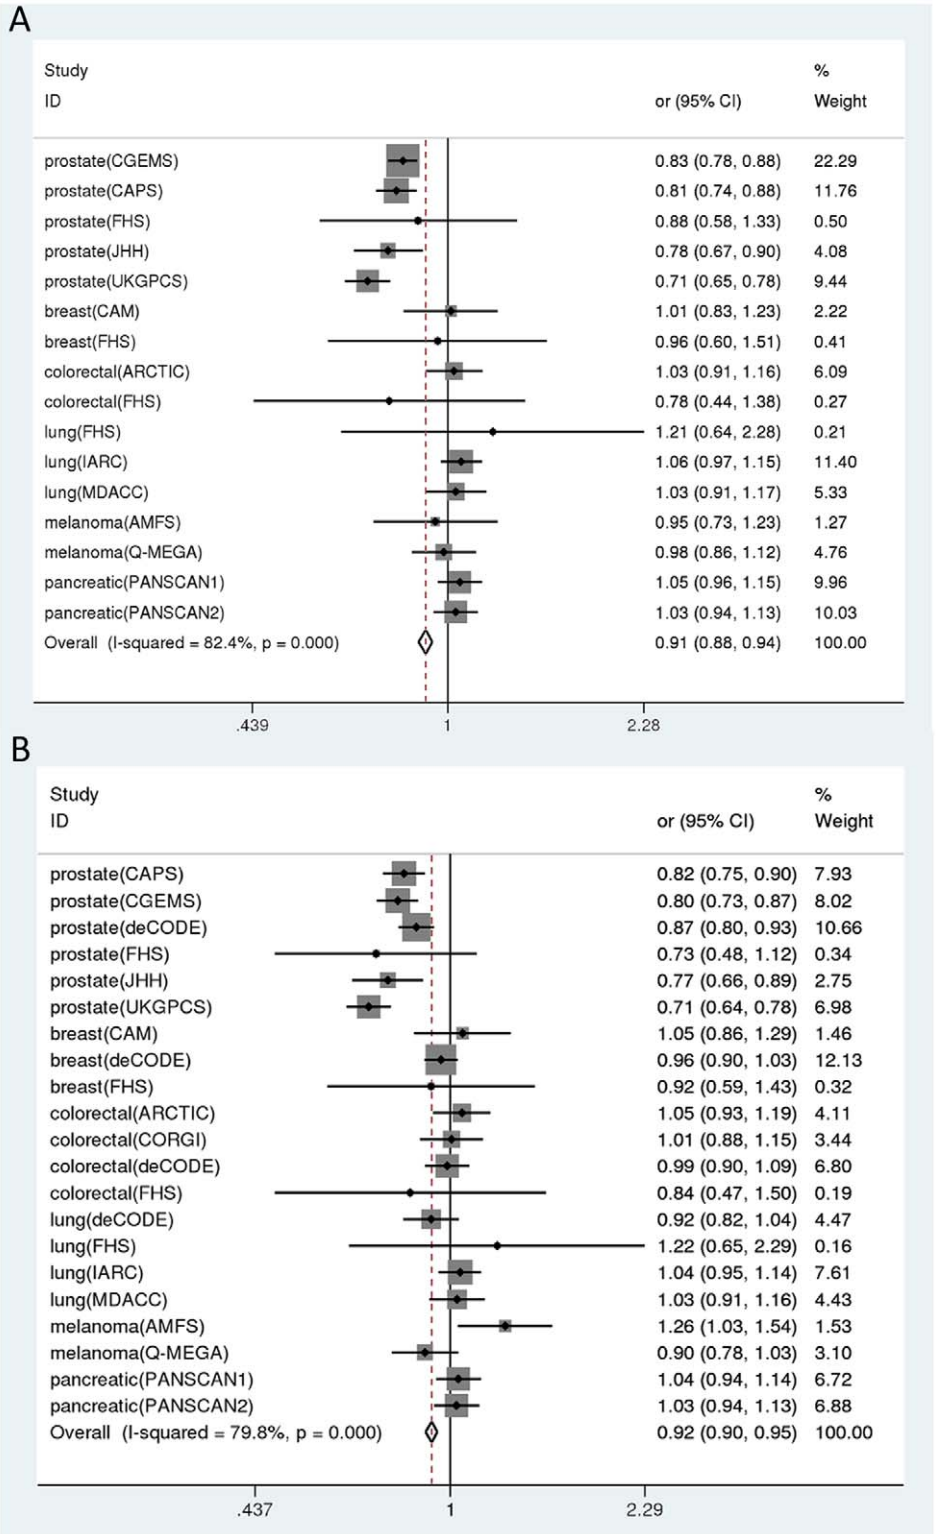

Figure 1. Association of rs4430796 and rs7501939 with diverse cancer types. Panel A shows results for rs4430796 and panel B shows results for rs7501939. Each study is shown by its odds ratio and 95% confidence intervals). Prostate cancer studies appear on the top and other cancer studies follow in alphabetical order. For the abbreviations of the names of the studies see Table 1. The summary diamond at the bottom corresponds to the fixed effects summary. Weight indicates the relative proportion of the total evidence found in each study (the weight is inversely proportional to the variance).

doi:10.1371/journal.pone.0010858.g001

We communicated with the corresponding and principal investigators of all of these studies to request their participation in the collaborative meta-analysis. The investigators of these studies were asked to contribute relevant data on genotype frequencies in cancer cases and non-cancer controls for the *HNF1B* variants, rs4430796 and rs7501939. The risk alleles for prostate cancer are A and C for rs4430796 and rs7501939 respectively. The risk alleles for T2D are G and T for rs4430796 and rs7501939 respectively. The two SNPs have modestly high LD in Caucasians, but low LD in Africans ($r^2 = 0.77$ and 0.22 in CEU and YRI, respectively). Investigators were requested to provide all GWA data that they had obtained for evaluation of any cancer phenotype, including any additional unpublished datasets. Additional genotyping for the two specific variants was encouraged, when a GWA platform had been used that did not directly genotype these polymorphisms (e.g. Affymetrix or Perlegen rather than Illumina). When a study had data on more than one cancer type, data were requested to be provided separately for each cancer type. Investigators were asked to provide also information and clarifications about the design of their studies, and to ensure that population stratification and cryptic relatedness had been appropriately addressed and appropriate quality controls were available for the genotyping. All GWAS investigations that contributed data on these SNPs used stringent QC standards (as described in detail in their original publications) and the two SNPs fulfilled these standards. Approval from local institutional review boards and steering committees was obtained, as deemed necessary for each study by its investigators. The contributed data were checked for completeness and with logical queries and any missing or unclear information was clarified through communication with the contributing investigators.

Meta-analysis

For each SNP, we performed meta-analyses including the data from all eligible cancer studies (regardless of the specific cancer phenotype addressed) and also subgroup meta-analyses, with each subgroup limited to studies addressing a specific cancer phenotype. A separate analysis compared the results of the association for prostate cancer versus the association for all other cancers combined.

All analyses followed the per allele (log-additive) model of inheritance with effect sizes expressed in the odds ratio (OR) scale using both fixed and random effects models[45]. Heterogeneity testing used the Q statistic (considered statistically significant at $p<0.10$), and the I^2 metric[46] and its 95% CIs [47]. Analyses excluding data from studies with pooled genotyping gave similar results (not shown).

Based on the accumulated total sample size and given the minor allele frequencies of these two polymorphisms in HapMap CEU (47% for rs4430796 A allele and 47% for rs7501939 T allele), the meta-analysis had 95% or higher power to detect an association of OR = 1.10 at alpha = 0.05 with each of the two polymorphisms for overall cancer risk, prostate cancer risk, or other cancer risk. Reported p-values are two-tailed. Analyses were performed in STATA 10.0 (College Station, Texas).

Periaortic Fat Deposition Is Associated With Peripheral Arterial Disease

The Framingham Heart Study

Caroline S. Fox, MD, MPH; Joseph M. Massaro, PhD; Christopher L. Schlett, MD; Sam J. Lehman, MBBS; James B. Meigs, MD, MPH; Christopher J. O'Donnell, MD, MPH; Udo Hoffmann, MD, MPH; Joanne M. Murabito, MD, ScM

Background—Central obesity is associated with peripheral arterial disease, suggesting that ectopic fat depots may be associated with localized diseases of the aorta and lower-extremity arteries. We hypothesized that persons with greater amounts of periaortic fat are more likely to have clinical PAD and a low ankle-brachial index.

Methods and Results—We quantified periaortic fat surrounding the thoracic aorta using a novel volumetric quantitative approach in 1205 participants from the Framingham Heart Study Offspring cohort (mean age, 65.9 years; women, 54%); visceral abdominal fat also was measured. Clinical peripheral arterial disease was defined as a history of intermittent claudication, and ankle-brachial index was dichotomized as low (≤0.9) or lower-extremity revascularization versus normal (>0.9 to <1.4). Regression models were created to examine the association between periaortic fat and intermittent claudication or low ankle-brachial index (n=66). In multivariable logistic regression, per 1 SD increase in periaortic fat, the odds ratio for the combined end point was 1.52 (P=0.004); these results were strengthened with additional adjustment for body mass index (odds ratio, 1.69; P=0.002) or visceral abdominal fat (odds ratio, 1.67; P=0.009), whereas no association was observed for visceral abdominal fat (P=0.16). Similarly, per SD increase in body mass index or waist circumference, no association was observed after accounting for visceral abdominal fat (body mass index, P=0.35; waist circumference, P=0.49).

Conclusions—Periaortic fat is associated with low ABI and intermittent claudication. **(*Circ Cardiovasc Imaging*. 2010; 3:515-519.)**

Key Words: obesity ■ atherosclerosis ■ peripheral vascular diseases

Peripheral arterial disease (PAD) affects >12% of adults in the United States and is strongly associated with multiple cardiovascular disease risk factors.[1,2] PAD is associated with an increased risk of cardiovascular disease and all-cause mortality,[3,4] highlighting the need for a better understanding of the pathogenesis of PAD.

Clinical Perspective on p 519

Although traditional cardiovascular disease risk factors such as smoking and diabetes also are strong risk factors for PAD,[5] only central obesity, but not generalized obesity, has been shown to be associated with PAD.[6,7] In this context, body fat distribution is an important factor in determining overall cardiometabolic risk.[8,9] Ectopic fat depots, defined as fat depots in nonclassical locations,[10] typically are believed to exert systemic effects on cardiometabolic risk. However, locally acting ectopic fat depots may contribute to obesity-mediated vascular disease.[10,11] In particular, perivascular fat, or fat that surrounds blood vessels, is a physiological modulator of vascular tone and adipocyte hypertrophy that can lead to hypoxia, inflammation, and oxidative stress.[12] Further, recent experimental work suggests that perivascular fat may provide a mechanistic link between metabolic signals and vessel wall inflammation[13] and vascular smooth muscle cell proliferation.[14]

We have developed a reproducible protocol to quantify periaortic fat[15] in order to examine whether perivascular fat may mediate diseases of the aorta. Because prior findings demonstrated an association of central but not generalized obesity with PAD, we hypothesized that persons with greater amounts of periaortic fat will have a higher prevalence of low ankle-brachial index (ABI) values and clinical PAD.

Figure. A, The upper boundaries of periaortic fat in an axial CT image. B, The corresponding 3D reconstruction. Periaortic fat, as measured by CT, was defined as any pixel of attenuation between −195 and −45 Hounsfield units within the region of interest.

Methods

Study Sample

In 1971, the Framingham Offspring Study enrolled children and spouses of the original Framingham Heart Study cohort. Participants for the current analysis took part in the multidetector CT substudy. From the Framingham Offspring Study, 1422 participants underwent chest and abdominal multidetector CT from 2002 to 2005. Of these, 1397 were analyzed for perivascular fat, and 1295 had nonmissing ABI ≤1.4. Of these, 1205 had nonmissing covariates and were included in the analysis.

The institutional review boards of Boston University Medical Center and Massachusetts General Hospital approved the study protocol. Written informed consent was provided by all participants.

Multidetector CT Scan Protocol

Scans of the abdomen and chest were performed with 8-slice multidetector CT. In the chest cavity, a series of 2.5-mm slices were acquired from the level of the carina to the diaphragm during an inspiratory breath-hold using prospective ECG triggering (120 kVp, 320 mA). In the abdomen, 2.5-mm slices (120 kVp, 320 mA) were obtained from the upper edge of the S1 vertebrae and 125 mm superiorly.

Measurement of Periaortic Fat Volume

Image analyses were performed on a dedicated workstation.[15] Using a semiautomated method, adipose tissue quantification was performed, which required manually defining the tissue borders. To calculate adipose tissue volumes, CT attenuation thresholds (window width, −195 to −45 Hounsfield units; window center, −120 Hounsfield units) were used. The anatomic borders to define thoracic periaortic fat were (1) anterior (indicating the area immediately surrounding the thoracic aorta), which was defined by a line drawn horizontally through the esophagus that connected to the left costovertebral joint, and (2) posterior, which was defined by the right lateral border of the vertebral body and the anterior edge of the vertebral body. These definitions resulted in a 6.75-cm column of fat (27 slices) surrounding the thoracic aorta. The Figure shows the region that was quantified. We also defined a measure consisting of abdominal periaortic fat, which consisted of tracing 5-mm rings calibrated to the vessel diameter. However, technical limitations, including the inherent relationship with the vessel diameter and the inability to visualize the retroperitoneal lining, limit the interpretation of these data, and hence, they are not included in the current analysis. Reproducibility was excellent for intra- and interreader measurements of the thoracic periaortic fat (intraclass correlation coefficient, 0.99 and 0.98, respectively).[15]

We quantified visceral abdominal fat (VAT) as previously described.[17] Briefly, the reader manually traced the abdominal muscular wall separating the subcutaneous from the VAT depot. Semiautomatic quantification of fat volumes was facilitated with a window width of −195 to −45 Hounsfield units.

ABI and PAD Assessment

At examination 8 (2005 to 2008), ankle and brachial blood pressures were routinely measured on all participants. Participants rested for a minimum of 5 minutes in the supine position on the examining table before blood pressure measurement. Blood pressure cuffs were applied to bare ankles with the midpoint of the bladder over the posterior tibial artery approximately 3 cm above the medial malleolus. Systolic blood pressure was obtained using a 9.6-MHz Doppler pen probe and an ultrasonic Doppler flow detector. For each limb, the cuff was inflated rapidly to the maximal inflation level and deflated at a rate of 2 mm Hg per second until the systolic blood pressure became audible. Measurements were obtained in the following order: right arm, right ankle, left ankle, left arm. All limb blood pressures were repeated in reverse order. Measurement was obtained from the dorsalis pedis artery only if the posterior tibial pulse could not be located by palpation or with the Doppler pen probe.

The ABI was calculated for each leg as the ratio of the average systolic blood pressure in the ankle divided by the average systolic blood pressure in the arm. The higher arm mean was used to calculate the ABI for each leg. The lower of the ABIs from the 2 legs was used for analysis.

As part of routine Framingham Heart Study research examinations, a physician-administered medical history interview was conducted that included queries about lower-extremity revascularization. Medical records were obtained to verify self-report of all revascularization procedures. The physician also used a standardized questionnaire to query the participant about symptoms of intermittent claudication (IC).[2] IC was defined as exertional discomfort in the calf that appeared sooner with uphill or more rapid walking pace and was relieved with rest. An end point review panel of 3 senior investigators made the final determination of the presence of IC. The mean time between CT scan acquisition and ABI measurement was 2.5 years.

Risk Factor Assessment

Cardiometabolic risk factors also were quantified during the examination 8. Body mass index (BMI) was defined as the weight (kg) divided by height (m^2). Waist circumference (WC) was ascertained at the umbilicus. Fasting morning blood samples were collected for blood glucose and lipids. Diabetes was defined as a fasting plasma glucose of at least 126 mg/dL or hypoglycemic treatment. Current-smokers were defined as participants who smoked at least 1 cigarette per day in the year prior to their eighth examination. The definition of hypertension used was systolic blood pressure of at least 140 mm Hg, diastolic blood pressure of at least 90 mm Hg, or antihypertensive therapy.

Circulating fasting plasma levels of resistin and adiponectin were quantified by ELISA. Intraassay coefficients of variation were 9.0% for resistin and 5.8% for adiponectin.

Statistical Analysis

Thoracic periaortic fat and VAT volumes were normally distributed. ABI was dichotomized at ≤0.9; participants with a history of

Lower-extremity revascularization‡	7 (0.6)

Data are presented as mean±SD or no. (%), unless otherwise indicated. HDL indicates high-density lipoprotein.

*Median with 25th to 75th percentiles.

†In a subsample of 975 participants.

‡Seven participants with lower-extremity revascularization were part of the 66 participants with IC or low ABI; 3 also had prevalent IC, 1 had an ABI ≤0.9, 1 had both IC and abnormal ABI, and 2 had neither.

lower-extremity surgery were considered in the low ABI category. Participants with an ABI >1.4 were excluded because none had any IC symptoms or a prior revascularization procedure. Low ABI and IC were combined as the primary analysis (n=66). Analyses were modeled with periaortic fat and VAT as exposures, and low ABI and IC were combined as outcomes. BMI and WC also were modeled as separate exposures; all adipose tissue data are presented per 1 SD increase. The multivariable logistic regression model included the covariates of age, sex, smoking, diabetes, hypertension, total and high-density lipoprotein cholesterol, lipid treatment, and log triglycerides. Additional models with periaortic fat included BMI or VAT as covariates. Analyses were performed with SAS version 9.1.3. $P<0.05$ was considered statistically significant.

Results

Study Sample Characteristics

The mean age of the study sample was 65.8 years, and 53.7% were women (Table 1). Overall, 45 participants had an ABI ≤0.9, 35 had a history of IC, and 66 had either a low ABI or IC. Thoracic periaortic fat was strongly associated with VAT ($r=0.74$; $P<0.001$).

Table 3. Multivariable-Adjusted Regressions for Periaortic Fat and Low ABI and IC Individually

	Low ABI (n=45)		IC (n=35)	
Model	OR (95% CI)	*P*	OR (95% CI)	*P*
Age, sex	1.89 (1.42–2.52)	<0.001	1.90 (1.39–2.59)	<0.001
Age, sex, MV	1.78 (1.27–2.48)	<0.001	1.54 (1.08–2.19)	0.02
Age, sex, MV+BMI	2.07 (1.41–3.04)	<0.001	1.62 (1.09–2.41)	0.02
Age, sex, MV+VAT	1.98 (1.25–3.13)	0.004	1.69 (1.05–2.72)	0.03

Data are presented as per 1 SD increase of periaortic fat. The multivariable was adjusted for smoking, diabetes, hypertension, total and high-density lipoprotein cholesterol, lipid treatment, and log triglycerides. MV indicates multivariable.

Association Between Periaortic Fat and Combined Low ABI and IC

In minimally adjusted models per SD increase in periaortic fat, the odds ratio (OR) for low ABI or IC was 1.79 (95% CI, 1.40 to 2.30; $P<0.001$) (Table 2). Further adjustment for clinical covariates modestly affected the OR (1.52; $P=0.004$). Similarly, additional adjustment for BMI or VAT did not materially affect the results (BMI-adjusted OR, 1.69; VAT-adjusted OR, 1.67). In contrast, VAT was associated with low ABI or IC in minimally adjusted models (OR, 1.44; 95% CI, 1.12 to 1.87; $P=0.005$), but these findings were attenuated after adjustment for standard covariates (OR, 1.23; $P=0.16$).

We also examined the associations between BMI and WC with low ABI or IC (Table 2). BMI was not associated with the combined end point in minimally adjusted models (OR, 1.19; $P=0.18$), whereas WC was modestly associated with low ABI or IC in age- and sex-adjusted models (OR, 1.37; $P=0.02$), which was attenuated on adjustment for VAT (OR, 1.14; $P=0.49$).

Association Between Periaortic Fat and Low ABI or IC

Results for low ABI or IC as separate outcomes were similar to the combined outcome models (Table 3).

Secondary Analysis

In secondary analyses of a subset of participants (n=975), we also adjusted our primary model of VAT as a correlate for

Table 2. Multivariable-Adjusted Regressions for Periaortic Fat and the Combined End Point of IC and Low ABI (n=66)

	Thoracic Periaortic Fat		VAT		BMI		WC	
	OR (95% CI)	*P*	OR (95% CI)	*P*	OR (95% CI)	*P*	OR (95% CI)	*P*
Age, sex	1.79 (1.40–2.30)	<0.001	1.44 (1.12–1.87)	0.005	1.19 (0.92–1.52)	0.18	1.37 (1.06–1.77)	0.02
Age, sex, MV	1.52 (1.15–2.02)	0.004	1.23 (0.92–1.65)	0.16	1.03 (0.78–1.36)	0.85	1.23 (0.93–1.65)	0.15
Age, sex, MV+BMI	1.69 (1.22–2.34)	0.002	1.40 (0.95–2.06)	0.09	…	…	1.64 (1.03–2.62)	0.04

Data are presented as per 1 SD increase of thoracic abdominal fat, VAT, BMI, or WC. The multivariable was adjusted for smoking, diabetes, hypertension, total and high-density lipoprotein cholesterol, lipid treatment, and log triglycerides. MV indicates multivariable.

low ABI or IC for adiponectin and resistin. The results were not materially different (OR, 1.73; $P=0.01$).

Discussion

Principal Findings

In our community-based sample of participants from the Framingham Heart Study, we demonstrated that periaortic fat is associated with low ABI and IC. We did not observe a similar association with BMI, WC, or VAT. Our findings suggest a potential role for periaortic fat in the pathogenesis of PAD.

In the Context of Current Literature

The association between BMI and PAD has been inconsistent.[18,19] Some studies demonstrate a linear association between BMI and ABI level,[20] whereas others showed no association[5] or an association with the highest BMI in participants within the lowest ABI category[21] or in those with a high ABI (>1.3).[18] Central obesity, but not BMI, has previously been associated with PAD in a cohort of elderly men.[6] Similarly, in a study of elderly participants from the Osteoporotic Fractures in Men study, waist-to-hip ratio, but not BMI, was associated with low ABI.[7] In the German cohort of the Reduction of Atherothrombosis for Continued Health registry, 50% of patients with PAD had abdominal obesity.[22] Obesity previously has been associated with the severity of PAD.[23] Obese patients report more calf pain than the general population, and obese patients who undergo surgical treatment for obesity have a lower risk of developing calf pain.[24] Taken together, the literature suggests that body composition, particularly for persons with increased central fat, may indicate increased risk for PAD. The present study extends these findings by identifying an association between periaortic fat and PAD.

Potential Mechanisms

Experiments in rat aorta demonstrate that periaortic adipose tissue releases growth factors that stimulate smooth muscle cell proliferation that is enhanced in aged rats and rats fed a high-fat diet.[14] These findings suggest that perivascular adipose tissue may promote vascular disease through dysfunction of smooth muscle cells. Adipocytes secrete numerous other factors, including proinflammatory cytokines and adipokines, that also may promote development of vascular disease.[13] Recent in vitro work demonstrated that under basal conditions, human perivascular adipocytes show evidence of a proinflammatory state and reduced adipocyte differentiation. Thus, perivascular adipocytes may contribute to adventitial inflammation and, in turn, the development of atherosclerosis. Greenstein et al[12] isolated perivascular adipose tissue from small arteries taken from gluteal fat biopsy samples and demonstrated that the adipocytes secrete adiponectin, a physiological modulator of vascular tone. On further examination of perivascular fat from obese subjects, the investigators noted a loss of this vasodilatory effect due to adipocyte hypertrophy, leading to inflammation and oxidative stress. In the obese Zucker rat, hind limb blood flow was reduced with concomitant stiffer vessels, and this was independent of muscle mass and physical activity,[25] providing a potential mechanism for which obesity can lead to PAD. The pathophysiologic mechanisms by which local adipose tissue influences development of vascular disease remain to be determined and represent an exciting area of active research.

Clinical and Research Implications

These findings highlight the potential toxic role of periaortic fat on the peripheral vasculature and suggest a potential mechanism whereby obesity might lead to the development of PAD. Further research is necessary to uncover the specific mechanisms of disease. Whether reduction of periaortic fat can lead to reduced PAD or PAD progression requires further examination.

Strengths and Limitations

The strength of the present analysis was the detailed characterization of ectopic fat depots, which allowed us to examine the associations between thoracic periaortic fat and VAT with low ABI and IC. Important covariates were routinely collected, limiting any potential for recall bias. Some limitations warrant mention. First, the participants were white, limiting generalizability to other races/ethnicities. Second, our measure of abdominal periaortic fat is not reliable, limiting our ability to directly quantify this fat depot in the abdomen. We used thoracic periaortic fat as a proxy measure of perivascular fat through the entire arterial tree because we were unable to quantify perifemoral artery fat. Further research is necessary to better understand the distribution of periaortic fat through the vascular territory. Ectopic fat depots are hypothesized to primarily have systemic effects, such as VAT,[8] or local effects, such as pericardial fat or periaortic fat. The results from the present study suggest that only periaortic fat and not BMI, WC, or VAT are associated with PAD, rendering a systemic effect of periaortic fat unlikely. However, this study is cross-sectional; therefore, causation cannot be inferred. Smoking was defined as cigarette smoking within the past 12 months; thus, some degree of misclassification may occur among participants who stopped smoking within this time interval.

Sources of Funding

This work was supported by the National Heart, Lung, and Blood Institute Framingham Heart Study (N01-HC-25195), the General Clinical Research Centers Program (grant number M01-RR-01066), and a Career Development Award from the American Diabetes Association and National Institute of Diabetes and Digestive and Kidney Diseases (K24 DK080140) to Dr Massaro.

Disclosures

Dr Massaro currently has research grants from GlaxoSmithKline and Sanofi-Aventis, and has consulting agreements with Eli Lilly and Interleukin Genetics. The other authors report no conflicts.

CLINICAL PERSPECTIVE

Central obesity is associated with peripheral arterial disease, suggesting that ectopic fat depots may be associated with localized diseases of the aorta and lower-extremity arteries. We hypothesized that persons with greater amounts of periaortic fat are more likely to have clinical peripheral arterial disease and a low ankle-brachial index. We found that periaortic fat is associated with peripheral arterial disease and low ABI, whereas no association with body mass index, waist circumference, or visceral abdominal fat was observed. Periaortic fat is associated with low ABI and intermittent claudication.

ALCOHOLISM CLINICAL & EXPERIMENTAL RESEARCH

The Mixed Evidence for Brief Intervention in Emergency Departments, Trauma Care Centers, and Inpatient Hospital Settings: What Should We Do?

Craig A. Field, Janette Baird, Richard Saitz, Raul Caetano, and Peter M. Monti

Background: This qualitative review is based on a symposia presented at the 2009 annual conference of the Research Society on Alcoholism (Baird et al., 2009; Field et al., 2009; Monti et al., 2009; Saitz et al., 2009a). The purpose is to describe the mixed evidence supporting brief interventions in the emergency department, trauma care, and in-patient medical care settings; examine potential moderators of treatment outcome in light of the mixed evidence; and identify methods to move the research and practice of brief interventions beyond their current state.

Methods: By drawing upon existing reviews and selected individual studies, we provide examples that reflect the current complexity of research in this area and propose steps for advancing the field.

Results: Emergency departments, inpatient hospital settings, and trauma care settings represent three unique contexts within which brief interventions have been tested. While the general efficacy of brief alcohol interventions in these settings has been recognized, the evidence is increasingly mixed. Recent studies investigating potential moderators of treatment outcomes suggest that a more sophisticated approach to evaluating the effectiveness of brief interventions across varying patient populations is needed to further understand its effectiveness.

Conclusions: Current dissemination efforts represent a significant advance in broadening the base of treatment for alcohol problems by providing an evidence-based intervention in health care settings and should not be curtailed. However, additional research is required to enhance treatment outcomes, refine current practice guidelines, and continue to bridge the gap between science and practice. Given the current state of research, a multisetting clinical trial is recommended to account for potential contextual differences while controlling for study design.

Key Words: Brief Intervention, Emergency Departments, Inpatient Hospital Settings, Review, Trauma Centers.

THE PURPOSE OF this qualitative review of the scientific literature on brief intervention is to (i) describe the mixed evidence supporting brief interventions in the emergency department, trauma care, and inpatient medical care settings; (ii) examine potential moderators of treatment outcome in light of the mixed evidence; and (iii) identify methods to move the research and practice of brief interventions beyond their current state. The intent is not to carry out a systematic review or meta-analysis of screening and brief intervention. Rather, the aim is to draw upon existing reviews and selected individual studies to provide examples that reflect the current complexity of research in this area and propose steps for advancing the field. The review is a product of a symposium presented at the 2009 annual conference of the Research Society on Alcoholism (Baird et al., 2009; Field et al., 2009; Monti et al., 2009; Saitz et al., 2009a,b), which focused on the moderating factors of brief interventions provided to adults in the emergency department, trauma care setting, and inpatient hospital setting.

Emergency departments, inpatient hospital settings, and trauma care settings represent 3 unique contexts within which brief interventions have been tested. In emergency departments, physicians provide care to patients with acute medical and surgical problems including injuries. Emergency department patients with more severe conditions are admitted to the hospital for inpatient care. Inpatient acute care hospital settings are staffed by doctors in medical and surgical specialties and serve a range of patients with diverse acute illnesses and

chronic comorbidities. Trauma centers are staffed by trauma surgeons and coexist with emergency departments and other inpatient hospital settings but have a separate accreditation process from emergency departments and hospitals. Trauma centers provide care to severely injured patients most of whom are hospitalized following acute medical treatment for the trauma. This qualitative review distinguishes between these settings given the different contexts in which brief intervention is provided and the differences in patient characteristics presenting to these medical settings. The overarching characteristic these contexts have in common is that they are appropriate settings for opportunistic interventions. Opportunistic interventions are provided to patients with at-risk drinking, alcohol abuse, or dependence who are not seeking treatment for alcohol problems, per se. Brief opportunistic interventions are short, face-to-face conversations regarding drinking, motivation to change, and options for change which are provided during a window of opportunity or potentially teachable moment occasioned by a medical event.

THE CASE FOR BRIEF INTERVENTION

Previous studies have demonstrated the general effectiveness of BI for alcohol problems among patients with trauma. For example, Gentilello and colleagues (1999) showed that adult injured patients with moderate alcohol problems who received BI after being admitted to a Level 1 trauma center decreased alcohol consumption significantly at 12 months, although there was substantial loss to follow-up. Gentilello and colleagues (1999) also observed a statistically nonsignificant reduction in injury requiring treatment in the emergency department or readmission to the trauma center. In an adjusted analysis, Schermer and colleagues (2006) determined that BI significantly reduced arrests for driving under the influence of alcohol (DUI) at 3-year follow-up such that for every 9 interventions provided, there was a reduction in 1 DUI arrest. Finally, Gentilello and colleagues (2005) conducted a cost–benefit analysis based, in part, on the efficacy data of the original clinical trial (Gentilello et al., 1999) and found that for every dollar spent, there was $3.81 saved in direct injury-related medical costs. Therefore, if BI were offered to every eligible injured person in the United States, the resulting savings from health care costs alone would be approximately $1.82 billion annually. On the basis of this evidence, the American College of Surgeons (ACS) mandated that all Level I and Level II trauma centers have a mechanism to identify patients with alcohol problems, and all Level I trauma centers have a mechanism to provide an intervention for patients identified as problem drinkers (Committee on Trauma, 2006). Coinciding with the ACS mandate, the evidence for the efficacy of BI in the trauma care setting became increasingly mixed.

In one of the earliest randomized controlled trials of BI conducted with adult emergency department patients, Longabaugh and colleagues (2001) showed that patients who received the BI in the ED along with a follow-up booster BI showed a significant decrease in alcohol-related negative consequences compared to a standard care group. However, there was no significant difference in reduction between the group receiving a single BI and the standard care group nor were there significant reductions in drinking associated with the BI with booster. More recently, in a quasi-experimental, nonrandomized study, the Academic ED SBIRT (Screening, Brief Intervention and Referral to Treatment in the Emergency Department) Collaborative reported a short-term reduction of 3.25 drinks per week versus controls across 14 ED sites, with 28% of the intervention group no longer exceeding drinking guidelines versus 18% of controls (Academic ED SBIRT Research Collaborative, 2007). In contrast, Daeppen and colleagues (2007), in a randomized trial that included a BI group and 2 control conditions (assessment only and no assessment), found no differential reduction between these 3 groups in terms of alcohol use or health care utilization. Another large randomized trial (D'Onofrio et al., 2008) also showed no significant differences in average volume per week or binge drinking episodes. It is worth noting that both of these negative studies had high follow-up rates. In conclusion, results of research on brief intervention in the emergency department setting are no less ambiguous than those conducted in the trauma center.

A recent review of 14 studies of brief intervention concluded that, in general, there was an effect of brief intervention on reduced alcohol consumption, hazardous use of alcohol, and alcohol-related injuries in comparison with usual emergency department care (Nilsen et al., 2008). However, 5 of the 14 studies found no effect of brief intervention on these outcomes, and even among the studies that found a treatment effect, the BI did not influence similar outcomes. That is, studies that reported a significant effect of BI tended to report either a reduction in alcohol consumption or a reduction in alcohol-related negative consequences, but not both. In almost all of these studies, the control or standard care group also showed decreases in either alcohol consumption or alcohol-related negative consequences that was either coincident with or related to the ED visit.

The general lack of consistency among studies regarding the effectiveness of BI in emergency and trauma departments or the nonspecific effect that BI has on varied alcohol-related outcomes raises questions about the optimal application of BI in these settings. While a substantial amount of research pertaining to the effectiveness of brief intervention has accumulated, inconsistencies in results and the potential impact of various moderators remain unreconciled. Moderators that may be related to patient characteristics, treatment dosing or fidelity factors, or site specific factors (e.g., the context for the intervention) may eliminate, attenuate, or amplify the effects of BI. Future research exploring these aspects may help determine what types of interventions are most effective and what types of patients benefit most. This research would enhance the overall effectiveness of these strategies and/or targeting of interventions to patients who are most likely to benefit.

MODERATORS AFFECTING TREATMENT OUTCOMES: THE USUAL SUSPECTS

One potential explanation for the mixed findings discussed earlier is that, while brief intervention is sometimes effective, certain patient and/or setting characteristics (i.e., context bound effects) are moderators of treatment outcomes following brief interventions. By moderators, we not only mean variation in levels of treatment (e.g., amount or intensity) or in other aspects of treatment (e.g., differences in intervention components or context) but also in participants' predispositions. These cannot be randomized but have to be statistically accounted for as potential sources of variation in treatment outcomes. In a recent systematic review, Nilsen and colleagues (2008) pointed out that moderator analyses of BI effectiveness for reducing alcohol use or alcohol-related negative consequences among trauma or emergency department patients have been empirically evaluated in too few studies to allow for definitive conclusions regarding their influence. However, a number of recent studies have begun to explore potential moderators of treatment outcome following brief intervention in the emergency department.

Monti and colleagues (2009) recently reported differences in treatment outcomes among patients with higher initial motivation to change and those recruited from a trauma unit (in contradistinction to those recruited from emergency department). These patients showed greater reductions in drinking and alcohol-related consequences, but they were not moderators of brief intervention. In their evaluation of moderating effects, Barnett and colleagues (2010) found that drinking at the time of the injury and attribution of the injury to alcohol moderated intervention effects. Participants who were not drinking prior to their injury and those with low or medium attributions and received brief intervention showed lower alcohol use at 12 -month follow-up. In contrast, those who were drinking at the time of their injury and those high in attribution did not show intervention group differences in alcohol use. In contrast, Walton and colleagues (2008) found that patients who received intervention and attributed their injury to alcohol use drank less and had fewer heavy drinking episodes than those who made no attribution of their injury to their alcohol use.

While these studies represent significant strides, they are perhaps no more definitive than studies regarding the main effect of brief intervention. As a result, research on moderators remains essential because, given the mixed findings regarding the main effects of brief intervention, it is essential to delineate subgroups of patients who may differentially benefit from brief intervention. For this review, we have chosen to focus on 2 commonly investigated moderators including severity of alcohol problems and readiness to change. The results of studies examining moderators of behavior change and the mixed findings from these studies further illustrate the challenge of reaching definitive conclusions from existing studies.

Readiness to change alcohol use and severity of alcohol problems have been the most commonly evaluated moderators in studies of BI. Walton and colleagues (2008) found that readiness to change alcohol use and self-efficacy for changing drinking behavior did not moderate effects of BI on alcohol consumption among adult emergency department patients. In contrast, Barnett and colleagues (2010) found that patients in the emergency department with low or medium readiness to change (vs. high) did evidence greater reductions in alcohol use after receiving BI. But, in the inpatient hospital setting, readiness did not appear to moderate the effects of brief intervention (Saitz et al., 2009a,b). Stein and colleagues (2009), in a secondary analysis of the data from the Longabaugh and colleagues (2001) study, found that readiness mediated the effect of treatment on alcohol-related consequences only for those highly motivated to change prior to the intervention but not for those with low pre-intervention motivation. Thus, the observed treatment effect on drinking-related consequences was due, in part, because it helped enhance or maintain readiness to change among those already highly motivated to change. Given that the BI in the Longabaugh study was based on the principles of motivational interviewing, which is intended to increase patient motivation change, the findings of Stein and colleagues (2009) are counterintuitive because ED patients who were less motivated to change (vs. those highly motivated to change) did not benefit from brief intervention. As both Longabaugh and colleagues (2001) and Stein and colleagues (2009) note, a BI delivered in the ED to nontreatment seeking patients may in itself lack the robustness to instigate change without some pre-existing recognition for the need and desire to change alcohol use behaviors among this patient population.

With regard to alcohol severity, a recent study conducted in the trauma care setting by Field and Caetano (2010) determined that brief intervention was effective among admitted injured patients who met DSM-IV criteria for alcohol dependence. This finding is noteworthy because BI has generally been targeted toward nondependent drinkers with the assumption that it was less effective among patients with alcohol dependence. Based on these clinical recommendations, many studies have included indicators of alcohol dependence (e.g., recent history of substance abuse treatment or prior diagnosis) as exclusion criteria. As a result, the findings from Field and Caetano (2010) are particularly important because they may help shed light on recent null findings (most notably, Daeppen et al., 2007; Soderstrom et al., 2007 and Sommers et al., 2006) from well-designed studies that excluded participants who were most likely to meet criteria for alcohol dependence. Mello and colleagues (2008) reporting on the 3-month results from a randomized control trial in which injured emergency department patients received standard care or 2 telephone BI's, found that only those patients who received BI and who had the most severe baseline alcohol scores (as mea-

sured by an Alcohol Use Disorders Identification Test or AUDIT score of 8 or more) showed significant reductions in alcohol-impaired driving. In contrast to the findings of Field and Caetano (2010) and Mello and colleagues (2008), Saitz and colleagues (2009a,b) recently reported that brief intervention was associated with improved outcomes among nondependent drinkers but not among those with alcohol dependence.

These initial studies of potential moderators suggest that BI may not be universally effective across settings and contexts, and that the medical care setting of a hospital emergency department, trauma center, or medical inpatient setting may differ from one another. For example, in the emergency department, there may be numerous interruptions to provide medical care. This may be the reason why Longabaugh found that to produce treatment effects, the participants needed to have received a booster session that took place outside of the emergency department. In contrast, the inpatient setting may present fewer interruptions, but the severity of the patient's medical condition, particularly among patients with trauma, may be a limiting factor to the provision of brief intervention. In addition to the provider's ability to conduct brief intervention, the severity of the medical condition may also influence the patient's receptivity to brief intervention. For example, brief intervention in the trauma department or emergency department may be more effective than inpatient hospital settings because of the saliency of the medical event. Alternatively, the saliency of the event may obviate the need for BI if the medical event itself is sufficient to prompt self-change. In general, differences with regard to findings pertaining to moderating effects may also be a function of different inclusion criteria, intervention conditions, differences in patient population (e.g., age, race/ethnicity, socioeconomic status etc.), or other methodological differences between the studies.

One common criticism of brief intervention studies conducted in the trauma care setting is the apparent inability to account for the impact of the injury event on subsequent drinking behavior. Mello and colleagues (2005) investigated type of injury as a potential moderator and found that brief intervention was effective among those in a motor vehicle collision as opposed to other unintentional or intentional injuries. However, this does not account for the psychological impact of the injury per se that may vary within patients from a particular setting and across treatment contexts. For example, some medical inpatients may have continued to drink despite the development of a symptomatic condition that leads to hospitalization, while others may be provided care for medical problems unassociated with their drinking. Thus, patient receptivity to brief intervention may also vary across hospital settings. Additional efforts to account for individual differences in response to the medical event are particularly important because patient characteristics and context factors may help explain the differential effectiveness of brief intervention across various medical settings.

WHAT IS BRIEF INTERVENTION IN THE MEDICAL SETTING?

While studies in diverse patient populations increase generalizability, the variation in setting and patient population across studies may be an important piece of the puzzle which is often disregarded in systematic reviews, meta-analyses and commentaries or editorials, which attempt to synthesize the results of studies conducted across medical settings as if they were uniform. Nilsen and colleagues (2008) noted that the studies included in their systematic review were conducted in 3 types of medical settings including outpatient emergency departments, inpatient hospitals or trauma centers, and outpatient clinics. This, in and of itself, creates significant problems in terms of deriving general statements about the effectiveness of BI and condensing the results of these studies to yield definitive conclusions. This is due in part because patient characteristics and contextual factors may influence the effectiveness of brief interventions. A meaningful synthesis of current studies also requires greater uniformity in the use of brief intervention, a common approach for identifying patients who receive brief intervention, and increased similarity in both operationalizing and measuring outcomes and consistency in statistical approaches for analyzing those outcomes (Nilsen et al., 2008). Given fundamental differences in these methodologies, we are far from being able to reach definitive conclusions based on the current body of research.

The research on brief intervention in the medical care setting also conflates several distinct types of interventions. For example, brief advice, brief intervention, and brief interventions with multiple visits are all referred to as brief intervention. In a recent meta-analysis of brief intervention in the emergency department setting, 14 studies were identified for inclusion (Moyer et al., 2002). Ten studies evaluated a single session, 8 incorporated principles of motivational interviewing, and 8 provided a handout that included generic advice, personalized advice or feedback based on blood alcohol concentration at the time of admission. In studies that reported the length of the session, the length of the session varied from 5 to 60 minutes. Six studies reported that for the majority of participants, the intervention took place in the emergency department; 2 reported that the majority of sessions took place on an outpatient basis, and 2 studies reported that missed participants were scheduled to return for a visit, and 2 did not indicate the location of the intervention. Beich and colleagues (2003), Emmen and colleagues (2004), and Nilsen and colleagues (2008) reported similar variability in duration, approach, content as well as target population and provider characteristics. As noted by Nilsen and colleagues (2008), the general lack of methodological detail in many studies of brief intervention makes it difficult to discern whether 1 treatment approach or a range of treatment approaches is being evaluated.

While efforts to standardize brief interventions are essential to ongoing research and dissemination, 1 approach for addressing differences in intervention protocols across studies

is to test the underlying theory of brief intervention. Apodaca and Longabaugh (2009), in a recent meta-analysis, evaluated the results of 19 studies and found that limited attention had been given to testing the underlying theory. The most consistent evidence found during their review was that client change talk and client experience of discrepancy were related to better outcomes, and clinician behavior inconsistent with motivational interviewing was related to worse outcomes. Furthermore, the use of a decisional balance exercise showed the strongest association with better outcomes. This initial review of early evidence pertaining to mechanisms of change may provide a starting point for future research investigating the active ingredients and mechanisms of behavior change underlying brief interventions in various medical settings.

RESEARCH ON BRIEF INTERVENTION: NEITHER HERE NOR THERE

Clinical trials are often categorized as either efficacy or effectiveness research that generally focuses on either internal or external validity, respectively. Advancement in clinical research typically proceeds from establishing efficacy in well-controlled clinical trials to testing the generalizability of those findings in effectiveness trials. More recently, alternative conceptualizations to this dichotomy have emerged. Specifically, the terms hybrid research, translational research, practical or pragmatic trials have emerged as similar concepts reflecting the merging of efficacy and effectiveness trials (Woolf, 2008). Brief interventions in the medical setting reflect the shades of gray in hybrid research. Hybrid trials attempt to control some of the parameters that affect outcome while allowing others to vary (Carroll and Rounsaville, 2003). On the one hand, clinical trials of brief intervention in medical settings, including the emergency department and trauma center, have well-established procedures for ensuring adherence to the study protocol such as standardized screening procedures, clearly defined inclusion and exclusion criteria, treatment protocol manuals and ensuring that those conducting assessments are blind to treatment condition. On the other hand, these clinical trials have involved a wide range of patients recruited from diverse settings to evaluate multiple outcomes of interest and diverse approaches to BI. To refer to BI in these settings as either efficacy or effectiveness studies is a misnomer that fails to capture the complexity of conducting clinical trials in these settings.

With regard to behavioral trials including brief intervention in the medical setting, the spectrum may be better be reflected by the framework described by Westfall and colleagues (2007). These authors describe a continuum of research that includes hybrid research as a stage beyond efficacy and effectiveness research but prior to implementation and dissemination. Between these stages of research development, Westfall and colleagues (2007) describe practice-based research, which is necessary before distilled knowledge can effectively be put into practice. Such research focuses on how beneficial and cost effective the treatment is in practice as well as questions about the optimal application and use of the treatment or intervention. This type of research more accurately reflects the challenge of conducting research on brief interventions in medical settings and reaching definitive conclusions regarding their effectiveness. In short, an efficacy study is an unachievable ideal in the medical setting and additional trials to attempt to establish the efficacy of brief intervention in various medical setting without accounting for differences in the treatment context and unique patient characteristics are unlikely to resolve current discrepancies in findings. In addition to testing BI in specific contexts, what is needed is a more sophisticated approach to determining when and how brief intervention is effective in an effort to enhance positive treatment outcomes in various patient populations identified as at-risk drinkers in different treatment contexts.

THEN WHAT SHOULD WE DO? DO NOT THROW THE BABY OUT WITH THE BATHWATER

While not precluding continuing efforts to implement screening and brief intervention, the emergence of mixed evidence should lead to a more careful consideration of the potential strengths and limitations of brief interventions from a research perspective. Given the hybrid nature of the research, highly controlled efficacy trials are not feasible in the emergency department, trauma care, and inpatient medical settings. To date, most studies of brief intervention have evaluated the general effectiveness of brief intervention and have supported the view that some patients do benefit from this approach to reduce at-risk drinking and its consequences. While such studies are an essential first step, similar investigations in the future are unlikely to clarify current ambiguities in the research. For future research to enhance the current knowledge base addressing differences in effects of BI, a systematic approach to evaluating effectiveness is required to continue to support and enhance efforts to effectively implement this evidence-based intervention strategy and to confidently advocate for its widespread dissemination in various medical settings.

As represented in this brief review, research on screening and brief intervention in the medical setting is undoubtedly in a transition period. The current status of research on brief interventions is by no means unique in the investigation of behavioral interventions (see for example, Crits-Christoph, 1997; Kendall, 1998; and Rounsaville and Carroll, 2002). For instance, in Longabaugh and Morgenstern's reviews of cognitive behavioral therapy (CBT), they noted that numerous studies failed to identify which components of CBT accounted for its effectiveness and that many more studies suggested that CBT's effectiveness was limited to specific treatment contexts or specific patient subgroups (Longabaugh and Morgenstern, 1999; Morgenstern and Longabaugh, 2000). Similarly, the most likely explanation for the mixed evidence reported herein is that brief intervention sometimes reduces alcohol use and its associated consequences among certain types of patients in particular treatment contexts.

The mixed results may be a function of the heterogeneity in the patient population, the characteristics of the intervention itself, the setting in which they are provided or differences in research methodology across studies. While single-site randomized trials currently being conducted will undoubtedly prove informative and further enhance the current knowledge base, they are unlikely to disentangle the issues discussed in this qualitative review. Nevertheless, existing research can help determine a path for building on current knowledge to clarify remaining ambiguities. To date, only peripheral or post hoc consideration has been given to the components of the intervention, which are most effective, the therapeutic processes that lead to improved outcomes, the characteristics of patients who respond most favorably to intervention, and contextual factors that may influence the effectiveness of brief intervention. Studies of these factors may help determine if and when these interventions should be offered and thus have important clinical implications that will guide clinical practice and ensure the efficient use of limited resources by targeting patients who are most likely to benefit from intervention and referral for treatment.

A POTENTIAL SOLUTION: ONE PROTOCOL TO RULE THEM ALL

To continue making progress in our understanding of the effectiveness of brief interventions and ensure ongoing dissemination efforts, a more refined approach to its evaluation is required. This review identified 3 core factors which may be influencing our ability to reach definitive conclusions. These include the context in which the intervention is being carried out, the characteristics of patients within these contexts and research methodology including the intervention protocol, measurement, and statistical analysis of data. Traditionally a multisite is considered beneficial, when multiple single-site RCT's are inconclusive because there is sufficient heterogeneity among their results and incongruity in study procedures (Kraemer, 2000). Multisite trials are particularly useful when initial positive findings from well-designed studies are not consistently replicated (Weinberger et al., 2001). A multisite trial would confer numerous benefits above and beyond the current body of single-site studies but would introduce site as a potential confounder to interpreting the findings. Thus, a large multisite trial may not yet be warranted and may not resolve current discrepancies in findings.

An alternative approach to advancing this line of research is to conduct a single-site, multisetting trial of brief intervention. Such a study might further establish the effectiveness of brief intervention, investigate its effectiveness across settings, begin to account for potential moderators unique to the medical setting and differences in patient population, and explore the underlying mechanisms of change. This novel approach would have the advantage of utilizing a single-study methodology, which would standardize the inclusion/exclusion criteria, intervention protocol, assessment procedures, and statistical analysis of the findings. Based on current research, such a study should carefully assess patient characteristics that may influence the effectiveness of brief intervention. Furthermore, the study should also formally test the theoretical mechanism of change underlying brief intervention based on motivational interviewing. Finally, a process evaluation and organizational assessment may help characterize differences between the emergency department, trauma care, and inpatient medical setting, which may influence the delivery of brief intervention and its effectiveness in these settings. Differences between these contexts are perhaps the most difficult and least often studied aspect of conducting behavioral interventions in medical settings. This nontraditional approach to behavioral research may help resolve some of the current discrepancies highlighted in this review by standardizing study procedures across settings and addressing the most likely factors accounting for variations in study findings.

Abstract—Methodological challenges arise when one uses various Veterans Health Administration (VHA) data sources, each created for distinct purposes, to characterize length of stay (LOS). To illustrate this issue, we examined how algorithm choice affects conclusions about mental health condition (MHC)-related differences in LOS for VHA patients with diabetes nationally (n = 784,321). We assembled a record-level database of all fiscal year (FY) 2003 inpatient care. In 10 steps, we sequentially added instances of inpatient care from various VHA sources. We processed databases in three stages, truncating stays at the beginning and end of FY03 and consolidating overlapping stays. For patients with MHCs versus those without MHCs, mean LOS was 17.7 versus 13.6 days, respectively ($p < 0.001$), for the crudest algorithm and 37.2 versus 21.7 days, respectively ($p < 0.001$), for the most refined algorithm. Researchers can improve the quality of data applied to VHA systems redesign by applying methodological considerations raised by this study to inform LOS algorithm choice.

INTRODUCTION

Health services researchers often use administrative data for characterizing length of stay (LOS) to address a range of objectives. For example, they may examine how LOS (as a dependent variable) varies as a function of patient characteristics (e.g., age, race, insurance status, presence of comorbidity), processes of care (e.g., speed of emergency department response, types of medications administered or interventions applied, discharge protocols, etc.), or institutional characteristics (e.g., teaching hospital, mental health facility, etc.) [1–7]. Alternatively,

Abbreviations: DEpiC = Diabetes Epidemiology Cohort, DSS = Decision Support System, EXT = extended care, FY = fiscal year, ICD-9 = International Classification of Diseases-9th Revision, LOS = length of stay, MHC = mental health condition, OBS = observation, OPAT = outpatient file, VHA = Veterans Health Administration.

DOI:10.1682/JRRD.2009.08.0112

they may examine LOS as a potential explanatory variable for predicting other outcomes [8] or they may restrict their cohort to patients meeting specific LOS criteria [9]. Furthermore, accurate identification of intervals of inpatient care is required for studies using an episodes-of-care approach [10].

The concept of LOS is simple: time from admission to discharge. However, a number of methodological considerations arise when Veterans Health Administration (VHA) data are used for calculating LOS. First, goals of the project must be carefully considered, because this will influence the algorithm selected. Is the focus on acute or long-term care, on medical-surgical or mental health stays? Is the objective to examine total LOS across multiple years or LOS during a particular interval of study? Second, the algorithm must account for technical, data-quality issues. These include duplicate records, overlapping or sequential inpatient stays, transfers between different inpatient units, and inpatient stays that are recorded in a subsequent year.

Despite that numerous studies focus on LOS, these subtleties of LOS calculation have received little attention. This oversight could have serious implications: algorithm choice can influence conclusions in health services studies [11–13], although to our knowledge this possibility has not been studied in the specific case of LOS. As VHA leadership increasingly seeks to obtain accurate estimates of healthcare costs and use evidence to guide strategic planning decisions, it is critical that the evidence base supporting those decisions be as accurate as possible.

One example of a clinical scenario wherein LOS algorithm choice could influence conclusions is mental health condition (MHC)-related differences in inpatient care use. Prior studies both within and outside the VHA have documented that, compared with patients without MHCs, patients with MHCs tend to use more inpatient care [6,14–19]. Thus, patients with MHCs represent a particularly high-intensity, high-cost group likely to merit special attention by VHA policy makers. However, some characteristics of the way patients with MHC receive inpatient care may make their VHA records disproportionately susceptible to variation in algorithm choice. For example, patients with MHC might be more likely to experience more complex patterns of inpatient care (e.g., transferring between a medical unit and a psychiatric unit during the course of a single hospitalization episode), or to receive care in extended-care settings, where stays can be long and can span multiple fiscal years (FYs). Such factors could potentially influence LOS calculations differently for patients with MHC versus those without MHC.

We used VHA administrative data to examine how application of incrementally more refined algorithms for calculating LOS during 1 year of care affected conclusions about mean LOS in a national cohort of VHA patients with diabetes. Then, as an illustrative example of the practical implications of such methodological decisions, we examined whether the magnitude of observed mental illness-related disparities in mean LOS varied as a function of LOS algorithm applied.

METHODS

Study Context

This work is part of a larger study examining the effect of MHC on processes of outpatient diabetes care in FY03. Because the focus of that study is on outpatient care, we wished to identify (and ultimately exclude from the larger study) patients who were institutionalized (i.e., on inpatient status) for the majority of FY03. Therefore, our goal was to identify, for each patient in our cohort, all days in FY03 during which the patient was on inpatient status (acute care or extended care). We were not seeking to characterize total LOS for the patients in our cohort (which could have spanned multiple years), but only those inpatient days that occurred during FY03. The process of creating our LOS variable and the effect of algorithm choice on conclusions about MHC-related differences in LOS is the focus of the present study.

Subjects

The cohort was drawn from the FY02 Diabetes Epidemiology Cohort (DEpiC), a census of patients with diabetes in VHA nationally. DEpiC is used extensively for VHA epidemiological and health services research [20]. DEpiC identifies patients with diabetes based on the presence of at least one instance of an antiglycemic prescription or at least two instances of a diabetes International Classification of Diseases-9th Revision (ICD-9) code in inpatient or outpatient records. Among the 911,451 FY02 DEpiC members who were veterans, used VHA outpatient care at least once in FY02, and were alive as of the first day of FY03, we selected the 784,321 whose MHC status could be verified, as described next (in subsidiary analyses, we included the full 911,451 subjects, including those with “MHC Possible” status).

Steps to Assemble Raw Record-Level Database of Inpatient Stays

We started by creating a record-level file containing every instance of inpatient care recorded in any inpatient database available in centralized VHA files. We selected only records that contained at least 1 day of inpatient care in FY03. We also deleted duplicate records. In 10 sequential "steps," we pulled all nonduplicate inpatient records containing any FY03 inpatient care for patients in our cohort from the following FY03 files:

Step 1. Bedsection file, which represents acute care hospital stays.

Step 2. OBS (Observation) file, which represents short (e.g., overnight) acute care stays during which the patient is observed regarding the potential need for admission to an acute care bed.

Step 3. EXT (Extended Care) file, which represents long-term care stays (such as rehabilitation stays or nursing home stays).

Step 4. Census file (for Bedsection, OBS, and EXT), which include records for all patients who still held inpatient status on the last day of the FY, and thus for whom a discharge date was not available when the files for that FY were created.

Step 5. Non-VHA file.

Step 6. Fee basis file.

(These latter two files reflect care received outside of VHA but with funding for the care provided by VHA.)

We then searched FY04 and FY05 files for any records that included some FY03 care:

Step 7. Sources 1 through 5, FY04.

Step 8. Fee basis FY04 file (presented separately from other FY04 files to emphasize that fee basis files are more likely to contain "late entry" records from prior years).

Step 9. Sources 1 through 5, FY05.

Step 10. Fee basis FY05 file.

Stages of Processing Record-Level Database of Inpatient Stays

Next, we processed this raw database in sequential "stages." Stage A represented the raw file at any given step. In stage B, we deleted pre-FY03 and post-FY03 care. Specifically, for records with an admission date earlier than the first day of FY03, we deleted any days preceding FY03 (i.e., we modified the record to begin on the first day of FY03), because we were interested in days of care during FY03, not total LOS for the patient across multiple years. Similarly, for records with a discharge date later than the last day of FY03, we modified the record to end on the last day of FY03.

In stage C, we addressed overlapping stays. Several types of overlap were observed, as illustrated in **Figure 1**. In some cases, the entire stay (admission date through discharge date) was contained within the time interval of another record. This might happen, for example, if a patient in a rehabilitation unit was temporarily transferred to an acute care observation bed for an intercurrent illness like pneumonia. If the patient was not formally discharged from the rehabilitation facility prior to the transfer, then the time interval of the short-term stay (appearing in the OBS file) could be bracketed by the interval of the long-term stay (appearing in the EXT file). In other cases an overlap occurred (e.g., the admission date of one record fell between the admission and discharge dates of a subsequent record, or the discharge date of a record fell between the admission and discharge date of a subsequent record). In other cases, contiguous admissions occurred (i.e., the discharge date of one record was the same as the admission date of a subsequent record). For all these overlap cases (which could involve a pair of records or even three or more records), we created a single contiguous episode of FY03 inpatient care by assigning the admission date to be the first admission date in FY03 among the overlapping records and the discharge date to be the last discharge date in FY03 among the overlapping records. The resulting file at step 10, stage C, was our final record-level file of inpatient stays.

Variables

We calculated LOS for each record as the number of days from its start through end dates. At each step/stage, we calculated a cumulative LOS for each patient by adding the record-level LOS for all records included in that step/stage.

To identify patients with MHC, we used the Agency for Health Research and Quality's Clinical Classifications Software (with minor modifications) to generate a list of ICD-9 codes indicating the presence of MHC [21]. A patient was assigned a "Yes" for MHC status if he/she had at least one instance of an MHC ICD-9 code in any inpatient record or outpatient face-to-face clinic visit at baseline (FY01–02) and at least one confirmatory ICD-9 in the study period (FY03). If he/she had no instance of an MHC ICD-9 in FY01 through 03, then he/she was assigned MHC status "No." Otherwise, MHC status was

considered "Possible." That is, the MHC Possible group represents those patients who had an MHC diagnosis in the baseline period or in the study period, but not both. Cases with MHC Possible status were excluded from main analyses; this allowed us to compare LOS in two more sharply defined groups (MHC Yes vs MHC No).

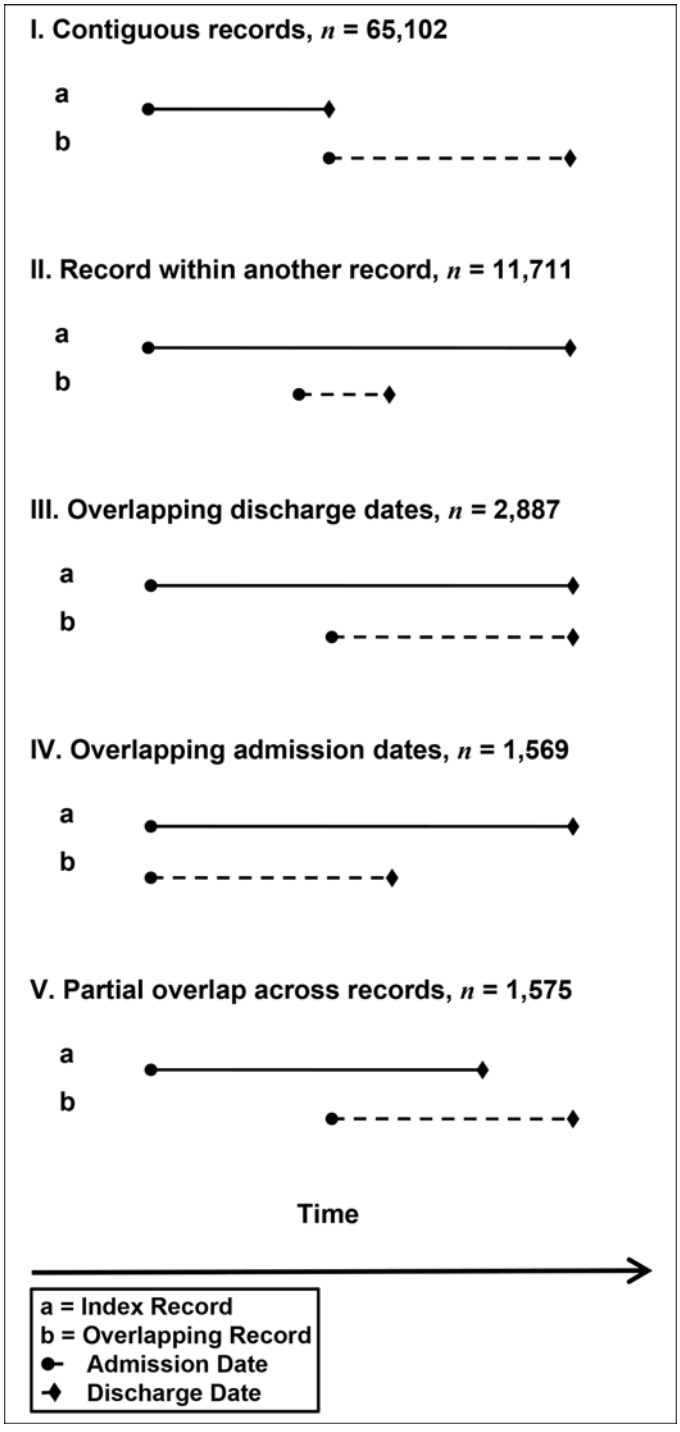

Figure 1.
Patterns I–V of overlap between pairwise records of an individual patient and record-level frequency of each pattern at step 10, stage C.

Analysis

We tabulated the number of records and calculated mean LOS within each cell of a 10 × 3 matrix representing the steps and stages of database development. Next, in each cell, we calculated mean LOS as a function of MHC status. We then calculated the difference (Δ) in mean LOS among patients with MHC versus those without MHC and compared mean LOS for the MHC Yes versus MHC No groups using a two-sample *t*-test. We applied Bonferroni correction for compounding of Type I error across multiple comparisons. Results of hypothesis tests are declared statistically significant for $p < 0.05$ after Bonferroni correction.

RESULTS

Among the 784,321 patients with diabetes in the full cohort, 152,591 were identified as having evidence of an MHC diagnosis (MHC Yes). Among the subset of 92,255 patients who received any inpatient care in FY03 (based on step 10, stage C), 39,452 had MHC Yes. **Table 1** presents the age, sex, Physical Comorbidity Index score (a count from 0–35, developed for case mix adjustment in VHA patients [22–23]), and primary care use in the full cohort and in the subset who used inpatient care, by MHC status.

Table 2 catalogs the number of records and LOS at each step/stage in the database assembly process. The cumulative number of patients who are identified as having received inpatient care in FY03 (based on stage C) increases progressively from step 1 to step 10 (as do the number of records). For example, when the OBS file was added to the Bedsection file, an additional 10,660 records were added for stays that did not perfectly duplicate a Bedsection file stay for that patient. This is expected, because additional evidence of inpatient care is added at each step. More noteworthy is that some steps contribute more records than others.

The number of records does not change at stage B (compared with stage A), because this processing step truncates records (to include only inpatient days during FY03) but does not delete records. However, at stage C (record consolidation), the number of records drops substantially, because overlapping stays are merged into a single, longer stay.

Table 1.
Characteristics of cohort by mental health condition (MHC) status (full cohort and subset who used Veterans Health Administration inpatient care).

Characteristic	Full Cohort, *n* = 784,321		Inpatient Users,* *n* = 92,255	
	MHC Yes	MHC No	MHC Yes	MHC No
n	152,591	631,730	39,452	52,803
Age (years, mean ± SD)	62.1 ± 11.6	69.6 ± 10.3	61.4 ± 11.9	69.1 ± 10.5
Male (%)	96.4	98.5	96.1	98.4
Physical Comorbidity Index (mean ± SD)	3.6 ± 2.4	2.8 ± 2.0	4.6 ± 2.8	4.5 ± 2.7
Used Primary Care in FY03 (%)	93.6	86.8	90.6	91.7

10. Fee FY05	92,255	293	241,318	241,318	152,157	74.8 ± 518.6	39.4 ± 113.4	28.4 ± 59.3

Note: To create table, we started with step 1 and completed cells across each stage sequentially. Then, for the step 2 analyses, we started with records from steps 1 and 2 and completed cells across each stage sequentially. Analyses for each subsequent step similarly included records from all prior steps. Stages were stage A (original record), stage B (delete days prior to first day of FY03 and after last day of FY03), and stage C (consolidate overlapping stays).
*Reflects cumulative number of patients who received inpatient care in FY03 at each step at stage C. Inpatient records were drawn from patients in analytical cohort (*n* = 784,321).
EXT = extended care, FY = fiscal year, OBS = observation, SD = standard deviation, VHA = Veterans Health Administration.

Consistent with these observations, mean LOS at stage C increased progressively with sequential steps (i.e., as more sources of data were added), except at step 2 (where patients with short OBS stays were added) and at step 5 (where patients with non-VHA stays were added). Similarly, mean LOS decreased progressively with sequential stages. That is, mean LOS decreased from stage A to stage B as non-FY03 days were deleted (which would be relevant to a study like ours that focuses on care received in a single FY). Mean LOS also decreased from stage B to stage C as overlapping days were deleted (which would be relevant to the accuracy of the LOS estimate in any study design). Across the 10 × 3 matrix, mean LOS ranged from 13.8 to 74.9 days.

Table 3 presents LOS by MHC status at every step/stage in the database assembly process. The calculated difference (Δ) in mean LOS between the MHC Yes and the MHC No groups varied markedly by algorithm and was statistically significant ($p < 0.001$) at every step/stage. Correction for multiple comparisons did not statistically affect any findings significantly. As illustrated in **Figure 2**, step 1, Δ = 4.1 at stage A and 3.8 at stage C. In contrast, at step 10, Δ = 57.8 at stage A and 15.5 at stage C ($p < 0.01$ for both between-algorithm comparisons of the values of Δ).

To obtain the LOS in stage C, for each pair of overlapping records, we generated a single record by setting the FY03 admission date as the earliest of the two admission dates and the FY03 discharge date as the latest of the two

Table 3.
Effect of sequential data assembly steps/data cleaning stages on fiscal year (FY) 2003 length of stay (LOS) calculations by mental health condition (MHC) status.

Step	Stage A			Stage B			Stage C		
	MHC Yes	MHC No	Δ	MHC Yes	MHC No	Δ	MHC Yes	MHC No	Δ
1. Bedsection FY03	17.7	13.6	4.1	17.0	13.2	3.8	16.4	12.6	3.8
2. OBS FY03	17.3	13.1	4.2	16.6	12.8	3.8	16.0	12.2	3.8
3. EXT FY03	36.6	20.4	16.2	27.5	17.4	10.1	26.4	16.5	9.9
4. Census FY03	51.6	27.2	24.4	34.0	21.3	12.7	32.7	20.3	12.4
5. Non-VHA FY03	51.0	26.9	24.1	33.7	21.1	12.6	32.4	20.1	12.3
6. Fee FY03	56.1	28.6	27.5	39.1	22.9	16.2	36.2	21.3	14.9
7. FY04 Records	82.1	40.5	41.6	47.1	27.3	19.8	36.7	21.5	15.2
8. Fee FY04	82.3	40.5	41.8	47.8	27.4	20.4	37.1	21.6	15.5
9. FY05 Records	108.0	50.2	57.8	52.5	29.6	22.9	37.3	21.7	15.6
10. Fee FY05	107.9	50.1	57.8	52.4	29.6	22.8	37.2	21.7	15.5

Note: Every difference (Δ) between mean LOS for MHC Yes vs MHC No in this table is statistically significant at $p < 0.001$. Stages were stage A (original record), stage B (delete days prior to first day of FY03 and after last day of FY03), and stage C (consolidate overlapping stays). Two sample *t*-tests were conducted for two key comparisons in this table: comparing within step 1 for stage A vs stage C and within step 10 for stage A vs stage C ($p < 0.01$ for both comparisons).
Δ = mean LOS (MHC Yes) minus mean LOS (MHC No), EXT = extended care, OBS = observation, VHA = Veterans Health Administration.

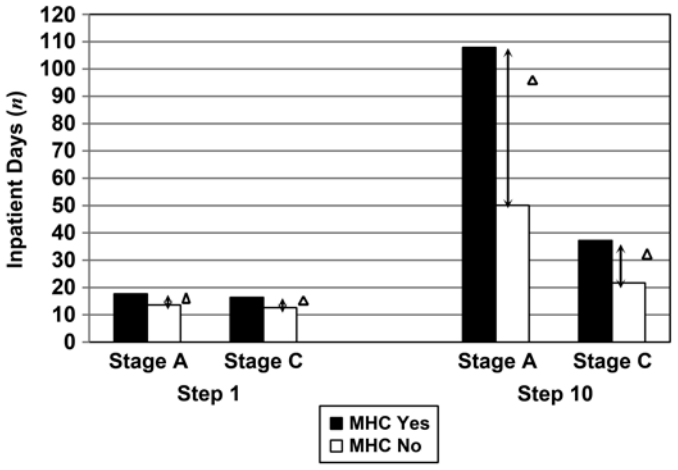

Figure 2.
Effect of sequential data assembly steps and data cleaning stages on fiscal year 2003 number of inpatient days. MHC = mental health condition, Δ = mean length of stay (LOS) (MHC Yes) – mean LOS (MHC No).

discharge dates. We repeated this process iteratively until all pairwise overlaps were addressed. This data processing stage was the most involved, because it needed to account for multiple potential overlap patterns, as illustrated schematically in **Figure 1**. The most common overlap pattern (pattern I) was contiguous records, i.e., where the discharge date of one record was the admission date of the following record. This pattern would happen, for example, if a patient were admitted to one bed section (e.g., to the Psychiatry Department for suicidal ideation) and then transferred to another bed section (e.g., to General Medicine for a hospital-acquired infection). Of note, we used the Bedsection files for these analyses. VA Bedsection files create a new record each time a patient transfers to a different clinical service ("bedsection") during a hospital stay. This is in contrast to the VA Main files, which create a new record for each stay; all contiguous bedsection stays are combined in a single record. Had we used the Main file instead of the Bedsection file, we expect that we would not have encountered this particular form of overlap. Other overlap patterns were also observed, as **Figure 1** shows. Of note, step 10, stage B, yielded LOSs of more than 365 days for 3.2 percent of the MHC Yes group and 1.4 percent of the MHC No group, clearly representing a residual problem with the algorithm; in contrast, no patient had LOS greater than 365 days at stage C. This finding supports the importance of the stage C processing.

In a subsidiary analysis, we found that both the admission and discharge dates fell within FY03 for 91 percent of records at step 10, stage A. In those instances, the full LOS for that episode of care was captured and no truncation was required.

Our main analyses excluded patients who had MHC Possible status (i.e., those patients who had an MHC diagnosis in the baseline period or in the study period, but not both). In another subsidiary analysis (see online **Appendix**), we repeated the main analysis in the initial cohort

(n = 911,451), calculating mean LOS as a function of MHC as a three-way variable (MHC Yes, MHC Possible, MHC No). Mean LOS for the MHC Possible group was consistently intermediate between that for the MHC Yes and MHC No groups. For example, for the MHC Possible group, mean LOS was 16.2 at step 1, stage A; 15.1 at step 1, stage C; 90.3 at step 10, stage A; and 34.4 at step 10, stage C.

DISCUSSION

Choices about what algorithm to use when identifying episodes of inpatient care substantially alter conclusions about the overall intensity of inpatient use and about MHC-related disparities in LOS. Not searching across all appropriate sources of data can lead to failure to capture a substantial amount of inpatient care, thus leading to underestimates of LOS. Decisions about how to process records can likewise influence calculated LOS. While other studies have documented that algorithm choice can influence conclusions drawn from VHA data [11–13], we are not aware of this result having been previously documented for LOS.

Researchers have access to many sources of data about VHA patients' nonambulatory care. Indeed, the large number of sources can bewilder investigators new to VHA administrative data, who may be unsure which files to select. Fortunately, the technical manuals developed by the Department of Veterans Affairs Information Resource Center (available at http://www.virec.research.va.gov/) and the Department of Veterans Affairs Health Economics Resource Center (available at http://www.herc.research.va.gov/) explain these files in detail. Our data provide further empiric information to help guide these decisions. First, our results confirm that adding more data sources identifies more inpatient days. Second, our results indicate that the EXT and Census files are especially important sources of incremental days of inpatient care. Third, our results indicate that adding more data sources also changes conclusions about the magnitude of effect (though not the direction of effect) of MHC on LOS. The step at which this has a particularly pronounced effect is the addition of EXT files, indicating that, compared with patients with no MHC, patients with MHC have disproportionately more frequent or prolonged stays in the long-term care setting.

Investigators using any VHA database need to examine data closely to determine whether data processing steps are necessary. In the case of inpatient files, our data indicate that in addition to the standard procedure of deleting pure duplicate records, investigators must account for overlapping stays (wherein a single day can be counted twice) and, for studies such as ours that focus on a single year of care, to truncate days falling before or after the FY of interest. Such pitfalls could, in some cases, reflect data quality problems, such as a data-entry error in admission or discharge date. However, in many cases, they may not represent deficits in the quality of VHA administrative data, but instead may reflect VHA clinical/administrative record-keeping practices. For example, a single stay could legitimately be recorded in more than one file if these files are used differently. Similarly, a fee basis stay (with the correct admission and discharge dates) could be filed in a subsequent year's records if a delay occurred in receipt of the bill from the outside vendor. Regardless of whether some of these factors represent data quality problems, investigators need to account for them; if not, some patients will have inflated estimates of LOS. Indeed, without such corrections, some patients will appear to be on inpatient status for more than 365 days in a single FY.

While the focus of this study is on the issue of algorithm choice for calculation of LOS, we use MHC-related disparities in LOS as a case study to illustrate what can happen if such issues are not considered. Health services researchers frequently examine disparities in processes and outcomes of care. Historically, interest in disparities related to characteristics like race, sex, and age has been great, but emerging evidence suggests that disparities related to MHC status are also common [9,24]. We demonstrated that the magnitude of MHC-related differences in LOS varied markedly as a function of LOS algorithm. Thus, the methodological issues raised here are not just theoretical: algorithm choice can have marked effects on conclusions in healthcare disparities research.

In the course of conducting analyses for this illustrative example, a subsidiary benefit was that informative findings about associations between MHC status and LOS emerged. Patients with MHC spent more of FY03 on inpatient status than did patients with no MHC; this was a consistent and robust finding across every algorithm examined. This finding is consistent with other studies that have shown heavier use of inpatient services by patients with MHC [6,14–19]. Our study also shows that some types of care (e.g., EXT) are associated with a disproportionately greater MHC effect. Another strength of our approach is that we distinguished between patients

with stronger evidence of MHC (i.e., at least one MHC diagnosis at baseline in FY01–02 and at least one confirmatory MHC diagnosis in the study period, FY03) and patients with less certain (Possible) MHC status (i.e., presence of an MHC diagnosis either at baseline or in the study period, but not both). Our subsidiary analyses provide information about MHC Possible patients, a group that has not been well characterized in prior work. The MHC Possible group is likely heterogeneous and includes patients with an erroneous MHC diagnosis, with transient or resolved MHC, or with less severe MHC, as well as patients who receive part of their care outside the VHA system. Mean LOS for the MHC Possible group consistently fell between the mean LOS observed for the MHC Yes and the MHC No groups.

Interpretation of our findings is subject to several caveats. First, our aim was to calculate total number of days spent on inpatient status during FY03; values should not be interpreted as indicating total LOS across years. However, for 91 percent of records, the patient's complete stay was contained within FY03. Second, we did not use the VHA Decision Support System (DSS) Outpatient (OPAT) file as a data assembly step. In the OPAT file, Stay Type 42, Bedsection 80 refers to nursing home care reimbursed by VHA in any particular month. However, dates of admission and discharge could not be accurately generated from that source. Third, our focus was on VHA use. Depending on an investigator's study question, capturing inpatient days spent in other settings might also be important, such as days identified from Medicare claims data, which can be linked to VHA administrative data [25]. Fourth, because the purpose of our study was to identify periods during which the patient was on nonoutpatient status, our LOS calculations included both acute care and long-term care days. Studies focusing on one or the other setting might need to consider other methodological issues. For example, a patient's stay in a skilled nursing facility could have short gaps (e.g., for a brief acute care stay), which might not be captured with the databases used. Fifth, our main analyses excluded patients whose MHC status could not be ascertained with certainty (MHC Possible), so LOS estimates cannot be generalized to all VHA patients. Subsidiary analyses suggested that these excluded patients had intermediate LOS and that algorithm choice similarly affected LOS calculations for them. Sixth, MHC diagnoses came from ICD-9 diagnosis codes in VHA administrative data rather than from direct assessment of patients' MHC. Given the known problem of underdiagnosis of MHC [26–27], some patients with MHC are likely included in the MHC No group. This would be expected to bias results toward the null.

This study examines methods that should be considered when an algorithm is developed that uses VHA data to calculate LOS. The specific algorithm selected will depend on the research question, such as—

- What types of inpatient care are of interest? For example, is the focus on acute care, extended care, care received on a fee basis outside of VHA or some combination of these sources? If rehabilitative/extended care is the focus, will additional sources (e.g., VHA EXT, fee basis, non-VHA and DSS OPAT files, as well as Medicare or Medicaid files) be queried, and how will multiyear stays be addressed?
- Is the focus on care received in a particular time interval (such as one FY) or on a full episode of inpatient care? If the former, will subsequent years' files be searched for stays recorded in a subsequent FY, and what is the expected incremental benefit versus cost of pulling data from multiple years? If the latter, how many years of data will be searched to identify the complete LOS, which could potentially span many years?
- Is the objective to characterize private sector inpatient care received as well, and if so, should other sources (such as Medicare claims data) be queried?

Careful consideration of these study design issues should yield an algorithm tailored to a particular study's objectives.

CONCLUSIONS

Accounting for the methodological issues raised here should help VHA health services researchers avoid pitfalls in calculation of VHA LOS, such as failure to capture care recorded in more obscure data sources (leading to underestimates of LOS) or duplicate counting of some days of care (leading to overestimates of LOS). This result is expected to support more robust estimates for economic analyses, since inpatient costs contribute disproportionately to total cost of VHA care. This result is also expected to enhance the accuracy of data VHA uses in its evidence-based efforts to redesign its healthcare delivery systems, which aim to improve the quality of care provided to veterans.

Using Administrative Data to Identify Mental Illness: What Approach Is Best?

Susan M. Frayne, MD, MPH,[1] Donald R. Miller, ScD,[2] Erica J. Sharkansky, PhD,[3] Valerie W. Jackson, MPH,[4] Fei Wang, PhD,[2] Jewell H. Halanych, MD, MSc,[5] Dan R. Berlowitz, PhD,[2] Boris Kader, PhD,[6] Craig S. Rosen, PhD,[7] and Terence M. Keane, PhD[8]

Abstract

The authors estimated the validity of algorithms for identification of mental health conditions (MHCs) in administrative data for the 133 068 diabetic patients who used Veterans Health Administration (VHA) nationally in 1998 and responded to the 1999 Large Health Survey of Veteran Enrollees. They compared various algorithms for identification of MHCs from *International Classification of Diseases, 9th Revision* (ICD-9) codes with self-reported depression, posttraumatic stress disorder, or schizophrenia from the survey. Positive predictive value (PPV) and negative predictive value (NPV) for identification of MHC varied by algorithm (0.65-0.86, 0.68-0.77, respectively). PPV was optimized by requiring ≥2 instances of MHC ICD-9 codes or by only accepting codes from mental health visits. NPV was optimized by supplementing VHA data with Medicare data. Findings inform efforts to identify MHC in quality improvement programs that assess health care disparities. When using administrative data in mental health studies, researchers should consider the nature of their research question in choosing algorithms for MHC identification.

Keywords

quality of health care, health services research/methods, algorithms, databases, factual, mental disorders

The burgeoning literature examining quality of care and outcomes for patients with mental health conditions (MHCs) often relies on secondary analyses of administrative databases to answer important questions about this vulnerable population.[1-8] Investigators must take several methodological considerations into account when using these databases to identify patients with MHCs because these databases were developed for clinical and administrative purposes, not for research. Clinical quality improvement programs, likewise, must accurately identify and classify patients with MHCs as part of their efforts to identify subgroups at potential risk for receipt of inferior care; indeed, the Institute of Medicine emphasizes the importance of measuring disparities as a core element of quality assessment.[9] Unfortunately, there is little guidance in the literature about how to accurately identify patients with MHCs from these data sources.

The most widely used typology for classifying MHCs is the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV*), which links explicitly to *International Classification of Diseases, 9th Revision* (ICD-9) codes[10] that are typically available in administrative data sources. When applying these codes, investigators must make various decisions such as which ICD-9 codes to use, the time window over which to search for codes, and

the number of times a code must appear for the patient to be considered to have that condition. Empirical data comparing various algorithms for using ICD-9 codes to identify specific MHCs are sparse.[11-13]

Therefore, as part of a national study to examine the effect of mental illness on quality of care for Veterans Health Administration (VHA) patients with diabetes,[14] we developed indicators for any MHC and for specific MHCs (ie, depressive disorders, anxiety, psychosis). To inform our methodological decisions and estimate the validity of our methods, we identified patients from our study who also completed a survey; among them, we compared those with MHCs identified from ICD-9 codes (using various algorithms) with self-report of MHC in the survey. The results of this comparison will be useful to investigators who seek an evidence-based rationale for their choice of methods to identify MHCs using ICD-9 codes.

Methods

Overview

The MEND (MENtal health-Diabetes) study examined disparities in processes and outcomes of diabetes care for diabetes patients with mental illness compared to those without mental illness.[14] Patients were considered to have a MHC if they had at least 1 instance of a MHC diagnosis code in outpatient or inpatient records across a 2-year time window.

For a random subset of patients in the MEND study, we had access to national survey data from VHA Fiscal Year 1999 (FY99), which included questions about a history of diagnosed MHC. Taking advantage of this additional data source, the current study describes our efforts to evaluate how well various ICD-9-based algorithms for identification of MHC predict the presence of self-reported MHCs.

Cohort

The MEND study used data and methods from the VHA Diabetes Epidemiology Cohort (DEpiC), a national database of linked VHA and Medicare data for all VHA diabetes patients since FY98.[15] The MEND cohort included all veterans with diabetes in FY98 who had at least 1 face-to-face outpatient visit at the VHA in FY99 and were alive at the end of FY99 (N = 392059). (DEpiC identifies diabetes patients based on receipt of an antiglycemic prescription or glucose monitoring strips in FY98, or having at least 2 inpatient stays or face-to-face outpatient visits in VHA/Medicare records in FY97-98, associated with diabetes ICD-9 codes 250, 357.2, 362.0, 366.41.) For the analyses presented here, we restricted the MEND cohort to the subset who participated in the 1999 Large Health Survey of Veteran Enrollees (N = 133068).

Data Sources

Data for this study came from 3 existing data sources: VHA's FY99 National Patient Care Database (supplemented with data from FY97-98), Medicare administrative records for the same years, and the VHA Office of Quality & Performance's 1999 Large Health Survey of Veteran Enrollees.[16] The National Patient Care Database contains administrative and clinical outpatient and inpatient records for every VHA patient nationally. Each clinic encounter and each inpatient stay generates a record that includes the clinician-identified ICD-9 diagnosis(es) for care received during that visit. For patients in our cohort, we linked Medicare records from the corresponding years to VHA files using encrypted social security numbers for linkage; sex and date of birth checks confirmed correct linkage.[17]

The 1999 Large Health Survey of Veteran Enrollees, which included questions about a history of diagnosed MHCs, sampled 1.5 million enrollees. Data collection occurred from July 1999 through January 2000. A response rate of 63.1% was achieved[16] using a modified Total Design Method.[18]

Defining MHC, Step 1: Selecting ICD-9 Codes for "Any MHC" and for Specific MHC Categories (The MEND Approach)

The first step was to identify the list of ICD-9 codes corresponding to MHCs. Conceptually, our objective was to identify patients whose clinical presentation would suggest the presence of mental illness to a primary care provider (ie, to clinicians providing diabetes care). We sought to identify a list of MHCs common in the primary care setting and to identify the ICD-9 codes that map to them. To do this, we drew from the conceptual framework developed by a panel of primary care and mental health experts for the American Psychiatric Association's *DSM-IV-Primary Care Edition* (*DSM-IV-PC*).[19,20] This scheme identifies broad clusters of MHCs commonly seen in primary care. It was designed to be used for several purposes, including research, and applies clinical criteria (rather than simply ranges of ICD-9 codes) to select clinically homogeneous clusters of codes. For example, the category "depressive disorder" includes a range of psychiatric conditions such as major depressive disorder, bipolar I disorder currently depressed, adjustment disorder with depressed mood, and depressive disorder not otherwise specified. These distinct

psychiatric conditions all present clinically as falling within the general depressive disorders category. Although the dominant presenting symptoms (eg, depressed mood, anhedonia, irritability) could vary from patient to patient, for a primary care provider, patients in this cluster would all have a somewhat similar clinical appearance. Because primary care providers should be able to recognize classes of psychiatric conditions but might not have the expertise to distinguish between specific psychiatric diagnoses within a class, we concluded that the appropriate level of granularity for grouping MHCs was at the level of condition category rather than at the level of specific diagnosis. The *DSM-IV-PC*'s clinical focus, its orientation toward the primary care setting (where diabetes care is typically delivered), its grouping strategy, and the fact that it explicitly maps to ICD-9 codes made it ideal for our purposes.

To apply this framework to our needs, a panel of 3 practicing internists reviewed the full list of *DSM-IV-PC* codes, eliminating categories (eg, abnormal movements/vocalizations or sexual dysfunction) and individual ICD-9 codes (eg, 305.10—nicotine dependence—or 307.23—Tourette's disorder) that would be seen by primary care providers as medical (rather than psychiatric) in nature. The panel also eliminated codes that reflect a cognitive deficit (eg, dementia, brain injury, learning disabilities), a social problem (eg, V62.89—religious or spiritual problem—or V60.9—housing problem), a condition of childhood (eg, 309.21—separation anxiety disorder—or V62.3—academic problem), or a resolved condition (eg, 291.2—alcohol-induced persisting dementia, implying a prior but not necessarily current substance use disorder). This left us with a set of ICD-9 codes that mapped to 10 specific MHC categories (Table 1): depressive disorder, anxiety, psychotic symptoms, manic symptoms, problematic substance use, dysfunctional personality traits, dissociative symptoms, somatoform symptoms, impulse control disorders, and eating disorders. Patients had *any MHC* if they fell into at least 1 of these condition categories.

Defining MHC, Step 2: Varying the Definition of Any MHC and Specific MHCs

After deciding on the MEND list of ICD-9 codes for MHCs, we developed the requirements for identifying an individual patient as having a MHC. Our base algorithm was algorithm A, which is described below.

Algorithm A. The base algorithm was the presence of at least 1 instance of an ICD-9 code from the MEND list occurring in FY98 or FY99 associated with any VHA inpatient stay or VHA outpatient face-to-face clinical encounter (ie, not telephone encounters, laboratory encounters, or radiology encounters). Many of the common psychiatric conditions we examined tend to be chronic in VHA patients,[21-24] so it is not unreasonable to assume that diagnoses present in one year may be present but not coded in subsequent years. Therefore, we counted codes that were present in the index year (FY99) or the preceding year.

We then sequentially examined 7 alternative algorithms, each of which differed from the base algorithm in 1 dimension.

Algorithm B. Instead of searching FY98-FY99 VHA records for MHC ICD-9 codes, we searched only FY99 records (to address the possibility that some conditions identified in FY98 could have resolved by FY99).

Algorithm C. Instead of requiring 1 or more instances of an MHC ICD-9 code, we required 2 or more instances. This addresses the concern that a single entry of a particular ICD-9 code could reflect a coding error or a "rule out" diagnosis, rather than the true presence of the condition, which is why some authors have required the presence of 2 instances of an ICD-9 code.[12,13]

Algorithm D. Instead of searching all outpatient and inpatient VHA records for MHC, we searched only records from outpatient primary care visits. Because mental illness often presents in a primary care (rather than mental health) setting, many studies focus on primary care diagnoses.

Algorithm E. Instead of searching all outpatient and inpatient VHA records for MHC, we searched only records from outpatient mental health visits. Although not all patients with mental illness receive care in mental health settings, those who do may receive more accurate psychiatric diagnoses than those who visit generalist physicians.

Algorithm F. Instead of using VHA records only, we supplemented VHA records with Medicare outpatient and inpatient administrative records, thereby expanding our scope to include diagnoses made in non-VHA settings.

Algorithm G. Instead of using all ICD-9 codes developed for MEND in step 1, we assembled a Delphi panel of 8 practicing VHA psychologists and psychiatrists to identify a more restricted list of MHC ICD-9 codes. To develop a list of ICD-9 codes expected (based on clinical expertise) to have greater specificity for the presence of MHCs than our full MEND list, the Delphi panel used a 5-point Likert scale to rate the degree of specificity each ICD-9 code possessed for the presence of the symptom category with which it was associated. For example, all Delphi panel members gave a score of 1 (highest specificity) to the ability of ICD-9 code 300.02 (generalized anxiety disorder) to predict the presence of the clinical category "anxiety." In other words, if a clinician coded a visit as having been related to ICD-9 300.02, the Delphi

Table 1. ICD-9 Diagnostic Codes Used to Identify MHCs: The MEND Approach*

Diagnostic Group	ICD-9 Codes
Any MHC	Any of the ICD-9 codes for the 10 categories listed below
Specific categories of MHC	
Depressive disorder	29189, 29284, **29620–29625, 29630–29635, 29650–29655**, 29660–29665, 29689, **3004x, 3090x, 30928, 311xx**
Anxiety	29189, 29289, **30000–30002, 30021–30023, 30029, 3003x, 3083x, 30924, 30981**
Psychosis	2910x, 29281, **2950x-2954x, 2956x, 2957x, 2959x, 29624, 29634, 29644, 29654, 2971x, 2988x, 2989x**
Manic symptoms	29189, 29284, **29600–29605, 29640–29645**, 29660–29665, 2967x, 29680, 29689, 30113
Problematic substance use	**2910x, 2913x, 2915x, 29181**, 29189, **2919x, 2920x**, 29211–29212, **29281**, 29284, 29289, **2929x**, 30300, **30390, 30400, 30410, 30420, 30430, 30440, 30450, 30460, 30490, 30500, 30520, 30530, 30540, 30550, 30560, 30570, 30590**
Dysfunctional personality traits	**3010x, 30120, 30122, 3014x, 30150, 3016x, 3017x, 30181–30183, 3019x**

*Following the *DSM-IV-PC* approach, a few ICD-9 codes map to more than 1 category and thus are listed under more than 1 category. This full set of ICD-9 codes was used for algorithms A to F. The subset of ICD-9 codes used in algorithm G (Delphi panel approach) are shown in bold face type.

panel felt that there was a high probability that the clinical presentation of the patient was consistent with anxiety. The Delphi score for each ICD-9 code was the mean of the 8 individual scores. In algorithm G, we examined the effect of using a list of ICD-9 codes that were more restricted than the full MEND list (Delphi score ≤1.1) (Table 1).

Defining MHC, Step 3: Developing a Literature-Based Comparison Algorithm

Algorithm X. To make it easier to put our findings in context with other studies, in our final algorithms, we departed from the MEND approach and developed an algorithm for identifying any MHC (and specific MHCs) using approaches commonly applied in the MHC quality of care literature. Instead of using the ICD-9 codes developed for MEND in step 1, we used a more inclusive set of codes: for any MHC, we used all codes falling within the range 290 to 319 (ie, the complete mental disorders section of the ICD-9 coding guide). This approach has been used by the authors of several major studies in the literature.[25] For the 3 specific MHCs of interest, we used common literature-based approaches to examine an important diagnosis within the depressive disorders category (major depression, defined as ICD-9 296.2x, 296.3x, 311[26,27]), an important diagnosis within the anxiety category (posttraumatic stress disorder [PTSD], defined as ICD-9 309.81), and an important diagnosis within the psychosis category (schizophrenia, defined as ICD-9 295.xx). These narrower diagnoses were selected in part to facilitate comparison with specific self-reported conditions (depression, PTSD, schizophrenia), described next.

Defining Self-Reported MHCs: The Frame of Reference

The 1999 Large Health Survey of Veteran Enrollees included a 15-item checklist that asked about lifetime history of a range of chronic conditions. Participants were asked, "Has a doctor ever told you that you have any of the following?" This stem was followed by a list including 3 MHCs: depression, PTSD, and schizophrenia. A patient responding positively to any of these 3 items was considered to have a self-reported MHC. There is evidence that self-reported medical conditions compare reasonably favorably to medical records, though there is some variability by condition type and less information about psychiatric diagnoses in particular.[28-33]

Analysis Approach

We used ICD-9 codes to calculate the prevalence of "ICD-9-based any MHC" among our full cohort of patients with diabetes who responded to the 1999 Large Health Survey of Veteran Enrollees, sequentially applying our 8 different algorithms (7 MEND-based algorithms and 1 literature-based comparison algorithm). Next, using self-reported MHC as the frame of reference, we calculated positive predictive value (PPV) and negative

Outpatient encounters, mental health, mean (SD)	2.3 (11.7)	2.1 (10.8)
Outpatient encounters, primary care, mean (SD)	4.4 (4.6)	4.6 (4.6)
Inpatient stays, mean (SD)	1.9 (1.5)	1.8 (1.5)
Inpatient stays in mental health units, mean (SD)	1.7 (1.4)	1.5 (1.5)

Abbreviations: VHA, Veterans Health Administration; SD, standard deviation; FY99, Fiscal Year 1999.

predictive value (NPV) for each algorithm. PPV is the probability that a patient identified as having a MHC by an ICD-9 code algorithm has independent evidence of having a MHC based on self-report. NPV is the probability that a patient identified as having no MHC by an ICD-9 code algorithm has independent evidence of having no MHC based on self-report.

We then repeated a similar process for 3 specific MHCs (depressive disorders, anxiety disorders, and psychotic disorders), calculating ICD-9-based prevalence of each by applying our 8 algorithms. We then calculated PPV and NPV for ICD-9-based depressive disorders (using self-reported depression as the frame of reference), for ICD-9-based anxiety (using self-reported PTSD as the frame of reference), and for ICD-9-based psychosis (using self-reported schizophrenia as the frame of reference) for each of the 8 algorithms. Note that for algorithm X, we examined ICD-9-based major depression (rather than depressive disorders more generally), ICD-9-based PTSD (rather than anxiety disorders more generally), and ICD-9-based schizophrenia (rather than psychotic disorders more generally).

Results

Our study sample included the 133 068 patients who responded to the 1999 Large Health Survey of Veteran Enrollees from among the total of 392 059 diabetes patients in the MEND cohort in FY99. There were only slight differences between the survey respondents and the overall cohort (Table 2), with survey respondents being older and more often white, having more physical comorbidity and primary care visits and fewer mental health visits. After removing survey respondents who did not answer questions about self-reported MHC, data were available for analysis from 94% of patients (N = 124 716).

Table 3 shows the prevalence, PPV, and NPV for the 8 ICD-9-based algorithms for defining any MHC. Thus, for example, our base algorithm, algorithm A, required that a patient have had at least 1 instance of any MEND ICD-9 code in FY98-99 VHA outpatient or inpatient files to qualify as having a MHC. Algorithm A had a PPV of 0.77 and an NPV of 0.76; this means that, using algorithm A, if we determine that the patient has "ICD-9-based any MHC," then there is a 77% likelihood that he or she has "self-reported MHC" (ie, patient-recalled lifetime history of physician-diagnosed depression, PTSD, and/or schizophrenia). Conversely, if we determine that a patient does not have "ICD-9-based any MHC," then there is a 76% likelihood that he or she has no "self-reported MHC" (ie, no recall of a lifetime history of depression, PTSD, or schizophrenia). We found that PPV could be optimized by requiring at least 2 instances of a MHC ICD-9 code (algorithm C) or by accepting only ICD-9 codes associated with mental health visits (algorithm E). The PPV of these approaches was superior to the PPV of the literature-based approach (algorithm X). In our analyses, NPV was optimized by supplementing VHA data with Medicare data (algorithm F). Estimated prevalence of MHCs also varied by algorithm.

Similarly, Table 4 shows the prevalence, PPV, and NPV for the 8 algorithms for defining the 3 specific MHCs of interest. For all 3 conditions, PPV was optimized by restricting the ICD-9 code list to those identified by the Delphi panel (algorithm G); PPV was also optimized for depression by requiring at least 2 instances of a depression ICD-9 code (algorithm C) and for PTSD by using the literature-based approach (algorithm X). For all 3 conditions, NPV was optimized by supplementing VHA data with Medicare data (algorithm F); the base algorithm also performed well (algorithm A), as did several other

Table 3. Varying Algorithms for Identifying MHCs From Administrative Data: Prevalence, PPV, and NPV Using Self-Reported MHC as the Frame of Reference*

	Any MHC		
	Prevalence	PPV	NPV
Base algorithm, MEND approach:

*n = 133 068; for calculation of PPV and NPV, n = 124 716 was used because of missing data for some self-reported MHC items.

algorithms. The generally strong performance of the literature-based approach is not surprising because it compared specific conditions (major depression, PTSD, schizophrenia) with self-reported specific conditions (depression, PTSD, schizophrenia). The frame of reference available to us was thus a better match for the literature-based approach than for the MEND approach, which compared broader categories (depressive disorders, anxiety disorders, psychotic disorders) with the self-reported specific conditions (depression, PTSD, schizophrenia).

Sensitivity and specificity of the various algorithms are available from the author on request.

Discussion

Using a national cohort of veterans with diabetes who use VHA care, we showed that many patients with a diagnosed psychiatric disorder can be detected from VHA administrative records, making this a promising source for quality assessment programs and mental health services research, albeit with several caveats. We demonstrated that choice of algorithm for identification of MHCs influences conclusions about which patients have MHC and, thereby, influences PPV and NPV of MHCs identified from ICD-9 codes.

Although many major studies use administrative data to identify patients with MHC,[1-5] relatively little information is available about how this source can be used most accurately. When using administrative data sources to identify other conditions, such as diabetes[34] and hypertension-related comorbidities,[35] it has been demonstrated that choice of algorithm influences case identification. In the case of psychiatric disorders, though, there is little guidance in the literature. Occasionally, investigators have examined a single algorithm against medical records to identify schizophrenia, depression, or psychiatric disorders as a group.[36-39] However, we are aware of only 1 study that explicitly examined the effect of varying algorithm choice on predictive value for a MHC. Spettell et al[11] compared 2 different algorithms for identification of depression from administrative data (ICD-9 codes and/or antidepressant prescription use) in a managed care organization population, using medical-record-based depression as the frame of reference; PPV varied from 49% to 61%, and NPV varied from 84% to 97%. They did not attempt to vary some of the factors that we varied (types of ICD-9 codes used, source of ICD-9 codes, time interval for ICD-9 code ascertainment, or number of ICD-9 codes used), and they did not examine conditions other than depression. Furthermore, their study was conducted in the private sector; patients with MHCs face fewer barriers (eg, carve-outs, co-pays) in the VHA than in the private sector, and MHC prevalence is particularly high in the VHA.[40-42] Thus, our study is complementary to the prior work by Spettell et al[11] and helps expand the very limited literature on this topic.

Our study has several limitations. First, we compared MHCs in ICD-9 codes against self-reported MHCs because that was the only independent source of information about MHCs available to us. This was by no means an ideal frame of reference because the self-reported data included only 3 psychiatric conditions (depression, PTSD, and schizophrenia), whereas the ICD-9 diagnoses covered depressive disorders, all anxiety disorders (not only PTSD), all psychotic disorders (not only schizophrenia), and multiple other MHCs. Furthermore, the self-reported data were based on lifetime histories of these diagnoses, whereas the ICD-9 code data examined only current conditions. Indeed, given these differences in the way MHC was defined in the 2 sources, it is surprising that we saw as much concordance as we did. Second, the ICD-9 codes

*The frame of reference for depressive disorder is self-reported depression; for anxiety, self-reported PTSD; and for psychosis, self-reported schizophrenia. For the calculation of PPV and NPV, participants with missing data for the depression, PTSD, or schizophrenia items on the survey were excluded; the number of participants for these analyses were 122 989, 120 860, and 118 202, respectively.

†Major depression: ICD-9, 296.2x, 296.3x, 311; PTSD, ICD-9 309.81; schizophrenia, ICD-9 295.xx.

identified only diagnosed MHCs; different methods would be needed to identify MHCs not recognized by clinicians[43,44] or MHCs that are recognized but not recorded in the administrative record.[45,46] Third, patients with more severe mental illness could be overrepresented among survey nonrespondents; it is possible that patients who are high functioning enough to reply to the survey are also better able to recall the diagnoses they received previously from a clinician. Fourth, the generalizability of our findings to non-VHA settings (in which the prevalence of MHCs is lower, typically, and mental health carve-outs are common) is unknown. Fifth, the list of ICD-9 codes we developed for the MEND study were designed to capture MHCs that are common in a primary care setting. This list of ICD-9 codes might not translate well to studies focused on care provided in a mental health setting. Finally, it is also noteworthy that although VHA data use ICD-9 codes, a number of institutions have transitioned to the newer ICD-10 coding scheme.

Despite these limitations, our study makes an important contribution to a sparse area in the literature. There have been increasing calls to take advantage of administrative data sources to study important quality of care issues and other health services questions.[47] These sources have significant advantages; for example, they overcome problems of response bias common to studies that seek to actively recruit patients with MHC, reduce human subject burden, and can answer timely questions at relatively low cost. Information about the performance characteristics of these data sets is critical as investigators and quality improvement programs seek to use these sources responsibly.

When applying administrative data to mental health studies, researchers and quality improvement programs should consider whether the nature of their question demands optimization of PPV (eg, by requiring a higher number of ICD-9 code occurrences or by selecting data from mental health clinical sources) or NPV (eg, by searching for diagnoses across more years of data or by supplementing diagnoses recorded in primary care settings with diagnoses recorded in mental health or another data source such as Medicare). Because the limitations of these data sources cannot be fully eliminated with any algorithm, investigators and quality improvement programs should also consider conducting sensitivity analyses in which they vary the algorithm for MHC case identification, so as to bracket their findings by showing how different assumptions affect conclusions.

Acknowledgments

The authors are very grateful to the members of the Delphi Panel (Tina T. Lee, MD, Louis A. Moffett, PhD, Steven E.

Lindley, MD, PhD, Darrah Westrup, PhD, Robert G. Hall, PhD, Gregory A. Leskin, PhD, Matthew Cordova, PhD); to Qing Shao, MD, MS, and William A. West, PhD, who provided technical support for portions of this study; to Rudolf Moos, PhD, who provided valuable comments on an earlier version of this manuscript; and to the Department of Veterans Affairs Office for Quality and Performance for providing the survey data used in this study. The late Mark A. Moskowitz, MD, made key contributions to the early conceptualization of this study.

Authors' Note

Prior presentation: Some of the findings included in this manuscript were part of an oral presentation to the Society of General Internal Medicine Regional Meeting in Stanford, California, in March 2006 an oral presentation to the Society of General Internal Medicine National Meeting in Los Angeles, California, in April 2006; a poster presentation at the Society of General Internal Medicine Regional Meeting in San Francisco, California, in March 2007; and a poster presentation at the American Psychological Association National Meeting in Kansas City, Missouri, in August 2007.

Declaration of Conflicting Interests

The authors declared no potential conflicts of interests with respect to the authorship and/or publication of this article.

Funding

The authors disclosed receipt of the following financial support for the research and/or authorship of this article: This material is based on work supported by the Department of Veterans Affairs Health Services Research & Development, grants IIR 20–041 and RCD 98–312, and by VA Medical Research-Epidemiology. The views expressed in this article are those of the authors and do not necessarily represent the views of the Department of Veterans Affairs. The funding sources had no role in the study design, data collection, analysis or interpretation, manuscript preparation, or decision to publish the manuscript.

The Association Between Alcohol Consumption and Prevalent Cardiovascular Diseases Among HIV-Infected and HIV-Uninfected Men

Matthew S. Freiberg, MD, MSc,† Kathleen A. McGinnis, MS,‡ Kevin Kraemer, MD, MSc,* Jeffrey H. Samet, MD, MPH, MA,§ Joseph Conigliaro, MD,‖ R. Curtis Ellison, MD,¶ Kendall Bryant, PhD,# Lewis H. Kuller, MD, DrPH,† and Amy C. Justice, MD, PhD**†† for the VACS Project Team*

Objective: To determine whether alcohol consumption is associated with cardiovascular disease (CVD) among HIV-infected veterans.

Methods: Using established thresholds for alcohol consumption, we analyzed cross-sectional data from 4743 men (51% HIV infected) from the Veterans Aging Cohort Study, a prospective cohort of HIV-infected veterans and demographically similar HIV-uninfected veterans. Using logistic regression, we estimated the odds ratio (OR) for the association between alcohol consumption and prevalent CVD.

Results: Among HIV-infected and HIV-uninfected men, respectively, hazardous drinking (33.2% vs. 30.9%,), alcohol abuse and dependence (20.9% vs. 26.2%), and CVD (14.6% vs. 19.8%) were common. Among HIV-infected men, hazardous drinking [OR = 1.43, 95% confidence interval (CI) = 1.05 to 1.94] and alcohol abuse and dependence (OR = 1.55, 95% CI = 1.07 to 2.23) were associated with a higher prevalence of CVD compared with infrequent and moderate drinking. Among HIV-uninfected men, past drinkers had a higher prevalence of CVD (OR = 1.30, 95% CI = 1.01 to 1.67). For HIV-infected and HIV-uninfected men, traditional risk factors and kidney disease were associated with CVD.

Conclusions: Among HIV-infected men, hazardous drinking and alcohol abuse and dependence were associated with a higher prevalence of CVD compared with infrequent and moderate drinking even after adjusting for traditional CVD risk factors, antiretroviral therapy, and CD4 count.

Key Words: alcohol consumption, alcohol abuse, alcohol dependence, cardiovascular disease, HIV infection, veterans

INTRODUCTION

With the advent of antiretroviral therapy (ART) and improved survival,[1] alcohol has become an important health issue among HIV-infected adults. It is likely that alcohol is related to several prominent health problems among HIV-infected people including ART adherence,[2] chronic liver disease,[3] possibly HIV disease progression,[4] and cardiovascular disease (CVD).[5] Although the mechanisms for the development of CVD in HIV-infected adults are unknown, ART[6] and perhaps HIV itself[7] are associated with dyslipidemia and increased insulin resistance. In uninfected adults, moderate alcohol consumption is associated with a reduced risk of CVD,[8] improved lipid profiles,[9] increased insulin sensitivity,[10,11] and altered clotting factor profiles.[12] In contrast, hazardous alcohol consumption is associated with hyperlipidemia,[12] incident diabetes,[13] and higher CVD and total mortality rates.[14,15] Although the association between alcohol consumption and CVD risk among uninfected adults is well documented,[16–19] sparse data describe this association among HIV-infected adults. Therefore, the objective of the

present study was to examine the association between alcohol consumption and prevalent CVD among HIV-infected and HIV-uninfected adults from the Veterans Aging Cohort Study (VACS).

METHODS

Veterans

In the present study, we analyzed data on 4743 veterans from the VACS, an observational longitudinal cohort of HIV-infected and HIV-uninfected race, age, and site-matched veterans designed to understand the role of comorbid medical and psychiatric disease in determining clinical outcomes in HIV infection.[20] VACS assesses patients and providers using surveys and electronic medical record review from 8 Veterans Affairs Medical Center Infectious Disease and General Internal Medicine clinics.[20] Data collected included AIDS-defining conditions, comorbidities, health and habits, information about health care provider characteristics, and provider assessments of the participants. A full description of the measures collected and other details regarding the VACS are described elsewhere.[20] From 2002 to 2006, VACS enrolled 6467 participants. Of these, because we know that CVD behaves differently in these groups and due to limited numbers with which to model these differences, women (n = 336) and lifetime abstainers (n = 299) were excluded. Lifetime abstainers were defined as a "No, never" response to, "Have you ever had a drink containing alcohol." Those who had no International Disease Classification 9 (ICD-9) diagnosis code for CVD and were missing self-report CVD information were not included (n = 78). Of the remaining 5762, 669 were excluded for missing alcohol use data and 342 for missing covariate data. The institutional review boards at all locations approved the study, and all veterans provided written informed consent.

Independent Variable

We ascertained infrequent, moderate, and hazardous alcohol consumption using the Alcohol Use Disorders Identification Test (AUDIT).[21] We estimated quantity and frequency of alcohol consumption using the product of the responses to the first 2 questions of the AUDIT: (1) "How often do you have a drink containing alcohol?" and (2) "How many standard drinks do you have on a typical day when you are drinking?" We converted the responses to the first AUDIT question into the following variables: never = 0 times per week; monthly or less = 0.25 times per week; 2–4 times per month = 0.75 times per week; 2–3 times a week = 2.5 times per week; and 4 or more times a week = 4 times per week. For the second AUDIT question, we converted the responses into the following variables: 1 = 1 drink per day; 2 = 2 drinks per day; 3 or 4 = 3.5 drinks per day; 5 or 6 = 5.5 drinks per day; and 7 or more = 7 drinks per day. We calculated weekly drinking as the product of converted responses to questions #1 and #2 (eg, 4 times per week $\times$ 2 drinks per day = 8 drinks per week). Using the question, "When you are drinking, how often do you have 6 or more drinks on one occasion?," we defined a binge drinker as anyone who reported consuming 6 or more drinks on 1 occasion less than monthly or more. Those who responded "never" to consuming 6 or more drinks on 1 occasions were not binge drinkers.

Using this methodology, we categorized alcohol into 3 groups: infrequent and moderate, hazardous, and abuse or dependence. Infrequent and moderate drinkers were combined to form the referent group. Using the National Institute on Alcoholism and Alcohol Abuse guidelines, we defined infrequent or moderate drinking as consuming $\leq$14 drinks per week and no binge drinking. Hazardous drinking was defined as $>$14 drinks per week or binge drinking.[22] Alcohol abuse or dependence was defined using ICD-9 codes based on prior work in the VACS.[23] Importantly, if a participant was a moderate drinker by self-report, but had an ICD-9 code documenting alcohol abuse or dependence, this participant was included in the alcohol abuse and dependent category. We defined past drinkers as those who had consumed $\geq$1 drink in their lifetime but responded "more than 12 months ago" to the question, "When was the last time you had a drink?" As stated earlier, lifetime abstainers were excluded.

Dependent Variable

Our primary outcome variable was prevalent total CVD. We defined CVD using self-reported survey data and VA ICD-9 codes. A participant had CVD if the participant responded yes to 1 of the following 4 separate questions, "Has a doctor ever told you that you had (1) angina or coronary heart disease (CHD), (2) a myocardial infarction, (3) congestive heart failure (CHF), or (4) stroke or transient ischemic attack?" or if the participant had a documented CHD, myocardial infarction, CHF, or stroke event using VA ICD-9 or CPT codes. The complete list of all ICD-9 and CPT codes used in the VACS to define CVD are listed on the VACS website.[24] Using similar methodology, variables were also constructed for CHD, CHF, and stroke, separately.

Covariates

Using VACS patient and provider survey data and Veterans Administration Medical Center pharmacy and laboratory records, we collected data on participant demographics, cardiovascular risk factors, and personal habits. Demographic data included age at VACS study entry and self-reported race/ethnicity (white, black, Hispanic, or other) and education level categorized as either having at least some college education versus high school diploma, general education development (GED), or less education. Cardiovascular risk factors were certain health conditions defined as "yes" response to the question, "Has a doctor ever told you that you had 'high cholesterol, lipids, or triglycerides,' 'diabetes or high blood sugar or sugar,' and 'hypertension or high blood pressure'." Participants were also considered to have "high cholesterol" if there was a documented prescription for an HMG-coreductase inhibitor identified in the pharmacy benefits management database. Current smoking was defined as a yes response to, "Do you now smoke cigarettes?" Body mass index was defined as self-reported weight in kilograms divided by self-reported height in meters squared. HIV-related risk factors included hepatitis C virus (HCV), defined as a positive HCV antibody test, HCV RNA test, or ICD-9 code (070.41, 070.44, 070.51, 070.54 or V02.62), CD4 cell count, and use of and

adherence to ART. We collected data on CD4 cell counts from 180 days before and up to 7 days after the time of enrollment. We defined ART as the use of any antiretroviral medication within the previous 90 days before and up to 7 days after the time of enrollment into the VACS study. For those participants taking ART, nonadherence was defined as having missed at least 1 dose of ART medication in the 4 days before completing the VACS baseline questionnaire. Adherent was not having missed any ART medications in the 4 days before completing the VACS baseline questionnaire. Additional covariates included cocaine use, defined as a yes response to having used cocaine at least once in the past year; self-reported "liver disease or bad liver or cirrhosis;" kidney disease defined as a glomerular filtration rate <30 mL·min^{-1}·1.73 m^{-2}; and regular exercise defined as engaging in regular activities (eg, brisk walking, jogging) long enough to work up a sweat at least 3 times a week.

Statistical Analysis

We obtained descriptive statistics for all variables and assessed the relationship between HIV, alcohol consumption, CVD, and other covariates using *t* tests for continuous variables and χ^2 analysis for categorical variables. We constructed 2 logistic regression models to estimate the odds ratio (OR) for prevalent CVD using level of alcohol use as the main independent variable although adjusting covariates for HIV-infected and HIV-uninfected participants separately. Model 1 adjusted for age, race/ethnicity, and traditional cardiovascular risk factors. Model II adjusted for all covariates in model 1 plus cocaine use, liver disease, kidney disease, exercise, and education. Model 2 for HIV infected also included CD4 cell count and use of and adherence to ART. Secondary analyses also examined the association between level of alcohol use and CVD-specific diagnoses (ie, CHD, CHF, and stroke). Additional analyses were also performed to test separately for the interaction between HIV status and alcohol consumption and the following traditional cardiovascular risk factors: hypertension, hypercholesterolemia, diabetes, and current smoking.

RESULTS

Hazardous alcohol consumption and alcohol abuse or dependence were common among both HIV-infected and HIV-uninfected veterans in the VACS (Table 1). Nearly two-thirds of the veterans were African American. As compared with uninfected veterans, HIV-infected veterans had significantly lower prevalence of several cardiovascular risk factors including hypercholesterolemia, diabetes, hypertension, and mean BMI levels ($P < 0.001$ for all, Table 1). In contrast, HIV-infected veterans had significantly higher prevalence of smoking, HCV, and liver disease ($P < 0.001$ for all). The prevalences of CVD (14.6% vs. 19.8%, $P < 0.001$), CHD (8.6% vs. 14.7%, $P < 0.001$), CHF (4.5% vs. 5.9%, $P = 0.03$), and stroke (5.8 vs. 6.5, $P = 0.30$) were lower among HIV-infected veterans compared with HIV-uninfected veterans.

In both model 1 (adjusted for traditional CVD risk factors) and model 2 (fully adjusted model), hazardous alcohol consumption and alcohol abuse or dependence were associated with an increased prevalence of CVD compared with infrequent or moderate alcohol use for HIV-infected veterans but not HIV-uninfected veterans (Tables 2 and 3). In a model including both HIV-infected and HIV-uninfected veterans (not shown), an interaction term between HIV status and alcohol level was statistically significant ($P = 0.01$). Among HIV-uninfected veterans, past alcohol consumption was associated with a higher prevalence of CVD in both models 1 and 2 (Table 3). For both HIV-infected and HIV-uninfected veterans, traditional risk factors including age, hypercholesterolemia, hypertension, and smoking were associated with a significantly increased prevalence of CVD in models 1 and 2. Kidney disease was also significantly associated with prevalent CVD among HIV-infected and HIV-uninfected veterans (Tables 2 and 3).

When we performed secondary analyses examining separately the interaction between HIV status and traditional cardiovascular risk factors, HIV infection interactions with hypertension ($P = 0.03$), diabetes ($P = 0.04$), and current smoking ($P = 0.01$) were all statistically significant.

We also ran models adjusted for traditional CVD risk factors predicting CHD, CHF, and stroke for HIV-infected and HIV-uninfected veterans. Among HIV-infected veterans, hazardous drinking was statistically significantly associated with CHF (OR = 1.74, 95% CI = 1.04 to 2.91); alcohol abuse or dependence was significantly associated with CHD (OR = 1.67, 95% CI = 1.06 to 2.64) and CHF (OR = 1.99, 95% CI = 1.12 to 3.55); and past drinking was significantly associated with stroke (OR = 1.97, 95% CI = 1.30 to 2.98). Among HIV-uninfected veterans, there were no statistically significant associations between hazardous alcohol consumption and alcohol abuse or dependence and CHD, CHF, or stroke. However, past drinking was statistically significantly associated with stroke (OR = 1.78, 95% CI = 1.24 to 2.54 (data not otherwise shown).

When we examined the association between binge drinking and CVD in a model adjusted for CVD risk factors, there was an increase in the prevalence of CVD among binge drinkers for HIV-infected veterans (OR = 1.30, 95% CI = 1.02 to 1.66). For uninfected veterans, there was no statistically significant increase in CVD among binge drinkers (OR = 1.03, 95% CI = 0.82 to 1.30).

DISCUSSION

In the VACS cohort, among HIV-infected veterans, hazardous drinking and alcohol abuse or dependence were significantly associated with an increased prevalence of CVD as compared with infrequent and moderate drinkers. This association remained significant after adjustment for age, race/ethnicity, traditional CVD risk factors, HCV and liver disease, kidney disease, exercise, education, CD4 count, and adherence to ART. Among HIV-uninfected veterans, past alcohol consumption was associated with a significantly increased prevalence of CVD. In addition to several of the traditional CVD risk factors, renal disease was also significantly associated with a higher prevalence of CVD for both HIV-infected and HIV-uninfected veterans.

Numerous prospective studies among men without HIV report that moderate alcohol consumption is associated with a lower risk of CHD, ischemic stroke, and CVD.[8,14,17,19] In

TABLE 1. Characteristics of the HIV-Infected and HIV-Uninfected Veterans

Characteristics	HIV infected (n = 2422)	Uninfected (n = 2321)	*P*

contrast, less data are available focusing on the association between hazardous alcohol consumption, alcohol abuse, and alcohol dependence and CVD. In the present study, among HIV-infected veterans, there was a significant increase in the prevalence of CVD for hazardous drinking and alcohol abuse and dependence as compared with infrequent and moderate drinking. Although the association between alcohol and CVD risk has been thought to be mediated in part by alterations in lipid profiles and levels of clotting factors, prior work in the VACS also demonstrates a temporal and dose–response relationship between alcohol consumption and medication adherence.[25]

Among HIV-uninfected veterans, the association between prevalent CVD and hazardous or abuse and dependence levels of alcohol consumption did not reach statistical significance. In our analyses, interaction terms between HIV status and alcohol consumption, hypertension, diabetes, and current smoking were all significant suggesting that the association between hazardous alcohol consumption, alcohol abuse and dependence, and prevalent CVD is more pronounced among HIV-infected compared with uninfected individuals.

Further, uninfected past drinkers had an increased prevalence of CVD compared to HIV infected past drinkers. It is possible that many of the uninfected veterans who were past drinkers were hazardous alcohol consumers who quit drinking for health-related reasons (ie, sick quitters). Prior research has suggested that "sick quitters" have a higher burden of comorbid disease and thus are at greater risk for CVD.[26] When determining whether HIV-infected individuals in care have a higher or lower risk of CVD compared with uninfected individuals, one must be very clear about the way in which risk

is measured (events being compared) and the comparison population being used. Some prior studies comparing HIV-infected and HIV-uninfected individuals have reported that HIV-infected individuals have a higher prevalence of CVD risk factors[27] or increased Framingham risk score.[28] These studies assume that CVD risk factors are identical between those with and without HIV infection, an assumption that may not be valid. Other studies have reported increased relative risk of incident CVD events or hospitalizations compared with uninfected individuals.[29–32] One of these[30] used a population-based control group. Population-based controls may represent a healthier population as compared with a demographically and behaviorally similar population. VACS used age, race/ethnicity, and clinical site-matched controls. All of the prior studies were conducted in substantially younger populations of both HIV-infected and HIV-uninfected individuals. We observed that the prevalence of CVD was lower among HIV-infected veterans as compared with HIV-uninfected veterans in a population predominated by middle aged and older men. Moreover, most prior studies did not include data on hazardous alcohol consumption, alcohol abuse and dependence, or HCV infection, each of which are important comorbidities among those infected with HIV and can potentially alter cardiovascular risk. Of note, the typical Framingham risk factors (ie, age, hypertension, hypercholesterolemia, diabetes, and smoking) were all significantly associated with CVD in our analyses among HIV-infected veterans. Additionally, kidney disease, as estimated by GFR,

was also significantly associated with CVD. This result is consistent with prior findings among HIV-uninfected people.[33]

The present study has several limitations that warrant comment. As this study is cross sectional, we cannot comment on cause and effect with regard to alcohol consumption and the risk of CVD. Further, associations with prevalent CVD may differ from those with incident disease in HIV because at least some risk factors (hyperlipidemia and glucose intolerance) increase with exposure to antiretroviral treatment. As there were only men in the present study, our findings may not be generalizable to women. As several variables in the analyses involved self-reported data, there is the possibility of nondifferential misclassification. Further, there may have been some nondifferential misclassification among those who were HCV antibody positive but without HCV RNA because HCV infection spontaneously resolves in 10%–15%.[34] In addition, there is the possibility of misclassification among the HIV-uninfected VACS participants. However, the possibility of seroconversion of an HIV-uninfected participant is unlikely. In the prior decade of conducting the VACS studies, less than 0.2% of the patients classified as HIV uninfected have been subsequently identified as infected. It would also be helpful to have had more complete data to differentiate past drinkers into those who quit for health-related reasons versus nonhealth-related reasons. However, we did include alcohol diagnoses which helped to further categorize current drinking, particularly among those who were currently infrequent or moderate drinkers. Finally, we found significant interaction terms suggesting that risk factors for CVD demonstrate different associations with CVD among those infected with HIV compared with uninfected individuals. These findings underscore the importance of studying actual clinical events rather than risk factors if we are to gain a better understanding of CVD risk among those with HIV infection.

In conclusion, hazardous alcohol consumption and alcohol abuse or dependence were associated with an increased prevalence of CVD among HIV-infected veterans compared with infrequent and moderate alcohol consumption. This association persisted even after adjustment for traditional CVD risk factors, HIV-related risk factors including HCV, use

of and adherence to ART, and CD4 count. This association did not reach significance among uninfected demographically similar comparators suggesting that the effect of alcohol may be more pronounced among those infected with HIV.

New-onset atrial fibrillation and warfarin initiation: High risk periods and implications for new antithrombotic drugs

David A. Garcia[1]; Renato D. Lopes[2]; Elaine M. Hylek[3]

[1]Department of Internal Medicine, University of New Mexico Health Sciences Center, Albuquerque, New Mexico, USA; [2]Duke Clinical Research Institute, Duke University Medical Center, Durham, North Carolina, USA; [3] Department of Medicine, Research Unit-Section of General Internal Medicine, Boston University School of Medicine, Boston, Massachusetts, USA

Summary

Atrial fibrillation is a common condition that increases the risk of stroke in many patients. Although warfarin has been shown to reduce the risk of stroke, many patients who might benefit from anticoagulation do not receive this therapy. Fear of bleeding is the most often cited reason. Several new anticoagulant medications are being studied to determine their efficacy and safety relative to warfarin. Unlike earlier trials that established the superiority of warfarin over placebo, recent trials in atrial fibrillation have enrolled a disproportionate number of patients already taking warfarin. This review suggests that the risk of both haemorrhage and stroke are highest when atrial fibrillation is newly diagnosed and during the initiation of anticoagulant medication. Randomised controlled trials designed to evaluate the safety and efficacy of new antithrombotic agents should include substantial numbers of patients without prior exposure to anticoagulation since these individuals are at the highest risk for bleeding and thromboembolism.

Introduction

Atrial fibrillation (AF) is a common dysrhythmia; its prevalence is increasing as the population ages (1). Recent projections indicate that by the year 2020, 7.5 million people in the United States will live with AF (2). Because AF results in disorganised electromechanical activity that promotes intra-atrial thrombus formation, the risk of embolic stroke is significant for many patients. The attributable risk of stroke from AF increases significantly with age, from 1.5% for individuals aged 50 to 59 years to 23.5% for individuals aged 80 to 89 years (3). Cardioembolic strokes are associated with substantial morbidity and mortality (4–8).

Between 1989 and 1993, the efficacy of warfarin for stroke prevention in AF was demonstrated decisively by five randomised controlled trials (9–13). Compared to placebo, warfarin use was associated with a 68% relative risk reduction of stroke (14). Despite this dramatic benefit, numerous studies have documented that warfarin is prescribed to only about 50% of at-risk patients with AF (15–18). Older age and perceived bleeding risk are often cited as reasons for not prescribing warfarin. In addition, the narrow therapeutic index of warfarin (combined with its variable dose-response) mandates frequent monitoring which, for many patients, precludes its use (19, 20). Newer antithrombotic agents that match the efficacy of warfarin while also offering a wider therapeutic index would likely increase the use of stroke prevention medications among patients with AF.

The first such new agent to be evaluated was ximelagatran, an oral direct thrombin inhibitor. This drug was studied in two clinical trials enrolling an unprecedented 7,329 patients with AF (SPORTIF-Stroke Prevention using an ORal Thrombin Inhibitor in atrial fibrillation). Based on the previous, placebo-controlled trials conducted in the late 1980s, a primary event (stroke or systemic embolism) rate of 3.1% per year was projected for the patients assigned to receive warfarin (21, 22). Although these studies included elderly populations with a high prevalence of stroke risk factors (▶Table 1), the annual rate of all strokes (ischaemic and haemorrhagic) among patients randomised to warfarin was 2.3% (SPORTIF III) and 1.2% (SPORTIF V) , both lower than the pre-trial estimates. This unexpectedly low rate of thrombotic events among AF patients randomised to warfarin was also reported in a large trial comparing warfarin to dual antiplatelet therapy. In the Atrial Fibrillation Clopidogrel Trial with Irbesartan for prevention of Vascular Events (ACTIVE W) trial, among the 3,371 patients assigned to oral anticoagulation therapy, the rate of stroke (ischaemic or haemorrhagic) plus systemic embolus was 1.5%, also lower than initial projections (23). Similarly, the Birmingham Atrial Fibrillation Treatment of the Aged study (BAFTA) reported low annual stroke rates in both treatment arms (1.8% for warfarin and 3.8% for aspirin) (25).

Table 1: Clinical characteristics of AF populations randomised to warfarin.

Although it is possible that the rate of stroke in AF has decreased since the early trials, an alternative hypothesis is that recent trials have enrolled patients who were at lower risk of stroke, despite the similar (or increased) prevalence of stroke risk factors shown in Table 1. Unlike earlier trials designed to establish the superiority of warfarin versus placebo, more recent trials of novel antithrombotic strategies have been designed to establish non-inferiority to warfarin. Thus, the majority of participants in recent trials were taking a vitamin K antagonist (VKA) at baseline. In SPORTIF III and V, 73% and 85%, respectively, of patients randomised to warfarin had been taking a VKA at study entry. The onset of AF was documented to be greater than one year prior to study entry for ≥80% of study participants. Similarly, in the ACTIVE W trial, 77% of participants were taking warfarin at the time of randomisation (warfarin-experienced patients) and duration of AF was six months or greater for 80% of patients and greater than two years for 59% (23). The high proportion of participants who entered these trials already taking warfarin (i.e. "warfarin-experienced") has been an under-appreciated significant difference from earlier AF trials in which greater than 90% of patients were receiving a VKA for the first time (i.e."warfarin-naïve"). A post-hoc analysis of the SPORTIF trial data suggested that the higher proportion of warfarin-naïve participants enrolled in SPORTIF III coupled with greater variability in the INR (International Normalised Ratio) contributed to the higher stroke rate in SPORTIF III versus SPORTIF V (26).

The importance of studying "new users" of a drug has been previously highlighted by Feinstein and Ray (27, 28). The efficacy and safety of new antithrombotic drugs for stroke prevention in AF can be best evaluated among patients who are new to anticoagulant therapy. Consideration of five key elements will demonstrate the chronology bias and survivor bias that impact trials that are dominated by warfarin-experienced patients: 1) bleeding risk during the early phase of anticoagulant therapy, 2) temporal relationship of stroke risk and incident AF, 3) differential early cessation of warfarin therapy among higher risk patients secondary to problems with adherence and tolerability, 4) improved efficacy of warfarin over time resulting from improved control of the INR and decreased INR variability, and 5) potential secondary benefits associated with monthly interface with health care providers (e.g. improved blood pressure control, improved rate control, improved adherence to warfarin and other stroke-modifying therapies), i.e. adherence bias.

I. Major haemorrhage: warfarin-naïve vs. warfarin-experienced

A number of studies have demonstrated that the risk of bleeding on anticoagulant therapy is highest during the period immediately after warfarin is initiated. Landefeld et al. performed a review of medical records from 565 patients prescribed warfarin (for conditions such as AF, venous thromboembolism [VTE] and heart valve replacement) upon hospital discharge. All patients in this cohort were warfarin-naive. The proportion of patients who experienced major bleeding during the first 30 days of outpatient treatment was 3%, 10-fold higher than the calculated monthly risk (0.3%) observed during the subsequent 11 months of follow-up (29). Similarly, in an analysis of data from a randomised controlled trial involving 1,021 patients being started on anticoagulation for VTE, Douketis et al. describe a significant early risk of major haemorrhagic events. Of the 28 major bleeds that occurred during the three months of warfarin treatment in this trial, 21 had occurred within three weeks and 13 had occurred within the first seven days of anticoagulant therapy (30). A meta-analysis of randomised controlled trials or prospective cohort studies of patients being treated for VTE also described a clustering of major bleeding events at the start of anticoagulant therapy: the rate of intracranial haemorrhage (expressed per 100 patient-years) was 5.92 during the first three months of anticoagulant therapy and 0.65 thereafter (31).

A retrospective, multi-center study of 928 consecutive warfarin-treated patients from five anticoagulation clinics yielded similar findings. In order to minimise survivor bias, this analysis included the records not only of patients actively receiving warfarin, but also of patients whose warfarin had been discontinued in the

previous 18–24 months. During a mean duration of follow-up of 1.9 years, being in the early phase of treatment was identified as an independent risk factor for major bleeding. In the first three months of treatment, "serious" bleeding occurred at a rate of 21 episodes per 100 patient-years. The authors found that, compared to the rest of the first year, the second year, and anytime thereafter, the relative risk for serious bleeding during the first three months of treatment was 1.9 (95% confidence interval [CI] 1.3–3.0), 3.0 (95% CI 1.8–4.8), and 5.9 (95% CI 3.8–9.3), respectively (32). When comparing the rate of major haemorrhage during the first 90 days of treatment to the rate of the same outcome after one year of warfarin exposure, a Danish study of warfarin-naïve patients reported a similar increase: incidence rate ratio,1.9 (95% CI 0.8–4.1) (33). ▶Table 2 summarises the evidence that the risk of warfarin-associated bleeding is highest during the initial weeks of treatment.

In an evaluation of all 21,785 patients enrolled in an acute coronary syndrome registry, 2,921 patients were found to have AF (1,700 pre-existing, 1,221 newly diagnosed). Compared to patients in this registry without AF, the patients with AF had increased morbidity and mortality. However, only *new-onset* AF was independently associated with an increased risk of several adverse events, including in-hospital major bleeding (34). Similar results have been demonstrated in a pooled analysis of over 120,000 trial participants with acute coronary syndromes as well as in a group of almost 6,000 patients with ST-segment elevation myocardial infarction treated with primary percutaneous coronary intervention (35, 36). Another large study, the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial, has reported similar findings: when compared to patients who entered the trial with a prior history of AF, major haemorrhage was reported to be more common among patients with new-onset AF (37). As noted by Ray, patients initiating therapy are often sicker than prevalent users (28).

This association of major bleeding with *newly diagnosed* (i.e. not pre-existing) AF provides further evidence that a group of patients being exposed to anticoagulation for the first time will have

Table 2: Summary of evidence that the risk of bleeding is highest during the initial days of anticoagulant treatment.

Study	Design + patient population	Length of follow-up	Evidence for "front-loading" of bleeding risk	Comments
Landefeld, 1989 (29)	Retrospective study of patients starting warfarin for a variety of indications	48 months	The monthly risk of major bleeding decreased over time from 3% during the first month to 0.3% per month after the first year of therapy.	All patients identified at the time of hospital discharge
Douketis, 2000 (30)	Analysis of RCT database with 1,021 VTE patients new to warfarin	3 months	28 major bleeds occurred during the initial 3 months of anticoagulation – 21 (75%) of these had occurred with 3 weeks and 13 (46%) had occurred within 7 days of starting anticoagulation	All patients received LMWH "overlap" therapy for the first days of treatment; no AF patients included
Linkins, 2003 (31)	Meta-analysis of 29 RCTs and 4 prospective cohort studies of VTE patients receiving oral anticoagulant therapy for at least 3 months	Variable, but ≥3 months in all cases	Intracranial bleeding during first 3 months of treatment occurred in 1.48% (95% CI 1.40% to 1.56%) of patients. After the first 3 months, the rate of intracranial bleeding was 0.65 (95% CI 0.63 to 0.68) per 100 patient-years.	Definitions of major bleeding differed across studies
Fihn, 1993 (32)	Retrospective study of 5 anticoagulation clinics; 928 patients receiving warfarin for a variety of indications	Median = 1.9 years	Compared to the rest of the first year, the second year, and anytime thereafter, the relative risk for "serious" bleeding during the first 3 months of treatment was 1.9 (95% CI 1.3–3.0), 3.0 (95% CI 1.8–4.8), and 5.9 (95% CI 3.8–9.3) respectively.	Retrospective study, some of the participating centers were not using INR (rather PT ratios) during part of the study
Steffensen, 1997 (33)	Retrospective, single-center cohort study of 682 warfarin-naïve patients being anticoagulated for a variety of reasons	756 treatment-years	The risk of a first major haemorrhagic episode was highest during the first 90 days of treatment; compared with treatment duration above one year, the incidence rate ratio was 1.9.	Although this incidence rate ratio did not reach statistical significance,the numeric difference is consistent with other studies cited
Hylek, 2007 (43)	Prospective, single-center cohort study of 472 warfarin-naïve patients being anticoagulated for AF	12 months	15 of 26 major hemorrhages occurred with 90 days, 11 of 26 within 30 days and 7 withiin the first 2 weeks of warfarin therapy	32% of patients were ≥80 years of age, 33% were identified at hospital discharge, 40% were also taking aspirin

a higher risk of haemorrhage than a group of prevalent users of oral anticoagulation. This may be related to patient-specific, period-specific, or drug-specific factors. Patient-specific factors include the unmasking of subclinical underlying pathologic lesions, labile INR measurements, and concomitant prevalent medications (e.g. anti-platelet therapy) that increase bleeding risk. Period-specific factors confer a transient increase in bleeding risk that would be expected to resolve within a short period of time. For example, the immediate post-hospitalisation period might be characterised by increased use of heparin transition therapy or dietary fluctuation; recently discharged populations will also have a higher prevalence of acute illness (e.g. gastrointestinal mucosal injury, stress-induced gastritis) associated with haemorrhage. Drug-specific factors include half-life, variability in dose-response, tendency toward erratic anticoagulation control with warfarin initiation, and individual rate of INR decay following an episode of excessive anticoagulation. For all of these reasons, it is important that the haemorrhagic risk profile of new anticoagulant drugs with different pharmacokinetic properties be assessed during the period of highest risk, i.e. the 90-day period following therapy initiation.

II. Temporal risk of stroke

Similar to major haemorrhage, the incidence of stroke is also time-dependent. The highest risk of stroke exists at the time of initial presentation with AF. In a registry of 5,477 patients with acute myocardial infarction and left ventricular dysfunction, 1,000 patients had concomitant AF; 655 of these individuals had AF at baseline (pre-existing) and 345 developed AF during the follow-up (median 3.0 years). The adjusted hazard ratio (HR) for 30-day risk of stroke among patients with new-onset AF was 14.6 (95% CI 5.87 – 36.3). In contrast, the adjusted HR for stroke during the whole trial among patients with new-onset AF was 2.29 (95% CI 1.43 – 3.68) (38).

▶Table 3 includes data from a population-based retrospective cohort study where it was noted that the early risk for both haemorrhagic and thromboembolic events was substantially higher than corresponding risks during later time periods of warfarin therapy (39). A third striking example of the high risk for thromboticevents associated with the first 30 days after the diagnosis of AF is seen in an observational study of the Framingham cohort. The authors studied only patients who were not treated with warfarin. Although their principal aim was to derive a stroke risk classification scheme for patients with AF, Wang et al. reported that out of 1,216 patients aged 55 to 94 years, 153 experienced stroke, transient ischaemic attack (TIA) or death within 30 days of AF diagnosis. These 153 individuals, along with others, were excluded from the final analysis of 705 patients who were not treated with warfarin and for whom longitudinal follow-up (mean 4.3 years) was available. The rate of the combined endpoint among the 705 patients who survived the first 30 days following AF diagnosis without suffering stroke, death or TIA was 13.4 per 100 person-years, more than 10 times lower than the corresponding calculated crude incidence rate (153 events per 100 patient-years) among patients who experienced stroke, death or TIA *less than* 30 days after being diagnosed with AF (40).

A study of patients with newly diagnosed AF found that 48% of them had evidence of intra-atrial spontaneous echo contrast by transesophageal echocardiography and 10% had visible intra-atrial thrombus (41). Serial studies have documented complete or near-complete resolution of these thrombi following anticoagulation (42). These observations further highlight the difference between patients with newly diagnosed AF and prevalent warfarin users, among whom visible left atrial thrombus would be very uncommon. The ability of new antithrombotic drugs to antagonise thrombus initiation, propagation, and embolisation will be most rigorously assessed among patients with newly diagnosed AF during this period of heightened risk for thromboembolism.

III. Early attrition of higher risk patients

There is little published data on the proportion of patients in clinical practice who remain on oral anticoagulant therapy over time. If patients with higher stroke risk disproportionately stop oral anticoagulant therapy, then the remaining population of warfarin-experienced patients will be at lower risk of stroke. Furthermore, because patients with a propensity to bleed will most likely experience this adverse event within the first few months of anticoagu-

Event type	Time interval (days)	Person-years at risk	No. of events	No. of censors	Hazard per year of risk
Major bleed	0 – 30	20.6	4	15	0.187
	31 – 90	35.4	4	57	0.116
	91 – 365	68.8	3	113	0.033
	1 – 4.2 years	87.3	7	58	0.068
Any embolism	0 – 30	20.8	7	12	0.328
	31 – 90	35.3	5	62	0.146
	91 – 365	66.7	3	110	0.034
	1 – 4.2 years	84.8	3	59	0.030

Table 3: Risk of haemorrhage or thromboembolism stratified by duration of anticoagulation with warfarin. These data come from a population-based retrospective cohort study that included all residents of Rochester, Minnesota for whom a course of warfarin therapy intended to last for more than four weeks was initiated between September 1, 1987 and December 31, 1989 (39).

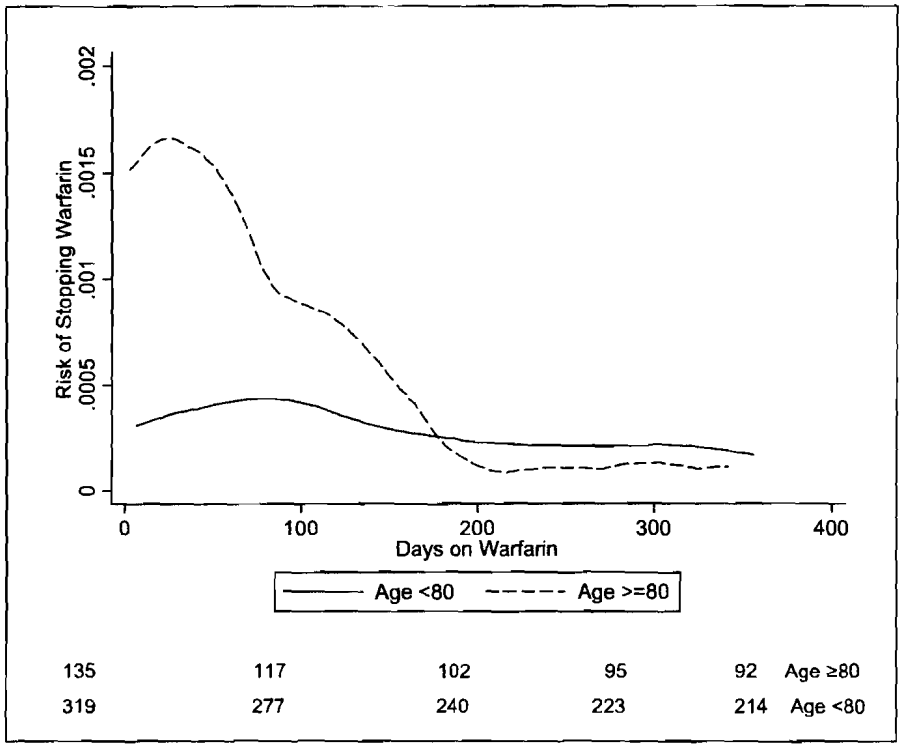

Figure 1: Risk of stopping warfarin in the first year due to perceived safety concerns by age (43). Numbers below graph are the number of patients taking warfarin at that time point. P<0.001, log-rank test.

lant therapy; many such patients will have their warfarin discontinued. Thus, the patients remaining on warfarin will also be at lower risk for haemorrhage. The potential for survivor bias that is introduced by enrolling predominantly prevalent users of warfarin is illustrated by two examples. First, in a cohort study of 472 patients with AF newly starting warfarin, both haemorrhagic events and unplanned discontinuations of therapy occurred more frequently among patients at highest risk of stroke. The risk of stopping warfarin therapy peaked early among patients aged 80 years and older and was similar to that of younger patients at six months (43) (▶Fig. 1). Another study of Medicare beneficiaries tracked adherence to warfarin and INR monitoring post-hospital discharge. The authors found that a subgroup of patients, black and Hispanic individuals, at high baseline risk for stroke were more often lost to follow-up within the first 90 days than their white counterparts (whose baseline stroke risk was lower) (19). Not surprisingly, the black and Hispanic patients in this cohort ultimately suffered higher annual stroke rates (11% and 12% vs. 5% among white patients). Taken together, these studies further emphasize the lower risk profile of patients who manage to remain on warfarin for extended periods of time.

IV. The anticoagulant effect of VKAs stabilises over time

Stability of anticoagulant effect is often not achieved for several months after initiating a VKA. Fluctuations are influenced by diet, drug interactions, genetic variation, and adherence. In a study of 2,223 patients with non-valvular AF, 52% of the INR values were outside the target range (INR 2.0 to 3.0) in the first month, whereas only 30% of INR measurements were not therapeutic after two years of monitoring time (44). Similarly, among 600 adults with AF randomly sampled from three health plans, patients newly started on warfarin at the time of referral to a dedicated anticoagulation clinic tended to have poorer control than patients already taking warfarin (adjusted odds ratio [OR] 0.59; 95% CI 0.35 to 1.08) (45). A comparable association of better anticoagulant control with increased time on warfarin was seen in a study of 254 subjects taking one of three fixed doses of ximelagatran or dose-adjusted warfarin. At study entry, 61% were warfarin-experienced. Among the patients assigned to warfarin, attainment of optimal INR increased from 34% at the start of therapy to 57% at 12 weeks (46).

Enrolment of warfarin-experienced patients in randomized trials confers an advantage to the group assigned to receive warfarin. Because these patients have taken warfarin for an extended period of time, they have become familiar with their own triggers for poor INR control. This training effect results from monthly INR measurements recommended for all warfarin-treated patients. In the ACTIVE W trial of warfarin versus dual antiplatelet therapy, warfarin-naïve patients had less time in the 2.0 to 3.0 range when compared to those who entered the trial on warfarin (warfain experienced), 60.4% versus 64.8% (p<0.001). Warfarin-naïve patients also spent more time with a sub-therapeutic INR, 24.6% versus 19.2% (p<0.001). At three months of follow-up, time in the therapeutic range for the warfarin-naïve group was 57.2% versus 62.4% for the warfarin-experienced group. Not surprisingly, the rates of both vascular events and major haemorrhage were higher in the warfarin-naïve versus warfarin-experienced

group. Patients who entered the trial already on warfarin were also less likely to discontinue the drug, 8.7% versus 15.3% at one year (23). White et al. studied the relationship between INR control and outcomes among 3,587 patients randomised to warfarin in the trials comparing ximelagatran to warfarin. The poor control group, defined as having less than 60% of time with a therapeutic INR, experienced higher rates of major bleeding, thromboembolic events, and annual mortality. Among the reference "good" control group (defined as spending greater than 75% of time with an INR between 2.0 and 3.0), 85% of the individuals entered the study taking warfarin. In contrast, the proportion of warfarin-experienced patients in the corresponding poor (70.8%) and moderate (81.9%) control groups was lower ($p<0.001$) (47). Again, these findings suggest that patients who have taken warfarin for at least several months will spend more time with a therapeutic INR than patients who are new to warfarin.

V. Secondary benefits of frequent medical contact

In addition to the adherence bias introduced by warfarin-experienced patients, long-term use of a medication may be a marker of a more adherent patient population overall. Adherence to antihypertensive medication, lifestyle measures, lipid-lowering agents and diabetes treatment regimens may all collectively decrease an individual's risk of stroke and other thrombotic events over time. The monthly interface with health care providers that occurs with each INR measurement would fortify efforts to control blood pressure, facilitate laboratory monitoring (e.g. measurement of glycated haemoglobin or lipids), minimise patient confusion over treatment plans, and reinforce treatment compliance.

Practical challenges to enrolling warfarin-naïve patients

Enrolling a high proportion of warfarin-naïve patients to participate in a clinical trial is challenging for several reasons. First, patients who are newly starting anticoagulant therapy will be far fewer in number compared to the prevalent user pool. This relative paucity of potential candidates is important because, unlike early placebo-controlled trials that enrolled approximately 250 patients in each arm, trials of non-inferiority require thousands of patients. Warfarin-naïve patients are also more likely to have acute medical conditions that might reduce the likelihood they would be approached about participating in a clinical study. Finally, for patients already taking warfarin, there is no "time limit" during which they need to be randomised. In contrast, the enrolment of patients with newly diagnosed AF is complicated by the fact that they can be considered warfarin-naïve only for a finite period. Given the time-intensive efforts necessary for patient identification, screening, consent, and randomisation, real barriers exist to enrolment of a true inception cohort of patients within a trial setting.

Conclusions

Enrolment of predominantly warfarin-experienced patients in clinical trials results in under-ascertainment of early events associated with initiation of anticoagulant therapy and newly diagnosed AF. The "warfarin surviving" patients also may introduce an adherence bias because of improved INR and blood pressure control over time. Before definitive conclusions about the relative safety and efficacy of novel anticoagulant drugs can be drawn, it is important that each of these agents be studied in warfarin-naïve patients because these patients are at the highest risk for both stroke and major haemorrhage.

Fife, M.D., M.P.H.,[6] Geralde Gabeau, M.S.M., M.P.H.,[2] Stacie E. Geller, Ph.D.,[7] Jeanette H. Magnus, M.D., Ph.D.,[8] Justina A. Trott, M.D.,[9] and Hilary F. White, B.S.[2]

Abstract

Objective: Following the initial wave of federal support to address women's health, there is a need to assess successes and determine the next priorities to advance the health of women. The objective of this study was to systematically collect expert opinion on the major advances in women's health in the past decade and priorities for women's health research and service in the coming decade.
Methods: We utilized a Delphi method to query the leadership from academic and community Centers of Excellence in Women's Health, as designated by the Department of Health and Human Services. Leaders from 36 of the 48 centers responded to a series of questions about the major advances and critical indicators to evaluate future needs in women's health. We utilized a social ecology model framework to organize the responses to each question.
Results: The experts identified increased health education for women and increased empowerment of women across multiple spheres as the major advances positively impacting the health of women. The experts selected the following areas as the most important indicators to measure the status of the health of women in the future: health education and promotion, rates and impact of interpersonal violence against women, and access to healthcare. The major advances and measures of the health of women did not focus on specific changes to individual women in illness management, clinical care, or individual behavioral change.
Conclusions: As we move to address health reform, we must be able to recognize and incorporate a broad perspective on public health and policy initiatives critical to the health and wellness of women and girls and, therefore, central to the well-being of the nation.

Introduction

Focus on all aspects of women's health has increased dramatically in the last two decades. The recognition that women were less likely to be included in clinical trials led to policy changes, including new National Institutes of Health (NIH) Requirements for the Inclusion of Women and Minorities as Subjects in Clinical Research.[1] Landmark studies that examined female-male differences provided important insights and unexpected findings that informed clinical and public health practices and led to a variety of federal initiatives to address the unique health and wellness needs of women and girls. These efforts resulted in the congressional mandate that established the Office for Research in Women's

Health (ORWH) at the NIH, and the establishment of the Offices on Women's Health (OWH) at the Department of Health and Human Services (DHHS) and the Office of Women's Health at the Food and Drug Administration (FDA).

A subsequent initiative was the establishment and funding of academic and community national Centers of Excellence in Women's Health (CoEs) by the DHHS Office on Women's Health from 1995 to 2007. These interdisciplinary model programs were funded to develop comprehensive, coordinated, and integrated female-focused programs that encompassed clinical care, gender-based research, professional education, community outreach, leadership development, and mentoring.

These comprehensive women's health programs have a lifespan perspective and address the needs of women and girls within the bio-psycho-social continuum. This view presents a challenge to a traditional medical model when one aims to develop a "roadmap" for women's health, particularly since unifying measures or benchmarks of success and accomplishments are clearly needed in women's health.

It is critical to view each woman as an individual, living in and affected by a specific physical and social environment: her community. Within that environment, many factors impinge upon her health from the moment of conception until her death. In an effort to evaluate the impact of both the individual and the environment, we have reached beyond the medical model to other fields. Recognizing the multiple influences that affect the health of women, we sought to understand the current status of the health of women and project emerging needs as we move forward. We used the multi-level Bronfenbrenner's Ecology of Human Development[2] or Social Ecology Model to survey opinion leaders in the CoE programs about their understanding of women's health today, from the individual, interpersonal, community, institutional/organizational, and public policy levels. The model recognizes that decisions and behavior are the result of a synergy among these levels and cannot be interpreted well without a good understanding of the context in which such decisions and behaviors occur.[2]

Materials and Methods

The goals of this project were to describe the most significant advances in women's health during the past decade and to identify important indicators that assess whether improvements are being achieved. This was accomplished by performing a theory-based survey of directors or senior leaders of the CoE programs funded by the DHHS OWH, as of 2006.[3] These centers, and the populations they served, broadly reflected the geographic and racial/ethnic diversity of the nation. They included: (1) academically based Centers of Excellence in Women's Health; (2) community-based Centers of Excellence (CCoEs); (3) Rural/Frontier Women's Health Coordinating Centers (RFCC); and (4) Region VIII Demonstration Sites in the intermountain West and Dakota regions.

All programs, hereafter referred to as CoEs, funded by OWH in 2006 were invited to participate in the survey. We collected the opinions of 36 of the 48 designated centers using a Delphi process. The Delphi process is a method for achieving consensus by completion of two or more rounds of questionnaires, with feedback on the group's and one's own results between administrations.[4] The process was originally developed for participants who could not meet; however, group discussion between rounds can, and were, used to facilitate consensus.[4] Even when consensus is not achieved, the method allows one to assess the degree of agreement in a group. For this study we used a three-round, conventional Delphi method.

We were interested in two specific questions: (1) What have been the most important advances in women's health in the past decade? and (2) What are the most important indicators to observe in the future to evaluate whether the health of women is improving?

The flow of the Delphi process is presented in Figure 1. In the first round, the writing group developed the strategy for organizing responses using the social ecology model and submitted a list of possible responses to both of the questions. The results of the first round were submitted in written form to all CoE directors to review at their sites for the second round of the Delphi process. Directors were given the option of reviewing individually or obtaining the consensus from the leadership at their site. They were asked to expand and list additional responses to each question not included in the list. They were then asked to provide written responses to the two principal questions. The third round of the Delphi process took place at an in-person conference of all 48 directors or their designees. The written compilation of responses from the second round of the Delphi process was provided to all directors for review. The directors were then divided into five working groups each, which formed their own summary of the key responses and presented their findings to the entire group. Following this process, each director or designee was given the same written document and asked to list his/her top responses to the two questions.

After the third round of the Delphi process, two authors (FG and KF) reviewed these responses and collapsed the raw responses into major themes. This summary was placed into two tables to demonstrate the interrelatedness of the themes across the five levels of the model. Internal feedback was provided by the writing group to develop the themes. The entire writing group then reviewed and revised the themes into the final format presented.

Results

Two tables summarize the major themes identified within the context of social ecology model structure. Table 1 contains advances in women's health and Table 2 lists indicators to assess progress in women's health. The institutional/organizational and public policy levels were collapsed into one column, to reflect the substantial overlap in the responses for these two categories. The themes (rows) were ordered based on the number of levels (columns) into which each theme fell. Boxes were bolded to indicate that at least 10 CoEs included this idea in their responses. Themes that were both included by fewer than 10 CoEs and were mentioned under only one level (column) were excluded from the tables. The following section summarizes the main patterns and findings derived from these tables.

Advances in women's health

Health education was cited across all levels of the model (Table 1). At the individual level, this included access by patients to health education, community health education

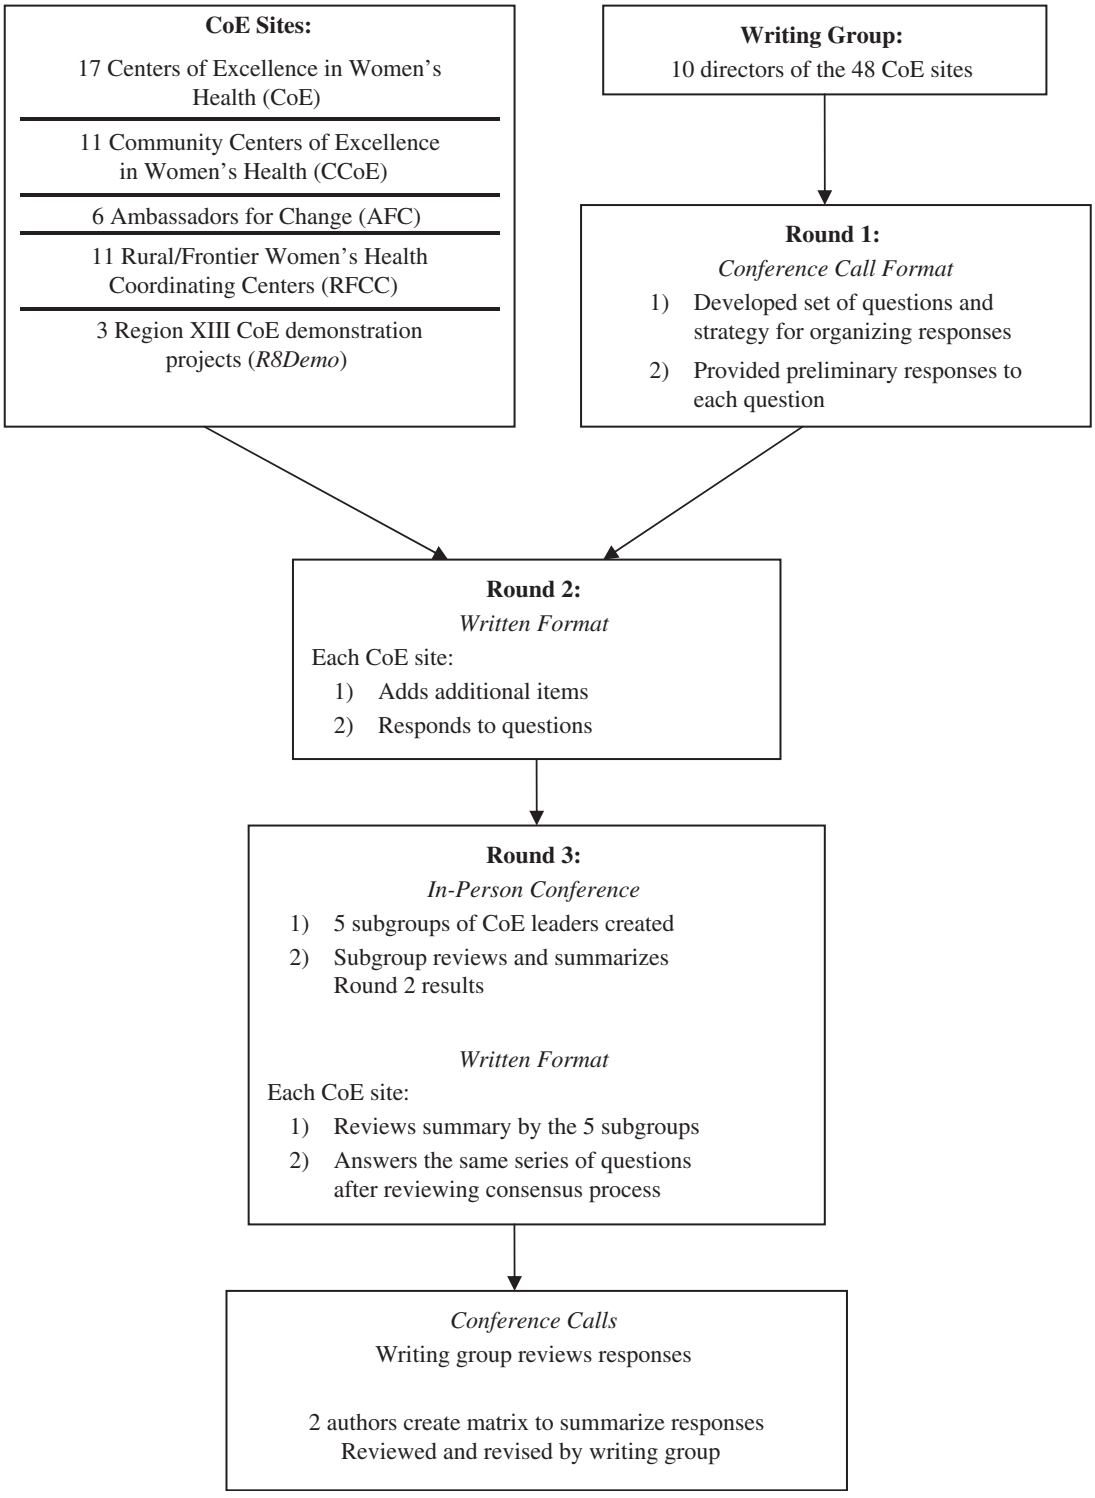

FIG. 1. Flow of the Delphi process.

programs, and increased knowledge of health issues. At the interpersonal level, the ubiquity and availability of accurate, relevant, and contextual health information for the individual woman and her family was cited by a number of respondents. By far the most frequently cited advance in community level women's health was the recognition of community-based partnerships in various forms as important and effective means for promoting health through health education. At institutional/public policy levels, respondents cited workplace-based wellness and health education programs as important advances, as well as increased public awareness of specific women's health issues, such as nonreproductive-related women's health, geriatric issues, disparities, and healthcare access and coverage issues.

Empowerment of women was cited at three levels: individual, interpersonal, and community. The increased

Table 1. Advances in Women's Health

	Individual	*Interpersonal*	*Community*	*Institutional/organizational and public policy*
Health education	Access by patients to health education Community health education programs Increased knowledge of health issues	Availability of accurate, relevant, and contextual health information	Via community-based partnerships	Workplace-based wellness and health education programs
Empowerment of women	Increased awareness of women as consumers of health Active/vocal role in decision-making Attending to self-care Personal initiative Activist role	Improved self-efficacy of women	Via community-based partnerships	
Employment-related factors/equity in the workplace		Recognition of workplace environmental influences on personal health	Worksite wellness programs Flexibility to attend to personal and family issues Economic sustainability	Advances in policies to promote gender equity in the workplace (especially salary equity) Policies in child/eldercare, medical/family leave, flex time, part-time employment
Safety/violence prevention		Child abuse Intimate partner violence Other domestic violence	Safe/low-crime neighborhoods	
Support and communication		Healthy/high quality interpersonal relationships in home and work environment Social support networks/groups (support personal development and self-efficacy)	*See* Community-based partnerships/initiatives	
Environmental factors		Recognize home and workplace environmental influences on personal health	Availability of public spaces for physical activity and recreation Safe and low-crime neighborhoods Adequate housing Tobacco-free communities	

Recognition of women's health issues	Comprehensive approach to health of women Sex and gender differences between men and women			
Community-based partnerships/ initiatives			Community-based organizations Faith-based organizations Neighborhoods Informal and formal social networks Lay health educators	
Women in leadership roles				Initiatives/programs to increase proportion of women leaders Evidence of an increase in women leadership
Focus on women's health				Financial support Focus of training, curriculum, and research on women's health
Women's health/ gender-based research				National initiatives promoting women's health research (e.g., Women's Health Initiative) Research offices within federal agencies (i.e., NIH, DDA, etc.) Specific funding Regulations requiring inclusion of women in clinical trials
Federal initiatives in women's health				Advent of federal and state support for women's health agencies to promote and sustain initiatives in women's health (e.g., BIRCWH, CoEs, national Offices on Women's Health in DHHS, NIH, FDA, etc.)

= ≥10 responses.
= <10 responses.

Table 2. Indicators to Measure Progress in Women's Health

	Individual	*Interpersonal*	*Community*	*Institutional/organizational and public policy*
Health education/ promotion	Access to health education Increases in health literacy Increased self-efficacy or participation in one's own health care	Access, exposure, and quality of health education programs and materials	Improving consumer information to support healthy lifestyle choices Availability of health education to students Quality of education and achievement in general	Employer support for health promotion and education activities
Rates of interpersonal violence	Rates of interpersonal violence	Rates of incidence of and screening for intimate partner violence and domestic violence Perceived safety	Rates of domestic violence, neighborhood crime, and incarceration Perceived safety of communities	Employer-based resources for domestic violence victims
Access to healthcare	Overall access to healthcare Access to a personal care provider and wellness care Mental health care Fertility control and prenatal care Insurance coverage		Availability of community-based and public sector health care providers and insurance	Universal health insurance Access to primary care and screening services Funding of essential therapeutics Access to mental health as part of employer-funded health insurance
Patient satisfaction	Patient satisfaction and quality-of-life indicators (as outcomes of healthcare)	"No show" and compliance rates Perceived empowerment Satisfaction with services provided		Patient satisfaction with their healthcare system
Preventive health	Health screenings Measures of lifestyle or behavior, including exercise, nutrition, and BMI, smoking, and drug abuse			Preconception health Infant wellness Family planning Nutrition Rates of specific screening tests (e.g., mammography)
Outcomes (prevalence of disease and morbidity/ mortality)	Incidence, prevalence, management markers, morbidity and mortality of chronic disease conditions and comparing these by sex and racial/ethnic group for disparities in outcomes			

Social measures of wellness	Economic indicators (poverty levels, rates of housing, etc)			
Relationship factors		Quality and effectiveness of communication with partner, family, and healthcare providers		
Community-level policy			"Grass roots" organizations Neighborhood resource centers Smoking bans Infrastructure to support physical activity Community alliances Lobbying policy makers	
Federal support for women's health research				NIH support for research training programs (BIRCWH) HHS support for CoE/CCOE program
Women in leadership positions				Within the institution

= ≥10 responses.
= <10 responses.

empowerment of women in their own health was the most commonly noted advance at the individual level. This was described as increased awareness of women as consumers of healthcare, women taking a more active and vocal role in decision-making, women attending more to self-care, and personal initiative, and women taking more of an activist role. At the interpersonal level, a number of respondents cited the development of social support networks to improve self-efficacy of women as an important advance. At the community level, respondents identified the development of community-based partnerships and initiatives aimed at empowering women as very important.

Employment-related factors and equity in the workplace were cited at the interpersonal, community, and institutional/public policy levels. At the interpersonal level, respondents noted the recognition of workplace environmental influences on personal health as an important advance. At the community level, employment-related factors such as worksite wellness programs, flexibility to attend to personal and family issues, and economic sustainability were mentioned by a minority of respondents. At the institutional/public policy level, respondents cited advances in policies to promote gender equity in the workplace (especially salary equity), as well as "female-friendly" and "family-friendly" workplace policies related to child and elder care, medical and family leave, flexible hours, and part-time employment, as critical advances.

Safety and violence prevention were cited at the interpersonal and community levels. Programs to promote safety and security of women were the most frequently cited advance in women's health at the interpersonal level. Specifically, respondents mentioned advances in prevention programs and policies of interpersonal violence, including child abuse, intimate partner violence, and other forms of domestic-related violent behaviors. At the community level, initiatives for safe and low-crime neighborhoods were considered to be important advances.

Support and communication were also mentioned at both the interpersonal and community levels, and constituted an especially important theme at the interpersonal level. Specifically, respondents cited healthy/high-quality interpersonal relationships in the home and work environment, as well as social support networks to promote personal development and self-efficacy, as important advances in women's health at the interpersonal level. Support and communication were also important at the community level, and the most frequently cited advance at this level was the recognition of community-based partnerships and initiatives (including community-based organizations, faith-based organizations, neighborhoods, informal and formal social networks, and lay health educators) as crucial mechanisms to support and promote health education, health promotion, and the empowerment of women.

Environment-related factors were another theme cited at both the interpersonal and community levels. At the interpersonal level, these included the recognition of home and workplace environmental influences on personal health. At the community level, advances in environmental factors included the availability of public spaces for physical activity and recreation, safe and low-crime neighborhoods, adequate housing, and promotion of tobacco-free communities.

Twelve themes were mentioned in just one of the four levels. Six of these were cited by more than 10 CoEs (shown in Table 1). At the individual level, CoEs noted the recognition of broader women's health issues, including a comprehensive approach to the health of women and recognition of sex and gender differences between men and women, as an important advance in women's health. At the community level, respondents identified advances regarding community-based partnerships/initiatives. At the institutional/public policy level, multiple CoEs cited women in leadership roles, an increased focus on women's health, federal/national funding for women's health/gender-based research (e.g., the Women's Health Initiative and federal regulations regarding the inclusion of women and minorities in clinical trials), and federal initiatives in women's health (e.g., the NIH Building Interdisciplinary Research Careers in Women's Health[5] and CoE programs[6]) as important advances.

Indicators to measure progress in women's health

The second set of questions asked the group of experts to identify measures or indicators that would best capture the status of the health of women and girls. Health education and health promotion are indicators that were found across all four levels of the model (Table 2). At the individual level, respondents cited access to health education, health literacy, and self-efficacy or participation in one's own healthcare as important indicators. Interpersonal-level indicators regarding health education/promotion included access/exposure and quality of health education programs and materials. At the community level, measures of consumer information to support healthy personal and lifestyle choices, measures of the educational content available to students regarding health-related topics, and quality of education and achievement in general were cited.

Rates of interpersonal violence were mentioned across all four levels. At the individual and interpersonal levels, respondents cited rates of intimate partner violence (domestic violence). At the interpersonal level, rates of screening for interpersonal violence, as well as perceived safety, were noted as important by a number of contributors. Community-level indicators concerning interpersonal violence included rates of domestic violence, neighborhood crime, and female incarceration, as well as perceived safety of communities. At the institutional/public policy level, respondents cited availability of employer-based resources for domestic violence victims as important.

Access to healthcare was cited as a critical measure at the individual, community, and institutional/public policy levels. At the individual and community levels, access to healthcare was the most commonly cited indicator for the measurement of women's health. At the individual level, indicators included overall access to health care, access to a primary care provider (PCP) and wellness care, mental healthcare, fertility control and prenatal care, and insurance coverage. At the community level, respondents cited availability of community-based and public sector healthcare providers and insurance as important measures. Indicators regarding access to healthcare at the institutional/public policy level included universal health insurance, access to primary care and screening coverage, funding for essential therapeutics, and access to mental health care as part of employer-funded health insurance.

Preventive health indicators were cited as important measures of health by a number of contributors at both the individual and institutional/public policy levels. At the individual level, respondents cited health screenings and mea-

sures of lifestyle and behavior, including exercise, nutrition and BMI, smoking, and drug abuse. Preventive health indicators at the institutional/public policy level included the availability of preventive service programs for women and families, including programs for preconception health, infant wellness, family planning, nutrition, and rates of specific screening tests, such as mammography.

Twelve measurement indicator themes were mentioned in just one of the four levels. Six of these were cited by more than 10 CoEs (shown in Table 2). Individual level outcomes of healthcare, including the incidence, prevalence, management markers, and morbidity and mortality of chronic disease conditions, compared by both sex and racial/ethnic group for disparities in outcomes, were emphasized. Social measures of wellness (including economic indicators such as poverty levels, rates of housing, and rates of interpersonal violence), were mentioned as important indicators to measure women's health at the individual level. At the interpersonal level, multiple sites mentioned relational factors, including measures of the quality and effectiveness of interpersonal relationships and communications with partner, family, and healthcare providers. At the community level policy engagement pertaining to "grass-roots" organizations, neighborhood resource centers, smoking bans, infrastructure to support physical activity, influence over school-based policies (e.g., dietary and physical education), formation of community alliances, and lobbying of policy makers were highlighted. At the institutional/public policy level, multiple sites mentioned federal support for women's health services and research (e.g., BIRCWH[5] and CoE/CCOE[6]). Multiple sites also listed the number of women in leadership positions as an important institutional indicator of women's health.

Discussion

We asked a group of experts in the healthcare of women to list the critical measures of the health of women, and the most useful advances in the health of women. Of interest, the major advances and measures of the health of women did not focus on specific changes to the individual women in illness management, clinical care, or individual behavioral change. Rather, they dealt with changes to the environment to promote health, and changes in women's self-empowerment to address their own health and wellness.

These findings are critical as we engage in a discussion about changes to the healthcare system, especially whether improvements in access to care will eliminate health disparities. Critical to the discussion of the nation's health is the assertion that healthcare access, although significant, cannot solve the spectrum of health needs of our population. Addressing health and wellness solely at the level of the individual is insufficient, since individual change alone does not address the spectrum of contextual issues that impact the health and wellness of the population. The social ecology model is informative since it offers a broader perspective for improving the health of the nation and, specifically, the health of women. Although health insurance reform is needed, the health of women and the factors associated with women's health go beyond coverage for illness and disease prevention, and must address the full spectrum of relevant social and public health issues. Furthermore, our concept of the health of any individual must go beyond the notion that the individual is solely responsible for his/her health. While personal responsibility for one's health and wellness is a necessary element, much of what influences health and wellness lies within spheres beyond the individual, including interpersonal, community, institutional, and public policy arenas.

The expert panel assembled to conduct this Delphi process represents an interdisciplinary approach to addressing health and wellness. The advances and the greatest needs in the health of women are therefore viewed across the spectrum of individual, interpersonal, community, and institutional/public policy issues. This approach has direct policy implications for changes to support the wellness of women in our society. The establishment of the Offices on Women's Health in the U.S. Department of Health and Human Services in 1991 facilitated the establishment of the National Centers of Excellence in Women's Health, a program aimed at increasing the focus on women's health across the United States, first in academic health centers and then in community settings.[6] Each CoE independently developed its version of the model based on the culture and policy of its institution, partner organizations, community, and state. However, all CoE models were charged to provide comprehensive, coordinated, and integrated gender-based programs in clinical care, gender-based research, professional education, community outreach, and leadership development/mentoring.[7]

Interpersonal violence is a good example of a health condition or problem of specific relevance to women, for which a social ecology approach is critical to effect change. Our panel identified interpersonal violence as one of the key areas—spanning the individual, interpersonal, community, and institutional/public policy realms—where metrics are needed to measure progress in the wellness of women. Each year, approximately 1,300 deaths and 2 million injuries among women are attributed to intimate partner violence.[8] Interpersonal violence against women results in increased morbidity and significant increases in physical and mental health problems.[9] The significant physical and mental health consequences of interpersonal violence also result in large long-term health expenditures, including an average increase in 3-year healthcare costs of $1,700 per abused woman[10] and an estimated cost of violence of 3.3% of the U.S. gross domestic product.[11] Yet, while individual programs to guarantee women's safety are critical, these interventions do little to address the prevention of injury and morbidity from interpersonal violence. Our analyses highlight a number of critical measures with which to assess improvements for the prevention of violence to women. These include increasing the rates of women reporting active threats or injury, programs to proactively screen and address safety issues in the clinical setting and to address safety issues on a community basis (including enforcement of restraining orders and programs to ensure safety overall in neighborhoods), and institutional programs to ensure the safety of individuals in the workplace and other institutional settings.

A number of markers of improvements in the health of women fall outside the realm of medicine. Pay equity and training and mentorship of women into leadership positions are examples of important indicators that lie in the institutional and public policy domains. Such nonmedical factors are just as crucial to the health of women as are medical concerns. These issues reflect the larger social relationship between a nation and its citizens and illustrate how the context of

women's lives has profound implications for the national economy, workplace productivity, education, the environment, and, of course, public health.

The strength of this paper is in the wide geographic and interdisciplinary natures of the institutions and experts who responded to the process. One limitation of the model, however, is that it views women as passive within the process and therefore being affected by their environment. In reality, women actively impact their environment and community, an aspect that was not captured in our model.

Conclusions

Healthcare reform has re-entered the national dialogue, providing an important opportunity to consider how best to impact the health and wellness of America's women and girls within the larger context of the nation's health. The Centers of Excellence provide a model of implementing healthcare reform through a broad array of programs and outreach mechanisms. The advances in women's health identified in this study reflect areas of relative success in communities and settings where a well-developed multidisciplinary model has been applied. Thematic areas (e.g., patient-centered care/customer satisfaction) and levels of intervention (community) that have received relatively less attention were identified and should be considered for future funding and support. Furthermore, our analysis identifies concrete and meaningful metrics to track as new programs and strategies develop to address the health and wellness of our population and of women and girls, in particular.

Racial and Ethnic Differences in Hospice Use Among Patients With Heart Failure

Jane L. Givens, MD, MSCE; Jennifer Tjia, MD, MSCE; Chao Zhou, MA; Ezekiel Emanuel, MD, PhD; Arlene S. Ash, PhD

Background: Heart failure is the leading noncancer diagnosis for patients in hospice care and the leading cause of hospitalization among Medicare beneficiaries. Racial and ethnic differences in hospice patients are well documented for patients with cancer but poorly described for those with heart failure.

Methods: On the basis of a national sample of 98 258 Medicare beneficiaries 66 years and older on January 1, 2001, with a diagnosis of heart failure who had at least 1 physician or hospital encounter and who were not enrolled in hospice care between January 1 and December 31, 2000, we determined the effect of race and ethnicity on hospice entry for patients with heart failure in 2001 after adjusting for sociodemographic, clinical, and geographic factors.

Results: In unadjusted analysis, blacks (odds ratio [OR],0.52) and Hispanics (0.43) used hospice care for heart failure less than whites. Racial and ethnic differences in patients who received hospice care for heart failure persisted after adjusting for markers of income, urbanicity, severity of illness, local density of hospice use, and medical comorbidity (adjusted OR for blacks, 0.59; 95% confidence interval, 0.47-0.73; and adjusted OR for Hispanics, 0.49; 95% confidence interval, 0.37-0.66; compared with whites). Advanced age, greater comorbidity, emergency department visits, hospitalizations, and greater local density of hospice use were also associated with hospice use.

Conclusions: In a national sample of Medicare beneficiaries with heart failure, blacks and Hispanics used hospice care for heart failure less than whites after adjustment for individual and market factors. To understand the mechanisms underlying these findings, further examination of patient preferences and physician referral behavior is needed.

HOSPICE CARE IS DESIGNED to provide comfort and emotional support to patients with terminal illness and their families and is most commonly (84%) provided through the Medicare hospice benefit.[1] Although patients dying of cancer comprised 44% of hospice admissions in 2006,[1] hospice care can also offer substantial benefit to patients with other terminal illnesses, such as end-stage heart failure (HF). However, patients in the terminal stages of noncancer conditions use hospice care less frequently than those with advanced malignant tumors.[1]

Currently, HF affects nearly 5 million people in the United States and is the leading cause of hospitalization among Medicare beneficiaries.[2] Despite progress in treatment,[3,4] patients with advanced HF have a 1-year mortality of 50% to 70%,[5] and hospice care is increasingly recommended in guidelines for such patients.[4,6-8] Although advanced heart disease represents the second most common hospice diagnosis, comprising 11.8% of hospice enrollees,[1] hospice services are generally recognized as underused by patients with HF.[4,9]

Underuse of hospice care is well documented, especially among racial and ethnic minorities.[10-14] Racial and ethnic differences in patients who use hospice care have been found across a spectrum of patients with cancer diagnoses[15-17] and may be more pronounced in patients with noncancer diagnoses.[18] However, previous studies[10,11,13-15,18] of ethnic differences in patients who use hospice care have been limited to cross-sectional or retrospective analyses, which have had limited ability to assess life expectancy or severity of illness among potential hospice care recipients. In this study, we use data from a large, nationally representative, ethnically diverse cohort of Medicare beneficiaries with HF to estimate the independent effect of race and ethnicity on hospice care for HF in the coming year, after adjusting for patient demographics, in-hospital interventions, comorbidity, and geographic variation in hospice use.

METHODS

DATA SOURCE

We used a national sample of Medicare beneficiaries oversampled for nonwhite patients as previously described.[19] The data source included merged Medicare claims files (denominator, inpatient, carrier, outpatient, and hospice files) from 2000 and 2001. An initial sample of 1 million beneficiaries 66 years and older was selected from the Medicare denominator file for 2001, with deliberate oversampling of beneficiaries who died in 2001 and racial and ethnic minorities categorized as black, Hispanic, and other. These files were merged with the National Death Index from 2001 to verify date of death.

STUDY POPULATION

We included Medicare beneficiaries who had complete claims data from 2000 and 2001, resided in the United States, were not enrolled in Medicare managed care organizations, and were not entitled to the Medicare end-stage renal disease benefit. Among those meeting these initial inclusion criteria (n=603 128), we limited the study sample to those beneficiaries (n=98 258) with a diagnosis of HF (*International Classification of Diseases, Ninth Revision, Clinical Modification* [*ICD-9-CM*][20] codes 428.xx, 398.91, 402.11, 402.91, 404.11, 404.13, 404.91, or 404.93) who had at least 1 physician or hospital encounter and who were not enrolled in hospice care between January 1 and December 31, 2000. On the basis of the sampling, these individuals reflect the experience of approximately 2.7 million beneficiaries.

MAIN OUTCOME MEASURES

Outcome Variable

Our primary outcome variable was entry into a hospice with an admitting diagnosis of HF between January 1 and December 31, 2001. We identified hospice entry from the first hospice admission date in 2001 and calculated hospice duration from first admission date until death or December 31, 2001, for nondecedents.

Predictor Variables

Race and Ethnicity. We used the Medicare denominator file categories of white, black, and Hispanic. We also collapsed all remaining categories (including Asian, North American natives, and unknown) into "other."

Medical Comorbidity. To characterize the morbidity of participants, we calculated prospective diagnostic cost group (DCG) scores derived from outpatient, inpatient, and carrier claims for the year 2000 (DxCG version 6.1 for SAS Windows; SAS Institute Inc, Cary, North Carolina). The DCG score predicts Medicare costs for the period designated as next year, as calculated from 1 year of *ICD-9-CM* diagnosis codes, age, and sex, and is expressed as a relative risk.[21] Thus, a score of 1.0 indicates an expected level of future health care use equal to the mean for Medicare beneficiaries, and 2.0 indicates expected costs that are twice as high. This score also predicts other outcomes, including mortality.[22]

Use of Medical Services and Other Sociodemographic Variables. To characterize each beneficiary's HF severity, we used the inpatient file from 2000 to calculate the number of emergency department (ED) visits and hospitalizations and the number of days spent in an intensive care unit (ICU) or coronary care unit (CCU). We used the denominator file to capture beneficiary age and sex and to define a geography-based socioeconomic status indicator (median income of zip code of residence) as determined from 2000 US Census data. We also used a marker for a state's Medicaid purchase (ie, Medicaid buy-in) of the Part B benefit as an indicator of low individual income.

Competing Hospice Diagnoses and Geographic Variables. We used our software's condition categories to identify other common morbidities present in 2000 that could lead to hospice care in 2001. These categories were cancer, dementia, stroke, and chronic obstructive pulmonary disease.

Because hospice availability[23] and use[4,10,24] differ by place of residence, we created 2 geographic variables from beneficiary zip code of residence. The first measures urbanicity because persons in rural settings typically have less access to hospice services.[10,23] We used the Beale rural-urban continuum codes[25] to categorize urbanicity as follows: metropolitan region with a population of 1 million or more, metropolitan region with a population of less than 1 million, nonmetropolitan region, and unknown.

We also developed a novel, hospice-specific, health service area (HSA)–based variable that we call *local hospice density*, derived from the larger data set of HF and non-HF beneficiaries who met our initial eligibility criteria (n=603 128). This variable describes the local prevalence of hospice use among the 2001 decedents in this data set (n=158 903). The HSAs are either single counties or clusters of counties that are relatively self-contained with respect to hospital care and delineate local health care markets for community-based primary inpatient care. We located each decedent in the HSA by his or her zip code of residence. We then defined the local density of hospice use as the percentage of the HSA's decedents who had entered into hospice care. For HSAs with fewer than 50 decedents in our data, we substituted the density of hospice use for the hospital referral region that contains it. Hospital referral regions consist of 1 or more HSAs and represent the tertiary market for medical care, including referral or specialty care.[26]

STATISTICAL ANALYSIS

We used descriptive statistics to characterize the demographics, health characteristics, health care use (including hospice entry), and mortality of the study population by racial or ethnic category. All analyses were conducted using sampling weights to obtain population-based estimates and a linearized variance estimator based on a first-order Taylor series linear approximation to compute standard errors.[27] The sample weights represent the reciprocal of the sampling probabilities for each of the 8 strata represented in the total sample of 1 million beneficiaries (2 based on decedent status and 4 based on race and ethnicity). To assess the statistical significance of bivariate associations, we used an adjusted Wald test for continuous variables, a design-based Pearson χ^2 test for categorical variables, and a nonparametric equality-of-medians test for medians.

To identify the independent association of race and ethnicity on hospice entry for HF, we developed a series of weighted logistic regression models with the outcome of hospice entry for HF in 2001. Models successively added covariate sets: race and ethnicity alone (model 1); age and sex (model 2); urbanicity, income, hospitalizations, ED visits, number of ICU and CCU days, diagnoses of cancer, chronic obstructive pulmonary disease, dementia, or stroke, and DCG score (model 3); and local hospice density (model 4). To examine whether our findings were attributable to differences in local health care delivery systems not captured in our data, we also developed a fixed-effects regression model that compares members of different racial and ethnic groups only when they reside in the

same HSA. Because the findings of this sensitivity analysis are similar to the more conceptually revealing original analysis described herein, we present the results of the original analysis.

Analyses were conducted using STATA statistical software, version 10.0 (StataCorp, College Station, Texas), and SAS statistical software, version 9.0 (SAS Institute Inc). This study was approved by the institutional review board of the Boston University School of Medicine.

RESULTS

CHARACTERISTICS OF THE STUDY POPULATION

The final study population included 98 258 Medicare beneficiaries (weighted population, n=2.7 million). The weighted percentages by race and ethnicity were as follows: white, 88.3%; black, 8.5%; Hispanic, 1.4%; and other, 1.8%. Many differences in sociodemographic characteristics, DCG scores, and severity of illness measures by race and ethnicity were statistically significant (**Table 1**). Beneficiaries who were of black, Hispanic, and other races and ethnicities were more likely to live in large metropolitan urban areas. Black and Hispanic beneficiaries had lower incomes and were more likely to have Medicaid buy-in. There were also notable age differences among the groups, with black and Hispanic beneficiaries being younger than whites and others. Differences in markers of health and health care use were notable, with Hispanics having the highest mean DCG score, number of hospitalizations, length of stays in the CCU and ICU, and number of ED visits. Unadjusted use of hospice care for HF and for any reason differed by race or ethnicity (**Table 2**). The percentage of beneficiaries using hospice care for any diagnosis in 2001 was small (3.9%). Of these, 18.2% entered because of HF. The percentage of decedents who had used hospice care was 19.9% overall, with a higher percentage of white decedents (20.4%) using hospice care compared with blacks (15.4%), Hispanics (16.9%), or those of other races or ethnicities (16.3%). Among those who used hospice care, a higher percentage of whites entered hospice care for HF treatment (18.5%) than blacks (14.1%), Hispanics (13.2%), and other racial and ethnic groups (15.8%). For HF, Hispanics had the longest median duration of hospice care (19 days), followed by blacks (14 days), whites (13 days), and other racial and ethnic groups (10 days).

MULTIVARIABLE MODELS FOR HOSPICE USE FOR HF

Nonwhite patients used hospice care for HF less than whites (**Table 3**). After adjusting for sociodemographics, urbanicity, comorbidities, DCG score, use of medical services, and local hospice density (model 4), hospice use remained lowest for Hispanic beneficiaries (adjusted odds ratio [aOR], 0.49) compared with whites.

Abbreviation: COPD, chronic obstructive pulmonary disease.
[a] Odds ratios were adjusted for models 2, 3, and 4.

Blacks (aOR, 0.59) and other nonwhite beneficiaries (aOR, 0.64) with HF were also less likely to use hospice care. Sex, income, Medicaid buy-in status, more days in the ICU or CCU, greater number of ED visits, and geographic residence in an urban area were not significantly associated with hospice entry. Higher DCG score, advanced age, ED visits and hospitalizations, and greater local hospice density were associated with hospice use. Competing hospice diagnoses of chronic obstructive pulmonary disease, dementia, and stroke were not associated with hospice use, but a diagnosis of cancer was protective against entry into hospice care for HF (aOR, 0.72).

COMMENT

This analysis of a national cohort of Medicare beneficiaries finds marked racial and ethnic differences among patients with HF who received hospice care. In our sample, blacks had 41.0% lower odds of hospice use and Hispanics 51.0% lower odds of receiving hospice care than whites. To our knowledge, our study is the largest longitudinal cohort study examining factors associated with hospice entry for a noncancer diagnosis. In addition, we use a prospective design and a novel measure of local hospice use.

Our finding that racial and ethnic minorities are less likely to use hospice care for HF is consistent with other hospice literature. Several studies have documented lower rates of hospice use among blacks, Hispanics, and Asian Americans compared with whites. However, these studies either have specifically focused on patients with cancer[14-16] or do not define the diagnosis determining hospice entry.[12,13,28] There is concern that racial and ethnic disparities may be more pronounced among patients with noncancer diagnoses than among those with cancer.[18] Our findings document significant racial and ethnic differences in hospice use and counter speculation that overall increases in the availability of hospice services in the 1990s may have erased racial and ethnic differences in hospice use.[11]

In this study, we have adjusted for numerous factors related to hospice entry, many of which vary substantially by race and ethnicity. Geographic variation in hospice availability is associated with patterns of hospice use,[10] including hospice entry for HF.[4] Hospice availability differs between urban and rural areas,[10,23,24] and lower hospice use has been documented among patients living in predominantly minority vs white areas.[29] On a state level, greater regional availability of hospice services is associated with less racial and ethnic disparity between blacks and whites in hospice use.[28] We created a variable to represent the prevalence of hospice use among Medicare decedents within smaller local geographic units (HSAs) and found that our observed ethnic differences in hospice use for HF persisted after accounting for local hospice availability and urbanicity.

In addition to sociodemographic, clinical, and geographic characteristics, cultural beliefs and values may contribute to differences between blacks and whites in end-of-life care and hospice use.[30,31] For example, compared with whites, blacks are less likely to complete advance directives, have less favorable beliefs about hospice care, opt for more aggressive treatments, and are more likely to have spiritual beliefs that conflict with the goals of palliative treatment.[19,30,32] In addition, lack of trust between patients and physicians may be more pronounced for ethnic minorities[33,34] and may contribute to ethnic differences in hospice entry.[35,36] Blacks more often report receiving inadequate information regarding end-of-life care[37] and are less likely to be informed about hospice services than whites.[38] Our administrative data contained information on neither patient cultural beliefs and values nor physician behavior, factors that may also help explain differences in hospice use. Finally, health literacy, also not measured in this study, has been found to partially explain racial and ethnic differences in end-of-life treatment preferences.[39]

This study has several limitations. First, we could not measure HF severity using clinical markers such as ejection fraction or exercise tolerance, and thus, HF severity might vary by race and ethnicity. However, we adjusted for prior-year measures of ED visits, hospitalizations, and ICU and CCU use as proxies for clinical complications and disease severity. Second, although race and ethnicity coding in the Medicare denominator file has a good positive predictive value for identifying whites, blacks, and Hispanics (>94%), it performs less well for Asians and American Indian/Alaskan Native beneficiaries,[40] making findings for the "other" race and ethnicity category difficult to interpret. Finally, although higher hospice use has been reported among enrollees from health maintenance organizations compared with patients with traditional Medicare coverage,[41] we could not include such patients in our study sample because of incomplete capture of diagnoses and health care use.

This article describes the largest noncancer study of hospice entry to date. It prospectively examines a national probability sample of people with HF, oversampled for racial and ethnic minorities and decedents. Large differences in racial and ethnic minority use of hospice care for HF compared with whites remain largely unchanged after adjusting for differences in income, urbanicity, comorbidity, severity of illness, and hospice use density. It is not clear how many of these differences reflect access issues as opposed to considered patient preferences.

Effectiveness of Policies Restricting Hours of Alcohol Sales in Preventing Excessive Alcohol Consumption and Related Harms

Robert A. Hahn, PhD, MPH, Jennifer L. Kuzara, MA, MPH, Randy Elder, PhD, Robert Brewer, MD, MSPH, Sajal Chattopadhyay, PhD, Jonathan Fielding, MD, MPH, MBA, Timothy S. Naimi, MD, MPH, Traci Toomey, PhD, Jennifer Cook Middleton, PhD, Briana Lawrence, MPH, the Task Force on Community Preventive Services

Abstract: Local, state, and national policies that limit the hours that alcoholic beverages may be available for sale might be a means of reducing excessive alcohol consumption and related harms. The methods of the *Guide to Community Preventive Services* were used to synthesize scientific evidence on the effectiveness of such policies. All of the studies included in this review assessed the effects of increasing hours of sale in on-premises settings (in which alcoholic beverages are consumed where purchased) in high-income nations. None of the studies was conducted in the U.S. The review team's initial assessment of this evidence suggested that changes of less than 2 hours were unlikely to significantly affect excessive alcohol consumption and related harms; to explore this hypothesis, studies assessing the effects of changing hours of sale by less than 2 hours and by 2 or more hours were assessed separately.

There was sufficient evidence in ten qualifying studies to conclude that increasing hours of sale by 2 or more hours increases alcohol-related harms. Thus, disallowing extensions of hours of alcohol sales by 2 or more should be expected to prevent alcohol-related harms, while policies decreasing hours of sale by 2 hours or more at on-premises alcohol outlets may be an effective strategy for preventing alcohol-related harms. The evidence from six qualifying studies was insufficient to determine whether increasing hours of sale by less than 2 hours increases excessive alcohol consumption and related harms.

(Am J Prev Med 2010;39(6):590–604) Published by Elsevier Inc. on behalf of American Journal of Preventive Medicine

Introduction

Excessive alcohol consumption is responsible for approximately 79,000 deaths per year in the U.S., making it the third-leading cause of preventable death.[1] Binge drinking (consuming five or more drinks per occasion for men and four or more drinks per occasion for women) is reported by approximately 15% of U.S. adults aged ≥18 years and by approximately 29% of high school students in the U.S.[2,3] The direct and indirect economic costs of excessive drinking in 1998 were $184.6 billion.[4] The reduction of excessive alcohol consumption in general and binge drinking in particular are thus matters of major public health and economic interest. Reducing binge drinking among U.S. adults has been a public health objective in *Healthy People 2010*.[5]

In the U.S., local control of the total or specific hours during which alcoholic beverages may be sold (hereafter referred to as "hours of sale") varies from one state to another. Some states allow cities, counties, and other local jurisdictions to enact their own alcohol control policies, and in these states, restrictions on hours of sale can vary from one location to another. In other states, local control may be pre-empted by state regulations that prohibit local authorities from enacting alcohol control regulations stricter than those that apply to the rest of the state.[6,7] As of 1953, American Indian reservations have the authority to establish their own alcohol-related policies, prior to which alcohol was formally prohibited.[8]

There is also wide variation among states in the specific restrictions they place on the hours of sale by retail setting (i.e., on- or off-premises) and by the day of the week.[9] For on-premises alcohol outlets, states allow facilities to serve alcohol for a median of 19 hours a day on weekdays and

Saturdays. Nine states (Alabama, Florida, Georgia, Illinois, Louisiana, Maryland, Nevada, New Jersey, and South Carolina) have no limits on hours of sale for on-premises alcohol outlets.[9] On Sundays, alcohol may be served for a median of 17 hours at on-premises facilities, with seven states placing no restrictions on Sunday on-premises sales; four states allow no sales of alcohol at on-premises facilities on Sundays. In off-premises settings, hours of sale are limited to a median of 18 hours on weekdays and Saturdays. Restrictions range from no limits on hours of sale in Alabama, Florida, Georgia, Illinois, Louisiana, Maryland, and Nevada to 8 hours of sale allowed in Idaho. On Sundays, states allow a median of 13 hours of alcohol sales at off-premises facilities, with five states having no restrictions; 18 states with "blue laws" allow no off-premises sales.

This review uses the methods of the *Guide to Community Preventive Services (Community Guide)*[10] to assess the effects of changes in the hours during which alcohol is served on excessive alcohol consumption and related harms. A separate review published in this issue assesses the effects of changing days of sale on excessive alcohol consumption and related harms and concludes that increasing days of sale leads to increased consumption and related harms. The focal question of the present review is how, within allowable days of sale, the number of hours available for acquisition and service of alcohol affects excessive alcohol consumption and related harms.

Findings and Recommendations from Other Reviews and Advisory Groups

Several scientific reviews[11–14] have concluded that restricting the hours when alcohol may be sold is an effective strategy for reducing excessive alcohol consumption and related harms. One review,[11] funded by the Center for Substance Abuse Prevention (CSAP), found substantial evidence of harms associated with expanding the hours and days of alcohol sales. This conclusion was based on previous empirical research indicating that the expansion of the hours and days of sale increased prevalence of excessive alcohol consumption and alcohol-related problems. Most prior reviews have combined findings on days and hours and none have examined a threshold effect. The CSAP review included studies prior to 1999; a recent review[14] includes studies published between 2000 and 2008. The present review covers both periods using the systematic methods of the *Community Guide* described below.

Several international bodies have also recommended the control of hours or days of sale, or both as means of reducing excessive alcohol consumption and related harms.[15] For example, a recent review[16] of alcohol control strategies by the WHO found that limiting of hours of sale was an effective method for reducing alcohol-related harms. In Ireland, the Department of Health and Children's Strategic Task Force on Alcohol[17] concluded (p. 30) that "restricting any further increases in the physical availability of alcohol (number of outlets and times of sales)" is among the most effective policy measures for influencing alcohol consumption and related harms.

Methods

The methods of the *Community Guide* were used to systematically review scientific studies that have evaluated the effectiveness of limiting or maintaining existing limits on the hours of sale for preventing excessive alcohol consumption and related harms.[10] In brief, the *Community Guide* process involves forming a systematic review development team (review team), consisting of subject matter and methodology experts from other parts of the CDC, other federal agencies, and academia, and the Task Force on Community Preventive Services (Task Force); developing a conceptual approach for organizing, grouping, and selecting interventions; selecting interventions to evaluate; searching for and retrieving available research evidence on the effects of those interventions; assessing the quality of and abstracting information from each study that meets inclusion criteria; assessing the quality of and drawing conclusions about the body of evidence on intervention effectiveness; and translating the evidence on effectiveness into recommendations. Evidence is collected and summarized on (1) the effectiveness of reviewed interventions in altering selected health-related outcomes and (2) positive or negative effects of the intervention on other health and nonhealth outcomes. When an intervention is shown to be effective, information is also included about (3) the applicability of evidence (i.e., the extent to which available effectiveness data might generalize to diverse population segments and settings); (4) barriers to implementation; and (5) the economic impact of the intervention. To help ensure objectivity, the review process is typically led by scientists who are not employed by a program that might be responsible for overseeing the implementation of the intervention being evaluated.

The results of this review process are then presented to the Task Force, an independent scientific review board that objectively considers the scientific evidence on intervention effectiveness presented to them and then determines, with the guidance of a translation table, whether the evidence is sufficient to warrant a recommendation on intervention effectiveness.[10] Evidence can be found to be strong, sufficient, or insufficient. Sufficient or strong evidence may indicate benefit, harm, or ineffectiveness of the intervention whereas insufficient evidence indicates more research is needed.

Conceptual Approach and Analytic Framework

The premise of this review is that increased availability of alcoholic beverages through any mechanism facilitates increases in excessive consumption and related harms, and that limiting hours of sale of alcoholic beverages is one way to reduce availability. The limitation of hours of sale of alcoholic beverages was defined as "applying regulatory authority to limit the hours that alcoholic beverages may be sold at on- and off-premises alcoholic beverage outlets." *Limiting* may refer to either *maintaining existing limits* in response to efforts to expand hours of sale or *reducing current limits on hours of sale.* Hours of sale may be regulated at the national, state, or local level or some combination of these. *Off-premises retailing* refers to

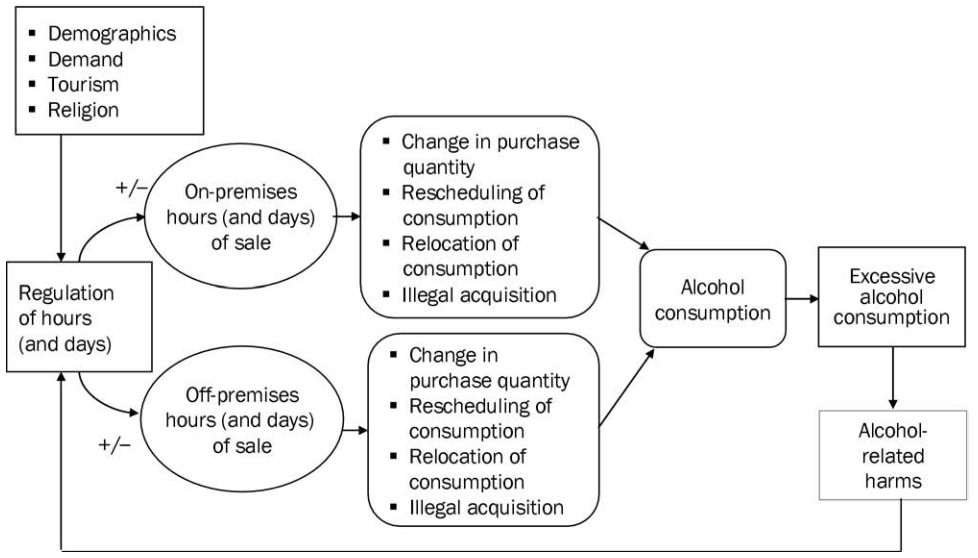

Figure 1. Effects of regulation of hours (and days) of alcohol sales on excessive alcohol consumption and related harms

the sale of contained alcoholic beverages, for instance, at package stores, liquor stores, grocery stores, or convenience stores, for consumption elsewhere. *On-premises retailing* refers to the sale of alcoholic beverages for consumption at the point of sale, for example, at bars, restaurants, or clubs.

Policies that regulate the hours of sale may be influenced by various characteristics of the affected population, including the demand for alcoholic beverages, the age distribution of the population, the religious affiliation and involvement of residents, and the amount of tourism the area attracts. Policies reducing or expanding hours of sale are hypothesized to affect alcohol consumption and alcohol-related harms through the following means (Figure 1). First, increases or decreases in the hours of sale affect consumers' ability to purchase alcohol by changing its availability. Second, when access to alcoholic beverages changes, consumers may alter their purchasing habits in several ways, including changing their purchase volume, rescheduling their purchases, relocating their purchases, or obtaining alcoholic beverages illegally. Changes in their purchasing habits may then affect their drinking patterns or overall levels of alcohol use, resulting in changes in alcohol-related problems.

Changes in the hours of sale may also affect alcohol-related health outcomes by other means. For example, increases in the hours that alcohol is available at on-premises outlets may be associated with increased social aggregation, which, in turn, may increase aggressive behaviors that are exacerbated by alcohol consumption.[18] Increases or decreases in the hours that alcohol is available in one jurisdiction may also increase or decrease alcohol consumption in adjacent jurisdictions if consumers travel from a jurisdiction with fewer hours to one with greater hours. This may also affect the number of miles traveled to purchase alcohol, and therefore the probability of alcohol-related motor vehicle crashes.

The present review addresses the following research question: what are the effects on excessive alcohol consumption and related harms of changing the hours of sale at on- or off-premises outlets? It was hypothesized that there would be a dose–response relationship related to the magnitude of the change in hours (i.e., the amount by which hours of sale are increased or decreased). Based on this hypothesis, the body of evidence for this review was stratified into studies examining changes of ≥2 hours and <2 hours per day. This cut point was chosen by the judgment of the review team that 2 hours might be a reasonable threshold for a substantial effect and on the distribution of available studies.

The process by which hours of alcohol sale are changed in different settings may also be an important variable to consider in evaluating the effects of such changes. In some settings in which the allowable hours of sale are increased, any licensed facility may extend hours. In others, facilities must apply for an extension and meet certain criteria, such as demonstrating a lack of facility crowding in a neighborhood. It was hypothesized that the additional level of regulation required to apply for extended opening hours might reduce the potential harm from greater access by restricting the implementation and extent of added hours.

Inclusion and Exclusion Criteria

To be included as evidence in this review, studies had to meet certain criteria. First, studies that assessed short-term changes in alcohol availability (e.g., alcohol sales related to a special event such as a sports competition) were not included. Second, eligible studies needed to assess the specific impact of changes in the hours of sale on excessive alcohol consumption, related harms, or both, as opposed to evaluating the effect of change in combination with other interventions. Studies of combined interventions may obscure the effects attributable specifically to changes in hours. Third, because the current focus was on the effects of changes in hours of sale in jurisdictions where these changes occurred, no review was made of studies that examined the effects of changes in hours in one jurisdiction on consumption elsewhere, for example, in neighboring jurisdictions or across a border. Fourth, to increase the applicability of the findings to the U.S., studies had to be conducted in countries with high-income economies[a] according to the World Bank.[19] Fifth, studies had to present primary research findings, not just review other research findings. Sixth, studies had to be published in English. Seventh, studies had to have a comparison group

[a]World Bank High-Income Economies (as of May 5, 2009): Andorra, Antigua and Barbuda, Aruba, Australia, Austria, The Bahamas, Bahrain, Barbados, Belgium, Bermuda, Brunei Darussalam, Canada, Cayman Islands, Channel Islands, Cyprus, Czech Republic, Denmark, Equatorial Guinea, Estonia, Faeroe Islands, Finland, France, French Polynesia, Germany, Greece, Greenland, Guam, Hong Kong (China), Hungary, Iceland, Ireland, Isle of Man, Israel, Italy, Japan, Republic of Korea, Kuwait, Liechtenstein, Luxembourg, Macao (China), Malta, Monaco, Netherlands, Netherlands Antilles, New Caledonia, New Zealand, Northern Mariana Islands, Norway, Oman, Portugal, Puerto Rico, Qatar, San Marino, Saudi Arabia, Singapore, Slovak Republic, Slovenia, Spain, Sweden, Switzerland, Trinidad and Tobago, United Arab Emirates, United Kingdom, U.S., Virgin Islands (U.S.).

or, at a minimum, compare outcomes of interest before and after a change in the policy related to hours of sale.

Specific types of alcohol-related harms of interest were alcohol-related diseases (e.g., liver cirrhosis), alcohol-impaired driving, alcohol-related crashes, unintentional or intentional injuries, and violent crime. When studies assessed multiple outcomes of interest, those outcomes with the strongest known association with excessive alcohol consumption were selected. Outcome measures that had the strongest known association with excessive alcohol consumption included binge drinking, heavy drinking, liver cirrhosis mortality, alcohol-related medical admissions, and alcohol-related motor vehicle crashes, including single-vehicle night-time crashes (which are widely used to indicate the involvement of excessive drinking).[20] Less-direct measures included per capita ethanol consumption, a recognized proxy for estimating the number of heavy drinkers in a population[21]; unintentional injuries; suicide; and crime, such as homicide and aggravated assault.

Search for Evidence

The following databases were searched: Econlit, PsycINFO, Sociology Abstracts, MEDLINE, Embase, and EtOH. All years of records available on the databases were searched up to February 2008. Although the systematic search ended at this date, the review team is not aware of additional hours of sale research published since this time. (The search strategy will be available on the Community Guide website.) The reference lists of articles reviewed were also searched as well as reference lists from other systematic reviews. Government reports were considered for inclusion, but unpublished papers were not. Subject matter experts were also consulted to identify studies that might have been missed.

Assessing the Quality and Summarizing the Body of Evidence on Effectiveness

Each study that met the inclusion criteria was read by two reviewers who used standardized criteria to assess the suitability of the study design and threats to validity.[10] Uncertainties and disagreements between the reviewers were reconciled by consensus among the review team members. Classification of the study designs accords with the standards of the *Community Guide* review process and may differ from the classification reported in the original studies.

Studies were evaluated based on their design and execution. Those that collected data on exposed and control populations prospectively were classified as having the greatest design suitability. Those that collected data retrospectively or lacked a comparison group, but that conducted multiple pre- and post-measurements on their study population(s), were rated as having moderate design suitability. Finally, cross-sectional studies, those without a comparison group, and those that involved only a single pre- or post-measurement in the intervention population were considered to have the least suitable design. Quality of execution was assessed by examining potential threats to study validity, including an inadequate description of the intervention or of the study population(s), poor measurement of the exposure or outcome, failure to control for potential confounders, and a high attrition rate among study participants. Based on these criteria, studies were characterized as having good quality of execution if they had at most one threat to validity; fair execution if they had two to four threats to validity, and limited quality of execution if they had five or more threats to validity. For example, studies that used only proxy outcome measures were assigned a penalty for this threat to validity. Only studies with good or fair quality of execution were included in the body of evidence; studies with any level of design suitability were included, other than those with cross-sectional design.

Effect estimates were calculated as relative percentage change in the intervention population compared with the control population using the following formulas:

1. For studies with pre- and post-measurements and concurrent comparison groups:
   Effect estimate $=(I_{post}/I_{pre})/(C_{post}/C_{pre})-1$,
   where:
   I_{post} = last reported outcome rate or count in the intervention group after the intervention;
   I_{pre} = reported outcome rate or count in the intervention group before the intervention;
   C_{post} = last reported outcome rate or count in the comparison group after the intervention;
   C_{pre} = reported outcome rate or count in the comparison group before the intervention.
2. For studies with pre- and post-measurements but no concurrent comparison:
   Effect estimate $=(I_{post}-I_{pre})/I_{pre}$

All studies included in this review assessed the effects of *increasing* hours of sale, and the control condition was *not increasing* hours of sale. Although the analysis here accordingly assesses the effects of increasing hours, the public health intervention of interest is the control condition, (i.e., *limiting or not increasing hours of sale*). This approach rests on the assumption that increasing availability by increasing hours is likely to increase excessive consumption and related harms, and thus not increasing hours when proposed is the public health intervention. For each body of evidence, the review reports a number of *events* of policy changes in hours in a given jurisdiction, each of which may have been the subject of more than one *study* (a research investigation carried out by a single researcher or research group), each of which, in turn, may have been reported in more than one *paper* or *report*.

Results on Intervention Effectiveness

Studies of Changes of >2 Hours in Hours of Sale

Ten studies[22–31] of six events that resulted in a change of ≥2 hours in the hours of alcohol sales met the inclusion criteria. Only one study[22] was of greatest design suitability; however, the principal analysis in this study was presented graphically and did not allow the estimation of a numeric effect size. One study[23] was of moderate design suitability and eight[24–31] were of least suitable design. All studies had fair quality of execution. (A summary evidence table [Table 1][22–40] accompanies this review.)

Four of the six events studied occurred in Australia (in 1966, 1977, 1984, and 1998–2000); one in London, England (in 2005); and one in Reykjavik, Iceland (in 2005). All of the events led to increased hours of sale at on-premises alcohol outlets.

In Victoria, Australia, weekday and Saturday hours were extended from 6:00 PM to 10:00 PM in 1966. Hours allowed prior to this change were not reported. One

study[22] compared trends in motor vehicle–related outcomes on weekdays and Saturdays before and after the hours of alcohol sales at on-premises alcohol outlets in Victoria, Australia, were extended, to the same outcomes on Sundays, when there was no change in hours. The author found that the increase in hours of sales on weekdays and Saturday did not significantly affect the number of crashes that occurred on these days. However, she observed a change in the timing of crashes corresponding to the change in the closing time of the on-premises alcohol outlets. Thus, in this study, it appeared that although the number of events may not have been affected by the change in the closing time of alcohol outlets, their timing was affected. In contrast to this study's findings, two subsequent analyses of the same event concluded that the increase in hours was associated with increases in consumption[23] and motor vehicle crash injuries.[24]

In 1984, hours available for alcohol service in Victoria were extended from 10:00PM until 12:00MN on weekdays and Saturdays and in length of time open from 4 hours to 8 hours on Sundays (a day on which alcohol sales had been previously allowed). Information on hours prior to the weekday and Saturday extension is not given. A study of this event[30] found an increase in motor vehicle crash injuries associated with these increases in hours.

Between July 1998 and June 2000, Victoria granted 24-hour permits to some on-premises alcohol outlets. A cross-sectional study comparing rates of assaults in outlets granted and not granted 24-hour permits is inconclusive.[31] Although authors claim that higher rates of assault are associated with 24-hour facilities, their statements describing results are inconsistent, and the authors do not provide data to allow re-evaluation.

In Tasmania (Australia), licensed premises were allowed to stay open until any hour in 1977. Prior Monday–Saturday opening hours were 10:00AM–10:00PM; Sunday hours, 12NOON– 8:00PM. The assumption by policymakers underlying unrestricted closing times was that possibly intoxicated clients would not be exiting the facilities at the same time, potentially decreasing risks, because different outlets would choose different closing hours. A study of this event[25] found an increase in motor vehicle crash injuries associated with these increases in hours.

In Reykjavik, licensed premises were allowed to stay open until any hour in the year 1999 on an experimental basis. Prior closing requirements were 11:30 PM on weekdays and 2:00 AM on weekends. Researchers found increases in emergency room admissions, injuries, fighting, and suspected driving while intoxicated.[26]

Finally, the United Kingdom's Licensing Act of 2003 allowed sales of alcoholic beverages 24 hours a day in England and Wales, beginning in November 2005, subject to local licensing requirements. Three studies assessing the impact of this increase in hours of sale produced mixed results.[27–29] Two studies[28,29] found a relative decrease in harms (violent criminal offenses and alcohol-related maxillofacial trauma, respectively), whereas a third study[27] found a relative increase in harms (alcohol-related assault and injury) subsequent to this increase in hours of sale.

Among the ten studies in this body of evidence,[22–31] two studies[28,29] found that an increase of ≥2 hours in the hours of sale led to decreased alcohol-related harms (i.e., injury and serious violent crime), and six studies[23–27,30] found an increase in alcohol-related harms relative to the period before the increase in hours of sale took place (Figure 2). The study by Raymond[22] found no effect. One study[23] found a nonsignificant increase in alcohol consumption associated with the increase in hours in Victoria, Australia, in 1966.

Information on the requirement that premises seek permits prior to expanding hours may not have been complete in the studies reviewed. To the extent that stated permit requirements accurately reflect the expansion process, there appears to be no systematic effect of permitting. Although the harmful effects of permitted expansions appear to be larger than those in which permits were not required (Figure 2) there were also effects in the opposite direction for studies of permitted settings.

Studies of Changes of <2 Hours in Hours of Sale

Six studies of five events (reported in ten papers[32–41]) that resulted in a change of <2 hours of sale met the inclusion criteria. All studies were of on-premises alcohol outlets. Three studies (seven papers[32–35,39–41]) were of greatest design suitability, three[36–38] were of least suitable design; all were of fair quality of execution. One study (two papers[39,40]) of the extension of opening hours in England and Wales in 1988 did not allow the calculation of effects for several outcomes, but it reported small and inconsistent results on multiple alcohol-related outcomes. One[41] provides graphics and report using interrupted time series but does not report numeric results.

In 1993, Perth, Australia allowed on-premises outlets to extend their closing time from 12:00MN to 1:00AM.[32–35] Findings were inconsistent, with a reported increase of alcohol wholesale but a decline in drunk driving and an increase in assaults and in alcohol-related crashes. None of these findings was significant.

In December 1979, the state of New South Wales in Australia expanded on-premises alcohol outlet closing hours from 10:00PM to 11:00PM, at the same time expanding Sunday hours and outlet settings. A study of these events[36] proposed using the weekdays as the control in an assessment of the effects of increased Sunday sales on

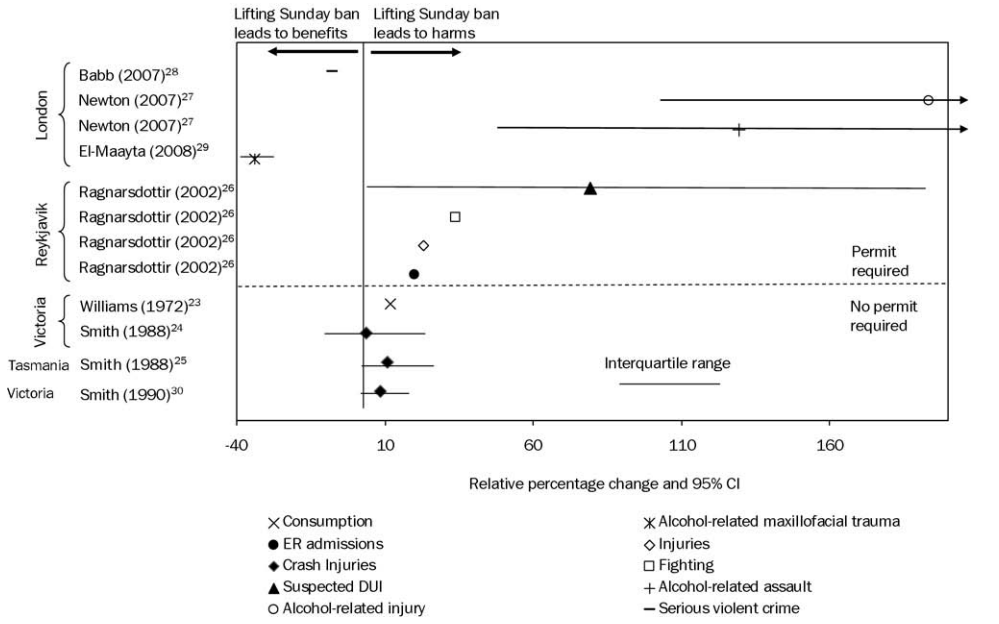

Figure 2. Relative percentage change in diverse outcomes associated with increases of ≥2 hours
DUI, driving under the influence

motor vehicle fatalities. However, this comparison is biased toward a null effect, given the change in weekday hours. A comparison of weekday fatalities before and after the weekday expansion indicates a reduction of 2.7% in motor vehicle fatalities over the study period associated with the weekday increase of 1 hour in closing time. However, this outcome may be confounded by a reduction from 0.08% to 0.05% in maximum legal blood alcohol levels in December 1980, which would have been expected to deter drunk driving and reduce motor vehicle injuries.

In 1976, Scotland allowed on-premises outlets to extend their closing time from 10:00PM to 11:00PM.[37,38] Reported changes were small and not consistent in direction. Knight found increased consumption for women and decreased consumption for men, and Bruce reported a small increase in the per capita consumption of beer.

In 1988, England and Wales extended the closing hours at on-premises outlets from 10:30PM to 11:00PM and moved the opening time from 11:00AM to 10:00AM.[39,40] The outcomes, including mortality from liver disease and cirrhosis, pancreatitis, alcohol poisoning, "alcohol-dependent syndrome," alcohol psychosis, workplace absenteeism and injury, and various motor vehicle–related outcomes) assessed in these studies were heterogeneous and included the seemingly contradictory findings that in comparison with changes in the control setting (Scotland), convictions for sales to underage patrons increased by 64.1% (95% CI=21.2%, 99.0%), whereas sales to minors fell substantially. Another finding was an increase in recorded violent crime of 15.5% (95% CI= 14.0%, 17.0%). (See Table 1.)

Finally, in 1996, Ontario Province extended closing hours in on-premises alcohol outlets from 1:00AM to 2:00AM. A study[41] of this event used graphics and interrupted time series to assess the effects of this change on all and alcohol-related fatal motor vehicle crashes. Changes in Ontario were compared with changes in Michigan and New York, neither of which changed hours of sale during the same period. The study also assessed changes in the sales of beer, wine, and spirits in Ontario from the period before to the period following the policy change. Numeric results are not reported. Beer consumption declined over the study period, whereas the consumption of wine and spirits declined in the early 1990s and then increased in the later 1990s. The authors conclude that changes in motor vehicle outcomes are "minimal." Their graphics suggest a shift of the timing of alcohol-related fatalities to later hours following the extension of hours of sale.

This small body of evidence indicates no consistent effects of changes of <2 hours on alcohol-related outcomes. Four events of increases in hours of sale were studied. Only one study of increased hours of sale in Perth, Australia, reported substantial increases in wholesale alcohol purchases, assaults, and motor vehicle crashes. Two studies (of events in England and Wales and in Ontario, Canada) did not provide numeric results but reported small and inconsistent changes in alcohol-related outcomes including alcohol consumption, multiple alcohol-related causes of mortality, and motor vehicle crashes. Two studies of increased hours of sale in Scotland also reported small and inconsistent changes in alcohol sales and consumption.

Again, information on the requirement that premises seek permits prior to expanding hours may not have been complete in the studies reviewed. To the extent that stated permit requirements accurately reflect the expansion

process, there appears to be no systematic effect of permitting (Figure 3).

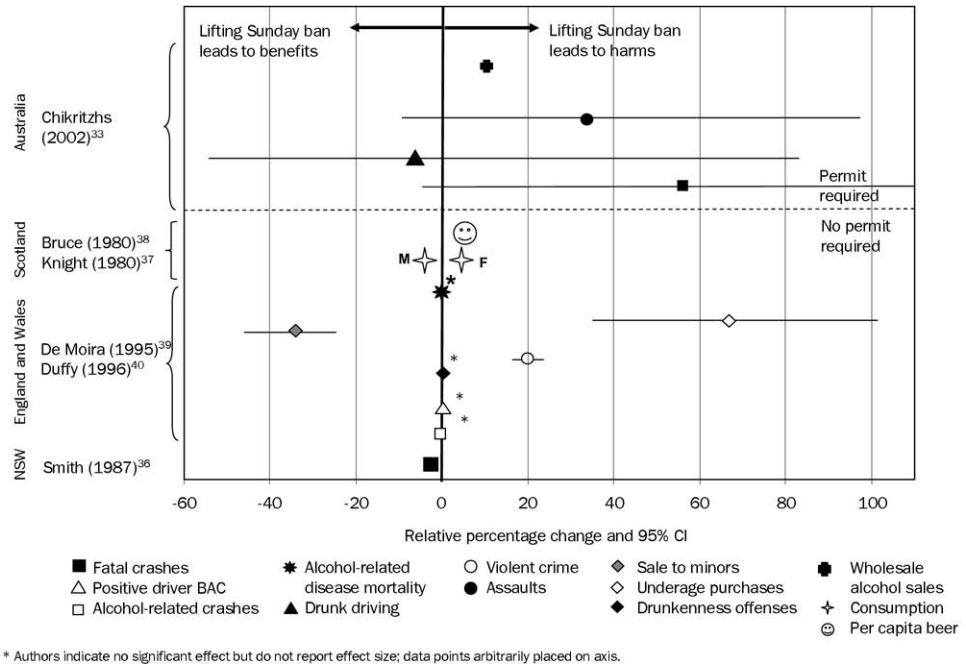

Figure 3. Relative percentage change in diverse outcomes associated with increases of <2 hours
NSW, New South Wales

Applicability

The studies in this review were conducted in a variety of settings outside the U.S. and during a wide range of time periods. Nonetheless, the association between restrictions on the hours when alcohol may be sold and alcohol-related harms was consistent across most geographic locations (all in high-income countries) and time periods, and the findings of this review are likely to be relevant for considering the potential impact of modifying the number of hours when alcohol may be sold in the U.S.

Other Harms and Benefits

Maintaining hours of sale may sustain quality of life in communities by controlling alcohol availability, excessive alcohol consumption, and health and social harms resulting from excessive alcohol use (e.g., public drunkenness); evidence of effects on quality of life were not provided by the studies reviewed. Although it is possible that crimes such as illicit alcohol sales may increase in localities where the hours of sale are limited, no evidence of such effects was found in any of the studies evaluated. One study[26] noted increased workload among law enforcement personnel associated with expanded hours of sale.

Barriers

The maintenance and reduction in the number of hours when alcohol may be sold may affect overall alcohol sales and may thus be opposed by commercial interests involved in manufacture, distribution, and sale of alcoholic beverages. The alcohol industry has generally supported policies that remove restrictions on the access to alcohol.[42]

State pre-emption laws (i.e., state laws that prevent the implementation and enforcement of local policies more restrictive than statewide regulations) can also undermine efforts by local governments to regulate hours of sale.[6] Indeed, the elimination of pre-emption laws related to the sale of tobacco products is one of the health promotion objectives in *Healthy People 2010*.[5] However, there is no similar objective in *Healthy People 2010* related to the local sale of alcoholic beverages.

Economics

No studies were identified that assessed the economic impact of reducing the number of hours when alcohol may be sold. No study was found that specifically estimated the magnitude of commercial losses in sales and tax revenues because of a policy of restricting hours of alcohol sales.

Summary

This review found that increasing the hours when alcohol may be sold by ≥2 hours increased alcohol-related harms. Evidence supporting this conclusion was based on studies conducted in on-premises settings outside the U.S. According to *Community Guide* rules of evidence, these findings provided sufficient evidence for the effectiveness of maintaining limits on hours of sale for the reduction of alcohol-related harms when efforts are made to increase hours by ≥2.[10] Because no qualifying study assessed the effects of reducing hours of sale, the only direct inference that can be made is that reducing hours of sale by ≥2 is likely to avert alcohol-related harms. How-

ever, it may also be reasonable to expect that reducing hours of sale would also reduce alcohol-related harms.

Because there was no consistent effect on excessive alcohol consumption or related harms of increasing hours of sales by <2 hours, according to *Community Guide* rules of evidence, there was insufficient evidence that this intervention had a meaningful effect.[10] Insufficient evidence means that it is not possible to determine from the available evidence whether this policy change had a meaningful effect.

Research Gaps

All existing research on hours of sale to date has been conducted in nations other than the U.S. It would be useful to have studies of changes in hours of sale in U.S. settings to confirm results from other settings. In addition, all research thus far has assessed the effects of *increasing* hours of sale. Although it may be a less-frequent event, evaluating the effects of *reducing* hours of sale for preventing excessive alcohol consumption and related harms would be useful. Evidence on changes in hours of sale of <2 hours is currently insufficient because of inconsistent findings. Thus, when such changes occur, it may be worthwhile to assess the effects of smaller changes in hours of sale on excessive alcohol consumption and related harms to improve our understanding of the "dose–response" and "threshold" relationships between changes in hours of sale and public health outcomes.

Additional research is also needed to more fully assess the costs and benefits of restricting the number of hours when alcohol is sold. From a societal perspective, economic elements should include intervention costs; loss in sales, tax revenues, and employment; reductions in fatal and nonfatal injuries, crime, and violence; gains in safety and public order; and averted loss of household and workplace productivity.

Finally, no studies were found that assessed the effects of changes in hours of sale in off-premises settings. Although consumers at off-premises settings are less likely to be directly affected by the effects of excessive consumption at the place of purchase, it is nevertheless possible that changes in availability in these settings may also affect alcohol-related harms. This issue merits investigation.

Discussion

Based on a systematic review of qualifying studies, this review confirms the findings of previous reviews and adds details regarding a possible dose or threshold effect. Evidence of the effects of changes in hours of sale of <2 hours was insufficient to determine effectiveness because of inconsistency among findings in the body of evidence, leaving unanswered the question of the effects of small increases in hours of sale. Data are not sufficient to allow systematic assessment of the relative percentage increase in hours (over a baseline) or the placement of the hours within the day.

All of the studies included in this review assessed the effects of increasing hours of sale at on-premises outlets, consistent with the international trend toward expanding the availability of alcoholic beverages. Further scientific evidence is needed to fully assess the symmetry between the effects of maintaining existing limits on the hours of sale compared with reducing hours of sale.

The only available evidence of the effects of reducing hours of sale was from a study in Brazil,[43] which did not qualify for inclusion in the review because Brazil is not a high-income nation, and, in general, studies of alcohol consumption from middle- and lower-income nations are thought not to be directly applicable to the contemporary U.S. context. In 1999, the city of Diadema had very high homicide rates; 65% of these were alcohol-related. Most of the homicides occurred between 11:00PM and 6:00AM. Diadema law allowed 24-hour opening of alcohol outlets. In July 2002, a new city law required bars to close at 11:00PM. From 2002 to 2005, homicide rates in the city declined by 44% (95% CI=27%, 61%), controlling for mortality trends. During this time period, there was also a 17% decline in assaults against women (the only additional outcome assessed); this finding, however, was not significant.

In addition to the lack of studies that assessed the effect of stricter limits on the hours when alcohol may be sold, the body of qualifying studies in this review had several other limitations. First, some studies did not directly assess the impact of relaxing restrictions on the hours of sales on excessive alcohol consumption and alcohol-related harms, but rather relied on proxy measures of these effect outcomes (e.g., criminal arrest rates). Second, nearly all of the studies relied on population-based data from public health surveillance systems that did not capture information on alcohol control policies. As a result, many of these studies were unable to control for some potential confounding factors. However, these studies generally assessed changes in the same geographic area before and after the implementation of changes in hours of sale over a fairly short time period. Other contextual factors that could also influence alcohol sales and consumption (e.g., changes in alcohol excise taxes) at the country, state, or community levels were likely to have remained fairly constant during the study periods, allowing for a valid assessment of the impact of changing hours of sale, independent of other factors, on alcohol-related harms.

The findings in this review support the potential value of allowing local communities to maintain restrictions on hours of sale. If further research supports the effectiveness of local restrictions on hours of sale, it would also argue for eliminating state pre-emption laws that prohibit local governments from enacting alcohol control policies more restrictive than those that exist statewide.

We acknowledge the support and contributions of Steven Wing of the Substance Abuse and Mental Health Services Administration (SAMHSA) in discussions of this and other reviews.

Alcohol and HIV Disease Progression: Weighing the Evidence

Judith A. Hahn · Jeffrey H. Samet

Published online: 3 September 2010

Abstract Heavy alcohol use is commonplace among HIV-infected individuals; however, the extent that alcohol use adversely impacts HIV disease progression has not been fully elucidated. Fairly strong evidence suggests that heavy alcohol consumption results in behavioral and biological processes that likely increase HIV disease progression, and experimental evidence of the biological effect of heavy alcohol on simian immunodeficiency virus in macaques is quite suggestive. However, several observational studies of the effect of heavy alcohol consumption on HIV progression conducted in the 1990s found no association of heavy alcohol consumption with time to AIDS diagnosis, while some more recent studies showed associations of heavy alcohol consumption with declines of CD4 cell counts and nonsuppression of HIV viral load. We discuss several plausible biological and behavioral mechanisms by which alcohol may cause HIV disease progression, evidence from prospective observational human studies, and suggest future research to further illuminate this important issue.

Introduction

Heavy alcohol use is commonplace among HIV-infected individuals and its impact upon behaviors and the course of disease has been examined over the past two decades [1–3]. However, the extent that alcohol use results in deleterious effects on the progression of HIV disease has not been fully elucidated. Although alcohol may directly affect HIV disease progression in multiple ways, obtaining data to document its overall impact and contributions associated with specific mechanisms is difficult. Alcohol consumption has direct effects on several aspects of the immune system; yet, experimental studies to assess more directly its impact on HIV disease have been limited to the related model of simian immunodeficiency virus (SIV) in primates. In humans, observational studies may be hampered by measurement error and confounding. Incomplete assessment of behavioral (eg, other substance use, medication adherence, nutritional deficiencies) and psychosocial (eg, depressive symptoms) factors associated with HIV disease progression impedes rigorous determination of alcohol's direct effects. In addition, traditional analytic methods may fail to account for the potential feedback loop between alcohol consumption and health status (ie, that alcohol consumption tends to decrease as health declines). In this article we review the empirical studies and the major mechanisms by which alcohol may affect HIV disease progression (Fig. 1) based on the literature available as of early 2010.

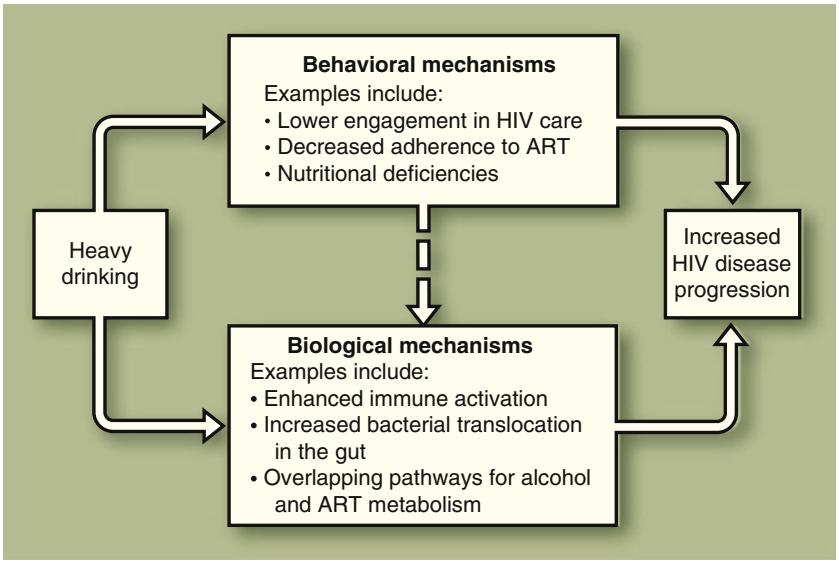

Fig. 1 Potential mechanisms of HIV disease progression. ART—antiretroviral therapy

HIV Disease Progression: Definitions

Progression of HIV infection in humans or SIV infection in the HIV primate model has been defined most typically in terms of viral load, CD4 cell count, AIDS-defining clinical end points (eg, opportunistic infections), and mortality. More recent evidence of the association of the level of immune activation with clinical outcomes is increasingly recognized; however, few data exist at present to consider this marker of HIV disease progression. In this literature review we sought published research that provided measurement of alcohol consumption as well as one of the following measures of HIV disease progression: HIV viral load, CD4 cell count, opportunistic infections, or death.

Alcohol Use: Definitions

Alcohol use can be defined by the amount consumed (eg, at-risk, heavy) or by the consequences of its use (eg, abuse, dependence). The consumption threshold for at-risk use as defined by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) is >4 drinks on an occasion or >14 drinks in a week for men, >3 and >7 respectively, for women [4]. This level of drinking has been used to define "heavy" drinking for those with HIV infection [5••], although its use was chosen based on NIAAA's use of the at-risk levels in the general population and was not specific for HIV-infected individuals. The category of "moderate" alcohol consumption is used for one whose alcohol use falls between abstinence (ie, no use of alcohol) and heavy use.

Another dimension to recognize when defining alcohol use is the variable nature of its use, in that for almost half of an HIV-infected cohort of persons with a history of alcohol problems, use was observed to increase or decline over a median period of 3.4 years [6]. Studies that only measure drinking at baseline fail to account for the dynamic nature of alcohol consumption, which may adversely affect study results and conclusions.

Biological Basis for Alcohol Affecting HIV Disease Progression

The Effects of Alcohol on the Immune System

Chronic alcohol consumption has been shown to be associated with increased susceptibility to infectious diseases (eg, tuberculosis and bacterial pneumonia), increased severity of diseases (eg, viral hepatitis), and increased risk of cancers (eg, hepatocellular carcinoma) [7]. These illnesses may also be accelerated by vitamin deficiencies, malnutrition, or other substance use. Chronic alcohol consumption can lead to liver disease and cirrhosis, which can impact immunocompetence. Recent animal and human studies have shown that alcohol consumption has deleterious effects on both the innate and the acquired immune responses. Impaired innate immune responses may cause susceptibility to infection, while impaired acquired immune responses such as impaired B lymphocyte function, altered cytokine balance, and chronic T-cell activation may accelerate disease progression, including that caused by HIV. In addition, alcohol may play a role in translocation of bacteria and bacterial products from the gut to cause HIV immune activation, resulting in increased HIV disease progression [8].

Alcohol and Nutrition

Micro-nutrient (ie, vitamin and mineral) deficiencies, including selenium and vitamins D, A, B-12, and E, zinc,

and iron, have been associated with more rapid HIV disease progression [9–11]. At the same time, antiretroviral therapy (ART) is thought to decrease some and restore other micronutrient levels [12, 13]. Overall nutritional status has been associated with HIV progression in several prospective studies [14–16], while there is also an effect of HIV infection on nutritional status [17]. Alcohol consumption is associated with nutritional deficiencies, due to a high percentage of caloric intake from alcohol, decreased absorption of nutrients, and interference with the metabolism of nutrients [18]. Therefore, it is plausible that nutritional deficiency is a mechanism by which alcohol might result in more rapid HIV disease progression. The link between alcohol use, decreased nutrition, and immune markers has been demonstrated experimentally in the SIV model [19]; however, it is not clear for HIV infection in humans.

Alcohol and ART Effectiveness

Some ART, including non-nucleoside reverse transcriptase inhibitors and protease inhibitors, is metabolized by the human cytochrome P450 system. There is evidence that alcohol may impact the metabolism of these medications by two different mechanisms, enzymatic induction [20], associated with chronic alcohol use, and enzymatic inhibition due to competition of ethanol for various cytochrome P450 isozymes, associated with acute ethanol use [21]. Because numerous drugs are metabolized by the P450 pathway, chronic alcohol users may be at higher risk for drug toxicities and ineffective therapy due to inadequate plasma drug concentration. Chronic alcohol consumption may also alter drug protein binding. We examine the evidence as to whether heavy alcohol consumption reduces the effectiveness of ART as measured by failure to achieve viral suppression, even with good adherence.

Behavioral/Psychosocial Basis for Alcohol Affecting HIV Disease Progression

Several behavioral and psychosocial factors that are associated with heavy alcohol consumption are also associated with HIV disease progression, and therefore should be considered when conducting multivariate modeling. We summarize these associations in the following sections.

Access to and Retention in HIV Care and Receipt of ART

Researchers in the United States and internationally have found that heavy drinkers are less likely than others to be receiving ART [22•, 23, 24••]. This may be a consequence of barriers to consistent medical treatment or due to physicians' impressions that heavy drinkers are unable to competently use ART. Indeed, heavy alcohol use was independently associated with lower retention in care among indigent patients [25]. Because early and consistent HIV care and receipt of opportunistic infection (OI) prophylaxis and ART are key factors in slowing the progression of HIV [26], these findings suggest one mechanism by which heavy alcohol consumption may accelerate HIV disease progression.

ART Adherence

Alcohol consumption has been consistently associated with poorer ART adherence. A recent meta-analysis found that those who used alcohol or drank relatively more were 50%–60% as likely to be classified as adherent compared with those who abstained or drank relatively less [27•]. Some studies have found a dose-response relationship between alcohol consumption and ART adherence [24••, 28], in addition to a temporal association between drinking episodes and missed doses [28]. As ART adherence is a known predictor of HIV outcome, this strongly suggests that decreased adherence is one mechanism by which alcohol may increase HIV disease progression. These findings elevate the importance of attempting to control for ART adherence in examining the biological impact of alcohol on HIV disease progression *apart* from its impact on adherence. However, adherence is challenging to accurately measure and therefore may pose problems even if included in statistical models. Alternatively and likely more effectively, studies of persons infected with HIV who are not yet on ART may reveal key insights about this important issue.

Alcohol and Comorbidities

Comorbidities may complicate the issue of alcohol's impact on HIV disease progression and make it difficult to determine the association. For example, depression, which can be exacerbated by the effects of alcohol [29], has been shown to reduce adherence to ART [30], and depression, stress, and trauma may have worsening effects on HIV progression [30, 31].

Illicit substance use is strongly associated with heavy alcohol consumption, especially in minority and inner-city populations. Several studies have shown associations between illicit substance use, especially crack cocaine, and HIV progression [32•, 33]. Substance use other than alcohol has also been associated with lower rates of receipt of ART [24••]. Hence, controlling for other non-alcohol substance use is important in seeking an understanding of the impact of alcohol consumption on HIV disease progression.

Evidence of a Causal Association between Alcohol Use and HIV Disease Progression

Experimental Studies

The direct impact of alcohol consumption on HIV disease progression has been studied using animal models. The strengths of these studies include the absence of ART adherence as a possible mediator of disease progression, and the capacity to control the quantity of alcohol consumed as well as behavioral factors (eg, nutrition), which are not easily accounted for in human studies. Evidence from studies in macaques suggests that heavy alcohol consumption has consequences for increased SIV progression. Experimental administration of the equivalent of heavy doses of alcohol as compared to sucrose to macaques infected with SIV was associated with early plasma CD4 cell loss in some studies [34, 35] but not others [36, 37], while several studies found greater SIV viral load at various times post-infection [19, 34, 36, 37]. Bagby et al. [36] found a significantly more rapid onset of end-stage disease in eight alcohol-administered macaques compared with eight controls. Higher viral load in alcohol-exposed macaques was associated with a higher percentage of SIV target cells (CD4) in the gut coupled with lower percentages of CD8 cells, creating a blunted mucosal immune response in early infection in one study [37]. The alcohol-exposed group consumed significantly fewer calories than the controls in another study [19]. Taken together, these findings suggest a biologically deleterious effect of heavy alcohol administration on disease progression in SIV-infected primates.

Human Observational Studies: Pre-Highly Active Antiretroviral Therapy (HAART)

A number of clinical studies assessed alcohol use in cross-sectional and prospective analyses. Associations between HIV outcomes such as CD4 cell counts and HIV viral load in cross-sectional studies may reflect differences in the time of study entry by alcohol consumption category, therefore we will focus in this review on prospective studies. Several prospective studies were published using data collected in the pre-HAART era, as described below.

An analysis conducted in the Multicenter AIDS Cohort Study (MACS) included 1706 HIV-infected men, and examined alcohol consumption by average number of drinks per day, ranging from zero to greater than two, the latter meeting the threshold for "heavy" drinking in men. There was no association between drinks per day both at enrollment and prospectively and the development of AIDS [38]. A later analysis of the MACS determined that decreasing alcohol consumption (ie, having a significantly negative slope in the average number of drinks per week in the prior 6 months) was associated with developing AIDS-related conditions, suggesting a decrease in alcohol consumption as HIV progressed [39]. Studies conducted in men in the Netherlands [40] and Norway [41] found no association between the number of drinks per day in the prior 6 months or daily drinking, respectively, with the development of AIDS. A study of vitamin deficiencies (n= 312) reported that in a multivariate model that included age, HIV-related symptoms, baseline CD4 cell count, and several vitamin concentrations, frequent alcohol consumption (>2 times/week) at study baseline was associated with increased time to CD4 cell count declines to 200 cells/mm^3 and time to AIDS [42]. A study of 403 persons seroconverting during the Tricontinental Seroconverter Study found that any alcohol use during the first three quarters of the follow-up period, limited to avoid the feedback loop between symptoms and alcohol consumption, was not associated with time to AIDS or death [43]. The selection of "any alcohol use" as a main independent variable, as in the latter study, is a coarse measure to assess alcohol's impact on HIV disease progression. All of the preceding studies were conducted among men who had sex with men.

Two early studies were conducted among injecting drug users. One study among 496 HIV-infected methadone maintenance patients found no association between daily alcohol consumption in the prior month and time to AIDS or death in a time-dependent multivariate model that included age, sex, CD4 cell count, zidovudine use, having two or more symptoms, and crack cocaine use, while crack cocaine use was independently associated with progression to AIDS [44]. A study conducted among 188 injection drug users found that very heavy alcohol consumption (>21 drinks per week) at baseline was associated with increased %CD8 cells 2–5 years after seroconversion; no impact on CD4 cell count or %CD4 was found [45].

The only study of the issue from a developing country was a cohort study of 105 HIV clinic patients who were not on ART, conducted in Zimbabwe. This study showed no association between any alcohol consumption at baseline and successive CD4 cell count and HIV viral loads over a period of 6 months; however, follow-up was quite limited and changes in these outcomes were not examined [46].

In summary, in the pre-HAART era, no association of alcohol use with more rapid HIV disease progression was identified; however, some studies' measurement of alcohol consumption was limited in detail or only measured at baseline, and the studies largely examined men.

Human Observational Studies: Post-HAART Studies

Studies conducted after the introduction of HAART differed from the earlier studies in that most used CD4 cell

count and/or HIV viral load as the study outcomes, an understandable strategy given the reduction in OI and death in the HAART era. Notably, these studies either stratified by or controlled for ART use, and the measurement of alcohol use was more detailed than in the previous studies.

Chander et al. [24••] reported observations among 1711 persons enrolled in an urban HIV clinic cohort from 1998–2003. They found that heavy alcohol use in the prior 6 months alone and combined with injection drug use was associated with decreased viral load suppression after adjusting for age, race, nadir CD4 cell count, and years on ART. Controlling for self-reported adherence in these analyses attenuated the effect of heavy drinking, providing evidence for the causal chain between alcohol and HIV outcomes via ART adherence. Because the attenuation of the effect from a 24% to a 14% reduction in odds of viral suppression was accompanied by somewhat wider confidence intervals and due to the imprecise nature of ART adherence measurement, these data are inconclusive as to whether there is an effect of alcohol on viral suppression beyond that attributed to poorer adherence.

An analysis of participants in two cohorts of a total of 595 HIV-infected persons with a history of alcohol problems examined CD4 cell counts and HIV viral loads at 6-month intervals for up to 7 years [5••]. Upon regression analysis, among subjects not on ART, heavy alcohol consumption was associated with a lower CD4 cell count, on average a difference of 49 cells/mm^3. There was no association between heavy alcohol consumption and CD4 cell count among those on ART, in analyses that adjusted for baseline CD4, adherence to ART, homelessness, depressive symptoms, and several other variables. Heavy alcohol use was not associated with HIV viral load in those on ART and those not on ART. All analyses among those on ART adjusted for 3-day self-reported adherence, suggesting that there is no detectable alcohol effect beyond the effect on adherence among those on ART. However, the CD4 cell count difference suggests that there might be an effect of heavy alcohol consumption on HIV progression among those not on ART.

A recent publication by Baum et al. [47••] examined the association between alcohol consumption and HIV outcomes in a cohort of active alcohol or illicit drug users. In this study, frequent alcohol consumption (defined as $\geq$ 2 drinks/day on average) compared to moderate alcohol use and abstention was associated with a decline of CD4 cell count to less than 200 cells/mm^3, among those who had a baseline CD4 cell count of greater than 200 cells/mm^3. The model in this study controlled for baseline CD4 cell count, HIV viral load, ART status, years since tested HIV positive, age, and gender. A similar model that examined the same factors but was restricted to those not on ART showed a stronger association. The effect size was also larger when the predictor variable was the combination of frequent alcohol use and crack cocaine use; however, the independent effects of alcohol and crack cocaine use were not shown. In addition, frequent alcohol consumption was associated with increased HIV viral load in a multivariate model controlling for the same variables as above except viral load. However, when stratifying by ART the association was significant only among those on ART, and the authors suggested that the association was mediated by adherence. These analyses are in contrast to a recent analysis of the same cohort, which found that crack cocaine use but not alcohol use, coded only as current yes versus no, was associated with HIV progression [33]. This illustrates the importance of using a more detailed alcohol consumption history to ascertain the relationship of alcohol use and HIV disease progression.

Two studies in women in the post-HAART era failed to find an association between alcohol consumption and HIV outcomes. A recent study of 516 women in the HIV Epidemiologic Research Study (HERS) cohort examined the effects of alcohol consumption (ie, none, moderate, and heavy) on both depressive symptoms and CD4 cell count [48••]. The analysis showed significant associations between both moderate and heavy alcohol consumption and depressive symptoms and between depressive symptoms and CD4 cell count. The direct association between alcohol consumption and CD4 cell count was not statistically significant. The indirect effects of alcohol consumption on CD4 cell count via depression were not reported; therefore, we cannot comment on effect of alcohol on CD4 cell count via the effect on depression. In addition, a large study of 1686 HIV-positive women in the Women's Interagency HIV Study (WIHS) found that there was no positive association between heavy alcohol consumption and time to newly acquired AIDS-defining illnesses or AIDS-related death, in repeated measures models that adjusted for crack use, ART use and adherence, CD4 cell count at baseline, HIV viral load at baseline, year of HIV diagnosis, and demographic variables [32•]. This study found a strong association of persistent crack use and AIDS-related mortality and both persistent and intermittent crack use and newly acquired AIDS illnesses. This result is consistent with other studies that included crack use in multivariate models [33, 34].

Lastly, a study conducted multivariate modeling of the effect of drink types on HIV viral load suppression, CD4 cell count, and thymus volume in 165 patients after 24 weeks of ART [49••]. In models that controlled for demographics, baseline Centers for Disease Control and Prevention HIV stage, and adherence, heavy alcohol consumption was not associated with the outcomes while consuming predominantly liquor compared to beer or wine was associated with lack of HIV viral suppression,

decreased thymus size, and change in CD4 cell count. This study highlights a potential future area of interest, that is, impact of alcohol beverage type.

In summary, we identified six studies in the post-HAART era, and three demonstrated an association between heavy alcohol use and at least one measure of HIV disease progression [5••, 24••, 47••].

Discussion

Overall, we found that there is strong biological plausibility that heavy alcohol consumption might hasten HIV disease progression. We touched on several biological mechanisms by which this might occur, including direct immunological effects of alcohol, interactions and competitions with drugs, nutritional intake, and metabolic deficiencies. In addition, we reviewed behavioral factors by which alcohol consumption could affect HIV progression, such as reduced/poor retention in HIV care, adherence, nutrition, and mental health. Given this strong evidence, one would expect that simple bivariate analyses would show strong associations between heavy alcohol consumption and HIV outcomes, and these associations would be attenuated when causal pathway variables are included in the model. However, this is not the case in most of the analyses reviewed above. Instead, pre-HAART studies showed no associations between heavy alcohol consumption and HIV outcomes, while some but not all of the later studies did find such an association. There are several possible explanations for these findings.

First, several of the early studies measured alcohol consumption at baseline, yet alcohol consumption changes over the course of HIV infection [6]. Such a misclassification of the exposure could cause an association to be obscured. However, for the studies that included time-dependent measures of heavy alcohol consumption, the feedback loop between declining health and subsequent declining alcohol consumption might have counteracted any deleterious effects of alcohol on disease progression. While some studies attempted to address that issue, by measuring changes in alcohol consumption or only measuring alcohol consumption in the first several years after diagnosis, current statistical methods such as marginal structural models may be more powerful in detecting associations [50]. This feedback loop may not have been an issue in the later studies, because ART is usually started before patients develop any outward signs of disease progression. Another issue is that some of the earlier studies focused on any or current alcohol consumption, rather than heavy alcohol consumption, which may explain the lack of associations in these studies if heavy alcohol consumption is needed to accelerate HIV disease progression.

Another possible issue is that the risk profile of the populations studied changed over time, with a shift from predominantly men who had sex with men, to inner-city clinic patients and poly-substance users. The latter groups of patients may have engaged in heavier levels of alcohol consumption or other illicit drug use which was associated with HIV disease progression.

Another possible explanation for the lack of association in the early studies is that the outcome measures shifted over time from AIDS-defining illnesses to biological markers of immunological decline (CD4) or viral replication. If alcohol has a direct effect on immune function, then it is more likely that there will be a significant association when CD4 cell count is used as the outcome variable.

Lastly, it is important to consider the possibility that publication bias became a more pervasive issue as the AIDS epidemic wore on. It seems quite conceivable that researchers evaluated associations between alcohol consumption and HIV disease outcomes in their cohorts, but did not pursue these analyses to the stage of publication if the findings were not statistically significant. Because this question is still unresolved, we suggest an analysis of existing cohort study datasets, taking into account the measurement and analysis issues raised above.

Given the ubiquitous nature of alcohol use among the people of the world who are infected with HIV, quantifying the impact of alcohol consumption on HIV disease progression has major implications on the AIDS epidemic if even only a modest effect is found. Hence, in addition to taking optimal advantage of existing data to further illuminate the relationship of HIV disease and alcohol use, identifying a cohort in which ART has not been initiated and in which alcohol is heavily consumed and can be measured would provide very valuable empirical data. Such a cohort could provide key insights into this issue, particularly if the data are collected in a manner that learns from past studies' limitations.

Conclusions

The link between alcohol use and HIV disease progression is clearly complicated to disentangle, and the more recent empirical evidence is suggestive but not strong. Although alcohol-related behavior appears to impact HIV disease progression through ART adherence, biological mechanisms are also likely to be implicated. Future studies should continue to investigate this important topic in order to provide clearer evidence, ultimately with the goals of utilizing the most valid measurement and statistical techniques and furthering our understanding by carefully controlling for confounding and meanwhile examining mechanisms of action. These studies are crucial so that

the true impact and cost-effectiveness of interventions designed to slow or prevent alcohol-associated HIV disease progression can be determined.

OBJECTIVES: To compare longitudinal patterns of health care utilization and quality of care for other health conditions between breast cancer-surviving older women and a matched cohort without breast cancer.

DESIGN: Prospective five-year longitudinal comparison of cases and matched controls.

SUBJECTS: Newly identified breast cancer patients recruited during 1997–1999 from four geographic regions (Los Angeles, CA; Minnesota; North Carolina; and Rhode Island; N=422) were matched by age, race, baseline comorbidity and zip code location with up to four non-breast-cancer controls (N=1,656).

OUTCOMES: Survival; numbers of hospitalized days and physician visits; total inpatient and outpatient Medicare payments; guideline monitoring for patients with cardiovascular disease and diabetes, and bone density testing and colorectal cancer screening.

RESULTS: Five-year survival was similar for cases and controls (80% and 82%, respectively; p=0.18). In the first follow-up year, comorbidity burden and health care utilization were higher for cases (p<0.01), with most differences diminishing over time. However, the number of physician visits was higher for cases (p<0.01) in every year, driven partly by more cancer and surgical specialist visits. Cases and controls adhered similarly to recommended bone density testing, and monitoring of cardiovascular disease and diabetes; adherence to recommended colorectal cancer screening was better among cases.

CONCLUSION: Breast cancer survivors' health care utilization and disease burden return to pre-diagnosis levels after one year, yet their greater use of outpatient care persists at least five years. Quality of care for other chronic health problems is similar for cases and controls.

Demographics and therapeutic progress in the United States are increasing the number of older cancer survivors. About 182,500 women were diagnosed with breast cancer in 2008, almost half occurring in women aged 65 or older. At five years, 89% remain alive;[1] of over 2.6 million breast cancer survivors in the United States, more than half are ≥65 years old.[2] Both the prevalence and absolute numbers of breast cancer survivors will grow, because aging is the most important risk factor for breast cancer;[3] gains in life expectancy and advances in detection and treatment will place more women at risk for breast cancer, and breast cancer survivorship.

Comorbidities also increase with age, for those with cancer and others.[4–7] Across most cancer types, older cancer patients report significantly more comorbidity and poorer physical health than non-cancer patients of the same age.[6–8] Since hypertension, heart conditions, arthritis, and diabetes are common in older breast cancer survivors,[7] the Institute of Medicine has emphasized quality follow-up care for this cohort.[9,10]

Although follow-up care is essential in cancer survivorship,[11–15] studies comparing the quality of care for cancer survivors to those without cancer are conflicting. A longitudinal study of patients with diabetes showed similar quality of diabetes care for patients with and without cancer.[16] Other studies have found that older cancer survivors receive similar, or less follow-up care than controls, or that the type of primary and cancer-related care varies by provider type.[9,11–14] Finally,

a SEER-Medicare study of older breast cancer survivors found them receiving more preventative services than non-cancer patients.[17] The inconsistent results may be due to different study populations (e.g. source, age, and type of cancer) and/or the kinds of follow-up care examined.

To answer whether overall healthcare utilization and quality of follow-up care for other conditions differs for older women with and without breast cancer, we conducted a multi-site study of women ≥65-years of age with breast cancer and age-, morbidity-, and geography-matched controls. We compared differences in survival and quality of follow-up care over five years.

METHODS

Study Design

In this prospective, longitudinal study, we compared survival, comorbidity, healthcare utilization, and quality of care between breast cancer patients and a matched control cohort using Medicare data from the Centers for Medicare and Medicaid Services (CMS). We examined annual comorbidity and healthcare utilization for five years following the date of breast cancer diagnosis. Quality of care was defined as guideline-consistent colorectal cancer screening, bone density testing, and monitoring of cardiovascular disease and diabetes.

Study Participants

Recruitment procedures for the breast cancer cohort are detailed elsewhere.[18] Briefly, we identified newly diagnosed breast cancer patients by reviewing pathology reports at hospitals or tumor registries in four geographic regions (Los Angeles, California; Minnesota; North Carolina; and Rhode Island). Each setting received Institutional Review Board (IRB) approval. Eligibility required: stage II–IIIA disease or stage I disease with a tumor diameter ≥1 cm; age at diagnosis ≥65 years; no prior history of primary breast cancer; no simultaneously diagnosed or treated second primary tumor at another site; English speaking; and, competent for interview.

Eligible participants were mailed an enrollment package and called by a research staff member. Between 1997 and 1999, 921 women agreed to participate by returning an IRB-approved signed consent form, and were enrolled. Tumor information was collected by medical record review, with date of definitive biopsy treated as the enrollment date for each case. Based on additional information, 56 respondents did not meet inclusion criteria, leaving 865 eligible cases.

Because fee-for-service CMS records were the only source of utilization information for both cases and controls, some otherwise eligible cases could not be included in this comparison study. Such records were only available for Medicare enrollees with both inpatient (Part A) and outpatient (Part B) entitlement and fee-for-service (FFS) coverage. We excluded 301 cases without such coverage for the entire period beginning one year before study enrollment and for five years following. Additional case exclusions were due to problematic Medicare identifiers (n=136); no matched controls (n=5); and no confirmation of breast cancer diagnosis in the administrative data (n=1).

For the remaining 422 cases, we selected controls in two stages. First, using the full (100%) Medicare data, we identified all potential controls (n=21,241) that exactly matched at least one case by age, race (White, Black or Other) and 5-digit zip code location. For 5.8% of cases we did not find exact matches and therefore relaxed the matching criteria for age (±/−2-years) and zip code (within 20-mile radius). We excluded women with a history of breast cancer.

From among the 21,241 potential controls for the 422 cases, we sought four controls for each case—specifically the four non-cases who best matched the comorbidity burden of the case in the year prior to her cancer diagnosis. Selected controls were assigned the same "enrollment date" as its matched case.

"Comorbidity burden" was measured by a prospective diagnostic cost group (DCG) score, calculated from age, sex and all ICD-9-CM diagnosis codes recorded—excluding breast cancer diagnosis codes—for inpatient and outpatient encounters during the year preceding "enrollment."[19] The diagnostic cost group (DCG) risk adjustment system is a validated risk adjustment system.[20,21] Originally developed for setting prospective Medicare payments, DCG models are now used to risk adjust various outcomes in a range of populations. The DCG score used here indicates the expected future cost of utilization, normalized to average 1.0 in the Medicare over-age-65 population. All but 13 of the 422 cases had at least five potential controls, from which the four potential controls with comorbidity burden (DCG score) nearest to that of the matched case were selected. Of the rest, one had four potential controls; two had three; and ten had one. These were all included in the final study population of 422 cases and 1,656 controls.

Data Sources and Variables

For the study population, we obtained Medicare eligibility files for 1996 to 2004 and Medicare claims files (MEDPAR, carrier and outpatient) for 1996 to 2003.

We defined outcome measures using the day after the study enrollment date (which differs by case), as the beginning of follow-up. We identified dates of death through 12/31/2004 from CMS denominator files. We measured comorbidity burden using the DCG score, as above, for each of five 365-day periods subsequent to the study enrollment date. To measure total *non-breast cancer* illness burden, we dropped breast cancer codes (ICD-9-CM 174.0-174.9, 198.81) before calculating the score. In each year, utilization was measured as follows: overall utilization as total Medicare payments; inpatient, as both 1) number of hospital days and 2) Medicare payments charged for inpatient care: outpatient, as payments for outpatient care (including physician visits, imaging, laboratory tests and procedures). We also examined payments by type of care,[22] and a narrow outpatient measure: number of physician visits. Using provider specialty codes we categorized visits by specialty—cancer, cardiopulmonary, mental health, surgery, generalist and other. Since outliers among individual expenditures would unduly influence overall statistics, annual inpatient payment measures above $50,000 were reset to $50,000; similarly, outpatient payment measures were top-coded at $25,000. This "top-coding" affected at most eight observations for any measure.

Quality of care was measured by adherence to a) guideline-consistent colorectal cancer screening[23] and b) bone density testing for all subjects[24], and c) recommended monitoring for those with cardiovascular disease (CVD) or with diabetes (DM),

identified from ICD-9-CM diagnosis codes prior to the enrollment date.

Analyses

We used baseline interview data to compare breast cancer patients included in this study (N=422) with the cases (N=443) that could not be included. The groups were similar with respect to age, race/ethnicity, and a range of comorbidity, tumor and treatment characteristics.

Our key comparisons were of the 422 cases and 1,656 controls, using t-tests, chi-square tests, and log-rank tests (for survival data) as appropriate. We used Kaplan-Meier survival analyses, with log-rank tests for differences by group, and proportional hazards regression models to examine group differences while controlling for differences in baseline comorbidity, age, race and geography between cases and controls.

For annual utilization measures, we report t-test comparisons between cohorts. Analogous adjusted comparisons were tested using linear multivariate regression. Given that the cohorts were fairly well matched on important predictors, regression-based findings were very like those based on t-tests. Thus, we only report the latter. Quality of care measures were compared using chi-square tests.

RESULTS

Table 1 characterizes the demographics and baseline comorbidity burden of the cases and the matched controls. In both groups, over half were aged 65 to 74; about 4% were black; over 70% of both cohorts had less comorbidity at baseline than the Medicare average (1.0), mainly due to younger ages. While not statistically significant, more cases (6.9%) than controls (5.0%) were in the highest comorbidity burden category (DCG >3.0).

Most subjects (74% of cases and 76% of controls) were alive as of 12/31/2004, the study end date (p=0.16). Five-year survival was 80% and 82% for cases and controls, respectively (p=0.18). Annual mortality (Fig. 1) was also similar by either log-rank test or Cox proportional hazards regression (both $p \geq 0.15$).

Table 1. Characteristics of the Study Population

	Cases (n=422)	Controls (n=1,656)
Age at study inception[a] (%)		
65–74	54.5	54.3
75–84	37.2	37.4
85+	8.3	8.3
% Black	4.3	4.4
Baseline comorbidity burden score[b] (DCG score) %		
<1.0	73.7	75.7
1.0 to 2.0	19.4	19.3
>3.0	6.9	5.0
Year of study inception[a]		
1997	19.7	20.0
1998	54.5	54.2
1999	25.8	25.8

Similarity between the two cohorts was not rejected for any of the characteristics (at 5% significance level)

[b]*Based on the 1-year prior to study inception*

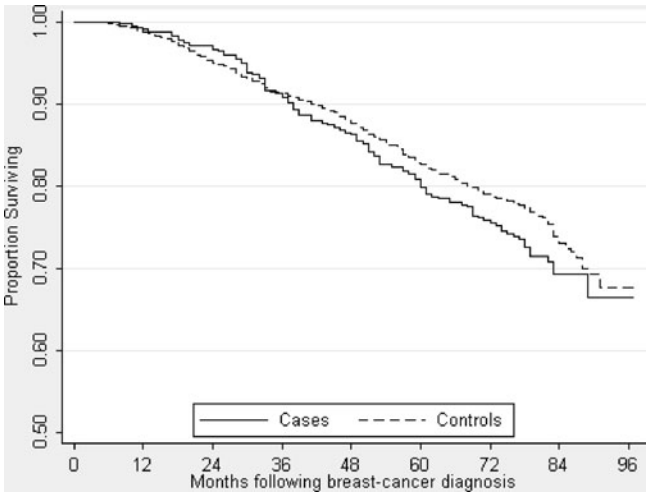

Figure 1. Survivorship of breast cancer cases and controls.

Table 2 compares healthcare utilization and comorbidity burden annually for five years following enrollment. During the first year following breast cancer diagnosis, Medicare payments for cases ($11,193) were significantly higher than for controls ($3,159; p<0.01). The magnitude of this difference decreased in subsequent years, yet Medicare payments remained significantly higher for cases in three of the four years. Non-breast cancer morbidity was higher for cases than controls in all years.

Table 3 characterizes utilization differences separately for inpatient and outpatient care. In the year following breast cancer diagnosis, average Medicare payments for cases were $3,935 for inpatient care and $7,259 for outpatient care. Both were notably higher than for controls ($1,710 and $1,450, respectively, p<0.01). This difference is reflected in the quantity measures: first-year hospital days averaged 3.9 for cases and 1.7 for controls (p<0.01), and average number of outpatient physician visits for cases (16.6) was twice that for controls (8.1; p<0.01). However, trends differed markedly for outpatient and inpatient care. The number of outpatient physician visits remained significantly higher for cases in each of the four subsequent years, although the year-five difference was smallest (cases=11.0; controls=8.8, p<0.01). In all five years, there were similar visit numbers for generalists and most specialists, but higher visit numbers for cancer and surgery specialists. In terms of Medicare payments, this difference was significant (in all but the fifth year). For outpatient payments by type of care—physician visits, imaging, laboratory tests and procedures—differences were uniform across all types. In contrast, differences in inpatient care, measured either as Medicare payments or hospital days, were not significantly different in three of the four years.

We also examined quality of care for all patients and for those with CVD or DM at study entry, which were similarly prevalent among cases and controls (Table 4). Among those with CVD, missing at least one biennial lipid test prior to the end of 2003 (for survivors) or the date of death (for non-survivors), was more likely than not for both cases and controls. Diabetes was also similarly prevalent (19% vs. 17%, for cases and controls, respectively), as were lipid and AIC testing, and eye examinations. Among all cases and controls,

Table 2. Total Medicare Payments and Comorbidity Burden Following Breast Cancer Diagnosis

Period after diagnosis	Total Medicare payments ('000 $)			Comorbidity burden (DCG) score		
	Mean (Std Dev)		P-value	Mean (Std Dev)		P-value
	Cases	Controls		Cases	Controls	
1st Year	11.2 (8.3)	3.2 (7.2)	<0.01	0.90 (0.84)	0.80 (0.68)	0.01
2nd Year	3.9 (7.0)	3.3 (7.1)	0.10	1.04 (1.01)	0.96 (0.87)	0.12
3rd Year	5.1 (8.2)	3.5 (7.0)	<0.01	1.11 (1.00)	0.98 (0.87)	0.01
4th Year	5.4 (9.1)	4.0 (7.7)	<0.01	1.15 (1.03)	1.06 (1.01)	0.12
5th Year	3.6 (5.6)	3.6 (7.9)	0.96	0.95 (0.76)	0.95 (0.82)	0.90

a Comorbidity burden, excluding breast cancer, is measured by diagnosis-based DCG score. Score=1 denotes mean Medicare enrollee burden
b P-value is from a t-test for equal means in same-year measure between cases and controls

bone density testing was also equally prevalent; however, non-adherence to colorectal cancer screening among cases (33%) was lower than that for controls (47%; p-value < 0.001).

DISCUSSION

This prospective study contrasted health outcomes and healthcare utilization for a cohort of breast cancer patients over five years following their cancer diagnosis with those of controls matched by age, geographic location and total comorbidity burden. Non-breast cancer comorbidity at baseline and five-year survival were similar in the two cohorts at baseline. Although similar in all other years, non-breast cancer comorbidity was significantly higher for cases in the first year following breast cancer diagnosis. Among survivors in each cohort, hospital utilization exhibited the same pattern, with more days of hospitalization and Medicare payments in the first follow-up year, but similar amounts subsequently. In contrast, both numbers of physician visits and total Medicare payments for outpatient services (as measured by Medicare payments) were notably higher for cases—by over 25%—during most of the five follow-up years. Quality of care, as measured by guideline-adherent monitoring for those with baseline CVD and DM, and bone density testing for all patients, was also similar in the groups. However, colorectal cancer screening guideline adherence was better for cases.

Our estimates of utilization following breast cancer diagnosis are like those of Yabroff et al. in which Medicare payments in the first year following breast cancer diagnosis were $11,728 (1999–2003), and higher than for a cohort matched by age and geographic location, but not comorbidity.[25] While the corresponding estimate from our study was $8,034, these figures are not directly comparable due to differences in control selection, study time-period, and geography. However, we estimated inpatient costs for our cases to be 27% of total Medicare payments for the cases, which is similar to the Yabroff et al. estimate of 25%. Note that Medicare payments serve as a good proxy for inpatient and outpatient health care services as Medicare is the primary payer, accounting for over 86% of such expenditures for the elderly.[26]

Some studies have found greater comorbidity among cancer patients than among age-similar non-cancer patients.[5–7] Therefore, when breast cancer patients are compared with non-cancer patients matched only on age and location,[25,27,28] the cancer patients could have higher healthcare utilization for this reason alone. In this study we matched by baseline comorbidity in addition to age, race and geography; this enabled us to ask if the breast cancer diagnosis and treatment itself have longer term effects on healthcare utilization? While inpatient care utilization was similar between the two cohorts, numbers of physician visits and Medicare payments for outpatient care were consistently greater among breast cancer survivors—by over 100% in the first year and at least 25% in all four subsequent years. Breast cancer survivors visited

Table 3. Inpatient and Outpatient Healthcare Use Following Breast Cancer Diagnosis

Period after diagnosis	Mean (Std Dev)		P-value	Mean (Std Dev)		P-value

Data on care received following breast cancer diagnosis till Dec 31, 2003
a The follow-up period extends from the day after enrollment to 12/31/2003 or the date of death if the latter is earlier. Using the U.S. Preventive Services Taskforce guideline for colorectal cancer screening, we defined compliance for this study cohort as one of the following during the follow-up period (for subjects in 65–75 year age group): i) annual screening with high-sensitivity fecal occult blood testing, ii) one sigmoidoscopy examination and one fecal occult blood test, and iii) one colonoscopy examination[23,39]

cancer specialists more often, but numbers of visits to mental health specialists and generalists were similar. Some of this difference may be due to a "volunteer effect", in which those who agree to enroll in a study are more likely to engage in systematic care-seeking than the controls who were selected by retrospective matching; the control group contains both women who would have and those who would not have accepted study enrollment had it been offered.[29,30]

Greater outpatient care among breast cancer survivors could also reflect long-term and late complications of cancer treatment,[13,31] since comorbid conditions and their treatment may interact with cancer and its treatment, leading to worse physical health and higher mortality risk.[6,32,33] However, survival for at least five years following diagnosis was quite similar for cases and controls, as was measured comorbidity levels in most years. Hence, more physician visits and outpatient care among breast cancer survivors does not appear to be due to their being sicker. More likely is that increased outpatient care is associated with breast cancer follow-up care. Indeed, the Institute of Medicine report *From Cancer Patient to Cancer Survivor: Lost in Transition* focuses on the complex follow-up needs of cancer survivors, including preventive care, monitoring for treatment side effects (e.g., adjuvant hormonal therapy) and recurrence surveillance.[9]

That is, breast cancer patients, after being drawn into the caregiving network, are likely to remain engaged. Several studies have examined whether breast cancer modifies care-seeking for comorbid conditions among older adults.[11,16,17,34–36] We examined colorectal cancer screening and bone density testing for all patients, and monitoring for two important chronic condition subgroups—those with CVD and DM. We found no differences between cases and controls, except in the case of colorectal cancer screening. Similar or better quality of care among breast cancer survivors is consistent with our finding that they had more physician visits compared to the controls. Differing study design makes comparisons with previous reports difficult. Snyder et al. found that in each of the five years of follow-up, breast cancer survivors had less colorectal cancer screening, bone density and lipid testing than matched controls.[36] However, their controls were chosen from women who had had a mammogram during the baseline year, making it likely that their overall quality of care was also above average. In contrast, Earle et al. found that breast cancer survivors with diabetes had higher rates of lipid testing than matched controls.[17] Since comorbidity was not a matching criterion, this could have been due to differences in comorbid disease burden. Ultimately it has not been clear whether breast cancer survivors receive either more or less chronic disease care than similarly-ill women with the same morbidity burden. Keating et al., which also matched controls by comorbidity, found any-cancer survivors with diabetes receiving diabetes screening "of generally similar quality" as non-cancer diabetics.[16] This is consistent with our findings.

Previous studies have examined breast cancer survivors retrospectively;[17,37] in contrast, we have been able to examine survival prospectively. The estimated five-year survival for this breast cancer cohort (79.6%), is lower than that for National Cancer Institute's Surveillance Epidemiology and End Results (SEER) regions (89.6%; 1996–2003).[38] This could partly be due to the difference in populations represented—our subjects were from four selected geographic areas, while SEER data is obtained from areas containing over 26% of the national population. Further, because we were also interested in studying utilization, we examined only fee-for-service Medicare beneficiaries.

This study has several limitations. The study population was clustered in four geographic areas and may not generalize nationally. The breast cancer cohort had volunteered for a study; they may be healthier, or more prone to positive health behaviors, than other survivors, or a matched cohort selected from the general population.[29,30] Also, we used only Medicare administrative data, with limited clinical detail on comorbidity severity and no pharmacy data; since patient comorbidity was identified from diagnoses coded on claim forms, breast cancer survivors' greater interaction with health care providers may partly explain their higher measured comorbidity. Both cases and controls participated in Medicare FFS; in this sense they were similar, but not fully representative of Medicare enrollees, upwards of 20% of whom are enrolled in managed care plans. Also, since studying survivorship requires waiting for the data to mature, our subjects' care does not reflect recent advances in breast cancer management, such as sentinel lymph node biopsy and the use of aromatase inhibitors. We also recognize that the sub-cohorts examined for quality of care, involving those with baseline CVD and diabetes, were small. The study cohort has few minorities (4.3% black), a result of a) the population distribution of the study regions and b) older black women being at lower risk of developing breast cancer, but at higher risk of presenting with late stage disease (and therefore excluded from our study). Finally, due to lack of completeness of provider specialty field, the provider type of a sizable proportion of physician visits (about 25%) could not be determined.

In summary, this study clarifies the mixed picture related to longitudinal health care for older breast cancer survivors. We found that, beyond the first year after breast cancer diagnosis, older survivors have patterns of disease burden, inpatient care and quality of care for other health problems quite similar to

those of women without breast cancer. There was one exception—they had notably more physician visits, especially for cancer and surgical specialists, than non-breast-cancer patients in each of five years of follow-up. Reasons for this should be pursued using more detailed clinical data. For example, were the excess visits for cancer surveillance, and, if so, did they follow accepted guidelines?

Abstract For many surgical procedures, apparent volume–outcome relationships may reflect differences in patient risk-profiles as well as quality of care. As some important patient profile differences may be unobserved, we use fixed effects (FE) regression to estimate the relationship between operative mortality and surgeon and hospital volumes, and compare this method with the more commonly used random effects (RE) regression approach. The 1998 and 1999 Medicare Inpatient and Denominator files for Medicare Fee for Service enrollees aged 65–99. Operative mortality rates are estimated for different surgeon and hospital volume tertiles (high, medium, low) using FE and RE regression methods, adjusted for patient demographics and morbidities. The data were collected by the Centers for Medicare and Medicaid Services (CMS). FE regression estimates that lowest volume tertile hospitals have 1.4 and lowest volume tertile surgeons have 1.6 additional

operative deaths (for every 100 CABG surgeries) compared to their highest volume tertile counterparts. The corresponding RE estimates are 0.5 and 1.4 respectively. The substantially higher FE hospital volume effect compared to RE indicates the presence of unobserved "protective" characteristics in lower volume providers, including a less complicated patient profile. Lower hospital and surgeon volumes are associated with substantially higher excess operative mortality from CABG surgeries than previously estimated.

Keywords Hospital volume · Surgeon volume · Fixed effects · Random effects

1 Introduction

An overwhelmingly large proportion of studies to date indicate that hospitals and surgeons who perform more surgeries have lower operative mortality (Halm et al. 2002; Shahian and Normand 2003). To what extent then can we infer that higher volume providers offer better quality care? At the provider level, lower operative mortality can result from better quality of care or from having more patients with fewer medical complications. Such variation of patients across providers can result from selective physician referral, patient choice or strategic selection by providers ("cherry picking"). An analyst using administrative or clinical data can identify and control for some of these patient profile differences using available clinical and demographic information. But there may still be other patient characteristics, largely unobserved by the analyst, that potentially influence operative mortality. We use an econometric method—"fixed effects" (FE) regression—that takes advantage of the dual clustering of patients among surgeons and hospitals, to estimate the association between provider volume and operative mortality in a way that adjusts even for unobserved provider-level differences in patient characteristics. Results are then compared with those from random effects (RE) regressions, the most commonly used approach in the literature.[1] Also referred to as 'hierarchical' models, they are commonly used in risk adjustment for evaluating health outcomes (Christiansen and Morris 1997; Krumholz et al. 2006; Normand et al. 1997; O'Brien et al. 2008; Shahian et al. 2005).

While the present study is limited to CABG surgeries, the significance of this methodological issue should be viewed in the context of the far-reaching impact of this voluminous literature, dating back over three decades (Luft et al. 1979). As indicated by recent surveys, interest in the volume–mortality relationship spans a wide range of surgeries (predominantly high risk cardiovascular surgeries and cancer resections) as well as non-surgical care (such as inpatient treatment for pneumonia or HIV positive patients)(Halm et al. 2000; Post et al. 2010; Shahian and Normand 2003). The findings from this literature

[1] As the term "fixed effects" used in the econometrics literature is quite different from that in the applied statistics/biostatistics literature, a clarification is in order. In regressions involving multilevel or hierarchical data, fixed effects regression is an approach in the econometrics literature wherein only intra-level variation is used to obtain regression coefficient estimates. For instance, in the context of longitudinal person-level data, fixed effects regression estimates are obtained by comparing only the temporal changes in measures, not the levels between individuals. The strength of this approach is that each individual is treated as a control for himself/herself. Random effects estimates utilize both within- and between-individual variation. (Johnston and DiNardo 1997; Wooldridge 2002). Alternately, in the applied statistics literature, the terms "fixed effects" and "random effects" are used to specify the nature of the regression coefficients in a multilevel regression. If a coefficient is permitted to vary—say across individuals in a longitudinal data framework—then it could be specified as a random variable; however, if a coefficient is not permitted to vary then it is described as a "fixed effect" (Raudenbush and Bryk 2002). Such a distinction does not arise in this study as none of the regression coefficients are random.

have attracted the attention of a variety of interest groups—consumer advocacy groups, health insurance coalitions and state agencies seeking to reduce costs and improve quality by enforcing protocols of proven efficacy. Strategies include regionalizing selected surgeries, publishing provider report cards and recommending provider minimum volumes for specified surgeries (Birkmeyer 2000, 2004; Birkmeyer and Birkmeyer 2006; Fredenheim 2005; Hewitt 2000).

Along with the growth of the volume-mortality literature has come a better understanding of its vulnerabilities, especially given that virtually all such studies are based on observational data, usually administrative or clinical databases. An enduring potential weakness arises from unobserved differences among patients seen by different providers. The multitude of processes that connect patients with surgeons and hospitals are not random, and are known to result in systematic differences, often large, in the patients treated by different surgeons at different hospitals (Auerbach et al. 2009; Kumbhani et al. 2009). Sicker patients are likely to gain more from higher-quality care and thus may be more prevalent among the patients of providers perceived to have higher quality. This matching may result from physician referrals or from patients' choice based on available information (including, report cards). Another sorting process involves a different kind of response to provider report cards: providers avoiding sicker patients ('cherry picking') possibly seeking a more favorable operative mortality record (Dranove et al. 2003). Recent evidence also points to systematic differences by hospitals in socioeconomic patient profiles—in particular, of significant clustering of black and other minority patients in relatively few hospitals (Jha et al. 2007; Losina et al. 2007). Not all the important differences among patients are observed, even in detailed clinical databases (Dranove et al. 2003; Gowrisankaran and Town 1999). To the extent that these unobserved factors significantly affect operative mortality, then traditional comparisons of operative mortality rates across all surgeons and hospitals risk mistaking differences in patient severity with differences in the quality of care. For instance, if higher volume hospitals attract disproportionately larger number of sicker patients and some important illness characteristics are not observed, then RE regression is likely to over-estimate adjusted mortality and under-estimate quality of care for the surgeons in higher volume hospitals. An attractive alternative is to limit comparisons of surgeons within each hospital, thereby sweeping out unobserved patient characteristics across hospitals. This is the basic logic behind the econometric approach to FE regression.

Given the clustering of patients at the surgeon and hospital levels, the advantage of FE regression is in exploiting the within-provider variation in operative mortality to estimate the volume–outcome relationships, thereby making it robust to systematic differences in unobserved characteristics at provider level. In contrast, the RE regression, the standard workhorse in this literature, is based on the assumption that there are no systematic differences across providers in unobserved patient characteristics. Given evidence of large socioeconomic patient profile differences across hospitals (due to residential segregation and other factors), cherry-picking and patient choice, the assumption of a standard random effects model needs to be validated. The only existing study using FE regression that we know of examined associations of longitudinal changes in hospital volume on two patient outcomes (length of stay and inpatient mortality) from hip fracture surgery (Hamilton and Ho 1998). They found that the apparent protective effect of higher volume from RE regression disappeared when adjusted for hospital fixed effects.

We use a readily available data set previously used to examine the association of operative mortality with hospital and surgeon volumes. To control for systematic provider-level differences in unobserved patient as well as provider characteristics, we use a FE regression approach modified to take advantage of the nature of surgeon and hospital level

clustering of patients. Two separate FE regressions are estimated, one to estimate the surgeon volume effect (i.e., association of surgeon volume and operative mortality) and another to estimate the hospital volume effect. As most hospitals in our data had two or more surgeons, to estimate surgeon volume effect, unobserved differences in patients across hospitals are controlled for by only comparing operative mortality of surgeons within same hospital. To estimate the hospital volume effect, we take advantage of the fact that surgeons are not nested in hospitals—a large proportion (51%) of surgeries are performed by surgeons who operated at two or more hospitals. This enables us to compare operative mortality across hospitals of patients operated by the same surgeon—thereby adjusting for systematic unobserved patient characteristics at the surgeon level.

By relying only on within-cluster comparisons, the FE approach offers a better approximation of the operative mortality differences arising from differences in quality of care indicators—including caregiver skill, experience and pre and post operative process of care. This is herein referred to as the *quality of care component* of the operative mortality differences by provider volume. Based on this we can also estimate the *unobserved factors component*—the residual mortality differences by provider volume that may be attributed to unobserved characteristics, including systematic unobserved patient differences across providers. We compare the estimates of this FE decomposition with the overall single estimate from a parallel RE regression. That is, does the sum of the two FE components equal the estimate from RE regression?

2 Data and methods

2.1 Data

We use an analytic data set of patient level CABG surgery mortality outcomes and covariates previously used to examine volume–outcome relationships, adopting all the variable definitions from that study (Birkmeyer et al. 2002, 2003). Briefly, using 100% of acute care hospitalization discharge data for Medicare fee-for-service beneficiaries in 1998 and 1999, admissions in which CABG surgery was performed for persons aged 65–99 are included (thereby excluding a small number of CABGs performed on younger patients with disability or End Stage Renal Disease). Discharges that also involved a valve replacement were excluded. The Institutional Review Board at Boston University School of Medicine approved the study protocol.

To identify the operating surgeon for each CABG, the unique provider identification number in the "primary operator" field in the Medicare Inpatient file was used. In 6% of procedures the provider identification numbers were invalid and therefore excluded. In addition, only CABGs performed by self-designated cardiothoracic surgeons were selected, to avoid cardiologists being wrongly identified as surgeons. This results in an additional 13% of the records being excluded, leading to a study sample of 220,592 patients.

2.2 Analytic cohorts

Patients in the data are clustered at the level of surgeons and hospitals. The FE approach to estimating the effect of surgeon volume consists of comparing surgeons in each hospital—thereby requiring at least two surgeons in every hospital. This cohort, herein called the *Within Hospital Cohort*, is obtained by excluding 60 hospitals (out of 958), because only one surgeon operated there, and 2,802 patients (out of 220,592).

An analogous FE approach is used to estimate the effect of hospital volume. Here we limit our analysis to outcome for patients of surgeons who operate at two or more hospitals ("splitters") so that we can compare outcome of patients from the same surgeon but at different hospitals. This cohort, called the *Within Surgeon Cohort*, retains 44% of all surgeons, 79% of the hospitals and 51% of all patients.

2.3 Outcome measure and covariates

Operative mortality for a patient is defined as death within 30 days of the procedure or before hospital discharge. Surgeon and hospital volumes are defined as the total number of CABG surgeries performed in a year, including Medicare as well as other payer patients. These are estimated for individual surgeons and hospitals by scaling up Medicare FFS volume to reflect total volume—the scale up multipliers are based on the proportion of all CABG patients who are Medicare FFS beneficiaries, obtained from 1997 Nationwide Inpatient Sample (NIS) and urban/rural location. Both surgeons and hospitals are categorized into patient-level tertiles—using 101 (33rd percentile) and 162 (66th percentile) surgeries per year as the cutoffs for surgeon volume and 314 and 628 for hospital volume. Patient covariates include age, sex, race, the Charlson comorbidity score and an area-level income measure (mean income from Social Security for the patient's residence ZIP code). The Charlson score is based on ICD-9-CM diagnosis codes from the index admission as well as any other inpatient admissions in the preceding 6 months, excluding primary indicators for the surgical procedure or post-operative complications. Hospital characteristics adjusted for are teaching status and ownership (not-for-profit, government and for-profit).

2.4 Estimation

Our interest is in estimating the relationship between operative mortality and both surgeon and hospital volumes. A general regression notation that encompasses the FE and RE approaches is as follows.

$$OM_{psh} = \alpha * PC_{psh} + \beta_S * SV_{sh} + \beta_H * HV_{sh} + \gamma * HC_{sh} + u_s + v_h + e_{sph} \qquad (1)$$

We reiterate that the terms random and fixed effects are not to be interpreted as describing whether regression coefficients are random variables or not; as described earlier, they refer to whether coefficients are estimated using only within-level variation (fixed effects) or within- and between-level variation (random effects). *OM* denotes operative mortality (with values 0 and 1, denoting survival and death respectively) of patient p operated by surgeon s in hospital h. The covariates are grouped as patient characteristics (*PC*), surgeon volume (*SV*), hospital volume (*HV*) and other hospital characteristics (*HC*). Unobserved cluster effects at the surgeon and hospital levels are denoted by u and v respectively. Finally e denotes the effect of unobserved patient characteristics. Both FE and RE regression models are estimated as linear regressions.[2] In both models e is specified to be independent and identically (normal) distributed random variable with mean 0. Mean of u and v are specified to be 0. Since all regression covariates are categorical groups, all

[2] Fixed effects logistic regression (also known as conditional logistic regression) requires at least one decedent and survivor from each fixed level (surgeon, hospital) (Chamberlain 1980). As 507 of the 2772 surgeons have no decedents, we have instead followed previous studies (Tsai et al. 2006) and chosen to use the linear probability specification that has the advantage of retaining data from all surgeons and hospitals.

the regression coefficients are interpreted as excess rates in operative mortality compared to the reference category.

RE estimates are obtained from a three-tiered hierarchical regression wherein surgeons are treated as being nested with in hospitals—with surgeons operating at two or more hospitals treated as distinct surgeons, using their combined volume across all hospitals (Raudenbush and Bryk 2002). This regression is estimated for both the analytic cohorts (within hospital and within surgeon) using the *xtmixed* procedure in Stata 9.2 (StataCorp 2005).

The FE estimates are obtained from two separate regressions, each estimating the volume effects for the two provider types, surgeons and hospitals. To estimate the effect of surgeon volume we limit comparisons of surgeons within the same hospital by the following transformation of Eq. 1, wherein the outcome measure as well as all the covariates are expressed in terms of within-hospital mean differences (Johnston and DiNardo 1997).

$$(OM_{psh} - \overline{OM}_h) = \alpha * (PC_{psh} - \overline{PC}_h) + \beta_s * (SV_{sh} - \overline{SV}_h) + (u_s - \overline{u}_h) + (e_{sph} - \overline{e}_h) \quad (2)$$

This transformation of all measures in terms of intra-cluster differences is the hallmark of the econometric fixed effects regression. Each variable transformation involves differencing cluster level means—for instance, $\overline{OM}_h$ denotes the mean operative mortality among all patients at hospital h. And $\overline{u}_h$ denotes the mean unobserved surgeon effects (u_s) across all the surgeons in hospital h. Note that with all hospital measures (*HV*, *HC* and *v*) eliminated, the resulting Eq. 2 has a two-tier structure (patients and surgeons). This transformed equation is estimated as a RE linear regression model using the within-hospital cohort—therefore, our approach is not purely fixed effects; instead it is a partial or quasi FE approach. The RE regression of (2) assumes that the mean differenced unobserved surgeon effect, $(u_s - \overline{u}_h)$, is uncorrelated with other covariates and error term, all of which are mean differenced—implying that, for instance, within-hospital differences around mean in volume across surgeons, $(SV_{sk} - \overline{SV}_h)$, is uncorrelated with within-hospital differences around mean in patient severity across surgeons, $(u_s - \overline{u}_h)$. However, this permits cluster-level measures (say, $\overline{SV}$ and $\overline{u}_h$) to be correlated.

Analogously, to estimate the effect of hospital volume we use the within-surgeon cohort with only patients of surgeons who operated at two or more hospitals—thereby permitting comparison of outcomes of patients across hospitals holding the surgeon characteristics the same. The corresponding transformation of (1) is

$$\begin{aligned}(OM_{psh} - \overline{OM}_s) = \alpha * (PC_{psh} - \overline{PC}_s) + \beta_h * (HV_{sh} - \overline{HV}_s) + \gamma(HC_{sh} - \overline{HC}_s) \\ + (v_h - \overline{v}_s) + (e_{sph} - \overline{e}_s)\end{aligned} \quad (3)$$

$\overline{OM}_s$ denotes the mean operative mortality for surgeon s patients across all the hospitals. Note that here surgeon characteristics (*SV* and *u*) are eliminated and the resulting structure is two-tiered (patients and hospitals). This equation is estimated as a RE linear regression model using the within-surgeon cohort.

The FE hospital volume effect is analogously estimated by limiting comparisons of operative mortality of patients with the same surgeon but who operates at different hospitals (i.e., the within surgeon cohort). Here transformation involves differencing surgeon-level averages, followed by a two-tiered RE regression involving hospital unobserved cluster effect. Additional technical details are elaborated in the Appendix. The *quality of care component* of the volume effect on operative mortality is measured by β_H for hospital volume and β_S for surgeon volume, both estimated from the FE regressions.

FE and RE approaches differ principally in the specification of cluster effects u_s and v_h. Note that v_h represents the operative mortality at hospital h resulting from unobserved factors that vary systematically across hospitals, and u_s is the analog for unobserved differences across surgeons. Therefore systematic differences in unobserved patient characteristics, if any, are captured by either u_s and v_h. The RE estimation assumes that u_s and v_h are uncorrelated with the model covariates (*PC, SV, HV* and *HC*) as well as residual e—in particular, this implies that there are no systematic differences in unobserved patient characteristics across providers. Violation of this assumption results in biased estimates—β_H and β_S from RE no longer reflect the *quality of care component*. In contrast the FE approach makes a weaker assumption, permitting this correlation at both the cluster levels (surgeons and hospitals), but assuming that within-cluster differences across measures are uncorrelated. This implies that even if provider volume were correlated with unobserved patient severity, β_H and β_S from FE remain unbiased estimates of *quality of care component*. Therefore, the greater the differences in FE and RE estimates of β_H and β_S, the greater is the influence of unobserved factor differences by providers.

The overall *unobserved factors component* is measured by the residual mortality—that is, the combined effect of unobserved hospital and surgeon factors ($u + v$). This is obtained by substituting the FE covariate estimates in Eq. 1 to obtain

$$OM_{psh} - (\alpha * PC_{psh} + \beta_S * SV_{sh} + \beta_H * HV_{sh} + \gamma * HC_{sh}) = u_s + v_h + e_{sph} \qquad (4)$$

We report the average of this measure by each provider volume.

Therefore, we not only compare RE estimates of β_H and β_S against those from FE, but also against the sum of *quality of care* and *unobserved factors components* from FE regressions.

3 Results

3.1 CABG patients, surgeons and hospitals

Table 1 provides sample characteristics of the entire study population (All column) as well as the two subsets—the within hospital and the within surgeon cohorts. The entire study population consists of 220,592 patients operated on by 2,772 surgeons in 958 hospitals during 1998 and 1999. The overall operative mortality was 50.5 per 1,000 surgeries. The average annual volume for surgeons was 85 and that for hospitals 297—note that these volumes refer to not only Medicare patients but to all patients. As mentioned earlier, 44% of surgeons operated at two or more hospitals (i.e., splitters) and 94% of hospitals had two or more surgeons.

All analyses are performed in terms of patient-level tertiles of hospital and surgeon volumes. Among the 2,772 surgeons, 377 were in the top tertile, with annual volume ranging from 162 to 567 surgeries, and 1,783 were in the bottom tertile, with a volume of less than 101 surgeries. Of the 958 hospitals, 101 are in the top tertile (again of patients) with an annual volume of at least 628 surgeries; 644 hospitals are in the bottom tertile with a volume of less than 314 surgeries. Patients in high/low volume hospital (i.e., highest/lowest volume tertile) were more likely to also have a high/low volume surgeon, and vice versa. Of the patients at high volume hospitals, half were operated on by high volume surgeons and about 15% by low volume surgeons; for the patients at low volume hospitals, half were operated on by low volume surgeons and about 15% by high volume surgeons. A

Table 1 Patient, surgeon and hospital characteristics: CABG admissions, 1998–99

	All	Within hospital cohort[a]	Within surgeon cohort[a]
# CABG admissions[b]	220,592	217,790	112,143

For profit	11%	11%	15%

All patients are 65 or older and Medicare Fee for Service enrolled

[a] Within Hospital Cohort excludes CABG admissions from 60 hospitals with only one surgeon, and Within Surgeon Cohort retains CABG admissions from the 1,216 surgeons who operated at two or more hospitals

[b] Among all these admission, there are no patients with more than one CABG surgery—each surgery admission refers to a distinct patient

[c] Note that surgeon and hospital volumes are estimates of annual volumes covering all payers

[d] Note that the Charlson score, based on ICD-9 diagnoses codes from the index admission as well as any other inpatient admissions in the preceding 6 months, excludes primary indicators for the surgical procedure or post-operative complications

similar pattern was observed for the converse distribution of patients at low and high volume surgeons across low and high volume hospitals.

3.2 The analytic cohorts

All summary figures in Table 1 for the within hospital cohort are virtually identical to that for the entire sample. However, the within surgeon cohort, containing surgeons operating at two or more hospitals, shows differences in provider profiles—surgeon volumes are larger (by 10%), hospital volumes are smaller (by 17%) and fewer hospitals are teaching (by 15%). More importantly, the patient profile appears to be no different compared to the overall population, and operative mortality rates and patient characteristics are very similar.

Table 2 gives the unadjusted operative mortality rates (per 1,000 CABG surgeries) for different strata cross-classified by provider volume for both analytic cohorts. Lower volume hospitals had 11 more operative deaths while lower volume surgeons had 14 more operative deaths compared to their high volume counterparts. Higher mortality is associated with older age, female gender, black race, higher Charlson score and emergent admission. With respect to provider volume two patterns emerged—(i) the magnitude of difference between high and low volume providers (either hospitals or surgeons) is constant across most strata, and (ii) the two analytic cohorts have very similar operative mortality rates for the same strata.

3.3 Estimates of surgeon and hospital volume effects

Table 3 presents the main regression estimates from both FE and RE approaches. Column 1 presents the RE estimates of operative mortality rates (%) associated with surgeon and hospital volumes using the within hospital cohort. For comparison this model is also estimated for the within surgeon cohort (column 2). Columns 3 and 4 give the corresponding estimates from the FE approach. Note that both the RE estimates are similar across all patient and hospital characteristics, although the hospital volume effects are smaller in column (2) but not (statistically) significantly different—the column (1) figure will be used for RE estimates herein. Using patients at high volume providers as the reference cohort, those treated by low and medium volume hospitals had 0.45 more operative deaths per 100 CABG surgeries (95% CI = [0.0008, 0.89]) and those treated by low volume surgeons had 1.41 more operative deaths (95% CI = [1.08, 1.74]). The FE approach estimates that, compared to their high volume provider counterparts, patients treated by low volume hospitals had 1.36 more operative deaths (95% CI = [0.34, 2.37] and those by low volume surgeons had 1.56 more operative deaths (95% CI = [0.67, 2.46]).

Estimates of other covariates that have statistically significant association with operative mortality—gender and age composition, Charlson score and admission type, have very similar estimates across all four regressions (columns 1–4). The teaching status of the hospital and the mean Social Security income in a patient's residence zip code were not associated with operative mortality in any of the models. However, for-profit hospitals had higher operative mortality in the RE models but not in the FE model.

As described in the Methods section, FE regression is used to decompose the total volume effect into *quality of care* component (obtained from FE regression coefficients in Table 3) and *unobserved factor* component (hospital or surgeon-level mean of FE regression residuals). These are presented in the first two columns of Table 4, followed by

Table 2 Operative Mortality Rate (%) for Highest & Lowest Volume Tertiles, by Sample Characteristics

Highest tertile (>162)	Reference	Reference	Reference	Reference

[a] These figures are from Table 3 (FE Expected values are from columns 3 or 4 while RE values are from column 1)

gives the sum of the two FE components. Combining the two components—1.36 additional deaths from the quality component and 0.84 fewer deaths due to other unobserved factors, lowest tertile hospitals have a total (net) excess mortality of 0.52 deaths (per 100 CABG surgeries)—as indicated in column 3. This figure is similar to the direct estimate of 0.45 excess deaths from RE regression (column 4). A similar pattern is true for medium volume hospitals, with a net FE effect of 0.40 and a direct RE estimate is 0.39 excess deaths, thereby suggesting that RE hospital volume effects approximate the sum of the quality and unobserved factor FE components. But this comparison does not hold for the surgeon volume comparison—particularly for the low volume surgeons. The average *unobserved factors component* for low volume surgeons is −5.8, thereby leading to the total FE estimate of 9.8 excess mortality rate—much lower than the RE direct estimate of 14.1.

3.4 Sensitivity analyses

An important step in the estimation process is the use of the two distinct subsets (cohorts) of the overall data. In particular, the within surgeon cohort excludes 49% of the patients and 44% of surgeons. We performed a number of robustness and sensitivity checks to validate the estimates obtained. First, to assess the robustness of the FE hospital effects estimates, we re-estimated the regression using bootstrapping (1,000 replications) randomly dropping 10% of the surgeons (and their patients). The results do not change—the average excess mortality rate for low volume hospitals is 1.4 (95% CI = [0.89, 1.86]) and for medium volume hospitals is 0.8 (95% CI = [0.42, 1.29]).

Second, we address the difference in hospital volume effects estimated by the two RE regressions (columns 1 and 2 of Table 3). For instance, for low volume hospitals, the excess mortality estimate is 0.45 using the within hospital cohort (column 1) but it is 0.09 using the within surgeon cohort (column 2). Note that while the within hospital cohort includes virtually all the study data, the within surgeon cohort excludes all patients treated by 44% of surgeons who operated at more than one hospital. It is unclear if this difference is indicative of systematic difference in the within surgeon cohort subset or indicative of lack of robustness of the estimate. To evaluate this we obtained 100 different sub-samples

of the overall data by excluding all patients from 44% of surgeons randomly selected—that is, exclusion of surgeons was not based on whether or not they operated at more than one hospital. The mean (from the 100 regressions) of low hospital volume effect is 0.39, with the range [−0.17, 0.88]—thereby suggesting that the aforementioned difference (betweens columns 1 and 2 of Table 3) may be due to the lack of robustness of the estimate and not necessarily indicative of systematic differences in patients in the two cohorts.

To further ascertain if the patients included in the within surgeon cohort are systematically different from those who are excluded, and in the spirit of marginal propensity score estimation, we performed a logistic regression with inclusion/exclusion as the outcome and all patient factors plus operative mortality as the covariates. We find that this model has poor discrimination—with only 51% of patients correctly classified (area under ROC was 51.3), thereby indicating little systematic difference between the included and excluded patients.

Finally, to examine if the results are sensitive to using distinct cohorts for the two FE regressions, we identified a sub-sample that simultaneously met the two criteria identifying each cohort (hospitals with at least two surgeons, and surgeons who operated at two or more hospitals)—this sub-sample has 104,340 patients, 596 hospitals and 1,126 surgeons. The RE and both the FE regressions estimated on this common data yielded virtually the same results as those in Table 3—in particular, a much higher estimate of excess deaths associated with low-hospital volume from FE regression (1.21 deaths) than from RE regression (0.66 deaths).

4 Discussion

Are lower operative mortality rates among higher volume surgeons and hospitals a signal of better quality of care, or is this association confounded by patient profile differences across providers? Providers may differ in the proportion of complicated patients they treat, and not all of these complications are adequately identifiable in administrative or clinical data. To better adjust for such differences, we used fixed effects (FE) regression methods to obtain estimates based only on within cluster comparisons. To avoid comparisons across hospitals, surgeons within same hospital were compared with each other in estimating the surgeon volume effect; and to estimate the hospital volume effect we compared operative mortality across hospitals for patients treated by the same surgeon. By overcoming the potential confounding from unobserved patient differences, this approach better approximates the volume effects associated with *quality of care* differences across providers. This regression approach indicates that, compared to hospitals that perform at least 628 CABG surgeries a year, those that perform less than 314 a year have an excess operative mortality rate of 1.36 deaths (per 100 surgeries) and those that perform between 314 and 628 surgeries have an excess mortality of 0.8. Further, compared to surgeons who perform at least 162 CABG surgeries a year, those who perform fewer than 101 surgeries have an excess operative mortality rate of 1.56.

Comparing FE and RE regression estimates indicate that they differ significantly with respect to the effects of hospital volume but not surgeon volume. Specifically, FE regression estimates that excess deaths associated with low volume hospitals (1.36 excess deaths per 100 CABG surgeries) is much higher than that estimated by RE regression (0.52). Recall that the FE estimate is based on comparing operative mortality of the same surgeon across hospitals—implying that even after adjusting for surgeon-level factors there are significant differences across hospitals in unobserved factors. On the other hand FE and

RE estimates of excess deaths associated with low surgeon volume are similar (1.56 and 1.41 respectively)—since FE estimates are based on within hospital comparison of surgeons, similarity between FE and RE estimates implies that, once unobserved factors at the hospital level are adjusted for (i.e., within each hospital), unobserved factors across surgeons by volume do not have significant effect on operative mortality. That is, within each hospital, there are no systematic differences in unobserved patient characteristics across surgeons—consequently the surgeon volume effects from RE and FE are very similar.

The FE approach also enables estimation of the effect of unobserved characteristics on operative mortality (*unobserved factors component)* at the provider level. This captures factors that are important determinants of operative mortality but not observed in the data. Averaging this component at provider volume level, we indeed find large differences in this component. Low volume hospitals and surgeons have much lower operative mortality than expected by the FE regression model. While the regression model predicts low volume hospitals to have an excess operative mortality rate of 1.36, the observed excess mortality rate is 0.52, leading to a large difference accounted for by unobserved factors. Similarly, while the low volume surgeons have an expected excess mortality rate of 1.56, the observed excess mortality rate is 0.98. Both these indicate the presence of large "protective" factors in low volume hospitals and providers. Note that process-of-care differences across providers that vary with volume are already captured explicitly in the regression, but other process differences (that affect quality) could contribute to this unobserved component.

Based on growing evidence from other studies, a plausible "protective" factor may be unobserved patient severity or complications, implying that high volume hospitals and surgeons have more complicated patients compared to their low volume counterparts. While this implication of a more complicated patient profile in higher volume hospitals contradicts some previous findings (Shahian and Normand 2003), a number of recent studies corroborate it. The strongest evidence comes from studies of the impact of mandatory annual reporting of risk-adjusted mortality from CABG surgery for each hospital and surgeon in New York and Pennsylvania since 1992. One study surveyed a sample of cardiologists and cardiac surgeons from the two states, finding that 59% of the cardiologists "reported increased difficulty in finding surgeons willing to perform CABG surgery in severely ill patients who required it, and 63% of the cardiac surgeons reported that they were less willing to operate on such patients" (Schneider and Epstein 1996). Another large study based on the majority of all CABG surgeries performed among Medicare population between 1987 and 1994, found that "report cards led to increased sorting of patients to providers on the basis of the severity of their illness … with those two states' teaching hospitals picking up an increasing share of patients with more severe illness" (Dranove et al. 2003). Since physician referral has been found to be the most important determinant of provider choice, it is likely that more complicated patients are referred to teaching and other high volume providers as they are expected to gain more than those with fewer complications (Schwartz et al. 2005). Despite this supportive evidence in the literature, we acknowledge that the present study provides not direct evidence of unobserved patient profile differences by provider volume. There may be other unobserved factors, including at provider levels, not adequately captured by the methods used here.

This study also has implications for the random effects (RE) regression approach to estimating volume effects. As this method does not adjust for unobserved factors that affect operative mortality, including important patient severity indicators, RE volume effect estimates may be an inappropriate measure of quality of care differences. Therefore if our interest is in volume effects driven by quality of care differences, say for report cards, then the appropriate estimates are those from FE regression. But if our interest is in the overall association of operative mortality with surgeon volume—either arising from quality of care

or other differences, then RE volume effect estimates appear to approximate the combined FE volume effect. Note that it is this overall measure is the appropriate measure in assessing the impact of regionalization of CABG surgery—since the quality of care benefit from regional centers is only experienced if complicated patients would otherwise have gone to "low-volume" providers, the appropriate accounting should therefore combine quality of care component with unobserved factor component from FE regression.

While the FE approach used here addresses some of the complexities of using observational data, a number of important limitations still remain. Firstly, given the two levels of clustering of patients (within surgeons and hospitals), the FE approach used here is a two-step procedure wherein the first step uses FE for one level of clustering while the second component is an RE regression at the other level. Although less restrictive than a three-tiered RE model, it nevertheless does not eliminate all forms of correlation of unobserved cluster effects. For instance, in comparing surgeons within each hospital it is assumed that patient profiles are similar across surgeons—to the extent that some of the patients are triaged to specific surgeons based on unobserved characteristics (including severity) the quality measure is confounded. Also, the fixed effects method does not allow interaction of unobserved hospital- and surgeon-level factors. Similarly, when comparing patient outcomes for the same surgeon but at different hospitals it is assumed that there are no systematic unobserved differences among patients across hospitals. The second limitation is that the range of clinical information to measure patients' disease burden is limited. The large unobserved mortality component estimated here might be the result of limited comorbidity information available (Charlson scores based only on ICD-9-CM codes from inpatient records for 6 months). Enriching this information, in particular, with data from clinical databases, might result in lower unobserved mortality. However it is not clear if the volume effects associated with quality of care differences will be affected with the use of richer patient information. The FE regression used to estimate hospital volume effects uses a subset that excludes 49% of the patient records in the available data. While we have performed a variety of sensitivity and robustness checks, there may still be other differences between those included and excluded. Third, we also recognize that this study does not attempt to disentangle the bi-directional relationship between volume and operative mortality—it only estimates a reduced form relationship between the two measures regardless of the underlying cause. While the "learning by doing" hypothesis posits volume as the cause, an alternative hypothesis ("selective referral") allows for quality (operative mortality rate) being the cause and volume the effect. Majority of the studies that have attempted to disentangle the causal direction, using instrumental variables regression, have found evidence for both effects at the hospital level (Farley and Ozminkowski 1992; Gaynor et al. 2005; Gowrisankaran et al. 2005; Luft 1980; Tsai et al. 2006)—we know of no studies that have modeled both surgeon and hospital volumes.

In conclusion, fixed effects (FE) regression estimates excess operative mortality from low volume hospitals to be much higher than previously estimated. This reflects differences in operative mortality arising from quality of care differences across providers by volume. It appears that the previous estimates using random effects (RE) regression captured not only quality of care differences but also other important operative mortality determinants unobserved in the data—in particular, unobserved patient complications.

Perceived Racial Discrimination in Health Care and its Association with Patients' Healthcare Experiences: Does the Measure Matter?

Leslie R. M. Hausmann, PhD; Nancy R. Kressin, PhD; Barbara H. Hanusa, PhD; Said A. Ibrahim, MD

Objectives: Examine whether three measures of perceived racial discrimination in health care detect similar rates of discrimination and show similar associations with patients' healthcare experiences.

Design: Cross-sectional observational study involving telephone surveys and medical record reviews.

Setting: Veterans Affairs Pittsburgh Healthcare System

Participants: 50 White and 50 African American veterans with diabetes

Main Outcome Measures: Three types of measures of perceived racial discrimination in health care were compared: single-item and multi-item measures assessing personal experiences of discrimination in healthcare settings, and a measure assessing general racism in the healthcare system. Associations of each measure with patient-reported problems with their medical care and receipt of recommended preventive screenings were also explored.

Results: More African American than White veterans reported perceived discrimination on all measures (personal discrimination, single-item: 42% vs 6%, $P<.001$; personal discrimination, multi-item: 42% vs 18%, $P=.01$; general racism: 74% vs 40%, $P=.001$). In the total sample, discrimination was more likely to be reported on the general racism measure than on the single-item (OR=36.53, 95% CI=7.95–167.89) or multi-item measures (OR=20.28, 95% CI=5.12–80.34) of personal discrimination. The multi-item measure of personal discrimination (OR=3.96, 95% CI=1.29–12.18) and general racism measure (OR=3.61, 95% CI=1.34–9.71) were significantly associated with patient-reported problems with their care. Receipt of recommended screenings was not associated with any of the discrimination measures.

Conclusions: Different measures of perceived racial discrimination in healthcare settings yield different rates of discrimination and show variable associations with patients' perceptions of care. (*Ethn Dis*. 2010;20:40–47)

Introduction

More than 200 empirical studies have investigated the health implications of discrimination,[1–3] which refers to differential and negative treatment of individuals because of their membership in a particular demographic group (eg, race, sex, class).[4] Although discrimination can be based on any characteristic and may affect health even when it is not directly perceived,[5] most research has focused on the health effects of race or ethnicity-based discrimination that is directly perceived by targeted individuals.[1–3] Such research has demonstrated that perceived racial and ethnic discrimination is associated with decrements in both mental and physical health, as well as an increase in negative health behaviors (eg, cigarette smoking, alcohol use).[1,2,6–11]

The current study focuses on perceptions of racial discrimination encountered in healthcare settings, which has been the focus of a relatively small subset of studies.[7,12–26] Discrimination may arise in healthcare settings due to a number of factors.[4,27] For instance, geographic location and bureaucratic complexity of medical facilities may result in differential access to and utilization of health services for different racial and ethnic groups. Unequal healthcare delivery can also result from the ambiguous nature of clinical decisions, misunderstandings in doctor-patient communication, provider attitudes and stereotypes, and/or expectations patients have regarding clinical encounters.

Understanding discrimination in healthcare settings is particularly important for several reasons. First, the healthcare system has a moral and legal obligation to provide equal care to all patients, regardless of their race, ethnicity, or other characteristics. Second, discrimination in healthcare settings may cultivate patient disengagement from the healthcare system, thereby negatively affecting future healthcare encounters and patient health.[12,17,18,22,23,25,26] Finally, discrimination that is perceived within healthcare settings can potentially be addressed through quality improvement efforts implemented by healthcare systems, whereas there may be little healthcare systems can do in response to discrimination that occurs outside of their institutions.

For these reasons, it is important to determine the prevalence of perceived discrimination in healthcare settings and to understand its potential impact. Unfortunately, work in this area is inhibited by a wide variation in how perceived discrimination in healthcare settings has been measured across studies.[28] Most studies have measured

healthcare discrimination with either a single item from a scale of perceived discrimination[26] or with unique items developed for inclusion in a given survey.[6,7,12,20,23–25] Others have adapted existing, multi-item measures of perceived discrimination to assess discrimination that is perceived particularly within healthcare settings.[16,29] Still others have asked patients about their general perceptions of racism in health care rather than whether patients have personally experienced such discrimination.[13,17] The variation in measurement has made it difficult to draw conclusions about the prevalence and impact of discrimination in health care.

The current study was undertaken as an initial effort to compare the prevalence of perceived discrimination in health care across multiple measures within a single patient population. In a sample of 100 African American and White adults with diabetes, this exploratory study measured perceived discrimination using 3 types of measures that have often been used in prior research: a single-item assessing personal experiences with discrimination in health care (ie, personal discrimination, single-item),[30] a multiple-item measure adapted from a commonly-used measure of personal experiences with discrimination (ie, personal discrimination, multi-item),[29] and a measure assessing perceptions of general racism in the healthcare system, regardless of one's personal experiences with discrimination (ie, general racism).[17]

The primary aim was to examine differences in the prevalence of perceived discrimination in health care across patient race and type of measure. Based on previous findings that discrimination is more commonly experienced by racial and ethnic minorities than by Whites,[7,30] we predicted that African Americans would report more perceived discrimination than Whites across all measures of discrimination. Given that rates of perceived discrimination have been somewhat lower when assessed with a single-item than with multiple-items[7,29], we also predicted that the prevalence of personal discrimination for both Whites and African Americans would be higher on the multi-item than single-item measure. Finally, it has been well-established in the psychological literature that people are more likely to perceive discrimination against their group in general rather than against themselves personally.[31] We therefore predicted that rates of perceived discrimination would be higher on the general racism measure than on either the single-item or multi-item measure of personal discrimination.

A secondary aim was to explore whether each measure of perceived discrimination was associated with patient experiences with the healthcare system, including patients' perceptions of problems with their medical care and their receipt of screenings recommended for optimal diabetes management. This aim was included to explore whether conflicting evidence in the literature regarding whether perceived discrimination is associated with less patient satisfaction and/or healthcare utilization could be due to different measures of perceived discrimination being used across studies.[17,18,24,25]

Table 1. Sociodemographic characteristics of the sample

	African American (*n*=50)	White (*n*=50)	*P*-value*
Age, mean (range, SD)	63 (40–86, 11)	70 (52–85, 9)	.002
Income			.049

>$20K	40%	64%	
Missing	10%	4%	
High school, GED or less	54%	46%	.424

* t-test with unequal variances for age, chi-square test for income and education.

METHODS

Study Sample

The sample included 100 patients from the Veterans Affairs Pittsburgh Healthcare System (VAPHS) who were aged ≥18 years, self-identified their race as White or African American, had a diagnosis of diabetes from at least 2 years prior to the start of the study, and had no diagnosis of Alzheimer's or dementia (Table 1). To recruit the sample, a random sample of 479 patients (234 African Americans, 245 Whites) who met the inclusion criteria were identified from a VAPHS administrative database. Patients were mailed an initial letter and up to 2 follow-up letters inviting them to participate in a 30-minute telephone survey regarding their experiences with seeking treatment for diabetes. Consistent with local Institutional Review Board policies, only patients who indicated their interest in the study by mail or telephone were able to be enrolled in the study. African American (n=82, 35%) and White (n=93, 38%) patients were equally likely to express interest in the study ($\chi^2(1)=0.44$, $P=.51$). Trained research staff telephoned interested patients to explain the study in more detail, obtain patients' verbal informed consent, and administer the survey. Due to funding limitations, recruitment efforts ended after the goal of enrolling 100 patients had been met. Patients were compensated $20 for their participation.

Measures of Perceived Discrimination in Health Care

Personal Discrimination, Single-Item

An item from the validated and reliable Experiences of Discrimination

Table 2. Race differences in prevalence of perceived racial discrimination in health care across three types of measures

	African Americans (*n*=50)	Whites (*n*=50)	Unadjusted *P*-value†	Adjusted *P*-value‡
Personal discrimination, single-item measure (PD-S): While getting medical care, have you ever experienced discrimination, been prevented from doing something, or been hassled or made to feel inferior because of your race ethnicity, or color (% reporting that it occurred at least once)*	42	6	<.001	.004
Personal discrimination, multi-item measure (PD-M): When getting health care, how often has each experience happened to you because of your race or color (% reporting that experience occurred at least once)				
Treated with less courtesy than other people	30	4	.001	.032
Treated with less respect than other people	30	2	<.001	.027
Received poorer services than other people	30	6	.002	.026
Had a doctor or nurse act as if he or she thinks you were not smart	28	6	.004	.135
Had a doctor or nurse act as if he or she was afraid of you	22	2	.002	.151
Had a doctor or nurse act as if he or she was better than you	24	14	.202	.870
Felt like a doctor or nurse was not listening to what you were saying	34	16	.038	.498
% reporting any of the above*	42	18	.009	.134
General racism measure				
Doctors treat African American and White people the same. (% disagree or strongly disagree)	65	37	.007	.041
Racial discrimination in a doctor's office is common. (% agree or strongly agree)	38	14	.009	.032
In most hospitals, African American and Whites receive the same kind of care. (% disagree or strongly disagree)	66	25	<.001	.001
African Americans can receive the care they want as equally as White people can. (% disagree or strongly disagree)	53	33	.050	.270
% perceived discrimination on any of the above*§	74	40	.001	.004

* Variable used in regression models.
† Unadjusted *P* values comparing African American and white responses using chi-square tests.
‡ *P*-values for association of race with each measure, adjusting for patient age, education, and income, using logistic regression models.
§ Responses consistent with perceived discrimination were disagree or strongly disagree for items 1, 3, and 4, and agree or strongly agree for item 2.

(EOD) measure[30] was used as the single-item measure of personal discrimination in healthcare settings (Table 2). The original EOD asks how often (never, once, 2 or 3 times, 4 or more times) patients have encountered discrimination in 9 different settings, one of which is while getting medical care. The single medical care item has been used in previous studies to examine perceptions of discrimination in health care.[25,26] Because the current study focused on a VA patient population, the item was modified slightly so that it assessed patients' experiences of discrimination while getting medical care in either Veterans Affairs or non-Veterans Affairs facilities. Responses were dichotomized into never vs ever for analyses.

Personal Discrimination, Multi-Item

The multi-item measure of personal discrimination in healthcare settings was an adaptation of Williams' validated and widely-used Everyday Discrimination measure.[32,33] Williams' original measure assesses how often (never, once, 2 or 3 times, or 4 times or more) one has encountered 7 types of unfair treatment and the reason for the treatment (eg, race, sex). In previous studies, an adapted version was created specifically to assess race-based unfair treatment encountered within healthcare settings.[16,29] The healthcare-specific adapted version has shown excellent reliability in a variety of diverse patient populations[16,29] and was used in the current study (Table 2). We dichotomized each response into never vs ever and counted the number of items on which patients reported perceiving discrimination (coefficient alpha = .94). Preliminary analyses indicated that this count variable was not normally-distributed and that responses were best categorized into 2 levels (none vs any) for analyses.

General Racism in the Healthcare System

Perceptions that racism against African Americans exists in the healthcare system were measured by the 4-item Racism in Health Care Index (Table 2).[17] This was referred to as the ''general racism'' measure in the current study to highlight that it assesses perceptions of racism in health care regardless of patients' personal experi-

ences with such discrimination, which are assessed by the single-item and multi-item measures of personal discrimination. For this measure, patients were asked to indicate the extent to which they agree with four statements about racial discrimination in healthcare settings (strongly disagree, disagree, neither disagree or agree, agree, strongly agree). The number of statements on which patients perceived discrimination was calculated (coefficient alpha = .87). Preliminary analyses indicated that this count variable was not normally-distributed and that responses were best categorized into 2 levels (perceived discrimination on 0 vs >0 items) for analyses.

Sociodemographic Variables

Self-reported race, age, highest level of education completed, and income were assessed during the telephone survey.

Exploratory Outcome Measures

Perceptions of Problems with Health Care

Patients' perceptions of the care they receive for diabetes were measured using the 4-item Doctor-Patient Relationship subscale of the Questionnaire on Stress in Patients with Diabetes – Revised.[34] This scale assesses whether each of the following is a problem for the patient: different doctors give you different information regarding your diabetes; you feel insufficiently informed about your diabetes; doctors do not spend enough time with you; and your doctor does not treat your diabetes in the best possible way (coefficient alpha = .80). For analyses, we categorized patients into those who reported no problems vs at least one problem.

Receipt of Screenings for Diabetes Complications

Electronic medical records were examined to assess whether patients had received all recommended screenings for diabetes complications in the past 2 years. Based on standards from the Diabetes Quality Improvement Project, these included at least one hemoglobin A1c test, dilated eye exam, comprehensive foot exam, and urine protein test within the past year, and a fasting lipid test within the past 2 years.[35] Because all 5 tests are recommended for optimal diabetes management, patients were categorized as having received all 5 or fewer than 5 tests. Given that this outcome was based on Veterans Affairs medical records, patients who reported receiving no care from Veterans Affairs facilities in the past 12 months (n=9) were excluded from analyses of this outcome.

Statistical Analyses

Individual items and dichotomized summary scores of perceived discrimination measures were compared between races using chi-square tests for bivariate comparisons and logistic regression for tests of racial differences controlling for patient age, education, and income. Correlations among the dichotomized measures of perceived discrimination were examined in the total sample and within each race using phi coefficients. Mixed effect logistic regression models, which take into account the dependence of multiple outcomes within the same individual, were used to compare the dichotomized measures of perceived discrimination, adjusting for patient race, age, education, and income. Interactions between race and each perceived discrimination measure were tested and none were found to be significant, so models without these interactions are reported.

Separate regression models were used to test the association of each discrimination measure with patients' perceptions of care and receipt of recommended screenings for diabetes management. First, base models that included race, age, education, and income as predictors of each outcome were tested. The effects of perceived discrimination were then tested by adding each of the three measures one at a time to the base models. A criterion of $P<.05$ was used to determine statistical significance. Analyses were conducted using STATA/MP 10.1 (College Station, TX, 2008).

RESULTS

Sample Characteristics

The sample included 50 African Americans and 50 Whites, 99% of whom were male. Compared to Whites, African Americans were significantly younger and had lower incomes, but did not differ in educational attainment (Table 1).

Race Differences in Perceived Discrimination across Measures

Racial differences in the percentage of patients reporting discrimination on each measure of perceived discrimination in health care are reported in Table 2. As expected, African Americans were more likely than Whites to perceive discrimination in health care, although exact rates varied across individual items and dichotomized summary measures. Based on the personal discrimination, single-item measure, 42% of African Americans and 6% of Whites had experienced discrimination while getting medical care, a difference that was significant even after adjusting for patient age, education, and income (P=.004).

On individual items within the personal discrimination, multi-item measure, rates of perceived discrimination tended to be higher among African Americans (22%–34% across items) than among Whites (2%–16% across items). Although more African Americans than Whites perceived discrimination on at least one of the items, this difference was not statistically significant after controlling for patient characteristics (42% vs 18%, P=.134).

Table 3. Phi correlation coefficients among perceived discrimination measures for total sample and each racial group

Measures of perceived discrimination	Total Sample		African Americans		Whites	
	PD-S	PD-M	PD-S	PD-M	PD-S	PD-M
PD-M	.55†		.51†		.54†	
General racism	.49†	.48†	.50†	.50†	.31*	.36*

PD-S: personal discrimination, single-item measure.
PD-M: personal discrimination, multi-item measure.
* $P<.05$.
† $P<.001$.

Finally, on most of the individual items assessing general racism in the healthcare system, rates of perceived discrimination were higher among African Americans (38%–66% across items) than among Whites (14%–37% across items). African Americans were significantly more likely than Whites to perceive discrimination on at least one of the 4 individual items (74% vs 40%, respectively, $P=.004$).

Comparisons across Measures of Perceived Discrimination

As shown in Table 3, the three dichotomized measures of perceived discrimination were significantly positively correlated with one another in the total sample and within each racial group. When all three measures were included in a mixed effect regression model (# of observations = 279, # of patients = 93), there was a significant effect for race such that African Americans reported more perceived discrimination than Whites (OR= 18.57, 95% CI= 2.43–142.04). Rates of discrimination also differed across measures, such that patients were more likely to report perceived discrimination on the general racism measure compared to the personal discrimination, single-item (OR=36.53, 95% CI=7.95–167.89) or multi-item (OR=20.28, 95% CI=5.12–80.34) measures. Responses were not significantly different on the personal discrimination, single-item and personal discrimination, multi-item measures (OR=1.80, 95% CI=.61–5.32).

Perceived Discrimination and Patients' Perceptions of Care

Overall, 56% of patients reported at least one problem with their diabetes care (54% and 58% of African Americans and Whites, respectively). In a model containing only patient characteristics as predictors, the likelihood of reporting a problem was not significantly associated with patient race, education, or income, but did decline with age (OR=.95, 95% CI=.91–1.00, $P=.047$; Table 4, Model 0). Models in which each measure of perceived discrimination was separately added to the base model indicated that the likelihood of patient-reported problems was not significantly associated with the personal discrimination, single-item measure (OR=2.57, 95% CI=.77–8.56; Table 4, Model 1). However, the personal discrimination, multi-item (OR=3.96, 95% CI=1.29–12.18; Table 4, Model 2) and general racism (OR=3.61, 95% CI=1.34–9.71; Table 4, Model 3) measures were each associated with nearly a four-fold increase in the likelihood of reporting a problem with care.

Perceived Discrimination and Patients' Receipt of Recommended Screenings

Patients received a median of 4 (IQR = 3–5) out of 5 recommended

Table 4. Logistic regression models testing association of perceived discrimination measures with patient-reported problems with diabetes care, adjusting for sociodemographic characteristics

screenings for diabetes complications within the prior two years, with 35% of both Whites and African Americans having received all 5 tests. Receiving all 5 tests was not significantly associated with patient characteristics or with any of the measures of perceived discrimination (data not shown).

DISCUSSION

This study compared rates of perceived racial discrimination in health care among African American and White patients using three different measures of discrimination. The measures were moderately correlated with one another, suggesting that they tap a similar underlying construct. However, rates of perceived discrimination were higher when assessed using a measure of general racism in health care than when assessed using a single-item or multi-item measure of personal experiences with discrimination in healthcare settings. This is consistent with the robust finding in psychological literature that people report less discrimination directed at themselves than at their group in general.[31] The current study indicates that this personal/group discrimination discrepancy extends to healthcare discrimination.

Rates of personal discrimination in healthcare settings did not differ significantly when assessed using a single-item or multi-item measure. This is somewhat surprising, given that rates of perceived discrimination in health care tend to be lower in studies using only a single item to assess discrimination than in those using multi-item measures.[7,22,25,26,29] Studies using single-item measures have found that 6%–12% of African American patients report having experienced racial discrimination in healthcare settings,[7,12,13,22,25,26] whereas discrimination was reported by 63% of African American patients in a study using a multi-item measure.[29] Past studies, however, have not compared single-item and multi-item measures within the same patient population, as in the current study.

A secondary goal of the current study was to explore whether the measure used to assess discrimination in health care influences the degree to which perceived discrimination is associated with patients' experiences with the healthcare system. It has been proposed that experiences of discrimination foster disengagement from the healthcare system.[25] Several studies have reported significant associations between perceived discrimination and indicators of patient disengagement (eg, delaying necessary care),[12,15–18,20,23] but conflicting evidence has also been reported.[12,16,18,24–26] Most studies that have found no association,[24–26] or inconsistent relationships across outcomes,[12,18,23] have relied on single-item measures of perceived discrimination, which may have contributed to the inconsistent findings. In the current study, a multi-item measure assessing personal discrimination encountered in healthcare settings was associated with patient-reported problems with their care, whereas a single-item measure failed to predict this outcome.

None of the measures in the current study were associated with patients' receipt of screenings recommended for optimal diabetes management, even though previous studies have reported that perceived discrimination among patients with diabetes is associated with a lower likelihood of obtaining A1c tests, eye exams, and diabetic foot exams.[12,23] Past studies relied on patient self-report to assess screening behavior whereas the current study obtained this information from medical records.

Several limitations should be considered when interpreting the findings of this study. This study was designed as an exploratory study with a small sample and, as such, is not powered to detect small effects or interactions among the variables. The sample size, coupled with the low prevalence of perceived discrimination reported by Whites, required the summary measures of discrimination to be dichotomized, which may have further limited the study's statistical power. The nature of the study sample, which consisted of older, primarily male Veterans with diabetes who were recruited by mail from a single Veterans Affairs facility, also constrained the generalizability of our findings. The differences found across measures in this sample, however, suggest the importance of examining these issues in a larger study with a more representative group of patients.

Although the study compared the 3 types of measures most commonly used in research on perceived discrimination in health care, it was not possible to assess the impact of every factor that could affect reports of discrimination, such as the timeframe in which patients experienced discrimination (eg, in the past 12 months vs ever) or whether the instruments are self-administered or interviewer-administered.[1] Furthermore, the measures of discrimination in this study assessed patients' perceptions of discrimination rather than verifiable instances of discrimination. It is therefore unclear whether the rates of discrimination reported by patients are over-, under-, or accurate estimates of patients' actual encounters with discrimination. However, patient perceptions of discrimination are likely to influence their reactions or behavior in a given situation,[36] regardless of whether discrimination has objectively occurred, thereby justifying the focus on perceived rather than actual discrimination.

This study also focused on only two measures of patient experiences with the healthcare system, including patient-reported problems with their care and screening behavior. There may be other aspects of patient experiences with the healthcare system that are more sensitive to patients' perceptions of discrimination that were not examined in this study. The study's cross-sectional design

also does not allow one to draw causal conclusions about the relationships observed between measures of perceived discrimination and patients' receipt of care.

These limitations notwithstanding, this study makes a notable contribution to existing literature on perceived discrimination and health care by examining how the prevalence of perceived discrimination in healthcare settings and its association with patient experiences depends on how perceived discrimination is measured. The current study suggests that measures that assess patients' perceptions of general racism in the healthcare system yield considerably higher rates of discrimination than measures that assess patients' personal experiences with such discrimination. Moreover, single-item measures of patients' personal experiences with discrimination in healthcare settings are less likely to be associated with patient-reported problems with their medical care than a multi-item measure of personal discrimination.

Based on these findings, healthcare systems should consider assessing patients' experiences with discrimination and how they relate to outcomes of interest using the multi-item measure of personal discrimination from the current study. Collecting this information as part of standard quality control activities would allow healthcare systems to monitor the extent to which their patients perceive discrimination while obtaining services. Assessing whether perceived discrimination is a problem for a given healthcare system is an important first step towards developing strategies to address it. Regularly assessing patients' perceptions of healthcare discrimination using a reliable, sensitive measure could provide valuable information to guide patient outreach or provider education activities designed, in part, to reduce perceived discrimination in health care and its negative influence on patients' perceptions of care.

ABSTRACT

Aim To assess the effects of binge drinking on students' next-day academic test-taking performance. **Design** A placebo-controlled cross-over design with randomly assigned order of conditions. Participants were randomized to either alcoholic beverage [mean = 0.12 g% breath alcohol concentration (BrAC)] or placebo on the first night and then received the other beverage a week later. The next day, participants were assessed on test-taking, neurocognitive performance and mood state. **Participants** A total of 196 college students (≥21 years) recruited from greater Boston. **Setting** The trial was conducted at the General Clinical Research Center at the Boston Medical Center. **Measurements** The Graduate Record Examinations© (GREs) and a quiz on a lecture presented the previous day measured test-taking performance; the Neurobehavioral Evaluation System (NES3) and the Psychomotor Vigilance Test (PVT) measured neurocognitive performance; and the Profile of Mood States (POMS) measured mood. **Findings** Test-taking performance was not affected on the morning after alcohol administration, but mood state and attention/reaction-time were affected. **Conclusion** Drinking to a level of 0.12 g% BrAC does not affect next-day test-taking performance, but does affect some neurocognitive measures and mood state.

Keywords Academic performance, binge drinking, intoxication, mood state, neurocognitive performance, students.

INTRODUCTION

The National Advisory Council of the National Institute on Alcohol Abuse and Alcoholism (NIAAA) defines binge drinking as attaining a blood alcohol concentration (BAC) of 0.08 g% or more, corresponding, for most adults, to five or more drinks (more than four if female) in about 2 hours [1]. In the United States, both binge drinking and heavy drinking (binge drinking at least five times in the last 30 days [1]) peak at age 21 [2].

Although college students have lower rates of daily drinking than their non-college peers, they have higher rates of binge drinking [3], with 32–44% reporting binge drinking [4]. Not surprisingly, 60–75% of college students experience at least one hangover a year, 27% report one to two hangovers and 34% report 12–51 hangovers [5].

Serious negative consequences associated with student drinking include death [6], injury, suicide, fighting, unprotected sex, rape, property damage, and legal problems; academic difficulties are, however, the most frequently reported consequence of excessive student drinking [7]. Academic problems resulting from heavy drinking can occur through several mechanisms: hangover results in missing morning classes; drinking uses time otherwise spent studying; drinking impedes next-day learning in class or, when studying, by affecting memory retention [8]; and personal and interpersonal problems resulting from heavy drinking may make it difficult to focus on school work [9,10].

A number of surveys have shown relationships between college students' drinking and academic difficulties [7,9–15]. Other survey studies, however, have found that the relationship of drinking and academic performance disappeared after controlling for pre-college differences in academic performance [16,17].

Little experimental work has been published on the effects of student drinking on academic performance. There is, however, a body of experimental research on the effects of intoxication on next-day performance ('residual effects of alcohol'), as measured by neurocognitive laboratory tests or occupational training simulators. Because academic performance is the occupation of students, this research is relevant to the question of whether intoxication in the evening impairs students' next-day test-taking ability, when blood alcohol concentration (BAC) has returned to zero. Several studies found residual alcohol effects on simulated occupational tasks [18–29]. However, in other experimental studies residual effects of intoxication were not found for occupational tasks [30–34]. Some investigators have found residual alcohol effects on various neurocognitive tests [35–44], but other studies found no impairment on tests of manual dexterity or neurocognitive performance [39,45–49].

Inconsistencies among study findings may be the result of factors such as the type of performance measured the amount of alcohol administered, the age and alcohol tolerance of participants and the length of time from drinking to testing [49].

We conducted a randomized cross-over trial to examine the extent to which alcohol intoxication affects college students' next-day academic performance at zero BAC. Neurocognitive tasks relevant to academic performance were also assessed. We hypothesized that drinking to about 0.12 g% BrAC would not affect next-day performance on academic tests requiring long-term memory (e.g. standardized academic achievement tests), but would affect performance on tests of recently learned material and on neurocognitive tests requiring sustained attention and speed. To our knowledge, this is the first study to explore experimentally the relationship between binge drinking and academic performance.

METHODS

Participants

Participants were university students recruited from greater Boston, Massachusetts, who were between 21 and 24 years of age and met the following criteria: (1) no drinking problems (score <5 on the Short Michigan Alcohol Screening Test (SMAST)) [50] and no history of treatment or counseling for chronic alcohol problems; (2) consumption of more than five drinks (more than four if female) on a single occasion at least once in the 30 days prior to screening; (3) no health problems or current medication use contraindicated for alcohol; (4) no diagnosis of sleep disorders or use of sleeping medications; (5) fluent English; (6) recently graduated from, or currently attending, an institution of higher learning; (7) not working night shifts; (8) not a daily smoker; (9) not traveled across two or more time zones in the prior month; and (10) if female, negative pregnancy test and not nursing. Female participants' menstrual cycle phase was documented, but not a factor in scheduling their experimental sessions [51–53]. For safety reasons, regular tobacco users were excluded because participants were not allowed to leave the laboratory to smoke. This exclusion also avoided possible confounding due to nicotine withdrawal during the study sessions. Before beverage administration, participants who reported consuming alcohol, caffeine, prescription or over-the-counter drugs within the prior 24 hours, or who had had a positive breath alcohol test (BrAC), were rescheduled (see Table 1 for participant characteristics).

No information about individuals' participation was provided to institutions attended by volunteers. Participants were paid $300 upon completion of the study, or a pro rata amount if their participation ended prior to completing the study. The Institutional Review Boards at Boston Medical Center and Brown University approved this study.

Study design

We used a placebo-controlled, double-blind, within-subjects, repeated-measures design to study the residual effects of alcohol, with participants serving as their own controls. Participants took part in the study over 4 days: an evening and the next morning, followed a week later by the same schedule. All participants received two beverages (alcohol and placebo) in counterbalanced order (alcohol week 1 versus alcohol week 2).

Study procedures

Recruitment and screening

Participants were recruited by advertisements in local newspapers and websites (e.g. Facebook and Craig's List). Interested individuals were first screened by telephone and then in person, including a physician examination (after informed consent). To reduce potential confounding by sleep pattern variations, participants were instructed to keep a sleep diary, comply with a minimum regimen of 8 hours sleep (retiring to bed no later than midnight and awaking no later than 8 a.m.), with confirmation call-ins to a time-stamped answering machine each evening and morning for the 3 nights prior to

Table 1 Participant characteristics.

Total (n = 193)

Table 2 Schedule of study procedures.

Orientation/consent 10 a.m.–12 p.m.	Orientation. Consent. Enrollment questionnaires. Medical screening by physician
Evening sessions 4 p.m.–5 p.m.	Dinner, screened for adherence to study protocol. BrAC tested. Pregnancy tests administered to females
5 p.m–6 p.m	Family Tree questionnaire administered. Practice tests to familiarize participants with GRE and PVT
6 p.m–7.30 p.m	Video lecture based on next-day's quiz. Participants study lecture notes for 1 hour
7.30 p.m–8.45 p.m	Practice NES3 test
8.45 p.m–11 p.m	Beverage administration
	Repeated BrAC tests
11 p.m	Lights out
	Observed throughout night by EMT
Morning sessions 7 a.m.–7.30 a.m.	Subjects awakened. Morning questionnaires
7.30 a.m.–8 a.m.	Breakfast
8 a.m.–11 a.m.	BrAC tests
	POMS questionnaire, quiz on video lecture, GRE, NES3, PVT, self-rated performance questionnaire
12.30 p.m.	Subjects dismissed

BrAC: breath alcohol concentration; GRE: Graduate Record Examinations; PVT: Psychomotor Vigilance Test; EMT: emergency medical technician; POMS: Profile of Mood States; NES3: Neurobehavioral Evaluation System.

experimental sessions. Participants were told not to nap and, for 24 hours prior to their experimental sessions, to abstain from alcohol, medications not already approved by the study physician, sleep aids, recreational drugs and caffeine. To familiarize participants with the standard academic achievement tests, they were required to read and complete a practice booklet issued by the testing service.

One week after screening and enrollment, participants returned in groups of three to five for the first overnight experimental session. They reported at 4 p.m.; car keys were collected from participants who drove to the study site; compliance with pre-laboratory regimens was checked; and, following a standardized dinner, participants were screened for zero breath alcohol (BrAC) and negative pregnancy test (if female). To prepare for a quiz the following morning, at 6 p.m. participants viewed randomly one of two 30-minute video lectures on a public health topic and had an hour to study an accompanying textbook chapter. They viewed the other video lecture the following week. To reduce potential learning effects, participants then practised the computer-based neurocognitive test prior to alcohol administration (Table 2).

Randomization procedures

For the first experimental session, participants received a study ID number and were assigned randomly to beverage (placebo or alcohol); they received the other beverage the following week. For safety reasons, no more than three of the five participants received alcohol on any given night. To maintain double blinding, the individual who prepared beverages and conducted breath tests had no other contact with participants; all other study assistants working directly with participants were unaware of participants' beverage assignments. Participants were told there was a 50–50 chance of receiving alcohol the first night and they were instructed not to inspect or taste each others' drinks or discuss the beverage they received.

Beverage administration procedures

Alcoholic beverage administration targeted 0.12 g% BrAC, adjusting the alcohol per kilogram of body weight for sex (1.068 g/kg body weight for men and 0.915 g/kg for women), as per Friel *et al.* [54]. Males received a mean of 1609.07 (SD: 288.55) ml of beverage (range: 1052.20–2308.00), or the equivalent of 6.75 12-oz cans of regular beer (at 4.82% alcohol by volume); females received a mean of 1122.09 (SD: 178.48) ml of beverage (range: 683.3–1606.60), or the equivalent of 4.72 12-oz cans of regular beer.

Beer controlled with non-alcoholic beer has been shown to be one of the two most effective beverage combinations for disguising placebo [55]. Beer was chosen because most young men and women find it palatable. Elephant Beer™ (Carlsberg, Copenhagen V, Denmark) with 7.2% alcohol and Clausthaler™ non-alcoholic beer (Radeberger Gruppe KG, Frankfurt am Main, Germany) were the beverages. High alcohol beer reduces the volume required to achieve the targeted BrAC. Beverage administration began 4 hours after eating and went from 8.45 p.m. to 9.45 p.m. (up to 10.00 p.m. as needed). Participants were told the total number of cups of beverage they were to consume in an hour. They were asked to drink the first two cups (330–340 ml) quickly and to pace the rest over the time allowed. Participants were breath tested 15 minutes after completing their beverage. If participants randomized to alcohol did not reach 0.12 g% BrAC, the ratio of obtained versus targeted BrAC was used to estimate the additional amount of beer to be administered. To maintain blinding, some of the placebo participants were given a matched extra dose of non-alcoholic beer. After participants finished drinking, they were breath tested every 15 minutes prior to bedtime, with the last BrAC measurement recorded 5 minutes before lights out.

Following beverage administration and a 30-minute absorption period, participants completed questionnaires, received snacks and prepared for bed. Participants had an 8-hour opportunity to sleep (no lights or television and cellphones turned off) between 11 p.m. and 7 a.m. in an individual bedroom with bathroom. They were monitored throughout the night for safety by an emergency medical technician (EMT).

At 7 a.m. participants were awakened, breath-tested and served breakfast (no caffeine). They then completed a questionnaire assessing mood state and, at 8 a.m., started testing. Sleep inertia during the first 30 minutes after waking is likely to impair performance [56]; allowing an hour before performance testing avoids this. To avoid confounding by alcohol remaining in the blood, performance testing was delayed, if necessary, until BrAC reached <0.00 g%. Participants were dismissed from this session at approximately 11.30 a.m. They were given an additional mood assessment questionnaire in a self-addressed, postage-paid return envelope and asked to complete it at 5 p.m. that day and mail it back to the study coordinator. One week later they returned for the second experimental session, identical except for beverage, video lecture and the standardized test version.

Individual difference measures

Recent drinking practice was estimated using a two-item alcohol use questionnaire: (i) 'Considering all your drinking times in the past 30 days, about how often did you have any beer, wine or liquor?', Likert-rated from 1 'once a day' to 7, 'did not drink', with each point anchored; and (ii) 'In the past 30 days, on a typical day that you drank, about how much did you have to drink in one day?', rated from 1 to 8, with choices of one to seven drinks and 'eight or more drinks'. (One drink was defined as 12 ounces of beer or wine cooler, 4 oz of wine or 1 oz of liquor.) Average daily volume (ADV) was calculated as the product of these. We also collected information on family history of drinking problems using the Family History Tree questionnaire developed by Mann *et al.* [57] and on age of drinking onset. These data are presented in Table 1, but were not included in th analyses.

Dependent measures of objective effects

Overview

Two tests of academic performance were used. Short-term recall was assessed by a quiz on a lecture delivered prior to beverage administration. Versions of the Graduate Record Examinations© (GREs) (Educational Testing Service, Princeton, NJ) were used to measure verbal and quantitative skills that have been acquired over a long period of time. Two methods of assessing neurocognitive performance were used: the Neurobehavioral Evaluation System (NES3), a neurocognitive battery; and the Psychomotor Vigilance Task (PVT), a measure of sustained attention/reaction-time.

Lecture quiz

First we administered a 30-question quiz based on the videotaped lecture and associated reading presented the day before. Two lectures and readings were used in counterbalanced order. The two lectures were based on chapters from a public health text, *Introduction to Public Health* [58]: Chapter 15, 'Tobacco: Public Health Threat Number One' and Chapter 16, 'Diet and Activity: Public Health Threat Number Two'. Quiz questions were derived from the teacher's guide. The quizzes were pilot-tested previously with 50 college students to ensure a normal distribution of scores.

GREs

After the quiz, we administered two parts of the GRE's General Test: a 30-minute verbal section (ability to discern, comprehend and analyze words, sentences and written passages) and a 45-minute quantitative section (basic mathematical skills, elementary mathematical concepts and ability to reason and to solve quantitative problems) in four broad content areas: arithmetic, algebra, geometry and data analysis [59]. Two different, but comparable, computer-administered and computer-scored tests were used, with order randomized by individual.

For assessments, participants had their own carrels and were monitored to ensure that they did not communicate. To enhance motivation, participants who scored in the top 50% of national averages on both sections received up to four complimentary movie tickets (two per study week). Participants were not informed of their scores or awarded tickets until they had completed the study.

NES3

The NES3 is a computer-assisted battery of cognitive tests validated for cognitive impairment [60]. As primary measures, we selected nine tests requiring speed, sustained attention or sustained attention/reaction-time, tests most apt to be affected the day after intoxication [61]. For manual dexterity tests that tested each hand individually, we used the test for the preferred hand; for tests that had forward and backward versions, we used the more difficult backward versions. The following tests assessed speed: Finger Tapping Test, preferred hand (FTT-P) (assesses manual motor speed and dexterity); and Sequences Test A, latency (ST-A-L); Digit-Symbol Test, latency (DST-L); Pattern Memory Test, latency (PMT-L) (all assessing speed of cognitive processing). The following tests assessed sustained attention: Auditory Digit Span Test, backwards (ADST-B); Adaptive Paced Auditory Serial Addition Test, number correct (APASAT-C); Visual Span Test, backward (VST-B); Pattern Memory Test, number correct (PMT-C). The Continuous Performance Test (CPT) measures both sustained attention and reaction-time.

PVT

As an additional test of sustained attention/reaction-time, we used the Psychomotor Vigilance Task [62] (Ambulatory Monitoring, Inc, Ardsley, NY, USA). On this hand-held unit participants press a button with their preferred hand as quickly as possible in response to numbers scrolling on an LCD screen, with a random 3–7-second interstimulus interval. Response time is counted in milliseconds. A solid-state storage unit collects data for downloading to a PC. The recorded outcome variable is median reaction-time.

Exploratory measures

As exploratory measures, we administered an additional nine NES-3 tests: FTT (non-preferred hand); ST (backward); ADST-F (forward); APASAT (stimulus response rate); VST (forward); VT (Vocabulary Test, a measure of general verbal ability); LOT (Line Orientation Test, number correct and latency, both measures of attention to visiospatial information); and LL (List Learning, a measure of quantitative aspects of several components of verbal learning and memory).

Dependent measures of subjective effects

Mood

Because the residual effects of alcohol on mood state might be salient to college students, we also measured next-day mood in both the morning and the afternoon. To assess mood, we used the Profile of Mood State Brief Form (POMS) [63], a validated self-administered questionnaire with 30 adjectives [each rated on a five-point Likert scale, from 0 (not at all) to 4 (extremely)]. These comprise six domains: fatigue–inertia (F); tension–anxiety (T); depression–dejection (D); anger–hostility (A); confusion–bewilderment (C); and vigor–activity (V). Only total mood disturbance score [(F+ T+D+A +C)-V] was scored for analyses because we had no hypotheses about individual mood domains.

Self-rated performance

To assess participants' perceptions of their performance on the morning quiz and GRE tests, they completed ratings of subjective performance, with every point anchored: 'Overall, how would you rate your performance on the test that you just completed?'. Response categories were: 1 = 'very poor'; 2 = 'poor'; 3 = 'good'; 4 = 'very good'; and 5 = 'excellent'.

Hangover

The Acute Hangover Scale (AHS) [64], developed based on empirical hangover data [36,65,66], consists of eight validated symptoms plus 'hangover' rated from 0, 'none' to 7, 'incapacitating' on anchored Likert-type scales. The nine items form a reliable and valid scale, scored using the mean.

Alcohol Administration Manipulation checks

An AlcoSensor-4 (Intoximeters, Inc., St Louis, MO, USA) was used for breath testing. Following beverage adminis-

tration, participants were asked to estimate their blood alcohol concentration on a scale ranging from 0 to 0.15 g%.

Statistical power

With a target enrollment of 200 participants, our study had 99% power of detecting the anticipated medium-sized effect of alcohol on next-day academic test performance ($d = 0.52$), a value derived from our previous studies. For comparison of the effects of alcohol versus placebo in females versus males, the study had 80% power of detecting a difference.

Data analysis approach

All measures were examined for normality and outliers, using the criteria set forth by Hoaglin *et al.* [67]. Outliers were recoded following recommendations by Tabachnick & Fidell [68]. Among the primary outcomes measures, there was one outlier for both the GRE verbal and GRE quantitative scores and five outliers for the quiz score.

Differences in outcomes following consumption of alcohol versus placebo were tested through mixed-effects regression models for repeated-measures data [69]. Our primary interest was in differences by experimental condition (alcohol versus placebo, a within-subjects factor). We controlled for randomly assigned order of beverage administration by including a session variable (indicating a first or second study evening, a within-subject factor) and also controlled for gender (a between-subject factor). Differences in alcohol effects for males and females were tested through the interaction between experimental condition and gender, and all other two-way and three-way interactions were also included in the model. Where significant interactions were found between experimental condition and gender, within-gender alcohol effects were tested through model contrasts.

Comparisonwise *P*-values are reported. When considering multiple testing issues, we grouped study outcomes as measures of: (i) academic performance (one quiz and two GRE scores); (ii) 10 primary neurocognitive performance measures (including the PVT); (iii) nine exploratory neurocognitive performance measures; (iv) mood state measures (a.m. and p.m. assessments); and (v) self-reported performance (one for the quiz and one for the two GRE scores). Analyses are interpreted to indicate an alcohol effect if either the main effect of beverage, or the interaction between experimental condition and gender, are significant. To account formally for multiple comparisons using a Bonferroni adjustment, comparisonwise *P*-values of 0.008 (academics) 0.0025 (primary neurocognitive) 0.0028 (exploratory neurocognitive) and 0.0125 (mood state and self-rated performance) would be required. Because Bonferroni is known to overcorrect, we used an $\alpha = 0.005$ throughout our analyses.

Although formal analyses were based on mixed effects regression models, rather than simple differences by beverage condition, difference scores and their standard deviations are presented for ease of interpretation. Differences in performance are also described as standardized effect sizes, calculated as the difference in mean performance under alcohol and placebo divided by the standard deviation of the difference scores (Cohen's *d*) [70]. Cohen [70] considers effect sizes (*d*) of 0.2, 0.5 and 0.8 as small, moderate and large, respectively.

RESULTS

Participant enrollment

Four hundred and thirteen participants were screened; 364 (88%) were eligible. Of these, 239 (65%) appeared for their scheduled experimental session, and of these 196 (82%) completed the study. Three of the 196 participants who completed the study were excluded from analyses because their maximum breath alcohol measures did not reach the minimum BrAC level (.09 g%). Seventy per cent of participants reported some hangover on the morning following alcohol administration. The mean AHS score was significantly higher under alcohol condition, relative to placebo condition (Table 1).

Objective performance outcomes

The morning after beverage administration, neither the quiz scores on the prior day's lecture nor the two GRE scores differed by beverage condition; effect sizes were close to zero (<0.06). None of the academic performance outcomes showed significant beverage–order or gender–beverage interactions (Table 3).

Of the nine primary NES3 measures, VST-B was significantly different by beverage. PMT-C showed significant gender by beverage interaction ($P = 0.032$); females performed worse (borderline significant) under alcohol condition, relative to placebo, but for males there was no difference. No interactions of beverage with order were significant. The morning after beverage administration, median attention/reaction-time scores, as measured by the PVT, were significantly longer under the alcohol condition, relative to the placebo condition (Table 4). Of the exploratory neurocognitive tests, none was significantly different by beverage condition at our α level.

Dependent measures of subjective effects

Mood

The day after beverage administration, the mean total mood disturbance score was significantly worse under

Table 3 Academic performance outcomes by experimental condition.

	Measure	*n*	*Alcohol*	*Placebo*	*Difference (SD)*	*Effect Size (d)*	*P-value*
GRE Raw Scores	GRE verbal	193	495.39 (87.79)	497.62 (86.43)	−2.23 (61.02)	0.04	NS
	GRE quantitative	193	615.75 (98.92)	612.38 (94.64)	+3.37 (62.57)	0.05	NS
Quiz no. correct		193	24.70 (2.26)	24.59 (2.48)	+0.11 (2.65)	0.04	NS

All *P*-values are based on mixed-effects models controlling for gender and session number. The interaction of gender and dose was tested in each model and found to be non-significant. GRE: Graduate Record Examinations; NS: not significant; SD: standard deviation.

Table 4 Neurobehavioral Evaluation System-3 and PVT outcomes by beverage condition.

NES3 outcomes	*n*	*Alcohol*	*Placebo*	*Difference (SD)*	*Effect size (d)*	*P-value*
Tests requiring speed						
Finger Tapping Test: mean number of taps, preferred hand (FTT-P)	188	59.68 (7.11)	60.12 (7.24)	−0.44 (4.73)	0.09	NS
Sequences Test (ST-A-L)						
Sequence A: latency (ms)[a]	188	14.35 (2.66)	14.48 (3.02)	−0.13 (2.59)	0.05	NS

All *P*-values are based on mixed-effects models controlling for gender and session number. The interaction of gender and dose was tested in each model. If interaction found to be significant, results were presented by gender. [a]Maximum time permitted to complete sequence A: 60 seconds; sequence B: 120 seconds. [b]Maximum time permitted to complete digit/symbol test: 180 seconds. [c]Valid range of span scores for the forward condition: 3–9; backward condition: 2–8. NS: not significant; SD: standard deviation.

alcohol condition, relative to placebo condition, in both the morning and the afternoon (Table 5).

Self-rated performance

Participants tended to rate their performance on the academic tests as worse under alcohol condition, compared to placebo condition. These differences were significant for self-rated performance on the quiz and GREs (Table 5). Participants' mean estimates of their BrACs following beverage administration were 0.006 g% and 0.098 g% under placebo and alcohol conditions, respectively.

DISCUSSION

College students' test-taking performance was not affected significantly on the morning after intoxication. Significant decrements in some laboratory tests of neu-

Table 5 Subjective measures by beverage condition.

Profile of Mood States (POMS) (higher scores reflect more negative mood state)

Measure	*n*	*Alcohol*	*Placebo*	*Difference (SD)*	*Effect Size (d)*	*P-value*
Morning: total mood disturbance score	193	6.71 (9.41)	1.90 (7.20)	+4.81 (7.95)	0.60	0.000

Self-rated performance						
Quiz performance	185	3.43 (0.77)	3.61 (0.79)	−0.18 (0.95)	0.19	0.005
GRE performance	188	2.48 (0.69)	2.65 (0.68)	−0.18 (0.76)	0.23	0.002

All *P*-values are based on mixed-effects models controlling for gender and session number. The interaction of gender and dose was tested in each model and found to be non-significant. GRE: Graduate Record Examinations; SD: standard deviation.

rocognitive function were observed on the morning after alcohol. The NES3 was administered to increase understanding of academic performance effects, should they be found. Under placebo condition, participants' NES3 performance scores were normative and most tests showed no alcohol effects. The pattern of residual alcohol effects we found clustered around visuospatial, motor function and attention/reaction-time deficits. These effects may not be central to performance on multiple choice tests based on recall and recognition, but may affect other types of academic performance (unmeasured by our study), such as essay-writing and problem-solving requiring higher-order cognitive skills, as well as safety-related performance such as ability to process information and respond quickly to unexpected events when driving or operating machinery. Mood states, both in the morning and afternoon, were significantly worse on the day after alcohol. Similarly, participants tended to rate their test-taking performance as significantly worse on the day after alcohol relative to placebo, even though no impairment in academic performance was actually observed.

We do not believe our outcomes were artifacts of participant motivation. The GRE scores were comparable to recent norms, with about 60% of participants scoring in the top 50th percentile of the national distribution. Similarly, the mean quiz scores were about 83%, high enough to indicate participant motivation, but low enough to suggest that the quizzes were not too easy (i.e. no ceiling effect). We also do not believe that participant blinding, which can be problematic at high alcohol doses, affected results because the bias would be away from the null hypothesis and we did not find differences on the primary outcome variables (academic test-taking performance). Although our procedures called for abstinence from recreational drugs 24 hours prior to experimental sessions, we used only self-report to check drug-use compliance. Moreover, we did not screen for, or document, drug-use history. Thus, participants' undisclosed drug use prior to experimental sessions could have. If so, there was no consistent effect, as some outcomes were affected significantly on the day after alcohol and others were not.

Although the morning and afternoon mood scores were significantly worse following the alcohol condition, these results may have been driven in part by fatigue resulting from alcohol's sleep-disturbing effects [36,71–73].

While our findings are discordant with results of survey studies that find associations between alcohol use and academic problems, these studies are potentially confounded in that a third factor (e.g. personality) may cause both excessive drinking and academic difficulties and causal order is unknown (i.e. academic difficulties could lead to excessive drinking). Our findings are consistent, however, with a study on the effects of intoxication on next-day occupational performance [33]. In that study, merchant marine cadets' performance on a diesel engine simulator was not affected significantly, relative to placebo, on the morning after intoxication (mean BrAC.115 g%), but self-rated performance was significantly worse. Similarly, another laboratory study found measures of combined attention and reaction-time to be the only neurocognitive measures affected on the morning after 0.11 g% BrAC [74].

We do not conclude, however, that excessive drinking is not a risk factor for academic problems. It is possible that a higher alcohol dose would have affected next-day academic test scores. Moreover, test-taking is only one factor in academic success. Study habits, motivation and class attendance also contribute to academic performance; each of these could be affected by intoxication. When drinking leads to staying up too late, sleeping in or getting too little sleep, it can disrupt next-morning attendance or focus. Moreover, we did not measure whether learning skills were impaired on the day after intoxication. The neurocognitive measures that were affected negatively on the day after alcohol could be related to the ability to process new information effectively. By neces-

sity, all participants were ≥21 years of age and thus were college juniors, seniors or recent graduates. It is possible that over the course of their education students develop skills that allow them to perform well on multiple-choice tests despite neurocognitive impairment resulting from intoxication the previous night. Accordingly, had our participants been freshmen or sophomores, they might have performed worse under alcohol, relative to placebo, condition. We excluded volunteers who had not engaged in recent binge drinking or who were at risk for alcohol dependence. It is possible that these excluded drinkers might be more susceptible to alcohol-related problems with test-taking. Nonetheless, in surveys almost half of college students report binge drinking and presumably most of these have not developed alcohol dependence. Thus, we believe that our findings are relevant to a substantial proportion of college students.

EDITORIAL

Therapeutic Potential of Oral Factor Xa Inhibitors

Elaine M. Hylek, M.D., M.P.H.

Venous thromboembolism is the third leading cause of cardiovascular death, after myocardial infarction and stroke.[1] Total hip or knee arthroplasty is the procedure with the highest risk of venous thromboembolism.[2] In this issue of the *Journal*, two studies affirm and extend the efficacy and safety of the novel oral factor Xa inhibitors, rivaroxaban and apixaban, in the management of venous thromboembolic disease.[3,4] In the Acute DVT Study,[3] rivaroxaban (at a dose of 15 mg twice daily for 3 weeks, followed by 20 mg once daily) was compared with enoxaparin followed by warfarin or acenocoumarol, for 3, 6, or 12 months, in patients with acute, symptomatic deep-vein thrombosis. Rivaroxaban had noninferior efficacy with respect to recurrent venous thromboembolism, with similar rates of hemorrhage. The Continued Treatment Study[3] confirmed the persistent risk of recurrent venous thromboembolism after initial treatment, as shown by Ridker and colleagues,[5] and lends further support to extending the duration of anticoagulant therapy, particularly given the low rates of major bleeding with rivaroxaban (0.7%). Lassen and colleagues studied thromboprophylactic regimens in patients undergoing total hip replacement.[4] Participants were randomly assigned to apixaban, at a dose of 2.5 mg orally twice daily, or enoxaparin, at a dose of 40 mg subcutaneously every 24 hours, with the treatments initiated perioperatively and continued for 35 days after surgery. Apixaban was associated with lower rates of venous thromboembolism without an increase in bleeding complications.

The oral factor Xa inhibitors represent a major advance in the prevention and treatment of thromboembolic disease. Factor Xa is strategically positioned at the juncture of the intrinsic and extrinsic coagulation pathways proximal to thrombin. The potential impact of these oral, highly specific, fixed-dose drugs that do not require routine monitoring will no doubt be substantial. Currently, millions of people worldwide are relegated to receiving no therapy or therapy that has been proven to be ineffective, because they lack access to the monitoring expertise needed to safely and effectively administer warfarin. It is conceivable that the oral factor Xa inhibitors, as compared with warfarin, will prove to be safer in clinical practice because they are administered in fixed doses, do not interfere with diet, and have fewer interactions with other drugs. Given the nine different tablet strengths of warfarin, transitions in care settings and fluctuations in health status invariably create opportunities for unintended harm. A growing appreciation of the hazards of warfarin therapy prompted the Food and Drug Administration to issue a black-box warning for warfarin in October 2006.[6] The factor Xa inhibitors that are most advanced in clinical development are rivaroxaban, apixaban, and edoxaban. (Other factor Xa inhibitors in development include betrixaban, YM150, and TAK-442.) Unlike the case with warfarin, drug elimination in the case of the factor Xa inhibitors involves multiple pathways. The degree of renal clearance is 66% in the case of rivaroxaban, 25% in the case of apixaban, and 35% in the case of edoxaban. As compared with warfarin's half-life of 20 to 60 hours, the respective half-lives of these agents are 7 to 11 hours, 12 hours, and 9 to 11 hours. As shown in the study by the EINSTEIN investigators, the rapid onset of action obviates the need for heparin in the acute management of venous thrombosis. The rapid onset of action also has impli-

cations for the appropriate timing of the initiation of the drug after the procedure, given the need for wound hemostasis. The shorter half-life of these agents may improve their overall safety profile but, conversely, will also result in the drugs' providing less protection if doses are missed. All these drugs are metabolized to different degrees by cytochrome P-450 3A4 (CYP3A4) and are substrates for P-glycoprotein. Therefore, the concomitant use of drugs that inhibit both pathways, such as azole antifungal agents or protease inhibitors, is contraindicated.[7]

Each of the factor Xa inhibitors is being evaluated in at least one large-scale phase 3 trial of stroke prevention in patients with atrial fibrillation. Positive results from the completed Rivaroxaban Once-Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF; ClinicalTrials.gov number, NCT00403767) were recently presented at the annual scientific sessions of the American Heart Association.[8] The randomized trial of Apixaban versus Acetylsalicylic Acid to Prevent Stroke in Atrial Fibrillation Patients Who Have Failed or Are Unsuitable for Vitamin K Antagonist Treatment (AVERROES, NCT00496769) was stopped early because the efficacy of apixaban had been shown.[9] The results of ongoing trials involving patients with atrial fibrillation, in which warfarin is the active comparator, are expected in 2011: the Apixaban for the Prevention of Stroke in Subjects With Atrial Fibrillation study (ARISTOTLE, NCT00412984), in which apixaban is being tested with a dose of 5 mg twice daily, and the Global Study to Assess the Safety and Effectiveness of DU-176b versus Standard Practice of Dosing With Warfarin in Patients With Atrial Fibrillation (EngageAFTIMI48, NCT00781391), in which two doses of edoxaban, 30 mg and 60 mg, each administered once daily, are being compared with warfarin.

Translating the efficacy and safety that have been shown in clinical trials to real-world practice is often a challenge because, as compared with patients in real-world practices, participants in trials are usually younger, have less medically complex illnesses, are more likely to be adherent, and have been specifically selected on the basis of having a lower risk of bleeding. Concomitant antiplatelet therapy is either discouraged or considered to be an exclusion criterion. The mean age of participants undergoing hip arthroplasty in the study by Lassen et al. was 60 years, and approximately 89% of the participants had normal renal function. Similarly, the mean age of participants with acute symptomatic deep-vein thrombosis in the study by the EINSTEIN investigators was 56 years, and 92% had a creatinine clearance of 50 ml per minute or more. Because both the risk of thrombosis and the risk of hemorrhage increase substantially with age and with burden of chronic disease, the effectiveness of the novel agents in real-world practice will need to be closely monitored, particularly among older adults with renal impairment. The critical role of baseline risk and the additive hazards of combination antiplatelet therapy and bleeding were highlighted by the recent early termination, because of increased bleeding with apixaban, of the Apixaban for Prevention of Acute Ischemic Events 2 trial (APPRAISE-2, NCT00831441), in which patients with a recent acute coronary syndrome who were receiving single or dual antiplatelet therapy were randomly assigned to apixaban or placebo.[10]

Alternatives to warfarin have been long awaited. The oral factor Xa inhibitors show great promise. The reversibility of the drugs' effects and the ability to measure the anticoagulant effect in specific situations will continue to be highly desirable features and will help to allay physicians' concerns. If these novel, breakthrough, oral anticoagulant drugs prove to be effective across the broad spectrum of patients in routine care and are conscientiously priced, the worldwide impact will be huge.

Internal medicine residency training for unhealthy alcohol and other drug use: recommendations for curriculum design

Angela H Jackson[1,2,3*], Daniel P Alford[1,2,3], Catherine E Dubé[3], Richard Saitz[1,2,3,4,5]

Abstract

Background: Unhealthy substance use is the spectrum from use that risks harm, to use associated with problems, to the diagnosable conditions of substance abuse and dependence, often referred to as substance abuse disorders. Despite the prevalence and impact of unhealthy substance use, medical education in this area remains lacking, not providing physicians with the necessary expertise to effectively address one of the most common and costly health conditions. Medical educators have begun to address the need for physician training in unhealthy substance use, and formal curricula have been developed and evaluated, though broad integration into busy residency curricula remains a challenge.

Discussion: We review the development of unhealthy substance use related competencies, and describe a curriculum in unhealthy substance use that integrates these competencies into internal medicine resident physician training. We outline strategies to facilitate adoption of such curricula by the residency programs. This paper provides an outline for the actual implementation of the curriculum within the structure of a training program, with examples using common teaching venues. We describe and link the content to the core competencies mandated by the Accreditation Council for Graduate Medical Education, the formal accrediting body for residency training programs in the United States. Specific topics are recommended, with suggestions on how to integrate such teaching into existing internal medicine residency training program curricula.

Summary: Given the burden of disease and effective interventions available that can be delivered by internal medicine physicians, teaching about unhealthy substance use must be incorporated into internal medicine residency training, and can be done within existing teaching venues.

Background

Unhealthy substance use (SU) is the spectrum from use that risks harm, to use associated with consequences or problems, to the diagnosable conditions substance abuse and dependence often referred to as substance use disorders [1]. Unhealthy SU is a major public health problem in the United States. Many physician interventions (e.g., brief counseling, pharmacotherapy) have proven efficacy. Internal medicine physicians are among the most commonly visited physicians in the US [2]. Yet internal medicine physician training in substance use-related preventive services, diagnosis, treatment, and chronic disease management has been inadequate. This inadequacy leaves patients and the health system without sufficient expertise to address one of the most common and costly health conditions.

Among people 12 and older, there were 20.4 million current users of illicit drugs, 125 million users of alcohol and 72.9 million users of tobacco products, according to the 2006 National Survey on Drug Use andHealth [3]. Of those, 22.6 million alcohol and illicit drug users (9.2% of the population 12 and older) met criteria for substance abuse or dependence. Drug abuse was responsible in 2002 for approximately 26,000 deaths and cost society $180.8 billion [4]. Alcohol use cost society similarly and was responsible for 85,000 deaths [5,6]. Comparatively, coronary heart disease, the leading cause of death in the United States for the past 80 years and a major cause of disability, cost an estimated $151.6 billion in 2007 [7,8].

[1]Residency Training Program in Internal Medicine, Boston University School of Medicine, Boston, MA, USA

Education about unhealthy SU is inadequate in medical training [9]. This deficiency persists despite the contribution of SU to disability and premature death, [10] and its prevalence and societal costs [6,11,12]. Screening and management of SU merits a position in medical curricula that reflects its importance and characteristics as a mainstream medical condition [13-17]. Although screening and brief intervention for unhealthy alcohol use is among the most effective and cost-effective preventive services delivered by physicians, its actual delivery is the lowest among comparably ranked services (most often not delivered to those eligible) [18-20].

Many physicians fail to address SU conditions due to discomfort with SU-related patient discussions, [21] deficient knowledge and clinical skills, [22,23] and negative attitudes, [24,25] all resulting in barriers to providing optimal medical care for their patients and reducing the consequences that affect their families and society [26]. The diagnosis of substance abuse or dependence is often missed by physicians and even when the diagnosis is made, many physicians do not know how to respond appropriately using brief intervention or developing an organized plan for referral or treatment and follow-up. While there are many reasons physicians are not performing screening and brief intervention, such as stigma or lack of skill, there may be few local referral resources for patients with SU, once identified. At minimum, the basic clinical skills of screening, assessment, diagnosis, negotiating treatment and ongoing monitoring in SU must be addressed in physician training. These are skills that physicians already routinely employ in the prevention and management of other chronic conditions [27]. SU conditions can be serious and chronic, and risk factors and earlier stage unhealthy use can be recognized, highlighting the need for physicians to embrace their role in preventing, identifying and managing patients with unhealthy SU [28].

Discussion

Physician education

Medical educators have started addressing the need for physician training in unhealthy SU screening, assessment, and management [29-34]. Formal curricula on these subjects have been developed [35,36] and evaluated [37,38] and recommendations for the medical care of addicted patients have been published [13,39,40] Nonetheless, dissemination of up-to-date addiction research and clinical recommendations into physician practice and residency curricula remains a significant challenge [41,42].

Unhealthy substance use education aimed at improving residents' attitudes and clinical practice behaviors has been shown to be effective [43,44]. When residents feel responsible for caring for patients with SU conditions (i.e., "role responsibility"), they develop greater confidence in their ability to screen and refer patients [45]. Wider implementation of known effective clinical practices for addressing SU conditions requires creative strategies to develop a workforce that sees the management of SU conditions as part of its overall mission, is knowledgeable about state-of-the-art approaches to patient management, and is motivated to implement such practices in a range of clinical settings [9,38,46,47]. As noted in the Institute of Medicine Report *Improving the Quality of Health Care for Mental and Substance-Use Conditions*, [26] medical educators have not adequately addressed past recommendations to update training of medical professionals, leaving trainees ill equipped in their ability to care for patients with SU conditions.

The need to implement SU curricula is also supported by the existence of several national initiatives regarding SU care in medical settings–the Joint Commission, which is considering SU-related performance measures for hospitals, a performance measure for alcohol screening included by the Center for Medicare and Medicaid Services in 2009, and national Screening Brief Intervention Referral and Treatment programs supported by federal grants to a number of states in the US [48-50].

Strategies for educational change

There are several strategies that may be employed to foster the adoption of core addiction medicine competencies into mainstream of graduate medical education curricula, each with strengths and limitations. Examples include:

1) **Modifying residency training to support the development of core skills and behaviors** by the program graduates, though residency programs may be reluctant to add new training initiatives to their busy schedules;

2) **Disseminating models for understanding SU conditions that are already familiar to physicians**, for example, highlighting that SU conditions are often chronic diseases with periods of remission and relapse for many patients; [51]

3) **Addressing attitudes towards unhealthy SU and patients with these conditions**, recognizing that attitudinal issues play a large role in physicians' willingness to address SU conditions in their patients. For example, clinical guidelines and protocols may be more readily accepted if championed by opinion leaders and role models who are trusted sources of clinical information (often requiring them to be from the same specialty and profession), effective presenters of new information about changes in clinical practice and viewed as mentors by colleagues and younger trainees;

4) **Recommendations and requirements of accreditation bodies** to serve as catalysts and ultimately for enforcement of change within training programs.

Accreditation and certification to improve resident physician unhealthy substance use education

Academic institutions provide learners with opportunities to develop knowledge and skills that are prerequisites for safe, effective, and competent practice. Accrediting organizations assess educational *programs* to determine whether their content is designed to produce fully competent graduates. Accreditation is granted to those programs meeting their standards. The Accreditation Council for Graduate Medical Education (ACGME) is a private, non-profit council that evaluates and accredits medical residency programs in the United States. The ACGME was established in 1981 based on a consensus in the academic medical community for an independent accrediting organization. Its forerunner was the Liaison Committee for Graduate Medical Education (LCGME) and had been established in 1972.

The mission of the ACGME is to improve health care by assessing and advancing the quality of resident physicians' education through accreditation. For each medical specialty, the ACGME has a Residency Review Committee (RRC) comprised of 6 to 15 volunteer physicians. Members of the residency review committees are appointed by the American Medical Association (AMA) Council on Medical Education and the appropriate medical specialty boards and organizations.

In the evaluation of graduate medical education, the ACGME has shifted from a *descriptive model* focused on structure and measurement of a program's "potential" to train competent physicians, to a model that measures actual training *outcomes*. In 1997, the ACGME initiated the Outcome Project and began to develop core competencies. The goal of the Outcomes Project is to enhance residency education through resident outcome assessment [52]. This project is a long-term initiative which emphasizes the attainment of a core set of competencies by the residents, as an indicator of a residency program's educational effectiveness and quality rather than simple compliance with regulations. In 1999, the AGGME endorsed six general competencies around which all residency curricula should be organized: 1) Medical Knowledge; 2) Patient Care; 3) Interpersonal and Communication Skills; 4) Professionalism; 5) Practice-based learning and improvement; 6) Systems-based practice. The ACGME has progressively moved to the present mandate for training programs to demonstrate data-driven changes and improvements in curricula based on resident performance data in each of the competencies, promoting continuous improvement in resident education and ultimately, in the healthcare workforce. Any efforts to improve resident physician unhealthy substance use education via accreditation will likely be most successful if they take into account and relate clearly to the ACGME core competencies.

Health professional organizations frequently rely on independent certifying bodies that grant certification recognizing that individuals have successfully demonstrated knowledge or competency in a particular specialty. The American Board of Internal Medicine (ABIM) is a non-profit, independent evaluation organization that, through the administration of a certifying examination, has for more than 70 years maintained the highest standard in internal medicine. ABIM certification has meant that internists have demonstrated - to their peers and to the public - that they have the clinical judgment, skills and attitudes essential for the delivery of excellent patient care. However, only 2% of the American Board of Internal Medicine certifying exam typically addresses substance use, which translates into 2-5 questions in the entire exam (compared to 14% for cardiovascular disease, 6% for nephrology, 2% for ophthalmology, and 10% for geriatrics). Regulatory bodies may provide some leverage in instituting more global implementation of resident training in substance abuse conditions by increasing the emphasis of substance use and related conditions on their examinations, such as on the ABIM certifying examination.

Unhealthy substance use-related competencies

The Health Resources and Services Administration (HRSA) and the Substance Abuse and Mental Health Services Administration (SAMHSA) Center for Substance Abuse Treatment (CSAT) supported an effort by the Association for Medical Education and Research in Substance Abuse (AMERSA) to implement an interdisciplinary project to improve health professional education in substance abuse [53]. The project was known as Project MAINSTREAM (the Multi-Agency INitiative on Substance abuse Training and Education for America).

A major aim of this project was to produce a national strategic plan to improve care for substance use problems, including state-of-the-art reviews and recommendations for health professional development by leading authorities. To develop the strategic plan, nationally recognized experts were invited to join a Strategic Planning Advisory Committee (SPAC) representing dentists, dietitians, nurse midwives, nurses, nurse practitioners, occupational therapists, pharmacists, physical therapists, physicians, physician assistants, psychologists, public health professionals, rehabilitation counselors, social workers, speech pathologists, and audiologists.

Using a modified consensus-development approach, they defined a set of core competencies for all health professionals, irrespective of discipline. In addition,

members of the SPAC, in conjunction with other national leaders in substance abuse, developed discipline-specific papers that summarize the state of the art regarding education of health professionals about SU conditions and provide recommendations and action steps for achieving desired goals within each discipline. All of the papers were subjected to peer review and were modified before being accepted for inclusion in the Strategic Plan. Following further review of the papers, an exhaustive stratification process was used to derive key recommendations that cut across the professional disciplines represented by the authors. The recommendations represent the collective input from SPAC members and outside experts from all of the disciplines and hundreds of other individuals who assisted in the review of materials in the Strategic Plan.

Since publication of the Strategic Plan in 2002, recommended physician competencies were adopted by the White House Office of National Drug Control Policy and by medical education leaders (including representatives from the ACGME, AMA, and the Society of General Internal Medicine) in a series of Leadership Conferences on Medical Education in Substance Abuse that took place in 2004, 2006, and twice in 2008, [28]

Unhealthy Substance Use Curriculum for Internal Medicine Residency Programs

Introduction to Unhealthy Substance Use Curriculum Many previous publications have outlined curricula for physicians at various stages of training and from various specialties, for medical schools and residencies. In this paper, we outline a curriculum in unhealthy substance use education for internal medicine resident physicians specifically, based on the core competencies developed as outlined above. We provide an outline to assist in the actual implementation of such a curriculum within an internal medicine residency training program.

We have organized the curriculum into modules, with didactic as well as experiential components, utilizing a variety of educational venues, some new and some typically found within the existing framework of an internal medicine residency curriculum. Residency training programs may opt to deliver this curriculum via a dedicated rotation. While a dedicated rotation may be more efficient, it may also be less likely to be implemented as required components of residencies already replete with such rotations (e.g., intensive care unit). More importantly, we believe that addiction medicine is best taught to medical residents when the training is *integrated* into general medical care, modeling comprehensive care delivery. In this format, components of the unhealthy substance use curriculum are inserted into existing internal medicine teaching venues, both didactic and clinical, and the competencies contribute to the core general competencies addressed by residencies and monitored by the ACGME.

This model relies heavily on faculty who are well trained in addiction medicine and can serve as effective teachers. Such a model may also provide only limited exposure to patients in recovery after having received specialty treatment, who are less often recognized in internal medicine clinical settings. Finally, we link the proposed curricular modules to the ACGME core competencies. These modules may be modified and adapted to meet specific program needs and available resources.

Goal of the unhealthy substance use curriculum The goal of an unhealthy substance use (SU) curriculum for internal medicine residents is two-fold. The first goal is to highlight the importance of addiction medicine in patient care. The second is to provide internal medicine residents, regardless of ultimate career choice, with the core knowledge and skills necessary for all internists who provide clinical care. Of note, internists include those in general internal medicine (many of whom deliver primary medical care) as well as subspecialists (e.g., cardiologists, gastroenterologists, endocrinologists, nephrologists). Unhealthy SU condition knowledge and skills address appropriate prevention, early detection, diagnosis, treatment and referral for patients with substance use conditions. We outline herein a curriculum in unhealthy SU for internal medicine residents, based on the recommendations of AMERSA's Project MAINSTREAM regarding physician competencies. These **core competencies in unhealthy substance use for internal medicine residents** are as follows:

1) Residents will perform age, gender and culturally appropriate unhealthy substance use screening
2) Residents will effectively assess patients with unhealthy substance use
3) Residents will provide brief interventions to patients with unhealthy substance use
4) Residents will demonstrate effective counseling methods to help prevent unhealthy substance use
5) Residents will refer patients with substance use disorders to treatment settings that provide pharmacotherapy for relapse prevention
6) Residents will recognize, treat or refer co-morbid medical and psychiatric conditions in patients with substance use conditions
7) Residents will refer patients with substance use disorders to appropriate treatment and supportive services
8) Residents will be aware of the ethical and legal issues around physician impairment from substance use and of resources for referring potential impaired colleagues, including employee assistance programs, hospital based committees, and state physician health programs and licensure boards

9) Residents will identify the legal and ethical issues involved in the care of patients with unhealthy substance use
10) Residents will provide pharmacologic withdrawal to patients with substance dependence
11) Residents will provide or refer for treatment for relapse prevention in patients with substance use disorders, both pharmacotherapy and psychosocial counseling

Unhealthy substance use curriculum The curriculum is presented in eight modules, outlined in Table 1. The modules address the substance use competencies outlined by Project MAINSTREAM and are linked to the ACGME competencies that they can meet. Table 1

Table 1 Unhealthy substance use curricular modules, corresponding ACGME competencies and suggested internal medicine residency clinical venues

Modules	ACGME Competencies	Suggested Clinical Venue	Time
1) Addiction and the brain: principles of addiction	Medical knowledge; Patient care	All patient care activities, especially continuity clinic experiences; inpatient medicine; emergency department	45-60 minute lecture
2) Complications and comorbidities of unhealthy substance use	Medical knowledge; Patient care; Systems-based practice	Medical consultation rotations; inpatient medicine; emergency department; intensive care unit rotations	45-60 minute case-based lecture
3) Screening and assessment of unhealthy substance use	Practice-based learning;	Continuity clinic; inpatient medicine; subspecialty electives; emergency department	45-60 minute interactive lecture and 45-60 minute skills practice session
4) Effective methods of counseling patients including brief intervention	Patient care Medical knowledge; Interpersonal and communication skills; Systems-based practice	Continuity clinic; inpatient medicine; emergency department	45-60 minute interactive lecture and 45-90 minute skills practice (1-2 sessions)
5) Substance abuse treatment including pharmacotherapy	Systems-based practice; Medical knowledge; Patient care	Intensive care units, medical wards, continuity clinics, emergency department	60-90 minute lecture
6) Substance-specific inpatient and outpatient management	Medical knowledge; Patient care; Practice-based learning; Systems-based practice; Interpersonal and communication skills	Continuity clinic; inpatient medicine; emergency department	60 minute case-based lecture
7) Prescription drug abuse	Professionalism; Interpersonal and communication skills; System-based practice; Practice-based learning; Patient care; Medical knowledge	Continuity clinic; emergency department	60 minute case-based lecture
8) Legal and ethical considerations for patients and physicians	Professionalism; Systems-based practice; Practice-based learning; Medical knowledge	All patient care activities; continuity clinic; inpatient medicine; emergency department	60 minute lecture

suggests where to integrate the modules into an internal medicine residency program's existing clinical venues and an anticipated minimum time for each. The didactic sessions for each of the eight modules listed in Table 1 may be appropriate for more than one didactic session depending on the depth of teaching and the availability of group learning conference time. The curriculum is presented in separate modules, as a suggestion for implementation. However, these may be modified based on the needs of the individual training programs. For example, a residency program might opt to consolidate the screening and brief intervention modules into one didactic session, followed by a skill practice workshop.

1) Addiction and the brain: principles of addiction medicine

Module relevance This introductory module sets the stage for covering substance use conditions as important and relevant, often chronic conditions, for generalists. It will teach learners the pathophysiology of addiction.

Module content The session should introduce addiction as a chronic relapsing brain disease by reviewing the neurobiology of addiction. The neurobiology of addiction should include where in the brain substances of abuse act, how they cause intoxicating effects and how they alter the brain when used chronically. In this way, addiction medicine is framed similarly to how other chronic diseases (e.g., chronic obstructive lung disease, congestive heart failure, and diabetes) are taught. The session should also include national and local epidemiology of substances of abuse and describe the full spectrum of unhealthy substance use from at-risk use (that risks consequences) to substance dependence. A general overview about how the severity of the substance use problem influences treatment choice and efficacy and relapse risk should be covered. The session should be clinically relevant to the learner, for example, epidemiology and treatment should be presented in a way that is relevant to the specific residency program's needs and to the specific residents' rotation. For example, if the module is being taught to an inpatient team in an urban setting where heroin dependence is prevalent, then the prevalence, neurobiology and management of heroin dependence in hospitalized patients should be included. Discussion about the genetic vulnerabilities, risk and protective factors of addiction should also be covered.

Module special considerations Depending on the population served by the residency program's clinical sites, the curriculum should address the specific needs for special populations (adolescent, geriatric, racial/ethnic/cultural groups) and for specific substances of abuse.

2) Complications and comorbidities of substance abuse

Module relevance This module serves to highlight the impact SU has on other common medical and psychiatric diseases. The module is also important because of the high prevalence of medical and psychiatric comorbidities in patients with substance use conditions. As such it has particular relevance for internal medicine physicians focused on medical conditions, and common psychiatric conditions such as depression and anxiety. Addressing substance use allows more effective management of these conditions.

Module content It will be important for learners to understand how substance use causes or worsens other chronic diseases (e.g., cirrhosis, cardiomyopathy, depression) and has important interactions with treatments for other chronic diseases (e.g., anticoagulation therapy, sedatives for anxiety, opioids for chronic pain). This module highlights how common medical conditions (e.g., hypertension, insomnia) can be adversely affected by substance use. In addition, injection drug use and risky sexual behavior during substance use has been associated with conditions such as endocarditis, hepatitis B and C and HIV/AIDS. Topics such as cocaine associated chest pain or injection drug using patients with fever are useful contexts to present this topic.

3) Screening and assessment for unhealthy substance use

Module relevance This module has relevance for residents as screening and early intervention for unhealthy substance use are recommended practices for all adults [54]. Many internal medicine patients are unrecognized and once identified the problem can be addressed to prevent and manage substance use conditions. It also serves to teach specific skills on how to detect unhealthy (covering the spectrum from "at risk use" to "dependence") alcohol and drug use, using appropriate screening tools based on their validity, applicability and purpose.

Module content This module should cover how unhealthy substance use meets the criteria for widespread screening based on high quality evidence (high prevalence, significant consequences, valid screening tests, effective and safe treatments, early identification and treatment are preferable). The evidence behind effective formal screening methods (rationale, utility, operating characteristics) should be covered. Learners should practice specific techniques (single item screening tests, quantity and frequency, CAGE, AUDIT, DAST) [1,55] demonstrating age, gender and culturally appropriate unhealthy substance use screening skills. Learners should appreciate the limitations of biological markers (e.g., urine drug testing, blood mean corpuscular volume, gamma-glutamyl-transferase, carbohydrate-deficient transferrin). This module should address steps to be taken to assess patient's severity of substance use and readiness to change their use in patients who screen positive. Using the stages of change model, learners should be able to assess a patient's readiness to change. Assessment should include identifying substance use disorders (e.g., whether the patient has dependence, or

abuse, any consequences, or no consequences but excessive use). Teaching of assessment should also cover patient factors that increase the risk of any use, such as pregnancy or trying to conceive; medications contraindicated with substance use (e.g., warfarin); medical conditions that contraindicate alcohol or drug use (e.g., hepatitis); blackouts; failed attempts to cut down; family history of substance conditions; injuries related to substance use; medical conditions that may be caused by substance use (e.g., hypertension, trauma, anxiety, sleep disorders); and behavioral problems that can result from or be worsened by substance use (e.g., problems with work, school, or family).

4) Effective methods of counseling patients including brief interventions

Module relevance This module covers the effectiveness and skills development of counseling to help prevent the development of or progression of unhealthy substance use using formal psychological counseling and brief interventions. Brief counseling is one of the key skills in the recommended practice of screening and intervention. Motivational Interviewing and brief counseling are particularly important skills for managing patients with unhealthy substance use because many such patients do not recognize their condition, and when they do, they may not be ready to change. Brief counseling can facilitate change in this context. These skills also have relevance to internal medicine practice beyond addressing substance use, as they are useful for medication adherence, and behavior change counseling in general.

Module content Residents should learn stages of change (precontemplation, contemplation, determination, action, relapse and maintenance) and appropriate counseling strategies including patient advice and education about harms and risks. Residents should learn the skills of patient centered motivational interviewing and how they differ from confrontational approaches. They should be able to apply the principles of motivational interviewing including developing discrepancy, avoiding argumentation, rolling with resistance, expressing empathy and supporting self efficacy. They should be able to ask open ended questions, listen reflectively, affirm, summarize and elicit and recognize change talk (i.e., disadvantages of the status quo, advantages of change, optimism for change or intention to change; desire, ability and reasons for change statements, and commitment language). Residents should also be skilled in helping to strengthen a patient's commitment to change by negotiating a plan. Residents should learn the skills of brief intervention (i.e., counseling) including the components of patient feedback, emphasizing personal responsibility for change, giving clear advice, giving a menu of treatment options, having an empathic counseling style and enhancing a patients self-efficacy.

Module special considerations This module is best accomplished by employing skills practice where residents have a chance to role play brief intervention and motivational interviewing skills and receive feedback on their clinical skills.

5) Substance Abuse Treatment including Pharmacotherapy

Module relevance This module includes treatments that internal medicine physicians should have expertise in (e.g., pharmacotherapy for alcohol dependence) as well as treatments to which internists will generally refer patients (e.g., residential addiction specialty treatments).

Module content The module covers the effectiveness and content of substance abuse treatments including detoxification, (i.e., medically supervised withdrawal) residential treatment, 12 step and mutual help programs, outpatient treatment and pharmacotherapy (e.g., methadone, buprenorphine, naltrexone, acamprosate). Residents should learn how to work collaboratively with substance abuse specialty treatment programs and clinicians and specialists including counselors, psychologists and social workers. Emphasis should be on talking to patients about specialty treatment, making appropriate referrals and prescribing medications to treat dependence. Residents should know the efficacy and limitations of different treatment modalities. They should be familiar with web-based substance abuse treatment locator resources (e.g., Substance Abuse and Mental Health Services Administration (SAMHSA) homepage http://www.samhsa.gov).

Module special considerations Residents should have an opportunity to visit treatment programs (e.g., methadone maintenance program, alcoholics anonymous meeting) and interview patients who have undergone specialty treatment and/or attended mutual help groups, and those who are in recovery regardless of treatment history (many such patients can be found in the residents usual internal medicine training sites).

6) Substance Specific Inpatient and Outpatient Management

Module relevance This module serves to help residents identify specific substance intoxication and withdrawal syndromes, which are often seen in emergency, outpatient and inpatient medicine settings, and make evidence-based decisions on management strategies for specific substance (e.g., alcohol, opioid) intoxication, withdrawal and dependence.

Module content This module should cover substance specific epidemiology, biochemistry, clinical pharmacology (e.g., pharmacokinetics, drug testing, drug-drug interactions), neurobiology, and behavioral effects (e.g., intoxication, tolerance, physical dependence). The major substance categories should be covered including central nervous system depressants, psychomotor stimulants, nicotine, opioids, cannabis and alcohol. Residents should

be able to identify the signs and symptoms of intoxication, overdose and withdrawal of all the major categories of substances. Residents should learn how to manage acute intoxication and withdrawal syndromes of all the major categories of substances.

7) Prescription Drug Abuse

Module relevance The challenges of appropriate chronic pain treatment and recognition and prevention of prescription drug abuse are well known to internal medicine physicians. This module serves to give residents the knowledge and skills to prevent, and identify and manage a condition that is increasing in prevalence, prescription drug abuse (PDA).

Module content This module should include an overview of PDA including epidemiology, and important definitions (e.g., prescription drug misuse, tolerance, physical dependence, aberrant medication taking behavior, pseudoaddiction). Residents should know which medications are more likely to be abused and factors that lead to physicians overprescribing controlled substances. Residents should learn a framework for safe prescribing including understanding when controlled substances are indicated, and what their efficacy is, screening patients for PDA risk, setting realistic therapeutic goals and monitoring strategies including urine drug testing, pill counts, use of patient agreements and informed consent and use of prescription monitoring programs. Residents should be able to identify prescription drug abuse and have the skills to communicate with patients about either the lack of benefit from the controlled substance or apparent harm (e.g,, the possible diagnosis of addiction) to controlled substances. While not specifically part of a substance use curriculum, this module should be complemented by education on the treatment of acute and chronic pain.

8) Legal and Ethical Considerations for Patients and Physicians

Module relevance Documentation of substance use and care for substance use occurs in internal medicine patient encounters from screening for unhealthy SU to referral and treatment for dependence. Care for patients with unhealthy SU often involves challenges related to family and employment which can raise ethical issues. As physicians competent to recognize unhealthy substance use, internists are in a position to recognize it in their colleagues who may need help. Residents should be aware of the ethical and legal issues around caring for patients with substance use conditions as well as issues around physician impairment.

Module content This module should cover the patient confidentiality laws pertaining to managing patients with substance use conditions. Residents should also become aware of insurance coverage issues pertaining to substance use condition treatment and recognize that this coverage varies widely. Resources for information and updates on these topics should also be presented. Residents should be aware of the ethical and legal issues around physician impairment from substance use and of resources for referring potentially impaired colleagues including employee assistance programs, hospital-based committees, state physician health programs, and licensing boards.

Educational Venues

There are two components to the recommended curriculum-Didactic sessions and Clinical experiences.

Didactic sessions The core topics on substance use conditions outlined in each module may be presented using the teaching conferences already in place in internal medicine residency programs (e.g., departmental grand rounds, morbidity and mortality conference, noon conferences, etc.). In fact, doing so has the distinct advantage of treating unhealthy substance use in the same way that other medical conditions are treated in the residency curriculum. The didactic sessions will address concepts that will be reinforced during clinical rotations, or will provide a venue to address issues of addiction medicine that the residents may not be directly exposed to in their clinical rotations. Examples of common internal medicine residency didactic venues that can be used for unhealthy substance use teaching, and how they might be used, are:

- *Lectures and Morbidity and Mortality Rounds/ Conferences*: Overview of medical conditions with associated with substance abuse; overview of screening for substance abuse; detoxification procedures for alcohol and other drugs; medication management of addictions including relapse prevention; overview of appropriate prescribing practices for opioids and effective pain management strategies.
- *Grand Rounds*: As what is often the main academic conference within an entire department, this is an excellent venue for high profile, scientific presentations on unhealthy substance use.
- ***Case discussions****, such as Morning Report (inpatient and ambulatory), attending rounds or continuity clinic conferences*: Topics in unhealthy substance use may be presented *de novo* or previously presented topics can be reinforced during these case discussions. This is accomplished by discussing not only patients' medical conditions, but also by highlighting the underlying substance use conditions that may be associated with (having caused or worsened) them. Examples include: hepatitis C (injection drug use), cardiomyopathy (alcohol), and rhabdomyolisis (cocaine). During case presentations, any aspect may be highlighted along the spectrum of unhealthy SU, integrating substance use management principles seamlessly into the clinical discussions.

• *Journal Clubs*: Presentations would focus on critical appraisal skills while also addressing and reinforcing concepts in addiction medicine, through review of peer-reviewed articles on unhealthy substance use in the medical literature. Examples include: studies of the effectiveness of brief interventions or use of buprenorphine.

Additional teaching opportunities for addressing unhealthy substance use beyond traditional internal medicine residency conferences include:

• *Quality Improvement (QI) Projects*: With the implementation of an unhealthy substance use curriculum, residents may have the opportunity to meet the ACGME requirement of a QI project, within their own continuity clinic practice, or inpatient experience. Projects related to an assessment of institutional or administrative systems affecting implementation of screening, treatment protocols for substance withdrawal, or availability of treatment referrals for their patients are examples.
• ***Workshops***: Programs that include workshops or seminars (e.g., multi-hour small group sessions) for skills development can incorporate skills practice sessions in motivational interviewing and brief counseling interventions, as well as in the use of screening tools and approaches to assessment.
• ***Field Trips***: Visits outside the medical residency training program clinic and hospital setting to 12-step meetings, [56] methadone and buprenorphine clinics, needle exchange programs, other substance abuse treatment programs broaden the residents' view of the spectrum of substance use conditions and their treatment. These activities can be incorporated into conference series, ambulatory block experiences and seminars, inpatient rotations, and electives.
• ***Meetings with patients in recovery***: Residents can hear first-hand accounts of effective and ineffective ways that physicians approached their substance use condition from the patients themselves, creating powerful learning experiences. They can also be exposed to patients who are no longer severely affected. This venue may be incorporated into resident clinic conferences, including small or large group teaching sessions.
• *Video-taped and other observed patient encounters*: Direct observation of a patient encounter is the "gold standard" to assess residents' attitudes, knowledge and skills in the area of patient-doctor communication, and can teach and assess skills in screening, motivational interviewing and brief intervention. Guided by a trained preceptor, video-taped review is a powerful learning experience.

Clinical experiences Core concepts, presented in didactic sessions, can then be reinforced, and skills practiced, during residents' routine clinical rotations (inpatient medicine rotations, continuity clinics, emergency department, and intensive care unit rotations), complementing rather than replacing current curricular components, and delivered over the three years of training. Examples of experiential clinical learning experiences and opportunities include:

• *Inpatient hospital service rotations and intensive care rotations*: In these settings, residents can gain hands-on experience in the management of withdrawal syndromes (particularly opioids, alcohol and other sedatives), learn to assess the severity of addiction and readiness to change, and recognize and manage the complications and co-morbidities associated with substance use conditions, highlighting the importance of addressing the underlying substance use conditions. This is also a venue where resident physicians can have experiences and learning at the interface between pain and addiction.
• *Continuity clinics*: The resident continuity clinic is a site particularly well suited for the development of screening skills (and implementation–Practice-based learning), providing faculty with the opportunity to directly observe the resident selecting and performing the screening test. Specific curricula in patient-physician communication skills can easily incorporate a focus on screening for substance use conditions as one of the case examples. Screening and ongoing medical management of outpatients, referral to specialty treatment services and use of the electronic medical record-based screening and assessment systems are all learning opportunities that may be present at outpatient sites.
• *Emergency department*: Residents have the opportunity to assess patients with substance use conditions, and their consequences, both medical and social, and to identify existing local resources for referral to treatment. Residents will also see acute overdose and intoxication in this setting.
• *Medical consultation rotations/curriculum*: Residents may assist in the management of withdrawal syndromes on non-medical services, address perioperative issues of patients with substance use conditions, as well as the medical complications of addictions.
• *Specialty addiction treatment experiences*: We recommend that all residents experience at least one of the following specialty addiction treatment settings (to which they will refer patients, and from which they will receive patients), to broaden their view of addiction and recovery and to understand

the specialty care perspective. These programs include detoxification programs, needle exchange and methadone programs, 12-step meetings, residential rehabilitation programs and intensive outpatient treatment settings. These may be incorporated into an existing elective or ambulatory block, and need not be lengthy to be effective [56]. Residents' experience with substance use conditions would be further enriched by allowing residents to see patients in these settings, especially those in recovery who are doing well (who are often unlike patients residents recall from their internal medicine settings and experiences).

Evaluation of the Curriculum

The ability to demonstrate the achievement of competency-based learning objectives provides evidence that, when training is complete, graduating resident physicians can meet the health needs of the public [57]. In concordance with the ACGME's focus on *outcomes*, evaluation modalities should focus on whether and how fully internal medicine residents are incorporating concepts of addiction medicine into their practice, and whether residents are competently performing specific skills (e.g., screening and brief intervention) documented by direct observation and/or evidence in work products. Dimensions of evaluation of the unhealthy substance use curriculum include:

- Assessment of the effectiveness of didactic teaching
- Assessment of resident skill acquisition
- Clinical performance assessment and feedback
- Resident self-assessment and reflection
- Documentation of academic work products

Evaluation of the didactic sessions To measure learning in didactic presentations, before-after ("pre-post") measures can be administered with each conference to detect changes in targeted knowledge, skills (or perceived skills), and attitudes. Future intentions can also be measured to determine if teaching influenced residents' plans for changes or improvements in clinical practice. However, sometimes pre- post testing is difficult due both to time pressures and the common tendency for some residents to arrive to conferences late and others to leave early. Audience response technology, such as TurningPoint® (http://www.turningtechnologies.com accessed October 19, 2008), could be used as an alternative thereby integrating testing into an interactive presentation. This method would allow for the collection of real-time data using multiple choice questions near the beginning and the end of a teaching session. The quality and usefulness of the teaching can also be evaluated at the end of the didactic session employing a short resident questionnaire. Such evaluations are best kept to 3-5 questions to improve response rate.

Direct observation of resident skills A "mini-CEX (Clinical Evaluation Exercise)"-style evaluation card can be designed specifically for observation and evaluation of key addiction medicine clinical skills. The mini-CEX is a snapshot of doctor/patient interaction, designed to assess the clinical skills, attitudes and behaviors of trainees essential to providing high quality care by supervisors observing an actual clinical encounter. Not all elements need be assessed on each occasion. Specific unhealthy substance use clinical skills can easily be incorporated into routinely performed CEXs. The mini-CEX approach to resident clinical skills assessment is a feasible, reliable, valid, and widely used evaluation method [58]. For unhealthy substance use patients, the mini-CEX would be customized to focus on key substance use condition interactions and patient cases and different evaluation cards could be customized for both the inpatient and ambulatory setting.

If the appropriate equipment is available in the clinic setting and patient consent is obtained, video recording of encounters where screening or other targeted addiction medicine skills are employed provides the resident with the opportunity to self-assess and provides the faculty preceptor the opportunity to offer detailed feedback on resident performance. The key is to set aside sufficient time with resident and preceptor to review the video interaction in detail, stop and start the interaction frequently for reflection and skill assessment, and construct a dialogue focusing on reinforcement of skillful performance and opportunities for performance improvement.

Performance measures Teaching clinics may also opt to collect data on total number of patients screened and other individual resident performance statistics (e.g., brief intervention, referral to treatment). Data can be collected via medical record review and fed back to the resident. Key record indicators that can be measured include documentation of screening results, documentation of brief intervention provided, referrals, and follow-up.

Peer record reviews Peer medical record review can be a successful teaching strategy. Working in dyads, each resident conducts an annual review of a record of a patient with unhealthy substance use (or a patient screened for the condition)[59]. Residents select the record for their colleague to review, and together, they prepare a presentation for a pre-clinic conference, identifying challenges, treatment options, and community resources. In the process, residents have opportunity for reflection, self-assessment, and specific feedback on their approach to care and/or management.

Objective Structured Clinical Exams (OSCEs) The OSCE is an evaluation methodology where standardized patients (actors playing patient roles) are placed in mock healthcare settings to assess residents' clinical

skills. Standardized patients are trained to portray specific patient case scenarios in a standardized manner [60] so that clinical challenges can be consistently presented to the participating residents. OSCEs using standardized patients are employed for clinical skills assessment in many US residency programs and most US medical schools [61-63]. For these exams, residents engage in a clinical interaction with the standardized patient that is observed and/or video/audio-recorded for skill assessment by faculty. Standardized patients can also be trained to provide reliable assessments of residents' performance. The ACGME has identified OSCEs as the most desirable method for assessing interviewing, communication and counseling skills, and preventive health procedures, [64] and therefore can be an effective way to assess specific clinical skills key to substance use condition-related patient care. OSCEs are most cost-effective when a large number of residents participate during the same administration [64]. Resources needed for effective OSCE administration are substantial and include: space (a clinical facility or OSCE center), cases designed to call for the use of targeted unhealthy substance use skills, checklists for faculty and/or patients to use to assess targeted skills, trained standardized patients, and sufficient skilled faculty for observation or review of recorded interactions.

Portfolio submissions Portfolios are employed in resident evaluation for the documentation of clinical performance to meet competency criteria, documentation of program-related competence development, and documentation and tools for professional growth [65]. They are also commonly used to provide in-depth personalized mentoring to residents. There are a variety of different kinds of portfolios currently in use in residency training. Although many portfolios are paper, digital portfolios have also been shown to be well received in medical school and other settings, [66,67] as well as in residency training [68-71]. Digital portfolios can be employed not only to collect evidence of proficiency and professional growth, but can also enhance access and portability, organization, collaboration, and feedback [72].

For documentation and evaluation of addiction medicine skills, video recorded patient encounters on digital video discs (DVDs) or in digital format can be collected and maintained in the resident's academic portfolio. Pre-clinic conference presentations (slides, handouts, and presentation notes) can also be included. De-identified substance use condition management plans and reflective writings about related patient experiences or observations at AA meetings can also be valuable additions to resident portfolios. Portfolios are typically examined by program directors for the resident's annual review, are used as a basis for feedback on performance and resident professional development, and can be an important source of information for resident letters of recommendation for fellowship training or transition to private practice upon graduation.

Resources and implementation

Resources The delivery of the core curriculum, through our proposed modules would consist of, at minimum, 12 hours of didactics, over three years of residency training. Residents' same clinical experiences during standard internal medicine rotations would provide the clinical reinforcement of skills, and solidify the key concepts of addiction medicine/unhealthy substance use. Additional focused evaluation activities will reinforce both didactic and clinical teaching and provide outcome measures required by the ACGME. This time commitment represents only a fraction of the focus received by cardiology and diabetes care.

Costs Once a generation of internal medicine residency training program faculty with expertise sufficient to teach addiction medicine exist, teaching the required competencies to address unhealthy substance use should not require funds beyond those required for the whole program. Residency training programs often benefit from in-kind support or external support for special teaching efforts. Such added support would be useful for supporting experiences such as travel to treatment programs or standardized patients. However, these are the sorts of costs that, as for teaching of other competencies in other areas of medicine, are anticipated to be integrated with general funds for residency training, as part of the whole training program budget.

Achieving an adequate supply of internal medicine faculty capable of teaching unhealthy substance use competencies will be a cost. Unlike internal medicine subspecialty faculty, who are trained in medicine subspecialty fellowships and well-represented among internal medicine residency program faculty, medicine faculty with expertise in addiction medicine are not similarly well-represented. Such faculty will either need to come from new residency graduates, or from training current faculty, and in fairly large numbers. This training could occur by self-learning or specific continuing education experiences for existing faculty, or in national multidisciplinary training programs as have existed in the past and have been proposed recently (e.g., Centers of Excellence) [53].

Resources for Program Directors For training existing faculty, residency programs could link with local addiction treatment programs, and the few internal medicine or other faculty with this expertise in academic medical centers. Continuing medical education programs in person (e.g., as listed at http://www.motivationalinterview.org/ for motivational interviewing (accessed February 14, 2010), and perhaps more efficiently, online, exist for

training faculty. For example, the Alcohol Clinical Training Project (http://www.mdalcoholtraining.org accessed February 14, 2010) is a free resource for training faculty consisting of slides with case-based video vignettes, speaker notes and learner evaluation materials. The curriculum is flexible and modifiable and can be taught using all the components together in a 3-hour workshop or by using various components separately in 45 minute sessions (i.e., preclinic conference or attending rounds) or for self learning. The curriculum has been evaluated [37]. A related web publication ("Alcohol, other drugs and health: current evidence) can be used to for faculty (and residents) to keep up to date (http://www.aodhealth.org accessed February 14, 2008). Many teaching materials and information resources are available at http://www.nida.nih.gov, http://www.niaaa.nih.gov, and http://www.samhsa.gov (all accessed February 14, 2010). The NIAAA web site offers a clinician's guide to Helping Patients Who Drink Too Much and related continuing education materials (including slides and training videotapes).

Number of faculty needed Residency programs will need to have sufficient faculty (depending on the number of residents in the program) to assure their residents receive training, both to deliver the didactics, but even more importantly to mentor residents and serve as role models. Faculty serving as preceptors may need to be trained in the knowledge and skills slated for this curriculum. Thus faculty development efforts must be implemented, particularly when employing an integrated model. Residents value skill and competence in their teachers, and multifaceted teachers - those who have an excellent grasp on medicine, will be more effective teachers about unhealthy substance use for their residents.

Expertise Faculty teaching about unhealthy alcohol and drug use will need to have the competencies they are teaching (as noted previously). These faculty need not have addiction specialty expertise, and the expertise needed to address all competencies may be spread over a number of individuals. For example, one faculty member may have expertise in the management of inpatient alcohol withdrawal, another may be expert at screening and brief intervention. Many of the relevant competencies are similar to those that medicine faculty already must have to teach preventive medicine. These similar competencies are those that involve an understanding of modifiable risk factors and behaviors that risk chronic illnesses that are addressed by behavioral intervention aimed at lifestyle change (such as identification and addressing of depressive symptoms, medication nonadherence, physical inactivity). Such competencies are those reflected by ACGME competencies as communication skills (e.g., motivational counseling, for example is needed to address unhealthy drug use as well as lifestyle change and medication adherence). More teachers are needed to address competencies that all internists should have (e.g., prevention, screening, brief intervention, recognition of comorbidity, and ability to refer for pharmacotherapy and specialty care), whereas fewer teachers would be needed to address competencies needed to provide more specialized services such as prescription of buprenorphine for opioid dependence.

Required qualifications Recently, the American Board of Addiction Medicine was established to examine and certify diplomats (http://www.abam.net/ accessed February 24, 2010). While not yet recognized by the American Board of Medical Subspecialties (ABMS) it is the only US medical specialty board that certifies addiction medicine physicians across a range of medical specialties. The ABMS does recognize the specialty of addiction psychiatry (certification available to neurologists and psychiatrists) and the American Osteopathic Boards of Anesthesiology, Family Medicine, Internal Medicine and Neurology and Psychiatry recognize added qualifications in addiction medicine for their diplomates. Training and certification but not board certification can be obtained in other ways by (doctor of medicine) internists. In addition, much of the knowledge relevant to internists–the management of patients with unhealthy alcohol and other drug use in general populations and health settings–is not traditionally the focus of addiction specialty training (of note many leaders in the field of education and research on screening and brief intervention in the past 40 years have been generalist physicians).

The first qualification for training internal medicine residents is that the teachers be internal medicine physicians. It is important for internists to teach this (in distinction to psychiatrists or non-physicians) for several reasons. First, resident physicians see their mentors and attending physicians modeling appropriate care of patients with alcohol and drug problems. Second, internists are the most appropriate teachers to tailor the broad knowledge and evidence related to these conditions to the content most relevant for medicine residents and to the teaching venues most appropriate. Lastly, medicine teachers are most likely to demonstrate role responsibility for these conditions (and, as such, residency programs will take such responsibility). Interdisciplinary care and teaching is critical in the area of substance use conditions and faculty from other disciplines should be involved. Residents will most likely be receptive to such teaching when introduced by their primary clinical teachers (as other specialty subjects are taught during their residencies). There are parallels for this model in other areas of internal medicine such as depression and diabetes care.

Specialty credentials are not required for medicine faculty teaching about unhealthy SU. However,

continuing education courses and certification offered by the American Society of Addiction Medicine (ASAM) and attendance at professional continuing education meetings such as that of the Association for Medical Education and Research in Substance Abuse (AMERSA) can be helpful resources. Physicians teaching buprenorphine treatment of opioid dependence should be waivered by the Drug Enforcement Agency (DEA) by completing the required 8 hours of training or the other routes to achieve this goal (http://buprenorphine.samhsa.gov/index.html, accessed February 25, 2010). There have been numerous internists who have led teaching and educational efforts in internal medicine nationwide who have been successful without addiction specialty credentials or training. These teachers gain their expertise via generalist fellowships or focus on substance use during their residency training or via self- (by reading, online materials and workshops and courses at continuing education venues) and mentored teaching in their years as faculty.

Challenges in implementing new curricula in residency programs Internal medicine educators are bombarded with teaching requirements, for example in genetics, ethics, communication skills, molecular medicine, geriatrics, sexual health, computer literacy, and interdisciplinary team based care, to mention a few. These demands reflect continued rapid growth in scientific knowledge coupled with society's expectation that physicians minister to social and psychological as well as physical infirmities[73]. Training programs are challenged to produce competent, ethical and caring physicians in a defined time period of three years, but must address key health care needs of the population, among which unhealthy substance use certainly figures highly. As internal medicine educators, we cannot afford to ignore addiction medicine with the significant national burden of disease as well as proven treatment interventions. There is still a serious mismatch between what we know to be good quality care and the care that is actually delivered, [52] and residency programs are in a position to fill this gap. One way to address the challenge of a bursting curricula in residency training, is to integrate a new focus of discussion into standard teaching venues.

Champions For any curriculum change to be implemented and maintained there needs to be a motivated and vigilant faculty champion who is dedicated to providing appropriate intervention and support to the residency program as needed. Ideally, this champion would be a faculty member who is active in curriculum management and reform and willing to take on a leadership role. Designing an unhealthy substance use curriculum implementation strategy for any residency program will require a fundamental appreciation of the culture and resources of the program, its faculty, and its teaching venues, as well as an understanding of the addiction field itself. The champion would probably be active in teaching several didactic sessions to both residents and faculty as needed, and would monitor the status of the curriculum and its evaluation to fine-tune and improve the program over time.

Summary

Given the burden of disease and the effective interventions that can be delivered to patients by internal medicine physicians, teaching about unhealthy substance use must, and can be incorporated into internal medicine residency training. In part because clinical management for substance use conditions is most effective when integrated with medical and other care, education should mirror this approach, integrating curricula on unhealthy substance use into overall residency training. This integration is not particularly resource intensive and can be done by making use of many existing teaching venues. Perhaps the biggest challenge will be initially getting sufficient trained internal medicine faculty with expertise to teach the curriculum for residents. Getting sufficient faculty will likely require resources since unlike other medicine topics, a new faculty (or new expertise, or at least expertise that is not in abundant supply in internal medicine residency programs) is required. Many educational resources already exist to achieve this goal though the manpower and time for training will still require investment. Federally supported faculty development efforts have trained a small number of expert teachers. Programs similar to these will likely be needed to implement curricula such as we propose. Further, the development of addiction medicine as a specialty by the American Board of Addiction Medicine is likely to support implementation of such curricula in the future. With adequate faculty, few other challenges remain. Core unhealthy substance use competencies for physicians, easily adapted to internists, have been established, and they can contribute to meeting ACGME general competencies. A curriculum has been outlined herein, based on this guidance. Evaluation of outcomes is fairly straightforward and achievable. Accrediting bodies can have a significant role in improving the teaching and therefore care for patients with unhealthy substance use. The time is right to improve (and require excellence in) residency training about unhealthy substance use in internal medicine residency training programs.

Breast-feeding · Caries · Children · Snacks

Abstract
Dental caries is caused by a combination of infection and diet. This disease, if left untreated, may lead to pain, and impair the quality of life, nutritional status and development of young children. The objective was to investigate the association between snacking and caries in a population at high risk of dental caries. American preschool children (n = 1,206) were recruited in the offices of paediatricians. Data on sociodemographic characteristics, oral hygiene, breast-feeding, use of bottle and snacking were collected by questionnaire. Plaque presence, the number of teeth and their caries status (deft) were scored. The children sampled were 61% Black, 27% White and 10% Asian. Of the 1- to 2-, 2- to 3- and 3- to 4-year-old children, 93.8, 82.4 and 77.3% were caries free, and their mean caries scores were 0.16, 0.58 and 0.93, respectively. Multivariate partial least squares (PLS) modelling revealed plaque presence, lowest income, descriptors for tooth exposure time (number of teeth and age) and cariogenic challenge (total intake of sugar-containing snacks and chips/crisps, and chips intake with a sugar-containing drink) to be associated with more caries. These differences were also found in univariate analyses; in addition, children who continued breast-feeding after falling asleep had significantly higher deft values than those who did not. PLS modelling revealed that eating chips clustered with eating many sweet snacks, candies, popcorn and ice cream. We conclude that, in addition to the traditional risk indicators for caries – presence of plaque, sugar intake and socioeconomic status –, consumption of chips was associated with caries in young children.

Dietary habits have shifted in all age groups in the Western populations in recent decades, including a nearly doubled intake of energy-dense, low-nutrient-dense snack foods [Briefel and Johnson, 2004; Adair and Popkin, 2005]. In children, more than 30% of the daily energy intake was reported to come from such foods and, on average, 75% of Americans report daily snacking [Briefel and Johnson, 2004]. In addition, different snacking patterns have been reported based on household income: individuals with income at or below the poverty line in the USA more frequently consumed po-

KARGER

tato chips, fried potatoes, whole milk and fruit drinks, whereas those with higher incomes consumed more grain-based salty snacks, fruits, skim milk, soft drinks, coffee and tea [Briefel and Johnson, 2004]. The shifted dietary patterns have been associated with increased risk of endemic diseases such as type 2 diabetes, obesity and dental caries.

Dental caries is a chronic infectious disease characterized by demineralization of tooth tissues at lowered pH following bacterial fermentation of dietary carbohydrates. The period of critically lowered pH needed for caries to occur is mainly a function of the type and frequency of carbohydrates consumed, the microbial composition of the tooth biofilm and salivary factors. Sucrose and monosaccharides induce a rapid and deep pH drop, and accordingly increase the risk of caries [Azevedo et al., 2005; Seow et al., 2009]. Energy-dense, low-nutrient-dense foods are often characterized by a high content of added sugar, but several modern snack products such as chips (crisps), popcorn and shrimp crackers, while not sweet, are still potentially cariogenic due to their content of extensively hydrolysed starch [Lingström et al., 2000]. Snacking has gained an increasing role as a risk indicator for caries development in children [Milgrom and Reisine, 2000; Marshall, 2005], but so far the impact of products with extensively hydrolysed starch, such as potato chips, on caries risk has not been demonstrated in children or adults.

Caries in young children, often referred to as early childhood caries [American Academy of Pediatric Dentistry, 2008], may, if left untreated, lead to pain, reduced quality of life and impaired eating, and may impair a child's nutritional status and development. The prevalence of early childhood caries varies between communities but is frequently high in underprivileged communities and among disadvantaged immigrants [Grindefjord et al., 1993; Milnes, 1996; Petersen and Esheng, 1998; Wennhall et al., 2002; Jose and King, 2003; Stecksen-Blicks et al., 2004; Vachirarojpisan et al., 2004; Beltrán-Aguilar et al., 2005; Schroth et al., 2005]. Understanding the role of lifestyle-associated risk indicators for dental caries in young children in groups prone to caries development forms the basis for targeted caries prevention programs. The aim of the present study has been to investigate the association between snacking habits and caries, considering oral hygiene and socioeconomics as possible confounders, in a cohort of young children living in a population at high risk of dental caries in an industrialized country (USA).

Subjects and Methods

Study Cohort

Preschool children presenting for well-child visits at the paediatric clinics at Boston Medical Center, Boston University, and the Floating Hospital, Tufts Medical Center, Boston, USA, were recruited in a 12-month period in 2003–2005. These hospitals serve all racial and ethnic groups living in the Boston area but have a special mission for underserved groups [Kressin et al., 2009]. Inclusion criteria were that a child was 6 months to no more than 5 years of age, and that a parent or guardian was willing to consent to the child's clinical examinations [Kressin et al., 2009]. Children with congenital diseases affecting the dentition were excluded. The study design, protocol, questionnaire and informed consent were approved by the institutional review boards of the institutions involved.

Data Collection

Data on sociodemographic characteristics (gender, family income, education level, race and ethnicity) and oral hygiene, feeding (breast-feeding or use of bottle) and snacking habits were obtained from parents or guardians, collected at the offices of paediatricians via a structured questionnaire [Kressin et al., 2009].

The number of teeth, and their status as sound, precavitated (white spot lesion), cavitated, filled or sealed was recorded [Drury et al., 1999], using good light, a disposable mirror and an explorer. For each child, the total number of decayed (d; non-cavitated and cavitated), filled (f; sealants not included) and extracted (e) primary teeth (t) was calculated. Visible plaque was recorded on a 0–3 scale (no plaque, and plaque covering a mean surface area of $<1/3$, 1/3 to $<2/3$ or $>2/3$ of the tooth) [Kanasi et al., 2010]. Data collection and oral examinations were performed by 2 specially research-trained dental hygienists.

Data Analyses

For descriptive data and associated univariate analyses, family income status was dichotomized as relatively high or low [equal to or higher than or below the median income in 2006 in the state of Massachusetts (USD 56,292 in 2008) according to the US Census Bureau news release (www.census.gov)], education to high (higher than high school) or low (equal to or lower than high school), and other variables as yes or no – for example, presence of caries (deft ≥ 1) or not (deft = 0), visible plaque (score ≥ 1) or no visible plaque (score 0), daily cleaning of teeth or not, and reporting eating a snack most days or not.

Categorical data are presented as proportions (percent children), and distribution differences between groups were tested by a χ^2 test with $p < 0.01$ considered statistically significant. Caries data (deft scores) are presented as means with 95% CI after standardization for age group or number of teeth in age-merged and age-stratified groups, respectively. Standardized least square means with 95% CI were calculated using the general linear model (GLM) procedure followed by the Bonferroni multiple mean test, with $p < 0.05$ considered statistically significant. The SPSS software (version 16.0.1 for Windows; SPSS Inc., Chicago, Ill., USA) was used.

Table 1. Description of study cohort

	1–2 years (n = 678)	2–3 years (n = 312)	3–4 years (n = 216)
Teeth	9.6 (9.3–10.0)	18.0 (17.8–18.3)	19.9 (19.8–20.0)

Values other than percentages denote means with 95% CI in parentheses.

[1] deft = sum of decayed, extracted (caries) and filled deciduous teeth; caries free = no detectable white or cavitated lesions, restorations or teeth extracted due to caries.

[2] <0.5% were native Hawaiian or American Indian, respectively.

[3] Low income = annual income less than median income in Massachusetts (USD 56,000).

[4] Remaining children cleaned teeth several times a week or month. Tested among all levels.

[5] Daily snacking was reported for 96, 97 and 99% of the children in the 3 age groups, respectively. Snacks reported to be eaten daily by a child are listed. The numbers indicate the proportion (%) of children for whom daily intake was reported (consumer).

Multivariate Analysis

Partial least squares (PLS) modelling using SIMCA P+ (v. 12.0; Umetrics AB, Umeå, Sweden) was used for multivariate analysis. PLS is a multivariate linear regression model method that detects correlations between matrices of independent and covarying descriptor and response variables. The variables used were snack items and risk indicators or factors for dental caries in small children. These were modelled using logarithmically (ln) transformed deft (after addition of 0.01 to all values) and the dichotomized caries score. All variables were autoscaled to unit variance.

The importance of each variable of interest (x-variable) in explaining the variation among the outcome variables (y-variables) is given by a correlation coefficient and a variable importance in projection (VIP) value. A VIP value of >1.0 is influential, and a VIP value of ≥1.5 highly influential. The R^2 and Q^2 values give the capacity of the x-variables to explain (R^2) and predict (Q^2) the variance among the y-value(s). Q^2 values, which preferentially should not differ by more than 0.2 from model R^2 values, were obtained by cross-validation where every 7th observation was kept out of the model and predicted by a model from the remaining observations. This was repeated until all observations had been kept out once.

Results

A total of 1,291 children were examined, but the data are restricted to 1,206 children because 13 children were predentate and 43 children non-cooperative (no information on tooth status); further dentate children younger than 1 year of age (n = 29) were omitted as the distribution of several variables deviated markedly from the other age groups, including lack of clinical caries measurements (data not shown). No child was older than 4 years.

Demographic and Oral Characteristics

The racial and ethnic distributions of the 1,206 children examined were 61% Black, 10% Asian, 27% White and 15% Hispanic (table 1). Boys and girls were equally represented. Approximately half of the parents or guardians had an education lower than or equal to high school, and more than 70% had an annual income below the me-

dian income in the state (table 1). The variations between the 3 age groups are shown in table 1.

The number of erupted teeth ranged from 1–20, with an average of 13.6 teeth (95% CI: 13.3–14.0) and an expected increase by age (table 1). A high proportion of the parents or guardians stated that the teeth of the children were cleaned daily (73–97% by age group), but plaque was still visible in a considerable portion of the children (23–50% by age group) (table 1). In all age groups, most of the children did not have visible caries, i.e. 94% among the 1- to 2-year-olds, 82% among the 2- to 3-year-olds and 77% among the 3- to 4-year-olds were caries free. Accordingly, the mean deft scores (numbers in parenthesis for means among children with caries) increased by age group from 0.16 (0.48) over 0.58 (1.75) to 0.93 (2.78) (table 1). The proportion of children with untreated cavities increased from 1.3 over 8.7 to 17.2% by increasing age group.

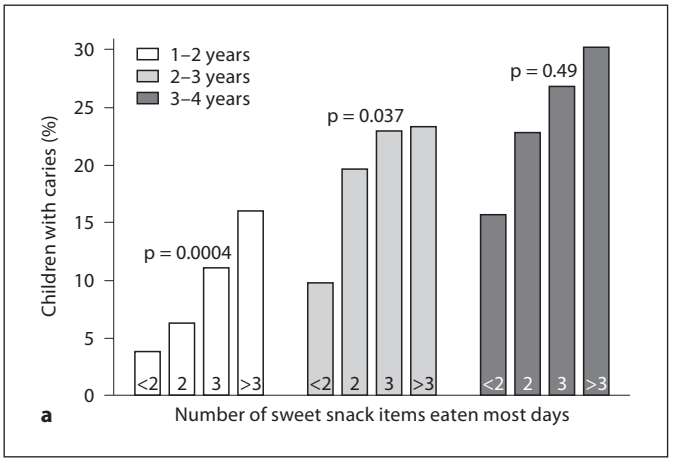
Visible Plaque and Income Are Highly Associated with Caries

A significantly higher proportion of the children with visible plaque had caries, and their age-standardized deft score was higher compared to plaque-free children (table 2). Similarly, children from homes with an income below the median, compared to those with an income at or above the median level, had more caries (table 2). The proportions of children with caries or mean deft scores did not differ between boys and girls, race or ethnicity, or parent/guardian education level groups (table 2).

Eating and Snacking Habits Are Associated with Caries

Nearly all children (97%) were reported to eat snacks most days, and 60% ate 1–2 sweet snack items most days (data not shown). The proportions of children with caries increased by increasing number of sweet items reported to be eaten most days (fig. 1a). There was less caries in children who drank milk compared with other drinks (non-sweetened or sweet) with the snacks (fig. 1b).

Caries was significantly more prevalent among children who ate chips most days, and their mean deft score was higher than in those who did not (table 3). Snacking on candies, cookies and ice cream was also associated with a higher proportion of children with caries. The mean deft score was significantly higher in children eating dry cereals and dried fruit. The most frequently consumed snack foods (fresh fruit, crackers and yoghurt), however, were not associated with caries (table 3).



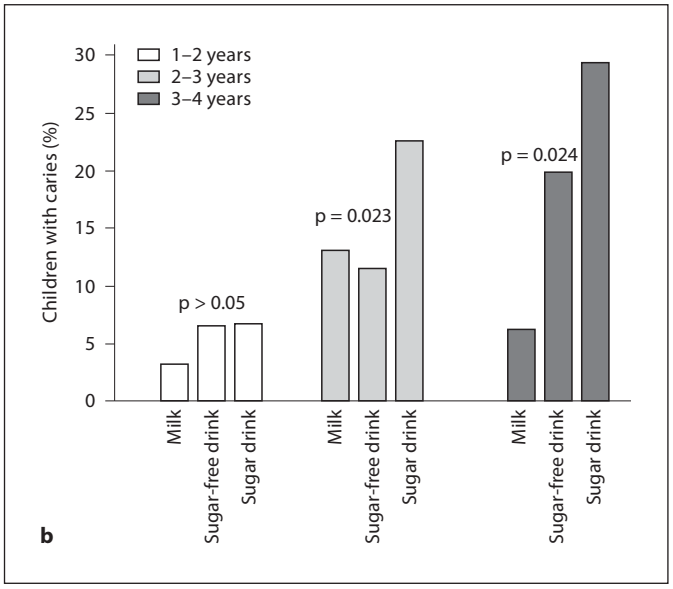


Fig. 1. p values from χ^2 analyses within each age category are indicated in the figures. p values for merged age categories were $p < 0.0001$ (**a**) and $p = 0.002$ (**b**). **a** Proportion of children with caries by number of sweet snack items eaten most days. **b** Proportion of children with caries by type of drink reported to be consumed with snack.

Children who were allowed to continue breast-feeding after falling asleep (mainly the same children reported to be breast-fed) had significantly higher deft values than those who were not (table 4). Allowing a bottle in bed was unrelated to caries prevalence in this population (table 4).

Multivariate Analysis

A multivariate PLS model with caries status was used to simultaneously evaluate the caries associations identified in the prior univariate analyses, and it included age

Table 3. Caries status by snack intake

and number of teeth. In this model (ln-transformed deft) as y, and all variables describing intake of snacks, breast- and bottle-feeding, oral hygiene, tooth exposure time (child age, number of teeth), socioeconomic status (income, education) and gender were tested. The model had 2 significant components explaining 13% ($R^2 = 0.134$) and predicting 11% ($Q^2 = 0.109$) of the caries variation (fig. 2a, loading scatter plot; fig. 2b, correlation coefficient plot). The most influential variables in the model (all associated with high caries scores) were presence of plaque (VIP value = 2.39), descriptors for tooth exposure time (number of teeth: VIP value = 1.68; child age: VIP value = 1.50) and several dietary components: total intake of sugar-containing snacks (VIP value = 1.56), intake of chips (VIP value = 1.36), and chips intake with a sugar-containing drink (VIP value = 1.24). Snacking on candies had a borderline effect (VIP value = 0.96), whereas all other snacks had a minimal effect (VIP values <0.9). Models using a dichotomous caries variable provided the same results (data not shown).

PLS modelling also indicated that eating chips as a snack clustered with eating a high number of sweet snacks most days, eating candies, popcorn and ice cream (fig. 3, encircled factors all have VIP values >1.0).

Discussion

Repeated pH drop on the tooth surface from carbohydrate fermentation by dental biofilm bacteria is aetiologic to dental caries, but disease outcome is modulated by host and other factors. The relative role of various risk indicators, however, differs between populations [Mattos-Graner et al., 1998; Ramos-Gomez et al., 1999; Tada et al., 1999; Dini et al., 2000; Dasanyake and Caufield, 2002; Santos and Soviero, 2002; van Palenstein Helderman et al., 2006]. Notably, an association between sugar intake and caries development could not be demonstrated in many industrialized 'low-caries' countries [Garcia-Closas et al., 1997; Dye et al., 2004; Öhlund et al., 2007]. The present study shows that snacking on sucrose-containing products, as well as starch-containing chips and presence of plaque are associated with caries in children living in a low-socioeconomic-status, 'high-caries' area in an industrialized country (USA) [Kressin et al., 2009; Nunn et al., 2009].

The present study showed an association between consumption of chips and caries status not previously demonstrated in humans. This association might be explained by a direct caries-inducing effect of chips, or by chips intake clustering with other caries-promoting lifestyle factors. The present study design did not allow for such a distinction, and both aspects might well be involved. In vitro and in vivo studies have shown the pH-lowering effect of hydrolysed starch to be as rapid and deep as that of sucrose [Lingström et al., 1994], and in animal studies there has been shown a caries-inducing potential similar to that of sucrose [Mundorff-Shrestha et al., 1994]. In addition, animal studies have demonstrated that starch potentiates the cariogenic effect of sucrose [Ribeiro et al., 2005]. The PLS modelling using chips intake as the dependant variable, however, showed that children who were given chips as a snack most days also had a high intake of sweet snacks, ice cream and candies, illustrating a clustering of an unfavourable dietary patterns. Notably, chips intake was unrelated to presence of visible plaque.

Besides chips intake and indicators of possible total tooth exposure to cariogenic products – i.e. child age and number of teeth –, presence of visible plaque, number of sweet items used for daily snacking and low family income were independently associated with caries status in the multivariate PLS modelling in this study population. This conforms with earlier studies showing childhood caries was experienced more frequently in children who live under poor economic circumstances, belong to ethnic and racial minorities, have single mothers or have parents with low education, as well as with studies identifying plaque presence and sugar intake as risk indicators for caries [Harris et al., 2004; Vachirarojpisan et al., 2004; Gussy et al., 2006; Kanasi et al., 2010]. We found

PLS modelling to be a useful tool for identifying caries risk indicators as it allows a large number of explanatory variables to be examined simultaneously even though these variables covary [Jonasson et al., 2007; Kanasi et al., 2010].

The cariogenic potential of human milk with approximately 7% lactose has been questioned [Caplan et al., 2008; Mohebbi et al., 2008]. Several recent studies have shown that breast-feeding by itself does not increase the risk of caries in infants [Mohan et al., 1998; Iida et al., 2007; Mohebbi et al., 2008], with the possible exception of continued feeding after the child has fallen asleep [Roberts et al., 1993; Valaitis et al., 2000], as supported by the present data. Thus, children who were breast-fed after having fallen asleep tended to have more caries, but this finding would need confirmation by additional study since only a few children were breast-fed, and only the mean deft value, and not the proportion of breast-fed children with caries, was higher in breast-fed children. Bottle-feeding with sucrose-containing infant formulas, fruit soups or syrups, especially in bed, were reported to be risk indicators for caries in young children [Seow et al., 2009], but this was not confirmed in the present children. In contrast, consumption of cow's milk together with the suspected cariogenic snacks was associated with less caries than consumption of sugar-free or sugar-containing drinks.

The strengths of the present study were that (i) children were recruited from the general population in an area where caries in very young or preschool children is prevalent, and that recruitment was not restricted to those seeing a dentist, (ii) the children represented diverse races and ethnicities, and (iii) the number of children was high. Limitations were (i) the potential for recall bias in the survey information, (ii) the highly skewed low-caries distribution, and (iii) the lack of radiographs to examine teeth (which was not possible in the paediatrician's office). Bratthall [2000] has suggested the use of a Significant Caries Index, corresponding to data from the highest caries tertile to overcome a skewed distribution, but this was not applicable to this population since less than one third of the children had carious lesions.

Caries in early childhood is frequently observed, which preferentially should be addressed by preventive measures as treatment is costly and children with caries in early childhood are prone to high caries activity in the permanent dentition [Alm et al., 2007]. Caries risk is especially high in underprivileged or vulnerable groups [Nunn et al., 2009]. The present study suggests that good oral hygiene and promotion of healthy snacking remain targets for prevention in these children. In the present study, however, the risk indicators examined only explained 13.4% of the disease variation; thus, further studies using additional and new improved risk markers are still desirable.

Microbial Risk Markers for Childhood Caries in Pediatricians' Offices

ABSTRACT

Dental caries in pre-school children has significant public health and health disparity implications. To determine microbial risk markers for this infection, this study aimed to compare the microbiota of children with early childhood caries with that of caries-free children. Plaque samples from incisors, molars, and the tongue from 195 children attending pediatricians' offices were assayed by 74 DNA probes and by PCR to *Streptococcus mutans.* Caries-associated factors included visible plaque, child age, race, and snacking habits. Species were detected more frequently from tooth than tongue samples. *Lactobacillus gasseri* ($p < 0.01$), *Lactobacillus fermentum, Lactobacillus vaginalis*, and *S. mutans* with *Streptococcus sobrinus* (all $p < 0.05$) were positively associated with caries. By multifactorial analysis, the probiotic *Lactobacillus acidophilus* was negatively associated with caries. *Prevotella nigrescens* was the only species ($p < 0.05$) significantly associated with caries by the 'false discovery' rate. Analysis of the data suggests that selected *Lactobacillus* species, in addition to mutans streptococci, are risk markers for early childhood caries.

KEY WORDS: early childhood caries, *S. mutans, Lactobacillus.*

INTRODUCTION

Despite a high dental caries prevalence (28%) in US pre-school children (Beltran-Aguilar *et al.,* 2005), treatment is not universally available, particularly for disadvantaged children (Siegal *et al*., 2005). Thus, there is need for dental care through government and state programs (Edelstein, 2000; Lee *et al*., 2004), as well as for dental screenings, parental counseling, and fluoride application in pediatricians' offices (Lewis *et al*., 2000). Since dental caries is a bacterial infection, testing for caries microbial biomarkers could facilitate identifying children at greatest risk for caries and most in need of care.

The primary pathogens associated with dental caries are *Streptococcus mutans* and *Streptococcus sobrinus,* the mutans streptococci. Other caries-associated species include non-mutans *Streptococcus*, *Lactobacillus, Actinomyces, Bifidobacterium,* and *Veillonella* species (Van Houte, 1993). Studies of early childhood caries (ECC) microbiota using cultural (Marchant *et al.*, 2001) and molecular approaches (Corby *et al.*, 2005; Aas *et al.*, 2008) further expanded the range of species detected in caries. Several reports have also documented the detection of periodontal species in young children, including *Porphyromonas gingivalis, Aggregatibacter actinomycetemcomitans, Parvimonas micra* (*Peptostreptococcus micros*), *Tannerella forsythia,* and *Treponema denticola* (Kamma *et al.*, 2000; Tanner *et al.*, 2002b). Early colonization with periodontal pathogens probably reflects gingival inflammation, but could indicate risk of periodontitis in adulthood.

This study aimed primarily to determine microbial risk markers for early childhood caries that could be used in risk assessment for caries development. As a possible location for screening young children, microbial samples were obtained from pediatricians who served socio-economically disadvantaged children at increased risk for ECC. Positive associations between bacterial species with caries would suggest that they are caries biomarkers. These could be used in risk assessment to identify children most at risk for caries development and progression, and who would benefit from dental counseling and preventive protocols.

Table 1. Demographic and Clinical Characteristics of Study Population

	Caries-free n = 160	Caries n = 35	Caries-positive	p-value

MATERIALS & METHODS

Study Population

Pre-school children were recruited in a cohort study from pediatric clinics (Boston Medical Center-Boston University, Floating Hospital-Tufts Medical Center, Boston, MA, USA). Inclusion criteria were that the child was from 1 to 6 yrs of age, had not taken antibiotics in the preceding 3 mos, and the parent or guardian was willing to consent to the child's clinical examination and microbial sampling. The study design, protocol, and informed consent were examined and approved by the Institutional Review Boards of the institutions involved. Children consenting to microbial samplings were from a larger cohort of children participating in a study to evaluate the efficacy of pediatrician training to reduce rates of early childhood caries (Kressin *et al.,* 2009).

Clinical Examination, Socio-demographic Information, and Bacterial Sampling

Children were examined by two trained and calibrated dental hygienists. The child's socio-demographic characteristics, diet, and oral health practices were collected by survey (Table 1). Presence of teeth and their status as sound, pre-cavitated, cavitated, filled, or sealed were recorded for each tooth (Drury *et al.*, 1999). Visible plaque was recorded on a 0-3 scale (no plaque, plaque covering a mean surface area of <1/3, 1/3 to <2/3, or >2/3 by tooth, respectively).

Plaque samples were taken with sterile toothpicks (Milgrom *et al*., 2000) from: (i) the gingival third of the labial coronal surfaces of incisors, (ii) the buccal and interproximal surfaces of molars, and (iii) across the midline of the tongue. In children with caries (pre-cavitated and cavitated), plaque was sampled from lesions. Samples were collected in 100 μL of 50 mM Tris-EDTA buffer (pH 7.6) and kept frozen at -70°C until microbial analysis.

Microbial Analyses

Plaque samples were analyzed by DNA probes to 74 species (Table 2) in a checkerboard assay as previously described (Tanner *et al.*, 2002a; Socransky *et al.*, 2004). Samples were denaturated, neutralized, and fixed onto a nylon membrane, the last lanes of which were used for quantitation, containing all probe species mixed as a DNA standard at 10^5 and 10^6 bacterial cell equivalents.

For *S. mutans* PCR detection, samples were treated with proteinase K (Dewhirst *et al*., 2000). The assay was run with *S. mutans*-specific reverse primer 5′-ACT CCA GAC TTT CCT GAC CG-3′ and forward universal primer 5′-GAG TTT GAT YMT GGC TCA G-3′ (Paster *et al.,* 1998). The amplification products were visualized with 1% agarose gels. If an amplicon was not detected, a universal PCR (primers: forward as above, reverse 5′-AAG GAG GTG WTC CAR CC-3′) was run to verify the presence of sample DNA.

Data Analyses

Decayed (d), comprising pre-cavitated and cavitated lesions, and filled (f), not including sealants, primary teeth (t) for each child were summarized by a decayed-filled tooth score (dft). Plaque was dichotomized to 'presence' and 'absence', since half (48%) of the observations were 'no plaque' and half (52%) were 'plaque detected'. Species detection was at $\geq 10^5$ cells with the use of DNA probes (equivalent to the lower DNA internal standard), or a positive PCR reaction. Tooth and tongue samples were matched by child. We used Student's *t* test to compare differences in means,

Table 2. Microbiota of Incisor, Molar, and Tongue Samples of Pre-school Children

Bacterial Species[a]	Percent Detection Frequency 10^5

[a] Species in Table 2 differed significantly between caries-affected and caries-free children (Fig. 1) or were significant in the PLS analysis (Fig. 2).

[b] Species with similar detection between incisors and tongue (McNemar's test, $p > 0.05$).

All tested species are in the Appendix Table. All species were detected at similar frequencies from incisors and molars and more frequently from teeth than from the tongue (McNemar's test, $p \leq 0.05$).

chi-square test for proportions between socio-demographics, plaque, species detection, and caries, and McNemar's test for species detection at paired intra-oral sites. A p-value ≤ 0.05 was considered significant. Results were also adjusted for multiple comparisons by the false-discovery rate ($\alpha = 0.05$) (Benjamini and Hochberg, 1995). We used regression analysis to evaluate child caries extent with age and plaque and their interactions, and model sensitivity analysis was performed by overdispersed Poisson regression. Statistical analyses were performed with SPSS® software.

Multivariate analysis was performed with Partial Least Squares (PLS) modeling (SIMCA P, Umetrics, Umeå, Sweden) (Hellberg *et al.,* 1986). PLS is a linear model that detects correlations between matrices of each independent (x) variable and outcome (y) variables to generate model R^2- (estimated model explanation) and Q^2- (estimated model prediction) values, and variable Importance in Projection (VIP) values, which, if >1.0, indicates influential and, if VIP $\geq$ 1.5, highly influential x-variables. Separate and combined microbial and survey data were modeled on caries (dft) by logarithmic transformation [$\log_{10}$(dft) after input of 0.01 for 0] and dichotomization (0 for dft = 0 and 1 for dft > 0) of dft values. SIMCA P auto-centering and scaling to unit variance were applied to all variables, and leave-one-out cross-validation was used. Generally, R^2- and Q^2- values should not differ by more than 0.2.

RESULTS

Demographic and Clinical Characteristics

The population sample was comprised of 195, predominantly Black (77%), children (Table 1). For most children, parental education was $\leq$ 12 yrs (57%), and annual household income was < $20,000 (46%). Caries was detected in 18% of the children, mainly affecting Asian (42%) and Black (19%) children ($p < 0.05$) (Table 1). Survey variables associated with caries were: previous child dental visits, crackers, potato chips, and cereal consumption (all $p < 0.05$), and visible plaque ($p < 0.001$) (Table 1). In the children without visible plaque, caries (6%) was unrelated to age. In the children with plaque (52% of children), caries (28%) was related to age ($p = 0.02$). Caries extent (dft) increased with plaque presence and higher age ($p < 0.05$, data not shown). Child age ($p = 0.0041$) and detectable plaque ($p < 0.0001$) were also significant after sensitivity analysis by overdispersed Poisson regression.

Microbiology

DNA probe data from matched tooth and tongue samples (Table 2 and Appendix Table) showed a consistently higher species detection frequency from teeth compared with the tongue. Species were detected at similar frequencies from incisor and molar samples ($p = 0.09$-1.00). The most frequently detected species (>60% of children) included *Streptococcus* and *Actinomyces* species, *Rothia dentocariosa, Filifactor alocis,* and *Veillonella parvula*. Caries-associated species ($p \leq 0.05$) from molar plaque samples (Fig. 1 and Appendix Fig) included: *S. mutans*, *S. mutans* with *S. sobrinus* ($p = 0.03$), *Streptococcus intermedius, Lactobacillus vaginalis, Lactobacillus fermentum, Lactobacillus gasseri* ($p < 0.01$), *Actinomyces odontolyticus*, *Actinomyces israelii,* and *V. parvula* ($p < 0.01$). Subgingival species detected more frequently from caries-affected children ($p \leq 0.05$) included *Eubacterium brachy, P. micra, F. alocis, P. gingivalis* ($p < 0.01$), *Prevotella nigrescens*, *Porphyromonas endodontalis*, *A. actinomycetemcomitans,* and *Leptotrichia buccalis* ($p < 0.05$). *P. nigrescens* remained significant ($p < 0.05$) after multiple-comparisons adjustment.

S. mutans was detected by PCR in 41% molar, 32% incisor, and 14% tongue plaque samples from 169 children with valid samples from all sites (data not shown). Detection frequencies of *S. mutans* from caries-affected and caries-free children,

respectively, were: molar, 69% and 35%; incisor, 63% and 25% (both $p < 0.001$); and tongue, 22% and 12% ($p = 0.167$). *S. mutans* was associated with children with plaque compared with plaque-free children in molar (51% and 31%) ($p < 0.01$), incisor (42% and 21%) ($p < 0.01$), and tongue (20% and 6%) ($p < 0.05$) samples, respectively.

Initial multivariate analyses (PLS) identified age and number of teeth at risk as influencing caries detection. Modeling, performed in age groups (< 2 yrs, ≥ 2 to < 3 yrs, and ≥ 3 yrs of age) with dft as the dependent variable, indicated that bacterial detection and the presence of visible plaque yielded statistically significant models for the three age groups ($R^2 = 0.78$, $Q^2 = 0.21$; $R^2 = 0.54$, $Q^2 = 0.15$; and $R^2 = 0.53$, $Q^2 = 0.14$, respectively). There were no significant models for caries with the survey data alone, and combining microbial and survey data improved the model values only marginally.

When data from all children were analyzed, plaque and *S. mutans* detection by PCR were highly influential variables for higher dft scores (VIP > 1.5) (data not shown). *L. vaginalis, A. odontolyticus*, *A. israelii, P. nigrescens*, *Prevotella loescheii*, *P. gingivalis, A. actinomycetemcomitans,* and *V. parvula* were consistently influential in children with higher dft (VIP > 1.0). In contrast, *Lactobacillus acidophilus*, *Lactobacillus reuteri*, *Eubacterium saburreum, Eubacterium nodatum,* and *Campylobacter gracilis* were consistently influential in children with lower dft (VIP > 1.0).

When data were restricted to children with visible plaque, *S. mutans* by PCR was highly associated with caries (model $R^2 = 0.48$, $Q^2 = 0.23$) (VIP>1.5, Fig. 2). *A. israelii, Eubacterium timidum, A. actinomycetemcomitans,* and *V. parvula* were influential with caries extent (higher dft) (VIP > 1.0-1.3), whereas *L. gasseri, B. dentium, A. odontolyticus,* and *P. nigrescens* were borderline influential (VIP = 0.9). In children with plaque, the significant negative influence of *L. acidophilus*, *E. saburreum,* and *E. nodatum* on caries was confirmed (VIP > 1.5), and several additional species exhibited highly influential negative associations with caries (VIP = 1.0-1.4, Fig. 2). Caries-associated species explained 50% of caries extent.

Log-transformed and dichotomized dft gave similar results in all PLS models.

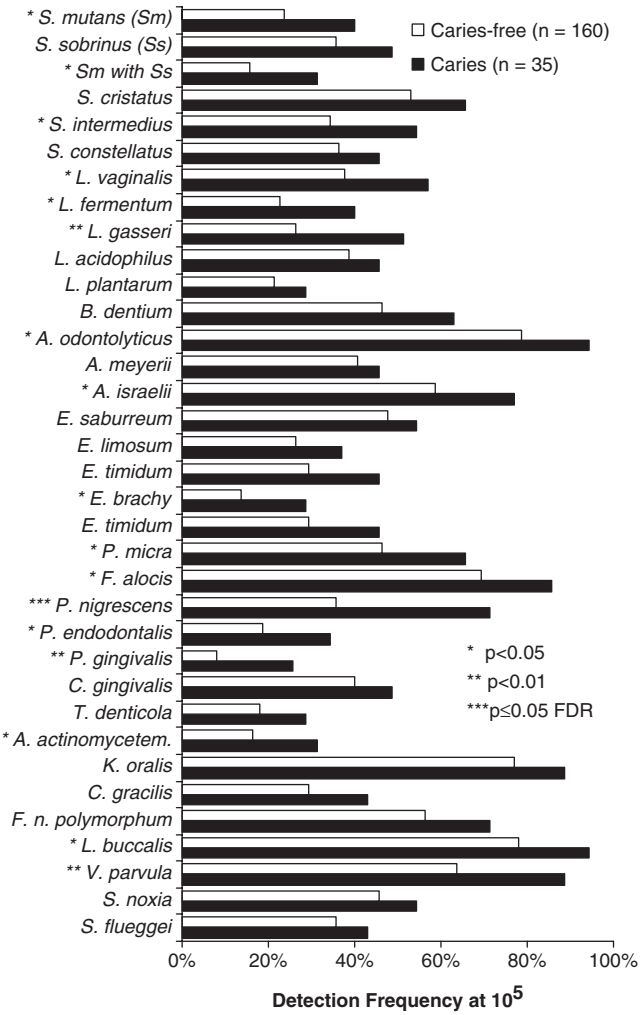

Figure 1. Microbiota of caries-affected and caries-free children. Bacterial species with > 5% difference in detection between caries-affected and caries-free children are in the same order as in Table 2. Most bacterial species assayed were detected more frequently (*$p \leq 0.05$ or **$p \leq 0.01$) from children with caries than from caries-free children. *P. nigrescens* association remained significant after adjustment for multiple comparisons by the false-discovery rate (***$p \leq 0.05$ FDR). *A. actinomycet.* is *Aggregatibacter actinomycetemcomitans,* and *F.n. polymorphum* is *Fusobacterium nucleatum* subspecies *polymorphum*.

DISCUSSION

Microbiology sampling was successfully integrated into pediatric practices serving low-income populations as a means of seeking microbial biomarkers for ECC. This study expanded microbial risk markers for ECC beyond mutans streptococci to include selected *Lactobacillus* species. Non-microbial caries risk factors included visible plaque, child age, race, and snacking habits. Detection of subgingival/periodontal species in children was confirmed. While the PLS statistical models showed low predictive power, R^2-$Q^2 > 0.2$, and suggested cautious interpretation of findings, overall the data are generally consistent with previous reports, as discussed below.

S. sobrinus detection with *S. mutans* showed high associations with ECC, which is consistent with studies correlating this species combination with caries development (Seki *et al.*, 2006) and higher caries prevalence than *S. mutans* alone (Okada *et al.*, 2005). Among the non-mutans streptococci, *S. intermedius* was associated with ECC, as previously reported in a different population of young children (Tanner *et al.*, 2002b).

Caries-associated *Lactobacillus* species in the current report included *L. gasseri*, previously detected in childhood and adult caries (Munson *et al.*, 2004; Corby *et al.*, 2005), *L. fermentum,* detected in childhood caries (Marchant *et al.*, 2001; Aas *et al.*, 2008), and *L. vaginalis,* reported in caries-active young women's saliva (Caufield *et al.,* 2007). Most of these *Lactobacillus* species were also detected by molecular methods from adult carious dentin (Chhour *et al.*, 2005). In contrast, the *Lactobacillus* species *L. rhamnosus, L. acidophilus*, *L. plantarum*, and *L. reuteri*, which are used in probiotic infant enteric and/or oral anti-caries therapy (Savino *et al.,* 2007; Twetman and Stecksén-Blicks, 2008), showed negative associations with caries. *A. israelii* and *A. odontolyticus* were detected more frequently in caries, as previously reported (Marchant *et al.,* 2001; Tanner *et al.*, 2002b).

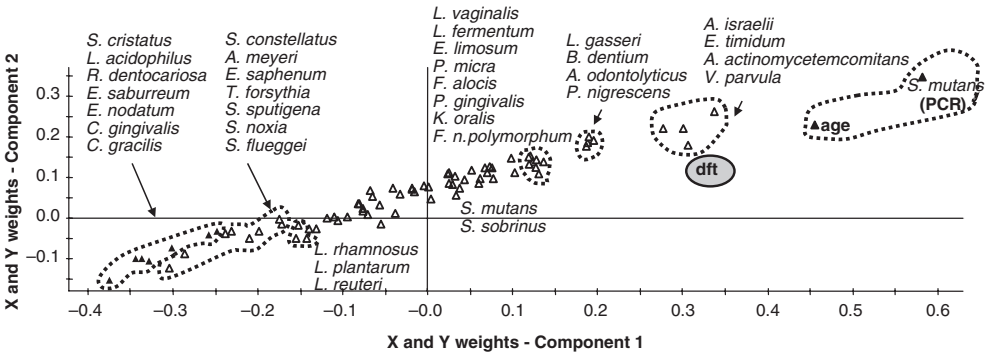

Figure 2. Scatter plot of Partial Least Squares (PLS) weights w*c for bacterial data modeled on caries prevalence (dft) in children with visible plaque (n = 102). For a given PLS model, one vector of X-weights w^*_a and one vector of Y-weights c_a are obtained for each model component (a). The X- and Y-weights are plotted together for the first two components (w*c [1] and w*c [2]). Variable importance in projection (VIP) indicates how influential the outcome (microbial) variables are in explaining the variable of interest (decayed filled teeth-dft). VIP > 1.0 is influential, and VIP ≥ 1.5 is highly influential. In this plot, species located close to the outcome variable dft were positively associated with dft, whereas those in the opposite direction represent species negatively associated with dft. Encircled ▲ indicate positions of highly influential species (VIP > 1.5), and encircled △ positions of influential (VIP 1.0-1.4) or borderline influential species (VIP 0.7-0.9). Non-labeled, not encircled △ indicate positions of non-influential species. *S. mutans* and *S. sobrinus* (when detected by checkerboard) were positively associated with caries, but were non-influential in this model.

Subgingival periodontal species were also detected in these young children, particularly from the molar plaque samples that included gingival bacteria. Subgingival species detected included *A. actinomycetemcomitans, P. micra, P. gingivalis, T. forsythia,* and *T. denticola,* as has previously been reported in young children (Könönen *et al.*, 1992; Tanner *et al.*, 2002b), at detection frequencies consistent with cultural assay (Kamma *et al.*, 2000). Other subgingival species associated with adult periodontitis (Kumar *et al.*, 2005), but infrequently reported in pre-school children, included *E. brachy*, *Eubacterium saphenum*, *F. alocis*, and *Selenomonas flueggei.* Colonization of these species probably reflected gingivitis (not consistently measured in this study), but may pose risk for future periodontitis.

Increased species detection in caries may be a reflection of larger plaque samples. Nonetheless, comparable caries-associated species were detected in all children compared with children with visible plaque. In other studies, visible plaque was strongly associated with caries (Wennhall *et al.*, 2002; Mohebbi *et al.*, 2006), and was an indicator for future caries development in young children (Alaluusua and Malmivirta, 1994).

For microbial screening, plaque sampling should be easy and rapid. Similar species detection rates between incisors and molars suggest that either tooth site could be sampled, in contrast to tongue samples, which exhibited lower detection frequencies of DNA probe species. Lower species detection from the tongue than from the teeth suggests that screening for caries pathogens in tongue samples is less sensitive than screening samples from teeth, and may result in false-negative data.

Caries prevalence in this study was similar to US national levels (Beltran-Aguilar *et al.*, 2005). Increased caries experience in Asian and Black compared with White children has also been reported, with Asians having the highest caries prevalence (30%) and untreated caries (49%) (Shiboski *et al*., 2003). There was more caries (dft) in the older children, reflecting the longer time teeth were exposed to caries-risk factors. Other caries-associated risk factors were consistent with previous findings. Frequent snacking was associated with caries. High-starch foods like potato chips and crackers stay in the mouth longer and aid in increased acid production, contributing to caries development (Kashket *et al.*, 1996). The association of ECC and having a dentist might seem counterintuitive. Families with children with cavities and possibly pain, however, are more likely to seek treatment than are dentally healthy children.

In conclusion, children in disadvantaged populations were sampled to evaluate microbial risk biomarkers for caries, indicating the feasibility of accessing these children while attending routine and emergency visits in pediatricians' offices. Using univariate and multivariate approaches, we associated selected *Lactobacillus* species, in addition to mutans streptococci, with early childhood caries. Future study will indicate if these species are risk indicators for future caries, and if they can be used to select children most in need of preventive and treatment regimens.

Abstract

Total hip and knee replacements (THR and TKR) are high-risk settings for venous thromboembolism (VTE). This review summarizes the cost effectiveness of VTE prophylaxis regimens for THR and TKR. We searched MEDLINE (January 1997 to October 2009), EMBASE (January 1997 to June 2009) and the UK NHS Economic Evaluation Database (1997 to October 2009).

We analysed recent cost-effectiveness studies examining five categories of comparisons: (i) anticoagulants (warfarin, low-molecular-weight heparin [LMWH] or fondaparinux) versus acetylsalicylic acid (aspirin); (ii) LMWH versus warfarin; (iii) fondaparinux versus LMWH; (iv) comparisons with new oral anticoagulants; and (v) extended-duration (≥3 weeks) versus short-duration (<3 weeks) prophylaxis. We abstracted information on cost and effectiveness for each prophylaxis regimen in order to calculate an incremental cost-effectiveness ratio. Because of variations in effectiveness units reported and horizon length analysed, we calculated two cost-effectiveness ratios, one for the number of symptomatic VTE events avoided at 90 days and the other for QALYs at the 1-year mark or beyond.

Our search identified 33 studies with 67 comparisons. After standardization, comparisons between LMWH and warfarin were inconclusive, whereas fondaparinux dominated LMWH in nearly every comparison. The latter results were derived from radiographic VTE rates. Extended-duration prophylaxis after THR was generally cost effective. Small numbers prohibit conclusions about aspirin, new oral anticoagulants or extended-duration prophylaxis after TKR.

Fondaparinux after both THR and TKR and extended-duration LMWH after THR appear to be cost-effective prophylaxis regimens. Small numbers for other comparisons and absence of trials reporting symptomatic endpoints prohibit comprehensive conclusions.

In 2005, there were 580 000 total hip or knee replacements (THR or TKR) performed in the US,[1] and that number is projected to increase to 4.5 million by 2030.[2] Although THR and TKR are generally safe procedures,[3] they have been identified[4] as high-risk events for venous thromboembolism (VTE), which includes deep venous thrombosis (DVT) and pulmonary embolism (PE). For almost 20 years, physicians have been offering pharmacological prophylaxis to patients undergoing THR and TKR; however, uncertainty exists about the optimal pharmacological regimen for prophylaxis.

Guidelines[4] published by the American College of Chest Physicians (ACCP) in 2008 support using potent anticoagulant regimens with agents such as fondaparinux sodium, low-molecular-weight heparin (LMWH) and warfarin (target international normalized ratio [INR] 2–3), and discourage acetylsalicylic acid (aspirin) therapy alone. In contrast, guidelines[5] by the American Academy of Orthopaedic Surgeons (AAOS) support the use of aspirin or a lower-potency warfarin regimen (INR < 2) in addition to LMWH and fondaparinux, stating that the latter agents do not offer increased protection against PE but substantially raise the rate of bleeding complications. New oral anticoagulants such as dabigatran etexilate, a direct thrombin inhibitor, are expected to gain US FDA approval within the next several months and it is anticipated that they too will be supported by the above professional societies.

Several studies have attempted to address these risk-benefit and also cost issues using decision analysis methodology. Some studies[6-8] indicate that the newer regimens are cost effective in preventing VTE, while others[9] do not. Individual study results vary depending on the setting, economic perspective (e.g. groups for which cost and effects will be aggregated – patients, payers or others), horizon (time course over which cost and effectiveness information was assessed) and effectiveness outcome analysed (e.g. VTE events averted, life-years gained, QALYs gained). Measuring effectiveness in QALYs, particularly over a horizon of ≥1 year, permits comparison of cost effectiveness of interventions across diseases, but some authors may choose not to measure QALYs because their focus resides in the economics related to the period immediately following surgery. To more meaningfully compare VTE prophylaxis regimens, we systematically reviewed recently published studies that evaluated the cost effectiveness of the different pharmacological options in patients undergoing THR and TKR. We abstracted information about cost and effects for both a short and long horizon. In each case, we calculated the incremental cost-effectiveness ratios (ICERs) using our abstractions and then converted our estimates into $US, year 2009 values.

1. Literature Review

1.1 Study Selection

Using published recommendations[10] for identification of cost-effectiveness studies, we searched MEDLINE (January 1997 to October 2009), EMBASE (January 1997 to June 2009) and the UK NHS Economic Evaluation Database[11] (1997 to October 2009) [for search strategies, see Appendix 1 in the Supplemental Digital Content 1, http://links.adisonline.com/PCZ/A73]). We also searched the bibliographies of included studies.

We included studies that evaluated the cost effectiveness of pharmacological agents in patients undergoing THR or TKR. Specifically, we focused our search on recent (1997 to October 2009) studies published in English that contained complete documentation of methods (as compared with abstracts or brief reports), had discrete information available for TKR or THR (i.e. not combined with other orthopaedic surgeries) and contained enough information to calculate an ICER for at least one of five important comparisons: (i) anticoagulants (fondaparinux, LMWH, warfarin) versus aspirin; (ii) LMWH versus warfarin; (iii) fondaparinux versus LMWH; (iv) comparisons including new oral anticoagulants; and (v) extended-duration prophylaxis (≥3 weeks with any agent) versus short-duration prophylaxis (<3 weeks with any agent). We did not analyse information about regimens not routinely recommended as sole therapy by the ACCP or AAOS. These include unfractionated heparin, parenteral thrombin inhibitors or non-pharmacological means such as intermittent pneumatic compression or graduated stockings. Two authors (AK and NR) evaluated each study for inclusion. Disagreements were resolved by discussion.

1.2 Study Abstraction and Quality Assessment

We derived an abstraction instrument based on the recommendations of the Panel on Cost-Effectiveness in Health and Medicine.[12-14] Two abstractors (NR and WC) assisted the primary author (AK) in recording, in duplicate, the description of the study setting, cohort age, economic perspective and presence of pharmaceutical industry sponsorship.

To summarize the cost-effectiveness information of our five main comparisons, we abstracted data on the incremental cost and effectiveness for both a short and a longer horizon when available. The horizon represents the period of time over which costs and effectiveness are aggregated. For certain diseases, such as the common cold, a short-horizon analysis may suffice. In other cases, long-term consequences must be accounted for, even for short-term interventions.[12-14] For the short horizon, we abstracted data on the projected costs incurred and VTE events avoided for the period closest to 90 days from surgery. For the purpose of calculating effectiveness, we

abstracted data on the combined incidence of DVT and PE that would be detected in routine clinical practice. If a study did not report such an outcome, we also accepted the incidence of radiographically detected events and noted the distinction. If effectiveness was defined only by life-years or QALYs, we recorded that information.

For the long horizon, we accepted any information that projected the cost and effectiveness for ≥1 year. We abstracted effectiveness information by prioritizing abstraction of the outcome of QALYs or unadjusted life-years.

For each study with missing information about drug regimen, dosage, duration of therapy, horizon of analysis, major bleeding rate, DVT, PE and death rate, we contacted corresponding authors first by email and then by letter. If the authors did not respond, we recorded the information as 'not reported'.

We adjusted all cost information to $US, year 2009 values, by inflating or deflating to the year 2005 according to readily available consumer price indices for each country,[15,16] converting to $US via WHO purchasing power parity indices,[17] and then inflating to $US using the Bureau of Labor Statistics consumer price calculator.[18] This approach followed the example of Bachmann.[19]

1.3 Study Quality

To assess study quality, we created an instrument adapted from 'Drummond's list'[20] and one other instrument from Brauer et al.[21] These included items about the use of cost data from a randomized controlled trial or other primary source, use of efficacy data from pooled results of a systematic review, identification of credible sources for all input parameters, appropriate calculation of an ICER and use of comprehensive one-way sensitivity analyses. The ICER is an expression of how much additionally it costs (in dollars) to achieve an additional unit of benefit (e.g. 1 more QALY). Policy makers are interested in the ICER value because it facilitates determination about whether newer, more effective interventions represent good value compared with existing, less expensive programmes.[22] The threshold for adoption in the US is thought to be somewhere between $US20 000 and $US100 000 per QALY gained.[23]

We also recorded quality items specific to VTE (including assessment of joint function following haemarthrosis, propagation of asymptomatic DVT to symptomatic PE, incidence of post-thrombotic syndrome, costs of major and minor bleeding) and future costs related to VTE (including blood monitoring and physician visits). Studies ignoring downstream bleeding consequences could make newer, more potent regimens appear more cost effective, whereas studies ignoring downstream costs of treating VTE will bias our interpretation in the other direction. We did not specifically document if individual studies included death costs related to VTE or bleeding. On the whole, death events were rare and the associated costs would be largely paid by the family of the patient and not the institution or health system, which was the economic perspective chosen by all but three of the studies analysed.

We did not pool the results of individual studies given the various modelling assumptions adopted by each author. Instead, we qualitatively compared studies to determine trends in the cost effectiveness of certain regimens compared with others.

1.4 Search Results

We identified 370 titles and abstracts meeting our search criteria. Of these, 56 were relevant and were entered for full-text review. Of these, 33 studies met all inclusion criteria[6-9,24-52] (figure 1).

Most studies were set in the US (14 of 33)[27-29,31-37,40,41,43,45] or Europe (14 of 33).[6-8,25,26,30,38,44,46-49,51,52] Twenty studies[6,7,24,27-37,40,41,43-46] adopted an institutional perspective; only three[9,48,49] adopted a societal perspective. Ten studies[6,8,24,28,31,36,46,47,50,52] reported pharmaceutical company sponsorship.

There was substantial variation in the quality of reporting. Only six of the 33 studies reported performing a systematic review and meta-analysis of

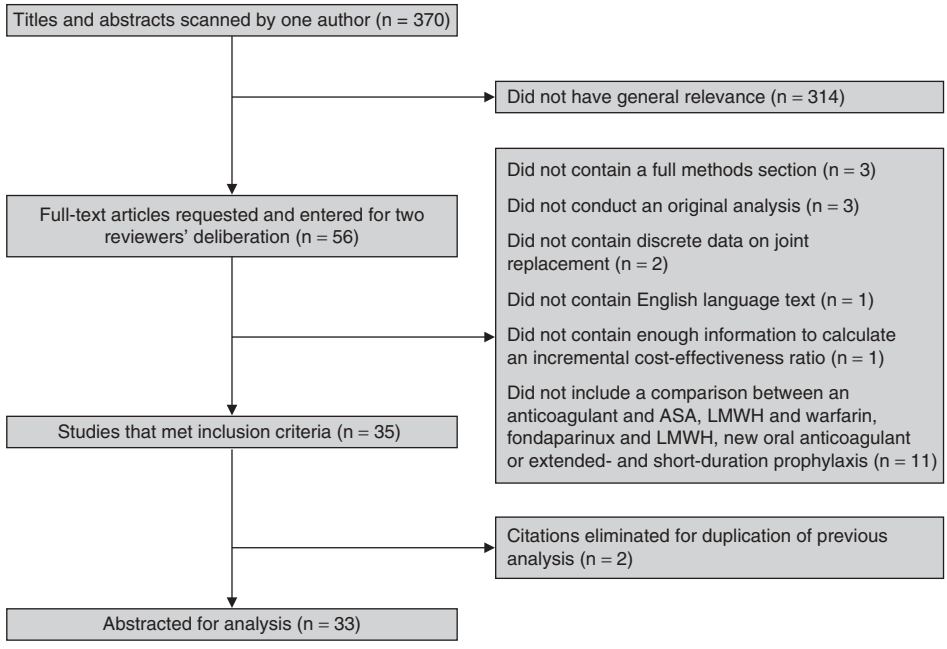

Fig. 1. Flow diagram of article selection. **ASA** = acetylsalicylic acid (aspirin); **LMWH** = low-molecular-weight heparin.

efficacy data.[9,26,28,35,36,50] In addition, only 13 studies[6,9,25,26,28,32-35,44,47,48,52] documented comprehensive use of one-way sensitivity analysis. Only four of 33 studies[9,28,49,50] measured effectiveness in QALYs to at least the 1-year horizon (table I, and table A1 in the Supplemental Digital Content).

2. Anticoagulants versus Aspirin

We included two studies[24,25] with three comparisons of an anticoagulant with aspirin (table II). In all three comparisons, results were available for THR exclusively. Sarasin and Bounameaux[25] found that the ICER was $US1700 per VTE avoided for 4 weeks of warfarin compared with aspirin and $US1300 per VTE avoided for 4 weeks of LMWH compared with aspirin. There was no apparent pharmaceutical company sponsorship for that study. The final comparison, sponsored by sanofi-aventis, the manufacturer of enoxaparin, was set in South Africa and reported an ICER of $US7200 per VTE avoided for 10 days of enoxaparin compared with 10 days of aspirin.

3. Low-Molecular-Weight Heparin (LMWH) versus Warfarin

We included 15 studies with comparisons of LMWH and warfarin[9,25-37,50] (table III). Twelve compared these agents in patients receiving THR. Of those documenting a short-horizon cost-effectiveness result, three[25,34,50] found that the ICER for LMWH was ≤$US2000 per VTE avoided compared with warfarin. In two other studies,[28,29] LMWH cost an additional $US2100 per VTE avoided. In a sixth study,[32] LMWH cost $US5200 per VTE avoided. In the next study,[9] LMWH cost $US109 000 per VTE avoided. This study by Skedgel et al.[9] examined 4 additional weeks (in addition to the hospital period) of LMWH compared with 4 additional weeks of warfarin. It found that the cost, in Canada, would be almost 10-fold higher for LMWH given the significant proportion of patients (39% at

baseline) that would require *daily* nursing supervision of LMWH injection in their homes than the same proportion that would require *weekly* home phlebotomy for monitoring INR while using warfarin. In the remaining four studies of short horizon,[26,30,31,36] warfarin dominated LMWH.

In two studies with a long horizon, results conflicted, with one study[28] finding that LMWH dominated warfarin while the other[37] found the opposite.

In comparisons that analysed cost effectiveness in the setting of TKR (or TKR cases combined with THR cases), LMWH dominated or cost <$US2000 per VTE avoided in five studies.[27,33-35,50] In the final study,[26] warfarin dominated LMWH.

Eight of 15 studies comparing LMWH with warfarin reported some pharmaceutical company sponsorship, grant support or involvement of pharmaceutical company consultants. In each case, the pharmaceutical company was the manufacturer of LMWH; either sanofi-aventis, Pfizer or a company that merged with these two. All but two[31,36] of these eight found favourable cost-effectiveness ratios for LMWH. The two studies[9,26] by government agencies indicated that LMWH was either poor value for its cost or was dominated by warfarin.

4. Fondaparinux versus LMWH

We included ten studies with comparisons of fondaparinux and LMWH[7,8,38-45] (table IV). Nine of ten analysed prophylaxis for THR. Six studies[7,8,38,39,41,45] analysed cost effectiveness over a short horizon. In all six, fondaparinux dominated or cost ≤$US1300 per VTE avoided. In four studies with a long horizon, fondaparinux dominated LMWH. In a fifth, LMWH cost $US40 per VTE avoided.

Of the eight studies reporting cost-effectiveness results for TKR,[7,8,38,39,42-45] all but one found that fondaparinux dominated LMWH over the short and long horizon. In this study,[42] fondaparinux cost an additional $US660 per VTE avoided.

Among the ten studies comparing fondaparinux with LMWH, a pharmaceutical company sponsored one and supported five more through

b DVT rate not specified according to clinical vs radiographic and proximal vs distal.

c Cost-effectiveness result is the ICER. To arrive at ICER values, incremental costs reported in foreign currencies were inflated or deflated according to readily available consumer price indices, converted to $US via 2005 WHO purchasing price parity indices, and then inflated to year 2009 values using the Bureau of Labor Statistics consumer price calculator.[18]

DVT = deep venous thrombosis; **ICER** = incremental cost-effectiveness ratio; **NR** = not reported; **od** = once daily; **PE** = pulmonary embolism; **VTE** = venous thromboembolism.

grants. In each case the sponsor or grantor was sanofi-aventis, the manufacturer of enoxaparin (the inferior comparator). Each result demonstrated good value with dominance by the use of fondaparinux.

5. Comparisons Including New Oral Anticoagulants

Only two studies to date have made comparisons with new oral anticoagulants (see table V). In the only one that made this comparison in patients undergoing THR, Wolowacz et al.[52] found that dabigatran dominated LMWH over a 60-year horizon (equivalent to a lifetime analysis, given the elderly age of the average patient undergoing THR).

In the setting of TKR, McCullagh et al.,[51] found that, in the short horizon of 180 days, rivarobaxan dominated both LMWH and dabigatran; dabigatran cost an additional $US750 per VTE avoided compared with LMWH. In the long horizon, Wolowacz et al.[52] found that dabigatran dominated LMWH.

The study by Wolowacz et al.[52] was sponsored by Boehringer Ingelheim, the manufacturer of dabigatran, whereas McCullagh et al.[51] reported no sponsorship or support.

6. Extended-Duration versus Short-Duration Prophylaxis

We found nine studies[6,9,30,46-51] with comparisons of extended- versus short-duration prophylaxis in patients undergoing THR (table VI). Among short-horizon results, three studies[30,46,51] with five comparisons found that extended-duration therapy after THR either dominated short-duration prophylaxis or the ICER was <$US120 per VTE avoided. In Skedgel et al.,[9] extended-duration warfarin prophylaxis cost an additional $US3200 per VTE avoided but extended-duration LMWH cost an additional $US27 400 per VTE avoided. In five other studies, the ICER for extended-duration therapy was between $US7800 and $US13 200 per VTE avoided. In McCullagh et al.,[51] dabigatran administered for 35 days cost $US730 000 per VTE

b Radiographic VTE rate.

c Cost-effectiveness result is the ICER. To arrive at ICER values, incremental costs reported in foreign currencies were inflated or deflated according to readily available consumer price indices, converted to $US via 2005 WHO purchasing price parity indices, and then inflated to 2009 values using the Bureau of Labor Statistics consumer price calculator.[18]

d DVT rate (i.e. symptomatic vs radiographic) not specified.

e ICER compares extended LMWH with extended-duration warfarin.

bid = twice daily; **DVT** = deep venous thrombosis; **ICER** = incremental cost-effectiveness ratio; **INR** = international normalized ratio; **NR** = not reported; **od** = once daily; **PE** = pulmonary embolism; **VTE** = venous thromboembolism.

avoided compared with short-duration LMWH; the high ICER results mainly from the many-fold increased bleeding rates found with dabigatran than with LMWH (2.0% vs 0.08%).

Among two THR studies with long-horizon results available, Bischof et al.[6] found that extended-duration fondaparinux dominated short-duration fondaparinux. Haentjens et al.[49] found that extended-duration enoxaparin cost an additional $US9300 per QALY gained compared with short-duration enoxaparin.

We found only two studies for TKR. At a 35-day horizon, Dranitsaris et al.[50] found that the extended-duration dalteparin cost an additional $US14 600 per VTE compared with short-duration warfarin and $US60 000 per VTE compared with short-duration dalteparin. At a 1-year horizon, Haentjens et al.[49] found that extended-duration enoxaparin cost an additional $US73 300 per QALY gained compared with short-duration enoxaparin.

Six of the nine studies comparing extended- with short-duration therapy included pharmaceutical company sponsorship or grant support. There was no clear trend among the results with respect to the presence of sponsorship, although two of the three studies sponsored exclusively by a government agency found that extended-duration therapy with LMWH or dabigatran delivered improved effectiveness at a relatively high cost ($US27 400–730 000 per VTE avoided). As mentioned above, the third study by Haentjens et al.[49] found that extended-duration LMWH was clearly cost effective after THR but poorer value after TKR.

7. Discussion

Although multiple VTE prophylaxis regimens are supported by the ACCP and the AAOS, our systematic review suggests that not all of them may be cost effective relative to other regimens. There was no consensus about the cost effectiveness of LMWH compared with warfarin. In contrast, fondaparinux dominated LMWH in nearly every comparison we found. Extended-duration prophylaxis with LMWH after THR appeared to be cost effective, with multiple

studies indicating that extended-duration prophylaxis dominated short-duration LMWH or cost no more than an additional $US10 000 per VTE avoided. The small numbers of studies, predominance of studies analysing only a short horizon, lack of established cost-effectiveness thresholds for VTE-based effectiveness units and reliance by study authors on venographic endpoints prohibit robust conclusions about the comparisons analysed.

Comparisons of our work with previous reviews of the economic literature are limited by differences in type of surgery included and publication dates of the included articles. Sullivan et al.[53] summarized the prophylaxis literature between 1984 and 2000 and found that most studies presented consistent findings, including that LMWH is cost effective compared with warfarin. Our results do not support this conclusion. Sullivan et al.[53] based their conclusions on many studies that we excluded because they were published prior to 1997 or that included outcomes from patients undergoing hip fracture surgery. We believe temporal trends[54,55] in the care of THR and TKR necessitated excluding earlier studies. We also felt that hip fracture surgery identified a distinctive patient population with respect to cost, risk and benefit issues.[4] Similar to our findings, Sullivan et al.[53] also found that extended-duration LMWH was generally cost effective compared with short-duration therapy.

Ivanovic et al.[56] summarized the literature on fondaparinux. These authors concluded that fondaparinux was *more* cost effective than LMWH (enoxaparin) 40 mg daily initiated *preoperatively* but *less* cost effective than LMWH 30 mg twice daily initiated *postoperatively*. Our review did not specifically compare the cost effectiveness of regimens with LMWH initiated at different times but we found that fondaparinux dominated LMWH in all but one when considering the longer horizon. LMWH dosages in the included studies were evenly distributed between 40 mg daily and 30 mg twice daily. Ivanovic et al.[56] also reported not being able to calculate ICERs for two studies, whereas we were able to calculate them based on data presented in tables included by the study authors.

Table V. Summary of cost-effectiveness studies of new oral anticoagulants[a]

a All doses are once daily.

b Figures presented as new oral anticoagulant/LMWH.

c Cost-effectiveness result is the ICER. To arrive at ICER values, incremental costs reported in foreign currencies were inflated or deflated according to readily available consumer price indices, converted to $US via 2005 WHO purchasing price parity indices, and then inflated to 2009 values using the Bureau of Labor Statistics consumer price calculator.[18]

DVT = deep venous thrombosis; **ICER** = incremental cost-effectiveness ratio; **LMWH** = low-molecular-weight heparin; **PE** = pulmonary embolism; **VTE** = venous thromboembolism.

Wolowacz et al.[57] also published a review discussing the evolution of model building over a 20-year time span (1987–2006). In terms of quality, the findings of that review were generally consistent with the abstractions we performed, particularly with respect to the paucity of studies measuring QALYs over a sufficiently long period. Unlike their review, we abstracted cost and effect information and independently calculated ICERs for each comparison discussed. We converted costs to $US, year 2009 values and measured effects in common units (total VTE events avoided for short-horizon studies and QALYs for long-horizon studies). This facilitated comparisons between the multiple regimens supported by major professional societies.

The most salient finding of our review is that fondaparinux dominates LMWH; however, these results should be interpreted cautiously. There have been only four randomized controlled trials comparing fondaparinux with enoxaparin[58-61] and only one[58] involved patients with TKR surgery. A summary estimate of risk calculated by Turpie et al.[62] suggested that fondaparinux offers a 55% reduction in the odds of venographic VTE but no difference in the incidence of symptomatic VTE at postoperative day 11 when screening venography was performed. The studies of cost effectiveness evaluating fondaparinux generally extrapolated these short-horizon venographic rates to estimate the number of symptomatic VTE events. Recent evidence[63] suggests that the ratio of asymptomatic venographic DVT rate to symptomatic DVT rate is between 3 and 7 for THR and between 15 and 24 for TKR. However, these ratios came from trials using enoxaparin only. Although they do not address this point specifically for fondaparinux, the 2008 ACCP guidelines[4] state that initial efficacy studies using venographic endpoints should be followed with trials that use symptomatic (and objectively confirmed) VTE as endpoints.

There is less conclusive evidence about the duration of prophylaxis, although extended prophylaxis with LMWH appears cost effective compared with short-duration therapy in the case of THR surgery. Authors of cost-effectiveness studies included in this review generally summarized efficacy of extended-duration prophylaxis with LMWH using one or more of the seven

b Figures presented as extended/short duration.

c Cost-effectiveness result is the ICER. To arrive at ICER values, incremental costs reported in foreign currencies were inflated or deflated according to readily available consumer price indices, converted to $US via 2005 WHO purchasing price parity indices, and then inflated to 2009 values using the Bureau of Labor Statistics consumer price calculator.[18]

DVT = deep venous thrombosis; **ICER** = incremental cost-effectiveness ratio; **INR** = international normalized ratio; **LMWH** = low-molecular-weight heparin; **NR** = not reported; **PE** = pulmonary embolism; **VTE** = venous thromboembolism.

randomized controlled trials[64-70] that reported on the efficacy of extended-duration prophylaxis. At least two of these trials[64,65] did not require venography at the time of discharge from the hospital, permitting assessment of symptomatic VTE rates from 4 to 7 weeks after operation. We cannot draw firm conclusions on the question of extended duration versus short duration of therapy with other agents that have not been studied extensively. Our review also suggests that there is insufficient cost-effectiveness evidence to support extended prophylaxis for TKR. The most recent update of the ACCP guidelines ''recommends'' extended prophylaxis for THR and ''suggests'' extended prophylaxis for TKR.

Limitations to our work include differences in economic perspective and setting. As our results overwhelmingly suggest that fondaparinux dominates LMWH, we believe our conclusions are sound for this comparison, keeping in mind the absence of trial data measuring symptomatic endpoints. The economic perspective did not appear to explain the variations in results found, but we did not have sufficient numbers of studies within each major comparison to make firm statements about the influence of individual differences in analytic methods. Although we converted from foreign currencies to $US using purchasing power parity, cost structures between countries may not be comparable.[71]

We also acknowledge the potential bias exerted by pharmaceutical company sponsorship of multiple studies. This bias could have played a role in the comparisons between LMWH and warfarin and extended- versus short-duration therapy. They do not appear to have played a role in the comparisons including fondaparinux. Multiple studies sponsored by the manufacturer of LMWH found fondaparinux to dominate LMWH. However, we generally did not have sufficient numbers of studies within each comparison type to determine if variation in study results was related to pharmaceutical company sponsorship.

Another major limitation is that there is no established threshold for declaring a prophylaxis regimen cost effective when disease-based units are used to express effectiveness. The QALY permits comparison of the value of interventions

across diseases given that the utilities that are used to calculate them are standardized to estimates between 0 and 1, where 1 represents perfect health and 0 represents death.

Another limitation includes absence of cost-effectiveness analyses about certain comparisons such as fondaparinux versus warfarin, fondaparinux versus aspirin, and low-intensity warfarin (INR < 2) versus any of the other regimens. We also acknowledge the possibility of English language and publication bias, as with any systematic review.

The demand for cost-effectiveness research is growing at a fervent pace. In early 2009, the US Government dedicated $US1.1 billion to comparative effectiveness research, including cost-effectiveness research.[72] The US Centers for Disease Control adopted the results of cost-effectiveness research when it prepared guidelines[73] about screening for HIV infection. Similarly, the US Preventive Services Task Force incorporated model results when it updated its most recent colorectal cancer screening recommendations.[74] As the demand for cost-effectiveness work grows, the need to be able to summarize and standardize the information will also grow. Our work was a comprehensive systematic review of the cost-effectiveness literature regarding VTE prophylaxis for patients undergoing total joint replacement. In addition, we improved upon previous reviews by standardizing cost-effectiveness information to a common currency and effectiveness unit.

8. Conclusions

We found that fondaparinux dominated LMWH in virtually all studies we analysed, but firm conclusions cannot be made until trial data are available that measure symptomatic VTE rates. Extended-duration LMWH prophylaxis also appears cost effective compared with short-duration prophylaxis in the case of THR. There is limited evidence to determine the cost effectiveness of other regimens, including extended-duration fondaparinux, extended-duration LMWH after TKR, prophylaxis with new oral anticoagulants, low-intensity warfarin therapy or aspirin. These knowledge gaps represent important areas for future research.

Risk of venous thromboembolism after total hip and knee replacement in older adults with comorbidity and co-occurring comorbidities in the Nationwide Inpatient Sample (2003-2006)

Alok Kapoor[1*], Alan J Labonte[2†], Michael R Winter[2†], Jodi B Segal[3†], Rebecca A Silliman[4,5†], Jeffrey N Katz[6,7†], Elena Losina[7,8,9†], Dan Berlowitz[10,11†]

Abstract

Background: Venous thromboembolism is a common, fatal, and costly injury which complicates major surgery in older adults. The American College of Chest Physicians recommends high potency prophylaxis regimens for individuals undergoing total hip or knee replacement (THR or TKR), but surgeons are reluctant to prescribe them due to fear of excess bleeding. Identifying a high risk cohort such as older adults with comorbidities and co-occurring comorbidities who might benefit most from high potency prophylaxis would improve how we currently perform preoperative assessment.

Methods: Using the Nationwide Inpatient Sample, we identified older adults who underwent THR or TKR in the U.S. between 2003 and 2006. Our outcome was VTE, including any pulmonary embolus or deep venous thrombosis. We performed multivariate logistic regression analyses to assess the effects of comorbidities on VTE occurrence. Comorbidities under consideration included coronary artery disease, congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), diabetes, and cerebrovascular disease. We also examined the impact of co-occurring comorbidities on VTE rates.

Results: CHF increased odds of VTE in both the THR cohort (OR = 3.08 95% CI 2.05-4.65) and TKR cohort (OR = 2.47 95% CI 1.95-3.14). COPD led to a 50% increase in odds in the TKR cohort (OR = 1.49 95% CI 1.31-1.70). The data did not support synergistic effect of co-occurring comorbidities with respect to VTE occurrence.

Conclusions: Older adults with CHF undergoing THR or TKR and with COPD undergoing TKR are at increased risk of VTE. If confirmed in other datasets, these older adults may benefit from higher potency prophylaxis.

Background

Medical injury, or harm associated with a therapeutic or diagnostic intervention [1], commonly complicates major surgery [2]. Age alone confers a small effect on postoperative injury but medical comorbidities and co-occurring comorbidities contribute substantially. Co-occurring comorbidities, that is, 2 comorbidities which frequently occur together, are part of a larger phenomenon of multiple morbidity [3].

Venous thromboembolism (VTE) is a common, often fatal, and costly injury which complicates major surgery in older adults. VTE is particularly common following total hip and knee replacement (THR and TKR), with venographic rates of up to 60% without prophylaxis [4]. Newer, more potent prophylaxis regimens including the synthetic pentasacchride fondaparinux and twice daily dosing of enoxaparin, a low molecular weight heparin, offer the ability to significantly reduce the risk of VTE. Their wide spread adoption has been slow, however, given the increased risk of bleeding [5]. The ability to identify a high risk cohort among older adults undergoing THR and TKR, who would potentially benefit

from high potency prophylaxis, would be an improvement in the way clinicians currently conduct preoperative assessments.

Comorbidities such as congestive heart failure (CHF) and chronic obstructive pulmonary disease (COPD) have been associated with increased VTE risk in some studies [6-8] but not in others [9,10]. The association with CHF may relate to blood flow stasis which is part of Virchow's triad [11] of alteration in blood flow (stasis), endothelial injury, and alterations in blood constituents (hypercoagulable factors). Similarly the association of COPD may be explained through an immobility or stasis mechanism. Newer evidence, in both surgical [6,7,9,10] and non-surgical settings [12], suggests that atherosclerotic conditions such as coronary artery disease (CAD) and cerebrovascular disease (CVD) are also associated with an increased risk of VTE. In general, these studies had a small number of observations and/or did not focus on discrete surgical procedures, making it difficult to draw conclusions about modest but clinically important effects on VTE of comorbidities for individual surgeries. The combined effect of comorbidities, i.e., co-occurring comorbidities, has been incompletely evaluated.

In this investigation, we assessed the Nationwide Inpatient Sample to determine the risk of VTE in older adults with prevalent comorbidities and co-occurring comorbidities undergoing THR or TKR. We hypothesized that CHF, CAD, CVD, and COPD would predict increased risk of VTE. We also proposed that the joint effect of co-occurring comorbidities – composed of comorbidities with distinct pathogenesis, such as CAD and COPD – would equal the sum of the component effects or possibly exceed their sum, indicating a positive interaction.

Methods

Data Sources and Study Sample

We used the Nationwide Inpatient Sample (NIS) from 2003-2006 for our analysis [13]. This work involves the use of publicly available, archival information abstracted from patient medical records and was approved by the Institutional Review Board at the Boston University Medical Center in Boston, Massachusetts. The NIS contains information from hospital inpatient stays collected at the state-level and then assembled by the Agency for Healthcare Research and Quality (AHRQ) as part of the Healthcare Utilization Project (HCUP). NIS includes primary and secondary diagnoses, procedures, admission and discharge status, patient demographics (gender, age, race, median income, and residence zip code), expected payment source, total charges, length of stay, and hospital characteristics (ownership, size, and teaching status). We identified a cohort of patients (age 65 or older) who underwent primary THR or TKR identified through ICD-9-CM procedure codes 81.51 and 81.54. We restricted our analysis to elective, primary THR and TKR because we felt that non-elective surgery and revision joint surgery represented a distinct population with different risks for VTE. We therefore excluded surgical cases conducted in the setting of fracture, pelvic or thigh infection, or removal of prior prosthesis, internal fixation device, implant or graft consistent with earlier work [14,15] conducted by members of our team.

Outcomes and Exposures

We determined VTE to have occurred if any one of eight ICD-9-CM DVT codes, three PE codes, and two non-specific VTE codes were present at discharge (Additional file 1).

We included specific comorbidities based on evidence of associations with VTE documented in the literature or a known biological link to the outcomes These included CAD, CHF, COPD, CVD, and diabetes. Comorbidities and presence of obesity were coded as by Elixhauser et al.[16] (Additional file 1). Multiple publications [17-19] have supported the use of the Elixhauser comorbidity coding algorithms rather than the earlier Charlson comorbidity index, including those looking at discrete surgical procedures [20,21]. The accuracy of coding of the comorbidities has been validated in multiple publications [22,23]. We also examined co-occurring comorbidities from the above mentioned comorbidities if they had a prevalence of greater than 2% (given that exposures occurring less frequently than 2% of the time would be infeasible to study because of sample size constraints).

Consistent with previous work [14,15,24], we evaluated the effects of potentially confounding factors, i.e., race, insurance status, hospital surgical volume, obesity, bi-laterality (two primary procedures during the same surgery), chronic kidney disease, and hypercoagulable state (including cancer and genetic predisposition), by adding them, one at a time, to the crude model (with comorbidity exposure, age group, and sex). If the addition of a given factor did not change the odds ratios for the comorbidity exposure by more than 10%, it was deleted from the final model.

Analysis

We calculated descriptive statistics and cross-tabular frequencies for each outcome and comorbidity to determine the shape of distributions, the extent of missing data, and the presence of small frequencies of the discrete comorbidity levels. We examined comorbidities for statistical interactions with each other. Specifically, we measured whether prevalent combinations of comorbidities (as defined above) produced statistically significant associations with VTE in multivariate models. Because we found

these to be present in the TKR cohort, for the ease of interpretability, we report the associations between co-occurring comorbidities and outcomes using a categorical comorbidity variable for both the THR and TKR cohorts. We created a ten level categorical variable with a separate, mutually exclusive, level for each of nine comorbidities or co-occurring comorbidities (with 1 additional for all other combinations of two or more comorbidities). While this limited the population size for each comorbidity group, it allowed us to compare the risk of VTE for groups of older adults with single or co-occurring comorbidities against a common reference group of older adults without any of the nine comorbidities.

Finally, we built multivariate logistic regression models to assess the independent effects of comorbidities. In our analysis we retained age and sex in all models. For remaining potential confounders, we retained any variable that changed the effect estimate for any comorbidity by more than 10%.

Results

In NIS 2003-2006, we identified 93,071 primary THR and 223,600 primary TKR surgeries. Overall, the age of older adults was evenly distributed into quartiles 65-69, 70-74, 75-79, and 80 or older. Sixty-three percent of subjects were female. (Table 1) CAD, COPD, and diabetes alone occurred most frequently (9.8%, 8.6%, and 8.4%, respectively for the THR cohort). CVD and CHF occurred much less frequently (0.6% and 1.2%, respectively for the THR cohort). (Table 1) CAD with diabetes was present in 2.5%, and CAD with COPD was present in 1.9% of the THR cohort. (Table 1) Other combinations occurred approximately 1% of the time. Similar trends occurred in the TKR cohort.

VTE during the index hospitalization occurred 0.8% of the time after THR and 1.2% of the time after TKR. In the THR cohort, the rate of VTE ranged from 0.6% in older adults with diabetes alone to 2.3% in older adults with CHF alone; the rate of VTE in older adults without any of the identified comorbidities was 0.7%. (Table 2) Similarly, in the TKR cohort, this range was 1.1% to 2.6%; the rate of VTE in older adults without any of the identified comorbidities was 1.1%. In multivariate analysis CHF predicted a threefold increase in the odds of VTE in the THR cohort (OR = 3.08 95% CI 2.05-4.65) and a similar increase in the TKR cohort (OR = 2.47 95% CI 1.95-3.14). (Table 3) COPD predicted a 50% increase in odds in the TKR cohort (OR = 1.49 95% CI 1.31-1.70). (Table 3)

We did not find any positive interactions between comorbidities in our analysis. The combination of CAD and CHF alone was associated with a twofold increase in odds in both the THR and TKR cohort, an effect which was smaller than for CHF alone. The combination of diabetes and CAD was associated with a 39% decrease in the odds of VTE only in the TKR cohort, an effect which was smaller, i.e., more protective, than either comorbidity alone. (Table 3) The six potential confounding factors that we tested were deleted from the final model for lack of confounding.

Discussion

We comprehensively examined the association of comorbidities and co-occurring comorbidities and VTE in a unique population of older adults undergoing primary total hip and knee replacement, high risk surgeries for VTE. We found that the rates of VTE captured in administrative data of older adults for the period immediately following THR and TKR to be low at 0.8-1.2%. Having CHF substantially increased the odds of VTE after THR or TKR and having COPD somewhat increased the odds of VTE after TKR. Co-occurring comorbidities did not increase the risk of VTE beyond their individual effects.

Comparison of our results with previous studies is limited by differences in outcomes measured and populations studied. Gangireddy et al. [9] conducted one of the largest studies to date using data from the Veterans Affairs National Surgical Quality Improvement Program (NSQIP), which included veterans undergoing nine different surgeries, including THR, between 1996 and 2001. After controlling for multiple preoperative and postoperative clinical variables, a multivariate analysis with 76,771 individuals showed that CHF and COPD were not associated with increased rates of VTE. This study supported our findings of the association between diabetes and a slightly lower rate of VTE (OR = 0.75).

We also detected a 29% reduction in the risk of VTE in patients undergoing THR with CVD. This result was not statistically significant nor did we detect an association in the knee population. There has been little evidence, however, regarding the relationship between CVD and postoperative VTE. Prior work [12] has suggested a common inflammatory pathway but this has not been evaluated extensively in the postoperative setting. In our study the association was not present for both knee and hip cohorts and was not statistically significant. We plan to re-assess this relationship in our future work.

Kikura et al. [6] examined 21,903 Japanese patients of multiple ages and multiple surgery types and found that history of acute myocardial infarction (AMI) was significantly related (OR = 7.7 95% CI 1.7-34.7) to the development of postoperative thrombotic events (including repeat AMI). Although we did collect information about the history of AMI in particular, we did not find an association with CAD in general in our analysis. In a cohort of 269 post-menopausal women undergoing THR and TKR, Jaffer et al. [7] found a trend towards

†Associations adjusted in multivariate logistic regression for each comorbidity exposure as compared with the group with none of the listed comorbidities or co-occurring comorbidities. All association were adjusted for age group and sex. We also assessed race, insurance status, hospital surgical volume, obesity, bi-laterality (two primary procedures during the same surgery) and hypercoagulable state but deleted them from the final model for lack of confounding.
Abbreviations: CAD = coronary artery disease, CHF = congestive heart failure, COPD = chronic obstructive pulmonary disease, CVD = cerebrovascular disease.

CHF predicting more postoperative VTE events (OR = 5.50 95% CI 0.94-43.3) but a trend towards COPD predicting fewer VTE events (OR = 0.42 95% CI 0.07-1.98).

The association of CHF and VTE may relate to blood flow stasis as discussed earlier. Alternatively, CHF may indicate a degree of immobility that was not measured in the data we analyzed. Other comorbidities may also contribute to the development of postoperative VTE but their effects may have been attenuated by a selection bias. Surgeons may select only the healthiest subset of older adults with comorbidities for surgery. The absence of positive interactions between frequently co-occurring comorbidities (especially CAD and CHF) also suggests a potential source of a selection bias. Older adults with co-occurring comorbidities deemed to be suitable surgical candidates are presumably healthier in other ways than other older adults with the same comorbidities.

In the case of COPD, we only detected an increase in risk for older adults undergoing knee surgery. This could be explained by the generally weak predictor effect of COPD on VTE or it could be related to the inherent differences between hip and knee surgery. Postoperative mobility may be significantly less for hip surgery and the effect of immobility in this group may dwarf other predictors such as COPD. Future work should examine the interaction between mobility and surgery type in data where this information is available.

The association of CHF and COPD with postoperative VTE has important implications. Although the American College of Chest Physicians currently recommends high potency prophylaxis such as fondaparinux or LMWH for all individuals undergoing THR and TKR [4], surgeons are reluctant to prescribe these regimens, fearing bleeding complications. Identification of a high risk subset among a group of older adults already at increased risk for VTE based on the surgery planned would be an important improvement in the way we currently perform preoperative assessment. In addition to the use of high potency prophylaxis, surgeons may also use the risk information to incorporate other practices, such as regional anesthesia, mechanical prophylaxis devices, or stockings, aimed at lowering VTE rates.

There are limitations to the work we presented. Due to the nature of the NIS administrative data we have limited ability to capture VTE. A recent study [24], suggests that administrative data capture only 58% of VTE events. There is no evidence, however, to suggest that the events indentified are differentially being diagnosed in individuals with CHF or other comorbidities. In addition, we did not have access to medication information including prophylaxis agent. A recent study by Cohen et al. in 2008 [25] indicated that in the United States, only 48% of medical patients are receiving the recommended ACCP prophylaxis and only 71% of surgical patients are

receiving prophylaxis [25]. If comorbidities prompted physicians to prescribe more potent prophylaxis in older adults with CHF or other comorbidities, however, the effects we observed would represent an underestimate of the true effect. A recent survey [26] suggests that orthopedic surgeons vary their prescribing patterns less than 10% of the time when evaluating a patient with cardiopulmonary disease. Future work should examine the relationship between comorbidities and VTE while controlling for prophylaxis agents in data where medication information is available.

We did not have information about events which took place after hospitalization. Given that the median time for development of DVT is 17 days for THR and 7 days for TKR [27] and the median length of stay was 3 or 4 days for each surgery in our analysis, the associations we present may not reflect the experience of older adults who develop injury in the post discharge period. Controlling for length of stay would not disentangle the relation between these comorbidities and VTE and we, therefore, did not control for it in our analysis. Length of stay may very well be a surrogate for immobility and stasis which are on the causal pathway of VTE development. Alternatively, increased length of stay may also be associated with VTE because of added time needed to achieve therapeutic levels of warfarin. Even though NIS data does not allow for measurement of the 30 or 90 day incidence of VTE, we believe that post discharge rates of VTE events will be similarly disparate in individuals with compared to those without comorbidities. In the future we plan to confirm these associations in data where this information is available.

Administrative data are susceptible to upcoding where medical coders assign a diagnosis that may have only been considered but not proven. We did not have information about those VTE events that were present on admission compared to those that occurred during hospitalization. We plan to conduct further validation studies in other databases where pre-existing diagnosis modifiers are available. We cannot firmly establish causality between comorbidities and VTE using the data available to us. Comorbidities may be linked to other processes such as increased operative time or difficulty weaning from a ventilator after surgery. Future research with datasets containing these clinical variables may clarify the exact causal pathway. Lastly, although in our analysis we controlled for the presence of several factors that might increase the risk of VTE, we did not have data on the smoking status of individuals, which might be related to both the exposure and outcome.

Conclusion

CHF is strongly associated with an increased risk of VTE after THR and TKR; COPD is associated with an increased risk of VTE after TKR. The absence of risk associated with other comorbidities and co-occurring comorbidities may be explained by the selection of healthier older adults for these surgeries or by some of the limiting factors described above. If these findings are confirmed in other datasets, higher risk older adults with comorbidities could potentially benefit from more aggressive preventive interventions including high potency pharmacologic prophylaxis.

Context: Mobility limitation is associated with increased morbidity and mortality. The relationship between circulating testosterone and mobility limitation and physical performance is incompletely understood.

Objective: Our objective was to examine cross-sectional and prospective relations between baseline sex hormones and mobility limitations and physical performance in community-dwelling older men.

Design, Setting, and Participants: We conducted cross-sectional and longitudinal analyses of 1445 men (mean age 61.0 ± 9.5 yr) who attended Framingham Offspring Study examinations 7 and 8 (mean 6.6 yr apart). Total testosterone (TT) was measured by liquid chromatography tandem mass spectrometry at examination 7. Cross-sectional and longitudinal analyses of mobility limitation and physical performance were performed with continuous (per SD) and dichotomized [low TT and free testosterone (FT) and high SHBG *vs.* normal] hormone levels.

Main Outcome Measures: Self-reported mobility limitation, subjective health, usual walking speed, and grip strength were assessed at examinations 7 and 8. Short physical performance battery was performed at examination 7.

Results: Higher continuous FT was positively associated with short physical performance battery score ($\beta = 0.13$; $P = 0.008$), usual walking speed ($\beta = 0.02$; $P = 0.048$), and lower risk of poor subjective health [odds ratio (OR) = 0.72; $P = 0.01$]. In prospective analysis, 1 SD increase in baseline FT was associated with lower risk of developing mobility limitation (OR = 0.78; 95% confidence interval = 0.62–0.97) and progression of mobility limitation (OR = 0.75; 95% confidence interval = 0.60–0.93). Men with low baseline FT had 57% higher odds of reporting incident mobility limitation ($P = 0.03$) and 68% higher odds of worsening of mobility limitation ($P = 0.007$).

Conclusions: Lower levels of baseline FT are associated with a greater risk of incident or worsening mobility limitation in community-dwelling older men. Whether this risk can be reduced with testosterone therapy needs to be determined by randomized trials. **(*J Clin Endocrinol Metab* 95: 2790–2799, 2010)**

Abbreviations: BMI, Body mass index; CI, confidence interval; FHS, Framingham Heart Study; FT, free testosterone; LC-MS/MS, liquid chromatography tandem mass spectrometry; OR, odds ratio; SPPB, short physical performance battery; TT, total testosterone.

The powerful demographic shift toward aging of human populations has focused attention on remediable factors that limit the ability of older individuals to live independently. Among individuals age 65 yr and older, 44% report some mobility limitation (1). Decline in mobility is associated with loss of independence (2) and increased risk of disability (3), institutionalization (4), decreased quality of life (5), and death (3, 6). Mobility limitation in older individuals is undoubtedly multifactorial, but age-related declines in muscle mass, strength, and power are important contributors (7, 8).

Total testosterone (TT) levels in men decline progressively with age (9–14). Because SHBG increases with age (9, 10, 15), the decline in free testosterone (FT) with aging is even greater than the decline in TT levels. Age-related decline in testosterone levels has been associated with reduced muscle mass and lower extremity strength in older men (16, 17).

Only a few studies have addressed the relationships between circulating testosterone levels and mobility and physical function, and the data are conflicting. The Longitudinal Ageing Study Amsterdam reported a significant positive association between low TT and low grip strength in older men, but no statistically significant relationship with self-reported functional limitations was observed in that study (18). The Massachusetts Male Ageing Study found no relationship between TT and grip strength (19). An analysis of longitudinal data from two independent cohorts of older men showed no association between TT and FT and the decline in physical performance (20). The BACH/Bone Study concluded age-associated alterations in sex hormone levels play a minor role in age-related declines in muscle strength and physical performance (21). These studies measured testosterone levels by RIAs, whose accuracy has been questioned (22, 23). Thus, the relationships among circulating levels of sex hormones and mobility limitations and physical performance in older men are inadequately understood.

Using data from the Framingham Offspring Study, we determined whether TT, FT, and SHBG are related cross-sectionally to mobility limitations, subjective health, and performance-based measures of physical function in community-dwelling older men. Additionally, in longitudinal analyses, we evaluated whether these hormones prospectively are associated with incident mobility limitation and worsening of mobility and subjective health in older men. We measured circulating TT levels by liquid chromatography tandem mass spectrometry (LC-MS/MS), widely considered the reference method for testosterone measurement (23).

Materials and Methods

The Boston University Institutional Review Board approved the study, and written informed consent was obtained from all participants.

Study sample

The Framingham Heart Study (FHS) began in 1948 as a prospective study to examine the risk factors for heart disease (24). In 1971, enrollment of offspring of the original cohort and spouses of the offspring constituted the Framingham Offspring Study (25). The offspring cohort has completed eight examinations at approximately 4- to 8-yr intervals. The men of the Offspring cohort who attended examination 7 (1998–2001) were eligible for the present study (n = 1625). Men with prostate cancer undergoing androgen deprivation therapy (n = 8) and those missing self-reported mobility data (n = 18) or TT (n = 154) at examination 7 were excluded, resulting in a sample size of 1445 for cross-sectional analyses (Fig. 1). To determine whether sex hormones are associated with incident and/or progression of mobility limitations, men who attended examination 8 (2005–2008) were examined on average 6.6 yr later. In the analysis of progression of mobility limitations, we excluded men who did not attend or had missing mobility data (n = 280) at examination 8 or missing covariate data (n = 1). We further excluded men reporting a mobility limitation at examination 7 (n = 53) when we examined incident mobility limitations. Hence, 1111 men were available to prospectively examine the association between circulating sex hormone levels and incident mobility limitations and 1164 men to determine the relationship between sex hormone levels and mobility limitation progression (Fig. 1).

We also determined the cross-sectional relationships between sex hormone levels and Short physical performance battery (SPPB), timed usual walk, and grip strength using a subset of men from an ancillary study to examination 7 that included the physical performance battery (n = 832, 1998–2002). Furthermore, we examined the association between sex hormone levels and the change in timed usual walk and hand grip strength among men who attended examination 8 (n = 693).

Measurement of circulating sex hormones

Serum TT, FT, and SHBG levels were measured at examination 7. TT level was measured by LC-MS/MS, as described (26–28). The sensitivity of the assay was 2 ng/dl, and interassay coefficients of variation (CV) were 7.8, 5.9, and 3.5% in samples with testosterone concentrations of 250, 500, and 1000 ng/dl, respectively. SHBG levels were measured using an immunofluorometric assay (DELFIA-Wallac, Inc., Turku, Finland). The interassay CV were 8.3, 7.9, and 10.9%, and intraassay CV were 7.3, 7.1, and 8.7%, respectively, in the low, medium, and high pools (29, 30). FT was calculated by using the law of mass action equation (31, 32). Calculated FT concentrations differ systematically from those measured by equilibrium dialysis and vary with the algorithm used for calculating FT (33).

Healthy men aged 19–40 yr enrolled in the FHS Generation 3 (children of the Offspring participants) cohort free of cardiovascular disease, cancer, diabetes, hypertension, smoking, hypercholesterolemia, and obesity (n = 456) served as the referent population to determine normative sex hormone values. For the purpose of this study, low TT and FT levels were defined as less than the 2.5th percentile for TT and FT of the referent population

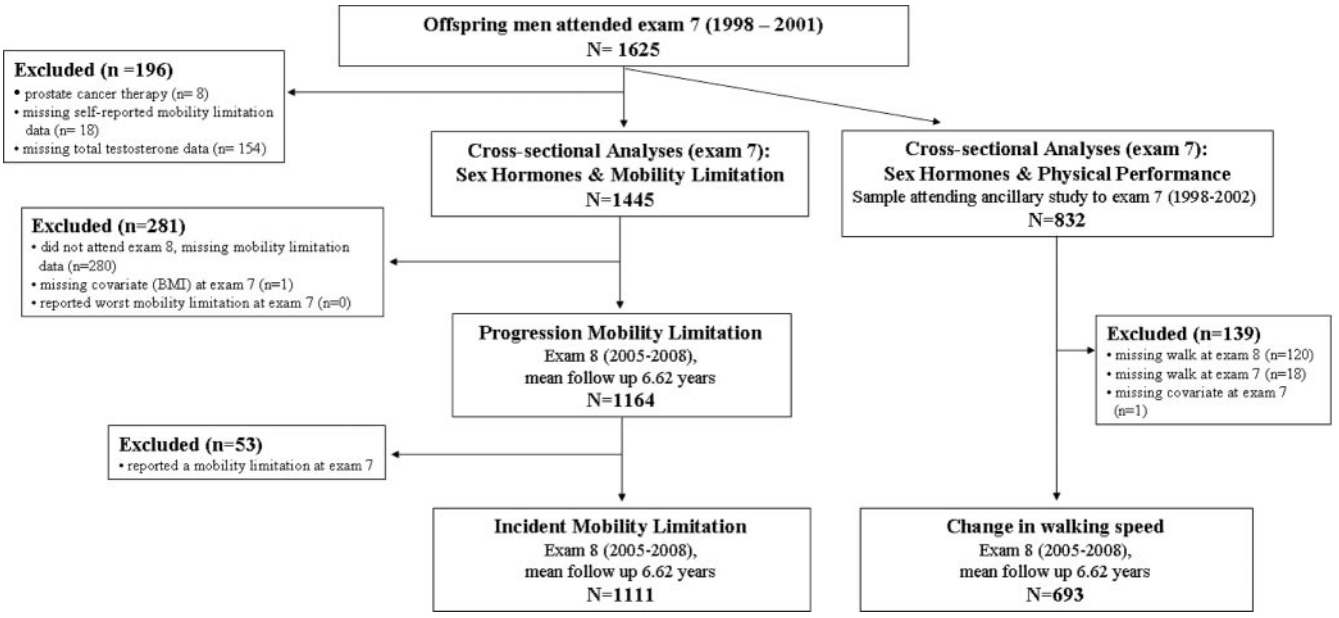

FIG. 1. Study design.

(TT <348.3 ng/dl; FT <70.0 pg/ml) and high SHBG levels as more than the 97.5th percentile of the referent sample (SHBG >81.6 nmol/liter).

Self-reported measurement of mobility limitation

At examinations 7 and 8, trained technicians queried participants about mobility limitations using a modified Rosow-Breslau questionnaire (34), which has been shown to have high test-retest reliability in other large population-based studies (35, 36). Participants were asked if they were able to 1) do heavy work around the house, like shovel snow or wash windows, walls, or floors without help; 2) walk half a mile without help (about four to six blocks); and 3) walk up and down one flight of stairs (37). At examination 7, the last item was asked as part of the Katz Activities of Daily Living scale with the following directive: during the course of a normal day, can you walk up and down one flight of stairs independently or do you need human assistance or the use of a device? Response choices included 1) no help needed, independent; 2) uses device, independent; 3) human assistance needed, minimally dependent; 4) dependent; and 5) do not do during a normal day. If the participant reported independence, he was considered able to perform the mobility task. A participant was considered to have a mobility limitation if he reported an inability to do one or more of the three items on the scale.

Subjective health

A standard single-item subjective health measure was used, "In general, how is your health now?" (examination 7) or "In general, how would you say your health is?" (examination 8). Response options at examination 7 included poor, fair, good, or excellent, and at examination 8, there was an additional response option of very good. The responses were reduced to a binary variable for analyses; 0 for good health (responses of good, very good, and excellent) and 1 for poor health (responses of poor or fair health).

Observed physical performance measures

Hand grip strength and performance-based measures of physical function were measured by trained technicians at an ancillary study to Offspring examination 7 (1998–2002). Measurements of hand grip strength and walking speed were repeated at Offspring examination 8.

SPPB

The SPPB is a validated battery that evaluates lower extremity function by measuring standing balance, gait speed, and time to rise from a chair five times (38). The standing balance measure was assigned a score ranging from 0–4, and gait speed and chair stands were assigned a score ranging from 1–4, with 4 indicating the highest level of performance. A summary performance score from 2 (worst) to 12 (best) was calculated by summing the individual scores.

Standing balance test. Participants were asked to maintain balance in three positions: feet in side by side position, feet in semi-tandem position, and feet in tandem position. For each of the three positions, participants were timed to a maximum of 10 sec. Participants were assigned a score of 0 if they were unable to hold the side-by-side standing position for 10 sec, a score of 1 if they could hold the side-by-side standing position for 10 sec but were unable to hold a semi-tandem position for 10 sec, a score of 2 if they could hold a semi-tandem position for 10 sec but were unable to hold a full-tandem position for 3 sec, a score of 3 if they could stand in a full-tandem position for 3–9 sec, or a score of 4 if they could stand in a full-tandem position for 10 sec.

Measured walk. Usual walking speed was assessed by asking the participants to walk at their usual pace over a 4-m course. Participants were allowed to use walking aids if necessary but not the assistance of another person. The test was repeated twice, and the faster of the two trials was used. Walking speed was scored as follows: less than 0.47 m/sec = 1; 0.47–0.64 m/sec = 2; 0.65–0.82 m/sec = 3; and 0.83 m/sec or faster = 4. For individuals who did not attempt or complete the walk, the value was set to the maximum value obtained by any individual.

Chair stand test. Participants were asked to stand from a sitting position in a straight-backed chair without using their arms. If

they were able to perform the task, they were asked to stand up and sit down five times, as quickly as possible. The time required to perform five chair stands was scored as follows: more than 16.6 sec = 1; 13.7–16.6 sec = 2; 11.2–13.6 sec = 3; and 11.1 sec or less = 4. If participants were unable to perform this task, then a score of 60 sec was assigned.

Hand grip strength

Grip strength was measured in both hands using an adjustable Jamar hydraulic dynamometer (Sammons Preston, Inc., Bolingbrook, IL). Participants were seated in a chair with elbow flexed at a 90° angle. Each trial consisted of a maximum squeeze for 3 sec. Three trials were performed with each hand, and the best performance in the six trials was used as the hand grip strength value.

Statistical analyses

Cross-sectional analyses

Baseline descriptive statistics (means ± SD) for continuous variables and percent for dichotomous variables were generated. Cross-sectional associations among sex hormones and binary self-reported mobility limitation and subjective health were assessed using multiple logistic regression, and multiple linear regression was used for continuous outcomes (usual walking speed, handgrip strength, and SPPB score).

Longitudinal analyses

The primary analyses employed multiple logistic regression to examine the relation between circulating sex hormone levels and 1) incident mobility limitation in men free of limitations at examination 7 and 2) decrease in subjective health between examination 7 and 8 from good or excellent to poor or fair. In secondary analyses, we examined progression of mobility limitations and decline in subjective health from examination 7 to 8, defined as a change of one or more response levels on the Rosow-Breslau scale or subjective health question (moving on Rosow-Breslau scale from 0 to 1, from 1 to 2, *etc.*). In additional analyses, we used multiple linear regression models to examine whether sex hormones measured at examination 7 were associated with change in gait speed and grip strength at examination 8 while adjusting for gait speed and grip strength at baseline (examination 7).

To account for potential confounders (variables related to outcomes that might affect the strength of association), all models were adjusted for age, body mass index (BMI), smoking, and comorbidities (cardiovascular disease and cancer) at examination 7. However, the univariate association of TT and FT levels with the Framingham physical activity index, a measure of physical activity, was either very weak (Pearson's correlation coefficient for TT = 0.07; $P = 0.008$) or not significant (Pearson correlation coefficient for FT = 0.01; $P = 0.6867$). Therefore, the analyses were not adjusted for physical activity index.

Furthermore, to examine the potential threshold effect, where hormone concentrations below a certain level relate to risk of poor outcomes, both cross-sectional and longitudinal analyses were repeated, defining low levels of TT and FT and high levels of SHBG based on the 2.5th percentile cutoff obtained from the Generation 3 healthy reference sample. Statistical significance level was set at two-sided $P < 0.05$.

Results

Demographic data

The baseline characteristics of men in our study sample with sex hormone and mobility data are shown in Table 1. The men in our sample were on average 61.0 yr at baseline with mean TT, FT, and SHBG levels of 583 ± 227 ng/dl, 86 ± 32 pg/ml, and 58 ± 27 nmol/liter, respectively, and 15.4% had low TT, 31.6% had low FT, and 15.5% had high SHBG levels. The proportion of men with self-reported mobility limitation at baseline was 6.4 and 7.1% of men reported poor subjective health. In the sample of men with physical performance data, the mean SPPB score was 10.9, usual walking speed 1.25 m/sec, and hand grip strength 42.4 kg. Thirteen percent (n = 144) of the sample reported an occurrence of mobility limitation at examination 8, and 14% (n = 163) reported a progression of their mobility limitation from examination 7 to 8.

Cross-sectional relation between sex hormones and mobility and physical performance

The cross-sectional associations between circulating levels of sex hormones and self-reported mobility limitations and subjective health at examination 7 are presented in Table 2. TT and SHBG were not significantly associated with mobility limitation or subjective health. FT levels were not significantly associated with mobility but were associated with subjective health. As FT increased, the chances of reporting poor subjective health decreased; 1 SD increase in FT was associated with a 28% decrease in the odds of reporting poor subjective health [multivariable-adjusted odds ratio (OR) = 0.72; 95% confidence interval (CI) = 0.56–0.94]. Compared with men with normal FT levels, men with low FT levels had an increased risk of reporting poor subjective health (OR = 1.61; 95% CI = 1.02–2.55). The cross-sectional associations between circulating levels of sex hormones and physical performance measures at baseline examination 7 are presented in Table 3. TT and SHBG were not significantly associated with any of the physical performance measures. FT levels were significantly associated with SPPB score and usual walking speed. As FT increased, SPPB score and usual walking speed increased as well; each SD increase in FT was associated with a 0.13-U increase in SPPB score ($P = 0.008$) and 0.02 m/sec increase in usual walking speed ($P = 0.048$). Men with low FT were also more likely to have lower grip strength (adjusted mean difference between men with low and high FT = −2.01; 95% CI = −3.95 to −0.07) than those with normal FT. Low TT and high SHBG were not significantly associated with any mobility or physical performance measure.

TABLE 1. Baseline characteristics at examination 7

Characteristic	Cross-sectional analyses: Men with mobility limitation data (n = 1445)	Cross-sectional analyses: Men with physical performance data (n = 832)	Longitudinal analyses: men with incident mobility limitation data (n = 1111)
Age (yr)	61.0 (9.5)	61.6 (9.3)	59.6 (9.0)
Smoking (%)	12.7	11.5	11.8
Alcohol consumption, drinks/wk (%)			
None	27.3	28.9	25.8
1–14	69.1	67.4	71.1
>14	3.6	3.7	3.1
BMI (kg/m^2)	28.8 (4.5)	28.8 (4.5)	28.7 (4.5)
Prevalent cardiovascular disease (%)	17.6	17.3	13.1
Cancer (%)	9.7	10.8	7.7
TT (ng/dl)	583.5 (226.5)	584.4 (229.4)	589.9 (228.7)
FT (pg/ml)	86.1 (31.8)	86.2 (32.0)	88.6 (31.4)
SHBG (nmol/liter)	58.2 (26.7)	58.2 (26.3)	56.4 (25.5)
Men with low TT (%)[a]	15.4	15.1	15.0
Men with low FT (%)	31.6	31.3	27.7
Men with high SHBG (%)	15.5	15.5	14.0
Self-reported mobility limitation (%)	6.4	5.8	0.0
Poor subjective health (%)	7.1	6.4	4.9
SPPB summary score		10.9 (1.30)	11.0 (1.10)
Usual walking speed (m/sec)		1.25 (0.30)	1.28 (0.29)
Grip strength (kg)		42.4 (12.5)	43.5 (12.0)

Values are mean (SD) for continuous variables and percentages for dichotomous characteristics. To convert TT to SI units (nanomoles per liter), multiply TT concentrations in nanograms per deciliter by 0.0347. To convert FT to SI units (picomoles per liter), multiply FT concentration in picograms per milliliter by 3.47.

[a] Sex hormones were defined as low or high *vs.* normal using healthy reference sample of FHS Generation 3 men. TT and FT levels below the 2.5th percentile of the referent sample (TT <348.3 ng/dl; FT <70.0 pg/ml) were deemed low, and SHBG levels above the 97.5th percentile of the referent sample (SHBG, 81.6 nmol/liter) were deemed high levels.

Longitudinal relation between sex hormones and mobility and physical performance

The results of our primary analyses of the impact of hormones on development of mobility limitations and decline in subjective health are presented in Table 4. Baseline low FT was a significant predictor of incident mobility limitation (Fig. 2). As FT increased by 1 SD, the risk of developing mobility limitation decreased by 22% (OR =

TABLE 2. Cross-sectional associations between baseline circulating sex hormone levels and self-reported mobility limitation at examination 7 (n = 1445)

	Multivariable logistic regression: Mobility limitation OR (95% CI)	*P*	Subjective health OR (95% CI)	*P*
Continuous hormone levels				
TT	0.89 (0.70–1.13)	0.34	0.80 (0.63–1.01)	0.06
FT	0.80 (0.61–1.03)	0.09	0.72 (0.56–0.94)	0.01
SHBG	1.13 (0.91–1.40)	0.28	1.05 (0.85–1.31)	0.64
Dichotomized sex hormone levels				
Low TT	1.12 (0.62–2.02)	0.70	1.09 (0.62–1.89)	0.77
Low FT	1.29 (0.80–2.08)	0.30	1.61 (1.02–2.55)	0.04
High SHBG	1.31 (0.75–2.28)	0.34	1.20 (0.69–2.09)	0.51

Continuous hormone levels and OR values are for 1 SD change in sex hormone levels. All models were adjusted for age, BMI, smoking, and comorbidities (cancer and cardiovascular disease) at examination 7. Sex hormones were defined as low or high *vs.* normal using healthy reference sample of FHS Generation 3 men. Low TT and FT levels were those below the 2.5th percentile of the referent sample (TT <348.3 ng/dl; FT <70.0 pg/ml), and SHBG levels above the 97.5th percentile of the referent sample (SHBG, 81.6 nmol/liter) represented high SHBG levels. Low FT levels (<70 pg/ml) were associated with increased risk (OR = 1.61) of poor subjective health; each SD increase in FT level was associated with a 28% decease (OR = 0.72) in risk of reporting poor subjective health.

TABLE 3. Cross-sectional associations between baseline circulating sex hormone levels and physical performance at examination 7 (n = 832)

	Multivariable linear regression					
	SPPB score		Usual walking speed (m/sec)		Grip strength (kg)	
	β (95% CI)	P	β (95% CI)	P	β (95% CI)	P
Continuous hormone levels						
TT	0.06 (−0.03–0.15)	0.18	0.02 (−0.006–0.04)	0.15	0.35 (−0.55–1.24)	0.45
FT	0.13 (0.03–0.22)	0.008	0.02 (0.0001–0.04)	0.048	0.57 (−0.33–1.48)	0.21
SHBG	−0.08 (−0.17–0.02)	0.13	−0.01 (−0.04–0.009)	0.23	−0.41 (−1.38–0.56)	0.41
Dichotomized sex hormone levels						
Low TT	−0.14 (−0.40–0.11)	0.27	−0.01 (−0.07–0.05)	0.65	−1.73 (−4.16–0.70)	0.16
Low FT	−0.13 (−0.34–0.07)	0.20	−0.03 (−0.08–0.01)	0.16	−2.01 (−3.95–0.07)	0.04
High SHBG	−0.08 (−0.33–0.18)	0.55	−0.05 (−0.11–0.007)	0.09	0.38 (−2.13–2.88)	0.77

Continuous hormone levels and β−values are for 1 SD change in sex hormone levels. All models were adjusted for age, BMI, smoking, and comorbidities (cancer and cardiovascular disease) at examination 7. Sex hormones were defined as low or high *vs.* normal using healthy reference sample of FHS Generation 3 men. Low TT and FT levels were those below the 2.5th percentile of the referent sample (TT <348.3 ng/dl; FT <70.0 pg/ml), and SHBG levels above the 97.5th percentile of the referent sample (SHBG, 81.6 nmol/liter) represented high SHBG levels. Low FT levels (<70 pg/ml) were associated with decreased grip strength. Each SD increase in FT level was associated with 0.13 U increase in SPPB score and 0.02 m/sec increase in usual walking speed.

0.78; 95% CI = 0.62–0.97). FT levels were also significantly associated with progression of mobility limitation (OR = 0.75; 95% CI = 0.60–0.93). Thus, men were 25% less likely to report worsening mobility limitation for each SD increase in circulating FT. No significant relationships were observed between FT and subjective health in the longitudinal analysis. TT, FT, and SHBG levels were not significantly associated with change in usual walking speed or handgrip strength from examination 7 to 8 (data not shown).

Men with low FT were 57% more likely to develop mobility limitation on follow-up (OR = 1.57; 95% CI = 1.06–2.32) and 68% more likely to experience worsening of mobility limitation (OR = 1.68; 95% CI = 1.16–2.45) compared with men with normal FT (Table 4 and Figure 2). Low TT and high SHBG were not associated with either incident mobility limitation or progression of mobility limitation.

Discussion

In our community-based sample of men, higher baseline FT levels (both continuous and threshold values) were significantly associated with lower odds of an incident mobility limitation. Baseline FT was also a significant cor-

TABLE 4. Longitudinal relations between baseline circulating sex hormone levels and incident mobility limitation: multivariable logistic regression (n = 1111)

	Mobility limitation		Subjective health	
	OR (95% CI)	P	OR (95% CI)	P
Continuous hormone levels				
TT	0.90 (0.74–1.09)	0.28	1.09 (0.80–1.47)	0.59
FT	0.78 (0.62−0.97)	0.03	0.87 (0.62–1.22)	0.42
SHBG	1.11 (0.91–1.34)	0.31	1.29 (0.97–1.72)	0.08
Dichotomized sex hormone levels				
Low TT	1.46 (0.91–2.34)	0.12	0.48 (0.19–1.24)	0.13
Low FT	1.57 (1.06–2.32)	0.03	1.23 (0.64–2.38)	0.53
High SHBG	1.29 (0.80–2.10)	0.30	1.59 (0.74–3.43)	0.24

OR values are for 1 SD change in hormone levels. For incidence, the sample excludes subjects at exam 7 with mobility limitation and poor subjective health. For progression, the sample excludes subjects at exam 7 with worst response choice for mobility limitation and subjective health. All models were adjusted for age, BMI, smoking, and comorbidities (cancer and cardiovascular disease). Sex hormones were defined as low or high *vs.* normal using healthy reference sample of FHS Generation 3 men. Low TT and FT levels were those below the 2.5th percentile of the referent sample (TT <348.3 ng/dl; FT <70.0 pg/ml), and SHBG levels above the 97.5th percentile of the referent sample (SHBG, 81.6 nmol/liter) represented high SHBG levels. Low FT levels (<70 pg/ml) at examination 7 were associated with increased risk (OR = 1.57) of developing mobility limitation at examination 8. Each SD increase in FT level at examination 7 was associated with a 22% decrease (OR = 0.78) in risk of reporting mobility limitation at examination 8.

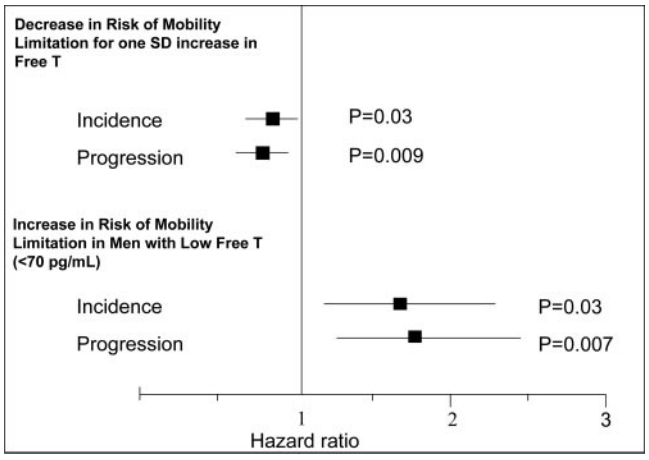

FIG. 2. Longitudinal analyses of incident mobility limitation. Continuous FT level hazard ratios are for 1 SD increase in hormone levels, adjusting for age, BMI, smoking, and comorbidities (cardiovascular disease and cancer). As shown in the *upper panel*, each SD increase in FT level was associated with 22% (OR = 0.78; 95% CI = 0.62–0.97) decrease in the risk of developing mobility limitation and 25% decrease in the risk of worsening mobility limitation (progression). The *lower panel* shows the association of low FT (<2.5th percentile (<70.0 pg/ml)) at baseline examination 7 with the risk of developing (incident) mobility limitation at examination 8 or of reporting worsening mobility limitation (progression) at examination 8. The FT hazard ratios were adjusted for age, BMI, smoking, and comorbidities. The *squares* indicate point estimates for hormones, and the *lines* indicate 95% CI.

relate of progression of mobility limitation, consistent with the incidence findings. Furthermore, FT was positively associated with faster baseline usual walking speed and SPPB score, a valid measure of lower extremity function and an important determinant of mobility. Thus, baseline FT is a significant correlate of both self-reported and performance-based measures of mobility. TT and SHBG were not associated with any of the mobility or physical performance measures.

According to the free hormone hypothesis, FT, representing the unbound hormone, is considered the biologically active fraction of testosterone. Although bioavailable testosterone has been reported to be associated with self-reported mobility limitation, muscle strength, and physical performance measures (39), we did not analyze bioavailable testosterone because it is a calculated multiple of FT. However, recent data suggest that SHBG-bound testosterone may be internalized through endocytic pits after binding to the megalin receptor and may also be biologically relevant (40). Indeed, in the Massachusetts Male Ageing Study, SHBG, rather than TT or FT, was associated with frailty (41). Our data support the free hormone hypothesis and suggest that FT may mediate most of the effects of testosterone on physical function measures because we did not find any relationship between SHBG and TT with mobility or physical performance measures.

FT levels were associated with subjective health in cross-sectional but not longitudinal analyses. Although testosterone may not be causally related to subjective health, it is possible that factors that contribute to poor subjective health such as comorbid conditions may also lower testosterone levels. It is possible that individuals whose health deteriorated between examinations 7 and 8 did not return for follow-up. Of the men that did not return for examination 8, or had missing incident mobility limitation at examination 8, 11.8% had reported poor subjective health at examination 7 compared with 7.1% of men in the total sample. This may also explain why fewer men reported poor subjective health at examination 8. Therefore, the positive longitudinal associations between FT and mobility limitations and their progression are all the more remarkable.

The observed association between FT and mobility measures has biological plausibility. Testosterone is an important determinant of skeletal muscle mass (17) and increases muscle mass by promoting myogenic differentiation of multipotent mesenchymal stem cells (42, 43) and by stimulating muscle protein synthesis (44, 45). Testosterone administration also increases maximal voluntary strength and power in men (29, 30, 46). However, the association of testosterone with physical function measures in epidemiological studies has been inconsistent. Although some studies have found testosterone levels to be related to self-reported (19) as well as performance-based measures of physical function (18, 21, 47), frailty (48), and falls (39), a recent prospective analysis of two cohorts did not find any significant association of either TT or FT with decline in physical function or muscle strength (20). The effects of testosterone therapy on physical function measures in randomized testosterone trials have been heterogeneous. Some trials have reported improvements in gait speed, stair climbing power, and composite measures of physical function (49, 50), whereas others failed to find significant effects (51–53). However, older men included in the first-generation testosterone trials were not uniformly hypogonadal (51–53). Also, most of the studies included healthy older men without functional limitations and used tests of physical function that had low ceiling (54). Finally, testosterone doses in some trials were small and did not significantly raise serum testosterone (51, 52). We have shown that testosterone administration in young and older men is associated with dose-dependent increments in skeletal muscle mass and maximal voluntary strength (30, 55, 56).

We observed that circulating FT levels were significantly associated with both SPPB scores and walking speed. Each SD increase in FT was associated with a 0.13-U increase in SPPB score and 0.02-m/sec in usual walking speed. Perera *et al.* (57) have deemed a 0.5-U change in SPPB score and a 0.05-m/sec change in gait speed to be

clinically important changes. Thus, testosterone levels have a small but significant effect on these measures of physical performance. Indeed, testosterone is only one of many physiological processes that regulate complex functions such as walking, although it is an important remediable factor and, therefore, the subject of current investigation.

Our study has significant strengths. First, the FHS cohort included community-dwelling men over a wider age range than has been included in some other studies that were focused mostly on older men. The longitudinal design of our analyses lends strength to our inferences. We adjusted our analyses for potential confounders, including age, BMI, smoking, and comorbidities. This is the first population study to evaluate the relationship between mobility and physical function with TT levels measured by LC-MS/MS, widely considered the gold standard for the measurement of testosterone levels (23). We defined reference ranges of testosterone levels by using healthy young men, age 19–40 yr, and evaluated the relationship between androgens and mobility based on these population-based thresholds.

Our study also has some limitations. First, epidemiological studies including longitudinal studies can define associations but not causality. Second, our study population was white, and therefore, our findings may not be generalizable to other race/ethnicities. Also, of the 1445 men who were evaluated for mobility limitation at examination 7, 280 did not return for examination 8 or had missing mobility limitation data at examination 8. Importantly, men who did not return for examination 8 had a higher frequency of mobility limitation, lower SPPB score, and slower walking speed at baseline than those who did return for examination 8. Thus, it is possible that some of the subjects with poor health whose health deteriorated did not return for follow-up, thus diluting the observed effects. Therefore, our longitudinal analyses likely represent a conservative estimate of the association between FT levels and mobility limitation and walking speed. We did not have sex hormones measured at examination 8 to evaluate the correlation between the change in testosterone levels and incident mobility. We did not measure estradiol levels and were unable to dissect out the possible role of aromatization on these outcomes. Serum testosterone levels are affected by pulsatile, diurnal, and circannual rhythms, and single samples ignore rhythmic hormone secretion. Our analyses show that single early morning testosterone levels, obtained in a manner similar to that by physicians in real practice, were associated with mobility limitation and some other measures of physical function. Therefore, even though our models did not factor in the complexities of biological rhythms, they are in concordance with the need of practitioners to depend on conveniently obtained single samples. Finally, the Framingham cohort was younger and healthier than some other epidemiological studies, resulting in fewer events and lower rates of worsening of physical function; this may have reduced the statistical power. We had 0.685 power to detect an association of similar magnitude for TT to that obtained from FT at an α of 0.05. The follow-up of these men over a still longer period of time resulting in potentially more events could increase the power.

These data have clinical implications. Mobility is one of the most important physical functions, essential for independent living. Our data show that men with low FT had a 57% greater risk of developing a mobility limitation and a 68% higher risk of deterioration in their mobility. Whether this risk can be reduced with exogenous testosterone therapy in older men with mobility limitation and low free testosterone levels would need to be determined by a randomized clinical trial.

Self-Reported Willingness to Have Cancer Screening and the Effects of Sociodemographic Factors

Nancy R. Kressin, PhD; Meredith Manze, MPH; Stefanie L. Russell, DDS, MPH, PhD; Ralph V. Katz, DMD, MPH, PhD; Cristina Claudio, PhD; B. Lee Green, PhD; Min Qi Wang, PhD

Disclaimer: The views expressed in this article are those of the authors and do not necessarily represent the views of the Department of Veterans Affairs.

Funding/Support: This study was supported by U54 DE 14257, and a VA Research Career Scientist award from the VA Health Services Research and Development Service to Dr Kressin.

Background: The relative effects of race/ethnicity and other sociodemographic factors, compared to those of attitudes and beliefs on willingness to have cancer screening, are not well understood.

Methods: We conducted telephone interviews with 1148 adults (31% African American, 27% Puerto Rican American, 43% white) from 3 cities in mainland United States and Puerto Rico. Respondents reported their sociodemographic characteristics, attitudes about barriers and facilitators of cancer screening, and willingness to have cancer screening under 4 scenarios: when done in the community vs one's doctor's office, and whether or not one had symptoms.

Results: Racial/ethnic minority status, age, and lower income were frequently associated with increased willingness to have cancer screening, even after including attitudes and beliefs about screening. Having screening nearby was important for community screening, and anticipation of embarrassment from screening for when there were no cancer symptoms. Associations varied across 4 screening scenarios, with the fewest predictors for screening by one's doctor when there were symptoms.

Conclusions: Sociodemographic characteristics not only were related to willingness to have cancer screenings in almost all cases, but were generally much stronger factors than attitudinal barriers and facilitators. Cancer screening campaigns should affect attitudinal change where possible, but should also recognize that targeting screening to specific population groups may be necessary.

INTRODUCTION

Cancer screening is crucial to identifying cancer in its early stages, when the disease is more amenable to treatment or cure. Screening rates among racial and ethnic minorities vary compared to whites, with minorities having lower screening rates for certain types of cancer, such as cervical and colorectal cancer.[1-3] Individuals with less education and income receive cancer screening less often than do those with higher levels of each.[4] These differential rates in screening may lead to disparities in cancer-related mortality[5-8] and highlight the need to understand the reasons for cancer screening disparities.[9-11] Several studies have examined the association of race/ethnicity with potential barriers to screening utilization, such as access to care through health insurance; relationship with health care providers; provider recommendation of screening; patient knowledge, and attitudes and beliefs about screening.[12-25] Often, these studies, many of them qualitative in nature, have focused on understanding the dynamics of these issues among a single racial/ethnic group, and they emphasized the importance of identifying the health beliefs of certain groups to help tailor interventions and understand their decisions for cancer screening.

However, the relative effects of race/ethnicity on willingness to have cancer screening, compared to other sociodemographic factors (including education, income,

and employment status), as well as to attitudes and beliefs about screening, are not well understood.[26] Although race has been associated with numerous negative predictors of cancer screening, it may be that many of the factors associated with race, rather than—or in addition to—race itself, are important driving forces behind such associations, as has been found with regard to health care utilization in general.[27,28] Prior findings also suggest that negative attitudes towards cancer screening, including fear of pain or diagnosis, disbelief in the efficacy of screening tests, or generalized distrust of others may be more predominant among racial and ethnic minorities and thus account for their lower rates of cancer screening.[16,17,21,23-25,29,30] It may be that such factors, which are closely associated with race, actually drive the race differences in cancer screening, but whether this is the case has not been well examined. An additional limitation of prior research on various minority populations which has examined the effects of attitudes and beliefs about cancer screening is that it has often included only limited sample sizes from single geographic areas. Further, few studies have specifically examined either the effects of having cancer-related symptoms (or not), or the type of setting in which cancer screening is provided, on individuals' willingness to have screening. Presentation of symptoms and screening setting both have the potential to impact the decision to seek testing,[31-33] so attention to these issues is important for a full understanding of patient attitudes about cancer screening.

Although it is important to identify barriers for specific subsets of the population for different types of cancer screening, there is also value in understanding general attitudes of patients about cancer screening in general in order to highlight common barriers for future research and interventions. While 2 recent papers by our research group addressed this latter issue and reported that blacks and Hispanics, after adjusting only for demographic factors, were either as or more likely than whites to self-report willingness to have cancer screenings, and perceived a higher risk of "not getting a thorough cancer screening" than did whites, neither of those analyses delved into underlying reasons for those observed differences.[34,35] Therefore, the purpose of this current analysis is to examine general willingness to engage in cancer screening, in the context of varied symptoms and screening settings, and among a diverse cohort from multiple geographic areas, with an emphasis on assessing the influence of race/ethnicity, relative to sociodemographic factors, to both positive and negative attitudes and beliefs about cancer screening on this willingness to utilize screening in general. We hypothesized that the association between race and willingness to receive cancer screening would be attenuated after taking into account a wide variety of attitudes, barriers, and facilitators to cancer screening, and after accounting for positive attitudes for screening.

Further, we anticipated that in the setting of both the greatest urgency (eg, the presence of symptoms) and most accessible and comfortable screening location (eg, one's doctor's office), the effects of barriers and facilitators to screening would be minimized. Our work was guided by the health decision model (HDM),[36] which is an expanded version of the patient-focused health belief model[37] and includes factors beyond the patient's own attitudes and beliefs, which might influence health decisions, such as sociodemographic factors, experiences with the health care system, and knowledge. In the HDM, there is not a particular causal ordering of factors influencing health decisions; rather, each of the domains of health beliefs, patient preferences, experience, and knowledge influence one another, and are also affected by social interaction and sociodemographic factors. Thus, in this study, we used the HDM as a guide for thinking about the various sociodemographic factors, barriers, facilitators hypothesized to affect willingness to have cancer screening, but not for positing causal relationships among the elements.

METHODS

Study Sample and Procedures

To ensure a wide geographic, racial/ethnic representation which included substantial representation of whites, African Americans, and Hispanics, we contacted a random sample of residents of 3 cities—San Juan, Puerto Rico; Baltimore, Maryland; and New York, New York—from September to December 2003. We conducted random-digit-dial telephone interviews to noninstitutionalized adults residing in telephone-equipped homes. A total of 1148 adult African Americans, Puerto-Rican Hispanics, and whites responded, with response rates of 58%, 51%, and 45%, respectively, and an overall completion rate of 82.6%. The final study sample consisted of 356 African Americans, 313 Puerto Rican Americans, and 493 non-Hispanic whites. Since we did not collect identifying information about respondents, our institutional review board (IRB) determined this study to be "exempt" from full IRB review.

MEASURES

Questionnaire

We administered a questionnaire to all study participants, which contained all measures used in this analysis, and which has been fully described (as regards development, administration, and data analysis decisions) in our prior publications based upon this survey.[34,35,38] The questionnaire was administered either in English or Spanish, at the preference of the respondent.

Dependent Variables

Willingness to have cancer screening under spe-

cific conditions. We asked questions about individuals' self-reported willingness to participate in cancer screening exams under 4 different conditions. These questions assessed the respondent's self-reported likelihood to have a cancer screening: (1) by their own *physician* when there are *no* symptoms ("doctor/no symptoms;" the question read, "How likely are you to go for a regular annual cancer screening exam given by your doctor, if you have NO symptoms?"); (2) by their own *physician* when there *are* symptoms ("doctor/symptoms;" the question was: "If your own doctor told you that you have some symptoms and needed a cancer screening exam, how likely are you to go and have *that* cancer screening exam?"); (3) when it is a free cancer screening exam in the *community* when there are *no* symptoms ("community/no symptoms:" the question read "Some group in your community, such as a school, church, or the Lions' Club, offers you the opportunity to have a free cancer screening exam. How likely are you to participate at a community-level *free* cancer screening exam if you *have no symptoms?"*); and (4) when it is a free cancer screening exam in the *community* when there *are* symptoms ("community/symptoms;" the question was: "Some group in your community, such as a school, church, or the Lions' Club, offers you the opportunity to have a free cancer screening exam. How likely are you to participate at a community level *free* cancer screening exam if you *have symptoms*?"). Responses for all questions were on a 5-point scale with 1 signifying "very unlikely" and 5 signifying "very likely." The respondent was not given

Table 1. Characteristics of Study Sample and Association of Sociodemographics With Dependent Variables

				Mean of Each Dependent Variable by Sociodemographic Characteristics			
	N	%	95% CI	MD/ No Symptoms	Community/ No symptoms	Community/ Symptoms	MD/ Symptoms
				P = .02	*P* = .61	*P* = 0.04	*P* = .35

a definition of what "by your doctor" referred to, so responses are based on their subjective interpretation of each item.

Independent Variables

Barriers to and facilitators of cancer screening. The questionnaire also included items to assess the impact of attitudes and beliefs about potential *barriers* to screening, including fear of: (1) getting AIDS; (2) being a "guinea pig;" (3) test results not being private or confidential; (4) how the disease would upset one's family; (5) hearing one has cancer; (6) feeling that one is unlikely to get cancer; (7) lack of trust in medical professionals; (8) fear that the test might be painful; and (9) fear of being embarrassed in the cancer screening exam. In addition, the questionnaire asked about factors that might *facilitate* an individual's participation in cancer screening, including: (1) the belief that early detection might save one's life; (2) having close friends or a relative encouraging participation in cancer screening; (3) having close friends or a relative participating in cancer screening; (4) having a close friend or relative who has had cancer; (5) encouragement of one's physician to be screened; (6) encouragement of one's dentist to be screened; (7) having one's insurance company paying for the screening exam; and (8) having a nearby location for the screening. A 5-point Likert scale was used for responses to all questions, ranging from "not at all" to "totally." These were analyzed as single items.

Sociodemographic factors. Respondents were asked to self-report their sex, race, ethnicity (Puerto Rican Hispanic or not), year of birth, income (in $5000 increments), highest education attained, whether they were currently employed, and health status (response categories: excellent, very good, good, fair, poor).

Covariates

General attitudes. We assessed respondents' general attitudes towards cancer screening exams, asking how effective the respondent believed cancer screening exams are in detecting cancer (higher scores indicate stronger beliefs in effectiveness). In addition, to understand if willingness to participate in cancer screening might be associated with a person's general trust in people, we included the Trust in People scale.[39] This scale includes the following questions: Generally speaking, would you say that: (1) most people can be trusted or that you can't be too careful in dealing with people?; (2) most of the time, people try to be helpful, or that they are mostly just looking out for themselves?; (3) most people would try to take advantage of you if they got the chance or would they try to be fair? The scale is the sum of these 3 items (range, 0-3); a higher score indicates greater trust in people.

Statistical Analysis

Initially, we examined descriptive statistics for all variables, including distributions of responses to each of the dependent variables by race/ethnicity. To explore

whether the dependent variables regarding willingness to have cancer screening would function better as a scale or several scales, we conducted exploratory factor analyses but found that the factors did not lead to scales with acceptable internal consistency reliability. Thus, we retained 4 separate items for the outcome variables. Next, we examined bivariate associations between each independent variable and the dependent variables, examining dependent variable means by each category of the independent sociodemographic variables and 0-order correlations between each barrier or facilitator and the dependent variables. Then, we computed multiple linear regression models to examine the effects of race/ethnicity and other sociodemographic factors, after adjusting for the barriers and facilitators to willingness to have cancer screening, under the four conditions.

RESULTS

Sociodemographic Characteristics of the Sample

The mean age of respondents was 44.9 years (not shown); 54.5% of the sample were female (Table 1). Puerto Rican Hispanics comprised 22.4% (n = 311) of the sample, while 31.1% were non-Hispanic African American (n = 355) and 46.5% were non-Hispanic white (n = 482). Regarding income, 24.2% earned less then $20 000; 24.5% earned between $20 000 and 34 999; 16.0% earned between $35 000 and $49 999; 16.7% earned between $50 000 and $74 999; and 18.6% earned more than $75 000. More than half of the sample (59.6%) was employed, 12.1% had a high school education or less, and 52.7% indicated a health status of excellent or very good.

Ranking of the 4 Scenarios by Willingness to Have Cancer Screenings by Race/Ethnicity

To examine the overall likelihood of respondents indicating they were "very likely" to obtain screening within the 4 scenarios (screening by one's own physician with and without symptoms; and screening in the community with and without symptoms), we found that the 4 scenarios were ranked in the same order by African Americans, Puerto Rican Hispanics, and whites: (1) "own MD, with symptoms" (with 92%-93% responding "very likely" across the racial/ethic groups); (2) "community screening, with symptoms" (47%-71%); (3) "own MD, no symptoms" (44%-50%), and (4) "community event, no symptoms" (23%-45%) (results not shown). With the exception of the first scenario, in which greater than 90% of each of the 3 racial/ethnic groups responded "very likely," Puerto Rican Hispanics were the most willing to have a cancer screening under each of the 3 other scenarios ($p \leq .0001$).

Factors Associated With Willingness to Have Cancer Screening

Screening by one's own physician given no symptoms. Bivariate analyses indicated that female sex, older age, and more education were associated with more willingness for cancer screening by one's own physician when there are no symptoms (Table 1). Beliefs in one's likelihood of getting cancer, fear of pain or embarrassment upon screening, the perception that screening saves lives, friends/family encouraged one to get screened, also participate in screening, and have had cancer, encouragement from one's physician or dentist, having insurance and screening nearby were all significantly associated with willingness to have screening (Table 2).

When we then adjusted for the effects of potential barriers and facilitators of screening by one's own physician given no symptoms, we found that the barrier of fear of getting cancer was associated with a greater likelihood of having screening, while beliefs about cancer screening's effectiveness, perceptions of likelihood of getting cancer, less concern about being embarrassed by the screening exam, and perceiving that screening saves lives were associated with the likelihood of having screening (Table 3). Although education was no longer significant in the multivariate model, we found that those with income levels between $50 000 and $75 000 were less likely to be willing to have cancer screening by one's own physician, compared to those of the highest income level, as were younger persons and males, while African Americans were more willing to have screening than whites.

Free community screening given no symptoms. Bivariate results (Table 1) indicated that Puerto Rican Hispanics and African Americans were more willing to obtain cancer screening in the community, given no symptoms, than were whites, as were those with lower incomes. In addition, those with the lower levels of education were more likely to express willingness to be screened in a community setting given no symptoms than those with more education. Fear of getting AIDS, cancer, lack of trust in the medical establishment, fear of pain, as well as the perception that screening saves lives, friends/family encouraged one to get screened, also participate in screening, and have had cancer, having insurance and screening nearby were all significantly associated with willingness to have screening (Table 2).

In the multivariate model, only 1 barrier—embarrassment—remained significant after adjustment for other factors (greater embarrassment was associated with less likelihood of screening). Two facilitators were significantly associated with screening willingness—physician encouragement, which was associated with less likelihood to get screening, and having screening nearby, which was associated with a greater willingness to be screened. Being Puerto Rican Hispanic or African American, having lower income and less education were

each associated with greater willingness for community cancer screening with no symptoms.

Free community screening given symptoms. In bivariate analyses, almost all sociodemographic factors were associated with screening willingness in this context: being male, younger, being Puerto Rican Hispanic or African American, having lower income, and less education were associated with greater likelihood of indicating willingness for community screening given symptoms. Fear of getting AIDS or cancer, or having pain, as well as the perception that screening saves lives, friends/family encouraged one to get screened, also par-

ticipate in screening, and have had cancer, having insurance and screening nearby were all significantly associated with willingness to have screening (Table 2).

In the final model, no barriers were significant, but beliefs in the effectiveness of screening were significantly associated with the outcome, and having screening nearby was associated with greater willingness for screening. Male sex, being Puerto Rican Hispanic, being of younger age, and having lower income were also all positively associated with willingness for community screening given symptoms.

Screening by one's own doctor given symptoms. No sociodemographic variables were associated with the likelihood of getting screening by one's own physician, given symptoms, in bivariate analyses (Table 1). Fear of begin a guinea pig, the perception that screening saves lives, having family or friends who have had cancer, having a physician or dentist encourage one to have screening, and having insurance were all significantly associated with willingness to have screening (Table 2).

In the full model (Table 3), no barriers or facilitators were significantly associated with screening willingness. Only being employed and having greater trust in people were significantly associated with increased willingness to participate in cancer screening by one's own physician, given symptoms; there were no significant effects of race/ethnicity.

SUMMARY OF RESULTS

Across the multivariate models for all dependent variables, health status was never significantly associated with screening willingness, and being employed was only associated with willingness for screening by one's physician when one has symptoms. Respondents' ratings of the effectiveness of screening were associated with likelihood of screening in 3 of the 4 scenarios. Trust in people was associated with screening willingness (in the context of having symptoms, and screening by one's physician such that more trust was associated with greater willingness to be screened). In bivariate results, Puerto Rican Hispanics and/or African Americans were significantly more willing than whites to have all types of screening, except for the scenarios in which screening would be done by one's own physician with or without symptoms (there were no race/ethnic differences and very few sociodemographic differences overall in endorsement of this outcome, with 92% to 93% of each racial/ethnic group indicating "very likely" for this specific scenario). Thus, some effects of race/ethnicity persisted across almost all

multivariate models (except for screening by a physician when symptoms existed), such that the effect remained, although it was slightly attenuated, even after adjusting for other sociodemographic factors, barriers and facilitators of screening.

DISCUSSION

We examined the effects of race/ethnicity and other sociodemographic characteristics on willingness for cancer screening, after accounting for the effects of attitudes about potential barriers and facilitators of cancer screening, drawing on data from a diverse sample. We considered these dynamics in the context in which screening would be done (community vs by one's own physician) and in the context of whether or not the respondent had cancer-related symptoms.

On the bivariate level, numerous sociodemographic factors were associated with willingness to have screening, with the exception of physician-administered screening when there were symptoms, where no sociodemographic variables were significant. Notably, the effects of the sociodemographic factors (especially race/ethnicity and income) consistently persisted in multivariate models. This suggests that effects of these characteristics are not attenuated by the inclusion of attitudes and beliefs, and points to the probable independent impact of these characteristics on screening willingness. The relative size of the effects we observed also supports this notion, as the size of the effects for sociodemographics were generally greater than those for the attitudinal/belief variables.

However, across the models, several barriers and facilitators of screening were associated with screening willingness, again with the exception of physician-administered screening with symptoms present. Thus, we conclude that sociodemographic factors are associated with willingness to have cancer screening in almost all cases, but that perceived barriers and facilitators also matter sometimes, as well.

Almost no variables in our multivariate models were significantly associated with willingness to have screening done by one's own physician given the presence of cancer-related symptoms. This suggests that the urgency or concern associated with such a screening, to be conducted in the relative privacy and familiarity of one's own doctor's office, overshadows any of the attitudinal or sociodemographic dimensions we measured. Thus, in situations where screening seems less "discretionary," neither sociodemographic factors nor attitudes contributed strongly to willingness for screening. Similarly, for community screenings in the presence of symptoms, almost no attitudes were significant, although sociodemographics were.

Being Puerto Rican Hispanic or African American was a fairly consistent predictor of willingness to have cancer screening. Thus, race/ethnicity may be a factor that needs to be considered in the case of public health outreach for cancer screening, but it seems less important in the context of individual clinicians recommending cancer screening within their own setting. These findings also support the idea that making free cancer screening available in the community will help to attract more African Americans and Hispanics.

The strengths of this study included the focus on an ethnically and racially diverse sample from multiple geographic areas, the availability of data on both sociodemographic and attitudinal factors and the inclusion of multiple questions about cancer screening in a variety of contexts. While it can be argued that this study was limited by its reliance on questions about potential willingness to seek cancer screening in general (vs actual receipt of screening), prior health behavior research has shown that intentions for health behavior are important predictors of actual health behavior.[40] There is also value in understanding individuals' beliefs about cancer screening in general, different from their thoughts about specific cancers and screening tests for them. We were unable to account for the effects of having a primary care physician, compared to not, which may impact willingness to seek screening, although our questions did ask about willingness to have cancer screening by one's own physician. Similarly, we did not have data on the proportion of patients having their own primary care physician available for this analysis, which is a limitation of the study. Our questionnaire also did not ask about other potential factors associated with screening, such as history of screening and family history of cancer. The general Trust in People scale may not translate into trust in the medical community, yet we felt it important to account for individuals' general levels of trust, which would likely affect their trust in the medical establishment as well. As previously noted, our questionnaire addressed cancer screening in general, though there is some evidence that willingness to screen may vary with the type of cancer. However, information of general attitudes towards cancer screening may be helpful in designing future interventions and campaigns to improve overall screening rates.

Our results document the important effects of sociodemographic factors on willingness to have cancer screening and echo others' findings that knowledge and attitudes about 1 particular cancer screening—mammography—did not independently predict its use.[41] As others have noted, more needs to be known about cancer screening practices among Hispanics in the United States.[4] The results of this investigation clearly show that Puerto Rican Hispanic ethnicity is an important predictor of willingness to have community based screening. This study contributes new information to the literature indicating that the relationship between race/ethnicity and willingness to be screened are not attenuated by attitudes about potential barriers and facilitators to screening, and also that screening site may influence individuals' willingness to be screened.

In summary, our results indicate that willingness to seek cancer screening is influenced by sociodemographic characteristics, over and above attitudes about screening, and yet, in some contexts, these latter factors should also be considered in promoting screenings. Since most sociodemographic characteristics are not easily mutable, their potential impact on cancer screening availability and awareness campaigns must be recognized, so as to target such campaigns to the populations which can most benefit from the needed cancer screening. In addition, it appears that both the location of screening and the potential urgency of screening influence the relative importance of each type of factor, suggesting that future efforts to increase screening should consider location and emphasize urgency, where appropriate.

ACKNOWLEDGMENT

We thank Karen Clements, PhD, for data analysis.

Understanding Contributors to Racial Disparities in Blood Pressure Control

Nancy R. Kressin, PhD; Michelle B. Orner, MPH; Meredith Manze, MPH;
Mark E. Glickman, PhD; Dan Berlowitz, MD, MPH

Background—Racial disparities in blood pressure (BP) control are well documented but poorly understood; prior studies have only included a limited range of potential explanatory factors. We examined a comprehensive set of putative factors related to blood pressure control, including patient clinical and sociodemographic characteristics, beliefs about BP and BP medications, medication adherence, and experiences of discrimination, to determine if the impact of race on BP control remains after accounting for such factors.

Methods and Results—We recruited 806 white and black patients with hypertension from an urban safety-net hospital. From a questionnaire administered to patients after their clinic visits, electronic medical record and BP data, we assessed an array of patient factors. We then examined the association of patient factors with BP control by modeling it as a function of the covariates using random-effects logistic regression. Blacks indicated worse medication adherence, more discrimination, and more concerns about high BP and BP medications, compared with whites. After accounting for all factors, race was no longer a significant predictor of BP control.

Conclusions—Results suggest that equalizing patients' health beliefs, medication adherence, and experiences with care could ameliorate disparities in BP control. Additional attention must focus on the factors associated with race to identify, and ultimately intervene on, the causes of racial disparities in BP outcomes. **(*Circ Cardiovasc Qual Outcomes*. 2010; 3:173-180.)**

Key Words: blood pressure ■ hypertension ■ race ■ disparities

Hypertension, which affects more than 73 million Americans, is a major risk factor for cardiovascular, cerebrovascular, and renal disease.[1] It is more frequent among African Americans[2] and accounts for a significant portion of racial differences in mortality, through excess cardiovascular morbidity.[3] Many patients with hypertension have poorly controlled blood pressure (BP), and African Americans are disproportionately represented among this group,[4] even after controlling for comorbidities such as diabetes and renal disease.[4–7]

The reason for this racial disparity is not well understood. Many prior studies of BP control have only examined a narrow range of potential etiologic factors—usually clinical characteristics and sometimes including selected sociodemographic factors.[8,9] Recently, authors have suggested that patient self-management attitudes and behaviors[10] and other attitudes, beliefs, and experiences that might affect medication nonadherence[11] might be potential causal pathways to disparities in chronic disease outcomes such as BP control.

Bosworth et al[12] proposed an organizing framework for the psychosocial and cultural domains they theorized would affect BP control, incorporating patient characteristics, including age, education, health literacy, and psychological factors such as beliefs and attitudes about health and illness, social/cultural environmental factors, including culturally linked perceptions of hypertension and therapies for it, and the medical environment, including the provider-patient relationship and interactions. The model does not specify causal associations, and, perhaps as a result, it has not been tested empirically, so the presence or strength of the hypothesized associations is not known. The model also did not include comorbid conditions. Thus, we sought to extend this work and the model itself by examining the contribution of the previously proposed and additional putative causal factors, in a more diverse sample in a different setting. We hypothesized that after adjusting for a more extensive set of potential confounders, race would no longer be significantly associated with BP control.

WHAT IS KNOWN

- Racial disparities in blood pressure (BP) control are well documented but poorly understood, and prior studies have only included a limited range of potential explanatory factors.

WHAT THE STUDY ADDS

- Blacks reported more experiences of discrimination, worse medication adherence, and more concerns about BP.
- Patient beliefs about hypertension can affect their BP control.
- Comorbid conditions, whose prevalence varies by race/ethnicity, can also affect BP control and thus are important to account for.
- We suggest an enhanced model of factors leading to disparities in BP control.

Methods

Sample

We identified all white and black patients ages 21 and older with 3 separate outpatient diagnoses of hypertension in 2004 in the primary care practices of a northeastern academically affiliated urban safety net tertiary care hospital. We use the term "black" to refer to patients of African or Caribbean descent. The study was approved by the institutional review board, and all subjects gave informed consent.
