Study staff tracked clinic visits of these 10 125 patients over 19 months (October 2004 to June 2006), and, as they presented for care, approached 3526 of them to request study participation. Those willing were asked a series of questions and administered a 6-item cognitive screen to determine eligibility.[13] However, 654 patients (19% of 3526) overtly refused to participate and 920 patients (26% of 3526) responded that they were unable to participate that day but were potentially willing in the future, all before we were able to assess their eligibility. Subsequently, 1083 patients (55% of the remaining 1952) were excluded for reasons including cognitive difficulties, hearing impairment, not speaking English, or not being prescribed antihypertensive medications; we enrolled 869 patients. We then applied this 55% exclusion rate to the 1574 nonrespondents whose eligibility we had been unable to assess (654 refusers and 920 with no time) and estimated that 708 (45%) probably would have been eligible. Thus, we calculated our participation rate as participants/participants+likely eligible subjects (869/869+708=55%). We subsequently excluded 63 additional patients for whom study staff were unable to obtain BPs, for a final sample of 806 (Figure 1).

We evaluated the representativeness of the enrolled cohort, compared with those eligible to be enrolled, using the limited data available on the nonenrolled patients. Enrolled patients were more likely to be white (43% versus 32%, $P<0.0001$) and were younger (mean age, 59 versus 65 for nonenrolled patients, $P<0.0001$), but there was no difference in sex distribution from the parent population of eligible patients (not shown).

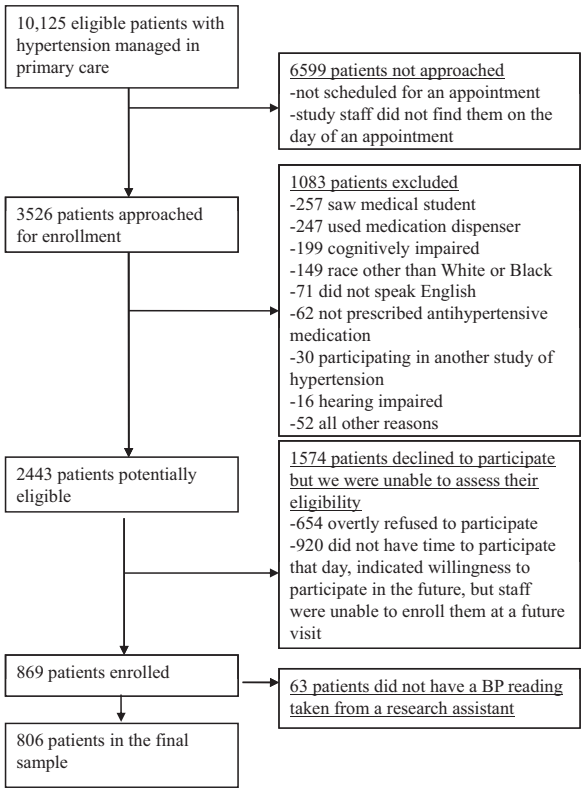

Figure 1. Flow chart of patient recruitment.

Measures

Patient Characteristics

Sociodemographic Characteristics and Medical History

Patient sociodemographic characteristics including race (assessed using US Census categories), education, and income were obtained through self-report. To assess patient literacy, we used the REALM-Short Form.[14] We used 5 separate dichotomous (yes/no) questions to assess insurance status, asking if patients currently have health insurance coverage through Medicare, Medicaid, Medigap, Free Care, or other insurance.

Patient clinical data were extracted from the electronic medical record, including age, sex, height, weight, and hypertension diagnosis. The electronic medical record was searched to obtain diagnoses of comorbid conditions including renal insufficiency, coronary artery disease, peripheral vascular disease, nicotine dependence, hyperlipidemia, diabetes mellitus, congestive heart failure, cerebrovascular disease, and obesity, because these conditions may influence the management of hypertension.[15] Obesity was considered a current diagnosis for any patient with an electronic medical record diagnosis or a calculated body mass index of at least 30.

Health Beliefs and Illness Perception

We examined a broad spectrum of patient beliefs and perceptions about high BP and related medications. We used the "Beliefs about Medicines Questionnaire"; 10 items assess patient concerns about present and potential future adverse effects from their medications and 8 items measure patients' beliefs regarding the necessity of their medications; we edited the items to relate responses specifically to BP medicines[16,17] (items scored on a 5-point scale: strongly agree to strongly disagree). Scores were summed within each scale to create an overall scale score (range, 8 to 40 for the "necessity" scale, Cronbach $\alpha=0.81$; 10 to 50 for the "concerns" scale, $\alpha=0.80$). Each score was divided by the number of items to obtain a mean summary score (range, 1 to 5); higher numbers indicated either greater concerns about medications or greater beliefs in their necessity.

We used 4 additional items from our prior work[18] to evaluate the degree of seriousness with which patients perceive hypertension, asking "How serious do you think high BP is, in general?"; "How serious do you think your high BP is, given your current use of medication?"; "If you did not take your BP medications, how likely do you think it would be that your BP would get worse over the next year?"; and "If you did not take your BP medications, how likely do you think it is that you would develop other health problems over the

next year?" (all scored on a scale of 1 to 5: extremely serious to not at all serious for the former 2 questions; very likely to very unlikely for the latter 2). We also included 10 individual items from the "cause" dimension of the "Illness Perception Questionnaire" to assess illness identity, cause, timeline, consequences, and cure control to examine patients' subjective beliefs about the etiology of their high BP (responses on a 5-point scale; range, strongly agree to strongly disagree).[19]

Perceived Discrimination in Health Care

We included 3 measures to assess patient perceptions of race-based discrimination in the health care setting. We used 5 questions that were a subset of the Commonwealth Fund 2001 Health Care Quality survey, focusing specifically on the patient perception of his/her provider and of encountering discrimination while receiving medical care, in general.[20] We created an additional question about the patient's perception of his/her provider's understanding of the patient's cultural background and how it affects his/her health; each item was examined individually. We also included 7 dichotomous items from a measure of patient perceptions of discrimination in accessing health care,[21] counting the number of experiences reported and creating a continuous variable (higher score indicates more experiences of discrimination[21]; α=0.90).

Medication Adherence and Hypertension Management

To assess medication adherence, we used the Hill-Bone Compliance to High Blood Pressure Therapy Scale, comprising items scored on a 4-point scale ("none of the time" to "all of the time").[22] We included the 9-item adherence subscale, which has been validated against BP control, summing the items to create a scale score (range, 9 to 36; higher scores indicate less adherence; α=0.74).

Outcome Assessment: BP Control

Research staff assessed patient BP using an automatic, portable machine (Omron HEM-907, Bannockburn, Ill), which was validated according to the international validation protocol and deemed an appropriate instrument for accurate BP measurement.[23] We excluded the 7% of patients without a BP reading from study staff. We dichotomized the BP readings to indicate whether each patients' BP was controlled or not, for example, when their systolic BP exceeded 140 mm Hg or their diastolic BP exceeded 90 mm Hg, according to the Joint National Committee on Hypertension 7 standards at the time of the study, which also specified that for patients with diabetes or renal insufficiency, BP should not exceed 130/80 mm Hg.[15]

Statistical Analyses

We first examined bivariate associations between race and each of the sociodemographic, clinical, attitudinal, experiential, and medication adherence variables, using χ^2 or t tests, as appropriate. Next, we performed bivariate analyses to determine whether this same set of variables was associated with BP control (yes/no). Finally, BP control was modeled as a function of the covariates using random-effects logistic regression. The random effects, which were assumed to be mean-zero gaussian additive errors on the logit scale, accounted for 2 levels of clustering: patients within providers and providers within clinics.

We fit 6 sets of models of increasing numbers of covariates, including only patients with complete data. In the first, we examined the effects of race alone on BP control. Next, we examined the effects of race on BP control, adjusting for age and other sociodemographic characteristics. The third model added medication adherence, the fourth added health beliefs, the fifth added experiences of discrimination, and the sixth added comorbid conditions. Within each model, we chose the subset of additional variables through an ordinary logistic regression stepwise selection procedure, forcing in provider indicators as fixed effects, keeping significant variables from the prior model, and including race in all models. This procedure prevents collinearity and overparameterization. We used a probability value of 0.05 for variables to enter or be removed from the model. *c*-Statistics and Hosmer-Lemeshow analyses were performed on the models resulting from the stepwise procedure. Each model was then rerun with the random effects terms. All analyses were conducted using SAS 9.1.3 (SAS Institute, Cary, NC) with the exception of the random-effects logistic regression, which was conducted using the statistics package *R* (version 2.8.0[24]).

Results

Sociodemographic Characteristics of the Sample

Most of the sample were black (57%) or female (65%), with an overall mean age of 59 years. White patients were older (61 versus 58 years), and more likely to have at least a high school education (90% versus 71%). Black patients were more likely to have insurance coverage through Medicaid or Free Care (42% versus 22%, 41% versus 25%, respectively), whereas white patients were more likely to have "other" (private) insurance (59% versus 35%). There were race differences in combined household family income, with a greater percentage of blacks earning low incomes of <$20 000 (58% versus 36% whites) and being less likely to have a literacy score of 9th grade or higher (48% versus 84%), (all P<0.001; Table 1).

BP and Medical History by Race

A greater percentage of white patients had controlled BP (65% versus 53%), with lower systolic and diastolic BP than blacks (white systolic BP, 130 mm Hg versus 132 mm Hg; white diastolic BP 76 mm Hg versus 81 mm Hg). White patients were more likely to have hyperlipidemia (60% versus 47%), peripheral vascular disease (7% versus 4%), benign prostatic hypertrophy (6% versus 2%), coronary artery disease (19% versus 8%), and cerebrovascular disease (7% versus 4%). Black patients were more likely to have diabetes (40% versus 24%), renal insufficiency (7% versus 4%), congestive heart failure (5% versus 1%), and to be obese (65% versus 52%, all P<0.05).

Health Beliefs and Illness Perceptions

Blacks had significantly more concerns about their BP medications than whites (2.5 versus 2.1, P<0.0001). White patients were significantly more likely to respond that their BP was less serious, given their current use of medications (3.3 versus 2.8, P<0.0001).

When asked about the causality of high BP, blacks agreed more with the notion that it is caused by a germ or virus or that diet, pollution, or heredity played a major role in causing BP (Table 1). Blacks were more likely to indicate that it was just by chance that they became ill with hypertension, that other people played a large role in causing their BP, or that high BP was caused by poor medical care in the past.

Perceived Discrimination

When asked if there was ever a time they would have gotten better medical care if they belonged to a different race or ethnic group or if they ever felt that a doctor or medical staff judged them unfairly or treated them with disrespect because of how well they spoke English, blacks were more likely to respond "yes" than whites (19% versus 1% and 4% versus 0%, respectively). Although all patients generally agreed that their provider understood their background and values, black patients agreed less strongly (1.5 versus 1.4), and though all patients disagreed that their provider looks down on them and

Hill Bone Adherence: Higher score indicates less adherence.
§Percent white.

the way they live their life, white patients disagreed more strongly (4.5 versus 4.3). Blacks reported more experiences of discrimination when receiving health care than did whites (1.1 versus 0.2, all $P<0.05$).

Medication Adherence

White patients reported better medication adherence than did black patients (9.9 versus 11.0, $P<0.0001$).

Covariates by BP Control

A greater proportion of patients with controlled BP were white compared with patients with uncontrolled BP (48% versus 36%). Patients with uncontrolled BP were more likely to have a household income of <$20 000 (56% versus 43%), were more likely to have Medicaid (40% versus 29%), and were less likely to have "other" insurance (38% versus 51%). Patients with uncontrolled BP were more likely to have

diabetes (45% versus 25%) and renal insufficiency (10% versus 3%) and concerns about their BP medications (2.4 versus 2.3). Patients with controlled BP were more likely to disagree that their own BP was serious, given their current use of medication (3.1 versus 2.9), and reported better medication adherence (10.4 versus 10.7, all $P<0.05$).

Multivariate Results

The first model, only adjusted for race, accounting for physician and clinic, indicated that white patients had higher odds of having controlled BP than blacks (model 1, b=0.42, $P=0.0068$; Table 2; *c*-statistic (*c*)=0.661; Hosmer and Lemeshow goodness-of-fit test [HL] $P=0.4226$). The effect of race on BP control persisted in the second model, after adjustment for income (other sociodemographic variables were excluded through the ordinary logistic regression stepwise procedure). The third model added a measure of adherence, which was not significantly related to BP control, so these 2 latter models had the same results, with race continuing to be a significant predictor of BP control (models 2 and 3, b=0.37, $P=0.0238$; model 2, $c=0.691$, HL $P=0.7127$; model 3, $c=0.670$, HL $P=0.9260$). In the fourth model, an item assessing patients' beliefs that high BP is largely due to one's own behavior was added, as well as 2 items assessing the degree of seriousness with which patients perceive hypertension (all other attitudinal and experiential factors were excluded through the stepwise procedure). In this model, race was no longer significantly associated with odds of BP control (model 4, b=0.33, $P=0.0531$, $c=0.713$, HL $P=0.3932$).

In the fifth model, 1 item assessing experiences with perceived discrimination in health care was added, specifically, perceptions about whether they would have ever gotten better medical care if they belonged to a different race or ethnic group (other items assessing discrimination were excluded through the stepwise procedure). Race was significant in this model (model 5, b=0.48, $P=0.0074$, $c=0.708$, HL $P=0.8660$).

In the final model, diabetes, renal insufficiency, and benign prostatic hypertrophy were added (other comorbid conditions were excluded during the stepwise procedure in SAS). Here, race was no longer a significant predictor of BP control (model 6, b=0.32, $P=0.0876$, $c=0.740$, HL $P=0.4274$).

Discussion

Understanding and ameliorating racial disparities in BP control is a major public health and clinical concern. We hypothesized that after adjusting for an extensive set of potential confounders, race would no longer be significantly associated with BP control, and the results generally supported this notion. Although the effects of race persisted after accounting for sociodemographic factors, the inclusion of BP-related attitudes and beliefs rendered race insignificant. However, the introduction of the discrimination variables made race significant again, in a counterintuitive fashion, although in the final model, with the inclusion of comorbid conditions, race was no longer significant. The finding that

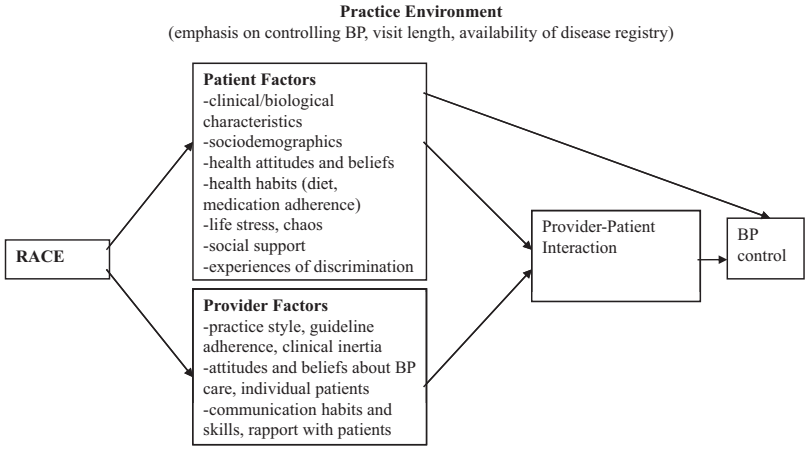

Figure 2. Expanded model of factors leading to disparities in BP control.

patients who agreed with the statement that there was "ever a time when they would have gotten better medical care if they had belonged to a different race/ethnic group" had better BP control is puzzling. We carefully explored this dynamic, ruling out the possibility that race-discrimination interactions were driving it, and finding that even if we removed this variable, another discrimination variable became significant in the same counterintuitive direction (not shown). The variable was limited by its reference point (eg, was there ever a time . . .), so it is possible that patients who felt they were getting bad care in the past had changed clinicians and are now getting good care, leading to better current BP care and control. It is also possible that another, unmeasured, confounder caused these results.

The study findings are different than the Bosworth study,[11] which indicated that after controlling for a similar range of factors (not including discrimination or comorbid conditions), race remained a significant predictor of BP control, among VA patients in one Southern city. They speculated that the results they obtained in that setting, where access to care is assured, might be different than those found elsewhere, and our results in a northeastern urban safety net hospital setting support this notion. Several other studies also controlled for subsets of the factors we included here, but race remained significant.[6,25,26] Thus, although our findings support Bosworth's proposed framework as a descriptive model, and the notion that numerous psychosocial, behavioral, and experiential factors mediate the relationship between race and BP control,[11] they indicate that comorbid conditions, whose prevalence varies by race/ethnicity, are also important to account for in models of disparities in BP control.

Several findings have clinical implications. Blacks reported more experiences of discrimination, and such experiences may erode overall trust in physicians, their diagnoses, and the therapies they prescribe. Experiences of discrimination in the community setting are generally associated with higher BP[27,29,30] with less use of chronic disease care[28] and may negatively affect patients' acceptance of their diagnosis and beliefs in the necessity of or concerns about the associated therapy, which are foundational to patient adherence to prescribed medications.[29] Unequal treatment, documented by us and others,[30,31] may also contribute to disparities in BP outcomes.

Blacks indicated worse medication adherence and more concerns about BP. Each of these is potentially ameliorable through educational or counseling interventions, and our results suggest that addressing these will help address disparities in BP control.

This study was limited by its focus on patients in a single setting and its inclusion of only black (albeit both African-American and Caribbean-born) and white patients. Although we required that participants have 3 separate outpatient diagnoses of hypertension, our inability to contact or enroll many eligible patients may have biased our sample toward more frequent users. The observational nature of these data limits our ability to form causal inferences because we were not able to randomize by attitudinal characteristics or ascertain that certain attitudes or experiences preceded BP outcomes in time. Further, our measure of adherence, although internally consistent and previously validated against BP control, was obtained by self-report. However, the large sample, which included women and detailed assessments of the richest array of putative factors examined to date, offsets the limitations.

Among the potential causes of disparities in BP control, the etiologic factors could arise from the patient (health beliefs and experiences, medication adherence or self-care behaviors, clinical or biological factors), the provider (practice style, communication skills, attitudes), the doctor-patient interaction, or the environment. Although the Bosworth model provided an excellent summary of the psychosocial and cultural factors that might be associated with BP control, we propose that a model for racial disparities in BP control should include a wider array of factors and include hypothesized associations (Figure 2). The present results help to demonstrate the effects of a variety of factors on race differences in BP, but we lacked data on other self-care behaviors important to hypertension management (eg, diet, exercise) to fully address this question. Nor are we able to rule out biological differences, such as race-linked nitric oxide deficiencies associated with cardiovascular disease[32] or differences in the process of care. Our future work will also examine the effects of racial differences in providers' therapeutic intensification, which varies by race,[33] on BP outcomes. Similar to our prior suggestions for future directions in research on racial differences in invasive cardiac procedure

use,[31] here we propose additional careful attention by clinicians, researchers, and, ultimately, policymakers, to a comprehensive array of factors associated with race to identify and intervene on the causes of racial disparities in BP outcomes.

NURSING HOME RESIDENCE CONFOUNDS GENDER DIFFERENCES IN MEDICARE UTILIZATION
An Example of Simpson's Paradox

Received 26 December 2007; revised 1 August 2009; accepted 21 November 2009

Background. **Gender differences in health care utilization in older Americans may be confounded by nursing home residence. Medicare data contain several files that can be used to create a measure of nursing home residence, but prior work has not addressed which best account for potential confounding. Simpson's paradox occurs when aggregated data support a different conclusion from what the disaggregated data show. We describe such a paradox that appeared when we sharpened our definition of "nursing home residence" while examining gender differences in Medicare utilization at the end of life.**

Methods. **To understand gender-specific health care utilization at the end of life, we conducted a retrospective analysis of a national random sample of Medicare beneficiaries aged 66 or older who died in 2001 with Parts A and B data for 18 months before death. We sought to associate each of total hospital days and costs during the final 6 months of life with numbers of primary care physician visits in the 12 preceding months. In addition to demographics, comorbidities, and geography, "nursing home residence" was a potential confounder, which we imputed in two ways: 1) from skilled nursing facility bills in the Part A Medicare Provider Analysis and Review (MedPAR) file; and 2) from Berenson-Eggers-Type-of-Service codes indicating widely spaced doctor visits in nursing homes obtained from Medicare's carrier file.**

Conclusion. **Gender differences in Medicare utilization are strongly confounded by nursing home resident status, which can be imputed well from Medicare's carrier file, but not MedPAR.**

Background

During this time of health care reform, understanding gender differences in health care utilization in the Medicare population is critical, because women live longer and make up a larger proportion of the Medicare population (Medicare Beneficiary Demographics, 2006). In addition, women live with greater disability and more chronic disease than men. For example, chronic conditions such as diabetes, arthritis, dementia, depression, and obesity are more common in women (Lubitz & Riley, 1993). As baby boomers age, Medicare faces escalating expenditures and dwindling numbers of workers to fund it. Because 30% of Medicare expenditures are spent on the 6% of beneficiaries who die each year (*Approaching Death*, 1997; Edwards & DeHaven, 2003; Hogan, Lunney, Gabel, & Lynn, 2001), there is strong interest in improving the efficiency of health care at the end of life. Primary care medicine may improve this efficiency, because it is intended to address comprehensiveness, coordination, continuity, and "sustained clinician–patient partnerships" with the family and community (Montgomery

Funded by the Office of Research on Women's Health (ORWH) K12-43444, with support from the Centers for Medicare and Medicaid Services (CMS) and the National Cancer Institute (NCI).

et al., 2004). In addition, primary care providers may focus—more than specialists—on preventing medical complications, discussing patient preferences, and coordinating home palliative care at life's end. Our prior work found more primary care visits in the preceding year were associated with reduced hospitalization, in-hospital death, and costs in the last 6 months of life (Kronman, Ash, Freund, Hanchate, & Emanuel, 2008).

We hypothesized that there were gender differences in the relationship between primary care and health care utilization at the end of life. Women tend to use more primary care and outpatient services, whereas men tend to use more in-patient hospital services (Bird, Shugarman, & Lynn, 2002; Song, Chang, Manheim, & Dunlop, 2006). Because Medicare currently rewards in-hospital services more than primary care, the program's financial incentives may affect men and women differently. To understand gender differences in the health care utilization of an elderly population, it is important to adjust for those who are nursing home residents, because more women are residents than men, and residents have different utilization of both primary care and hospital services. Because Medicare data do not contain a reliable indicator of nursing home resident status, we report here on two different methods of imputing nursing home resident status and demonstrate the effect on health care utilization outcomes.

Methods

Data source

To examine gender differences in end-of-life care, we used a randomly sampled population of 116,318 Medicare beneficiaries aged 66 or older who died in the last 6 months of 2001. Non-Whites were oversampled because the study population had been constructed to focus on end-of-life health care disparities (Hanchate, Kronman, Young-Xu, Ash, & Emanuel, 2009). To ensure completeness and comparability of health care utilization records before death, we excluded people who were not continuously enrolled in Medicare Parts A and B traditional fee-for-service program for the final 18 months of life. We also excluded decedents who could not be matched to the National Death Index, and those enrolled in the end-stage renal disease program, leaving a final analytical sample of 78,353.

Measures

We obtained age, gender, race, and zip code of residence from the Medicare denominator file, using the Medicare racial/ethnic categories of White, Black, Hispanic, and other (for those of Asian, North American Native, and other or unknown races and ethnicities). We used an indicator that Part B Medicare insurance had been purchased by a state in 2000 (state Medicaid "buy-in") as a proxy for low income. Place of death was derived from death certificates through the National Death Index. A summary comorbidity measure was determined using DxCG's prospective relative risk score (DCG version 6.1 for Windows [DxCG, 2004]), derived from the presence in the pre-period of ICD-9-CM diagnosis codes from inpatient and outpatient encounters in Medicare's utilization files. These encounters include all physician visits, hospital care, and nursing home care, but not codes used for diagnostic tests. The score is calibrated to associate 1.0 with average expected expenditures in the following year among all Medicare beneficiaries observed during routine 12-month periods (Ash et al., 2000).

Because Medicare Part A only pays for nursing home visits in the first 90 days after a hospitalization, we were unable to directly distinguish long-term nursing home residents from those in a nursing home for short-term rehabilitation after a hospitalization from our administrative billing data. We thus imputed two proxy measures. For the first measure, we defined those with "nursing home use" to be beneficiaries with at least one bill for residential costs in a skilled nursing facility (SNF) in the Part A Medicare Provider Analysis and Review (MedPAR) SNF file. This method is limited in not being able to distinguish nursing home residents from patients who are receiving short-term rehabilitation in a nursing facility. However, because MedPAR is more commonly utilized in health services research, this has the potential to be a readily utilized methodology. The second method utilizes the Medicare Part B carrier file. Unlike Medicare Part A, Medicare Part B does not pay for residential costs in a nursing home; however, it does pay for diagnostic tests and medical provider visits that take place in a nursing home. We used Berenson-Eggers-Type-Of-Service (BETOS) code 4B in Medicare's "Carrier" file (available from: http://www.cms.hhs.gov/HCPCSReleaseCodeSets/20_BETOS.asp) to define our second measure. This method of identifying nursing home use has been previously validated (Campbell et al., 2004). With it, a beneficiary was flagged for nursing home use if there were at least two health care encounters (e.g., blood draws and/or physician visits), separated by at least 90 days, that occurred in a nursing home. Because the maximum period of Medicare reimbursement for SNF care after a hospitalization is 90 days, people who received services spanning a longer period are likely to have resided in a nursing home receiving long-term care; although this method will also (spuriously) find occasional non-nursing home residents with rehabilitative SNF stays after two distinct hospitalizations.

Primary care visits

We used BETOS codes in the Medicare Carrier file to identify a visit in a nursing facility (code 4B) or office

(codes 1A and 1B). We then linked these codes to the Medicare Health Care Financing Administration specialty codes to define a visit to an internist (11), geriatrician (38), or family practitioner (08), as a "primary care visit." We used the number of these visits in the 12-month "pre-period" before the final 6 months of life to form five primary care groups: no visits, one or two, three to five, six to eight, and nine or more visits. We categorized visits that did not have these primary care Health Care Financing Administration specialty codes as "visits to specialists." We calculated the ratio of number of specialty visits to number of total outpatient encounters for each gender and by nursing home use.

Outcomes

We studied two outcomes during the last 6 months of life: 1) number of inpatient days (obtained from the MedPAR files) and 2) total costs paid by Medicare (from the MedPAR, Carrier, Durable Medical Equipment, Hospice, and Outpatient files).

Statistical analysis

We used bivariate analyses (chi-square test for categorical variables and analysis of variance for continuous variables) to identify differences in characteristics, end-of-life utilization, and costs across the primary care groups and genders. To compare the characteristics of our two definitions of nursing home use, we conducted bivariate analysis on the population within four groups, those with 1) both SNF bills from MEDPAR and encounters from carrier file, 2) only SNF bills, 3) only carrier file encounters, and 4) neither. STATA software version 9.1 (StataCorp, College Station, TX) was used for all analyses. We adjusted for factors from the pre-period that affect health care utilization and outcomes: age (Levinsky et al., 2001), race (Barnato, Lucas, Staiger, Wennberg, & Chandra, 2005; Degenholtz, Thomas, & Miller, 2003; Skinner, Weinstein, Sporer, & Wennberg, 2003), Medicaid buy-in, comorbidity (Ash et al., 2003; Hogan et al., 2001; Institute of Medicine, 1997), and place of residence (Baicker, Chandra, Skinner, & Wennberg, 2004; Fisher et al., 2000; Pritchard et al., 1998). For our first analysis, we adjusted for all confounders excluding either nursing home measure, which resulted in aggregated data around the confounder of nursing home use. To disaggregate the data, we then adjusted with the MedPAR-based measure of nursing home use, and a third time substituting the carrier file–based measure instead of the MedPAR measure. Our final analysis stratified the population by both gender and nursing home use based on the carrier file measure.

To account for geographic differences, we used multivariable cluster analysis, specifically, fixed effects regression with dichotomous indicators for each geographic unit. Contrasting each outcome only for beneficiaries residing in the same geographic area accounts for both measured and unmeasured factors (including health care supply and labor), which vary by geographic location (Johnston & DiNardo, 1997). We mapped each beneficiary's zip code of residence into its "hospital service area," defined by the Dartmouth as a geographic unit associated with health care utilization patterns (Fisher & Wennberg, 2008).

We calculated risk-adjusted, expected outcomes for each gender by primary care visit group by using its coefficient together with mean values for each of the other covariates in the model, using sample weights to reflect the entire Medicare population, and tested for statistical differences by gender. The key independent variables of our first three analyses were fully interacted 2×5 matrices of gender by number of pre-period primary care visits. Our final analyses used a fully interacted 4×5 matrix of gender and nursing home use by number of pre-period primary care visits.

Results

The general characteristics of the 78,356 Medicare decedents in our sample are as follows: the mean age is 81 years (range, 66–98), 56% are female; 40%, White; 36%, Black; and 11%, Hispanic. On average, women decedents are 3 years older than men decedents (mean age 82 vs. 79 years; $p < .001$) and have similar overall comorbidity (mean risk score for both genders is 2.2). In the 12 months before the final 6 months of life (the "pre-period"), more women receive Medicaid assistance (38% vs. 25%), and have more than 3 primary care visits (43% vs. 36%) than men (all p-values $< .001$; Table 1). The modal number of visits for both men and women is zero. Twenty-two percent of both genders have one or two visits, whereas only 18% of men have six or more visits, compared with 23% of women. In the final 6 months of life, both genders average 15 total hospital days (unadjusted); 74% of both men and women had at least one hospitalization. Compared with men, women cost $1,000 less per capita ($p < .05$) and use hospice a little more frequently (24% vs. 23%; $p < .001$) in the pre-period; they were more likely to die in a nursing home (29% vs. 20%; $p < .001$) and less likely in a hospital (41% vs. 45%; $p < .001$) or at home (19% vs. 22%; $p < .001$; Table 1).

Table 2 summarizes the unadjusted baseline comparisons by gender and nursing home resident status using each of our two definitions of nursing home residents: those with SNF bills from the MEDPAR files indicating a hospitalization during the pre-period, and those with BETOS code health care encounters from the carrier file received in a nursing home. We divided the population into four groups: Group 1 contains people who met both nursing home definitions (MedPAR and carrier file based); group 2 met the carrier file criterion only; group 3, MedPAR only; and, group 4, neither. During the pre-period, the

*** Pre-period, months 18–7 before death.
† Measured during final 180 days of life.
‡ Comorbidity risk score determined by the relative risk score from DxCG's prospective risk adjustment software, which organized ICD-9-CM diagnosis codes from the Medicare utilization files, assigns weights to them, and summarizes their expected impact on future expenditures via a relative risk score.

comorbidity scores of the SNF groups 1 and 3 were higher than the non-SNF groups 2 and 4: namely, 3.6 for group 1, 2.7 for group 3, 1.5 for group 2, and 0.87 for group 4. During the pre-period, those with CARRIER file code definitions had more primary care visits than those who did not (41% of group 1 and 37% of group 2 had at least nine primary care visits, compared with 11% of group 3 and 7% of group 4); more Medicaid use (46% of group 1 and 55% of group 2, compared with 33% of group 3 and 28% of group 4); and less specialty use (14% for group 1, 7% for group 2 compared with 33% for group 3 and 46% for group 4). During the last 6 months of life, the carrier file only group 2 had the lowest costs ($10,000 compared with $17,000 for group 1, $19,000 for group 3, and $15,000 for group 4); lowest use of hospice (17%, compared with 28% of group 1, 29% of group 3, and 25% of group 4); and the most deaths in a nursing home (66%, compared with 55% of group 1, 33% of group 3, and 16% of group 4). Within each group, men received more specialty care, and more women had Medicaid and died in a nursing home.

When adjusting for all confounders except either of the two measures of nursing home use, we found that among those with nine or more primary care visits, women spent less time in the hospital than men (11.8 vs. 13.4 days; $p < .05$; Figure 1A), and averaged $3,677 less than men ($p < .05$; Figure 2A). After a threshold of three to five visits, more primary care visits were associated with fewer hospital days for both genders, but the association was stronger for women (Figure 1A). After a threshold of one to two visits, more primary care visits were generally associated with lower costs for women, but not for men (Figure 2A). Our results were similar when adjusting for nursing home use using MedPAR data: of those with nine or more primary care visits, women spent less time in the hospital than men (13.2 vs. 14.1 days, $p < .05$; Figure 1B) and averaged $2,641 less than men ($p < .05$; Figure 2B).

After a threshold of three to five visits, more primary care visits were generally associated with less hospital utilization and lower costs for women, but not for men (Figures 1B and 2B). However, when we adjusted for nursing home use using carrier file data (having at least two separated encounters in a nursing home defined by BETOS codes), we found that more primary care was not associated with decreased hospital utilization (Figure 1C) or costs (Figure 2C). Moreover, we did not find a significant gender difference in total hospital days, although women with at least nine primary care visits still had lower costs than men ($20,594 for women vs. $24,157 for men). When we stratified the population by gender and the carrier file definition of nursing home residence, both men and women residents had remarkably lower costs than nonresidents. After accounting for nursing home residence, there were no significant gender differences within these strata (Figures 1D and 2D).

Discussion

We sought to examine gender differences in health care utilization at the end of life. We expected nursing home use to be a confounder, because more women are nursing home residents than men, and such residence affects several kinds of Medicare utilization. Because Medicare billing data do not have a direct indicator of nursing home residence, we imputed two different proxy measures of nursing home use using variables from different Medicare file sources. When we did not control either at all, or adequately, for nursing home residence (using MedPAR files only), we reached conclusions different from those when using a more reliable marker of nursing home residence (based on receiving services, widely spaced in time, in a nursing home). This is an example of Simpson's paradox. Health care utilization outcomes are influenced by nursing home resident status, with costs and utilization being much lower for nursing home residents than nonresidents, and women receiving Medicare being far more likely than men to reside in nursing homes.

* Pre-period, months 18–7 before death.

** Measured during final 180 days of life.

*** Comorbidity risk score determined by the relative risk score from DxCG's prospective risk adjustment software, which organized ICD-9-CM diagnosis codes from the Medicare utilization files, assigns weights to them, and summarizes their expected impact on future expenditures via a relative risk score.

Our first method of imputing nursing home use (1 billed day in a SNF) from Medicare MedPAR files is frequently used when analyzing costs and utilization at the end-of-life Medicare billing data (Lubitz & Riley, 1993; Shugarman, Bird, Schuster, & Lynn, 2007). When we used this definition in our analyses, we found the association between more primary care visits and decreased hospital utilization and costs to be stronger for women than men. This finding is consistent with studies showing that, because women generally use more primary care than men, they may have more trusting relationships with their health providers, and more easily express their preferences for end-of-life care (Bertakis, Azari, Helms, Callahan, & Robbins, 2000; Bird et al., 2002). Compared with men, women may value a dignified death over receiving intensive, life-sustaining treatments (Bookwala et al., 2001). These findings suggest a gender-related disparity, in which men receive more expensive and intensive procedures than women at the end of life (Ayanian & Epstein, 1991; Bird et al., 2002; Valentin, Jordan, Lang, Hiesmayr, & Metnitz, 2003).

However, this way of identifying nursing home users only identifies beneficiaries who have been hospitalized and used Medicare-financed SNF care for a period of at most 90 days of rehabilitation, leaving a record in the Medicare's MedPAR (SNF) file. Beneficiaries in this group are heterogeneous, containing both outpatients who require nursing care or rehabilitation after a hospitalization and nursing home residents. It includes a mix of nursing home residents and nonresidents.

Our second definition of nursing home use (at least two BETOS codes in the Medicare carrier file for nursing home encounters, separated by at least 90 days) distinguished a population likely to be nursing home residents. This is confirmed by the high percentage Medicaid receipt, high numbers of primary care visits, high proportion of nursing home deaths, and lower overall costs. When we stratified the population with this definition of nursing home use, we found no gender differences among either nursing home residents or nonresidents. Thus, the gender differences we observed seem to be principally driven by the fact

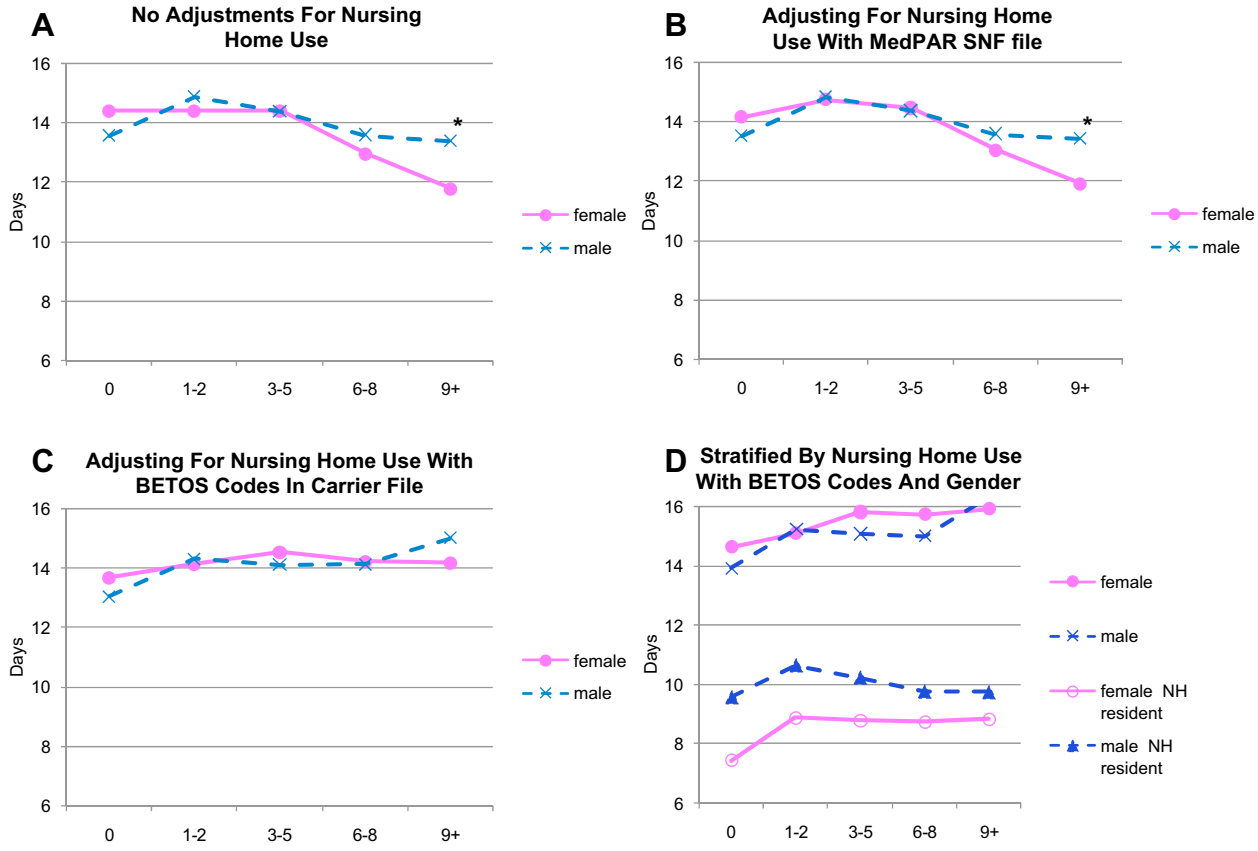

Figure 1. Preceding primary care visits** and total hospital days at the end of life***, by gender. **A,** No adjustments for nursing home use. **B,** Adjusting for nursing home use with MedPar SNF file. **C,** Adjusting for nursing home use with BETOS codes in carrier file. **D,** Stratified by nursing home use with BETOS codes and gender. *Abbreviations*: NH, nursing home; BETOS, separated health care encounters in nursing facility based on BETOS code 4B in the Medicare Carrier file; SNF = nursing home use based on bills in Medicare MedPAR Skilled Nursing Facility file. *$p < .05$, difference between genders. **Pre-period, months 18–7 before death; ***measured during final 180 days of life, adjusted for age, race, Medicaid use, comorbidity, geographic variation (hospital service area).

that far more women are nursing home residents, who (be they male or female) have lower hospital utilization and costs and more primary care visits than nonresidents. Our findings illustrate Simpson's paradox, in that relationships among utilization, cost, and primary care visits that seemed to differ by gender, disappear when beneficiaries were disaggregated by nursing home status. Although examples of Simpson's paradox have been described in clinical data (Charig, Webb, Payne, & Wickham, 1986) and meta-analyses (Cates, 2002), to our knowledge this is the first example of Simpson's paradox reported in Medicare data.

The difference between nursing home residents and nonresidents for both hospital utilization and costs was noteworthy. Nursing home residents had significantly more primary care visits than nonresidents, likely because Medicare nursing home regulations require at least one primary care visit every one or two months (*Medicare Claims Processing Manual*, N.D.). It is possible that regular primary care visits for nursing home residents may prevent hospitalization by better management of chronic conditions. In addition to using less specialty care, doctors who specialize in nursing home care may be better situated to implement directives that avoid hospitalization. Even when stratified by nursing home use, men received a higher proportion of their care by specialists compared with women.

The study has several limitations. Although we measured the quantity of primary care by counting visits to a primary care physician, we did not count other forms of primary care such as nurse visits, telephone consultations, or primary care provided by specialists. If there was a differential receipt of these services between men and women, these services could also be confounders when comparing genders in the receipt of primary care. Medicare claims data provide little to no information on the quality of primary care provided, the nature of clinician–patient interactions, beneficiary preferences, and the appropriateness of clinical treatment. Our findings do not address non-Medicare costs, such as for home health aides and nursing home residence, which can be considerable, and may not generalize to Medicare beneficiaries in managed care plans or to those without optional Medicare Part B (ambulatory care) coverage.

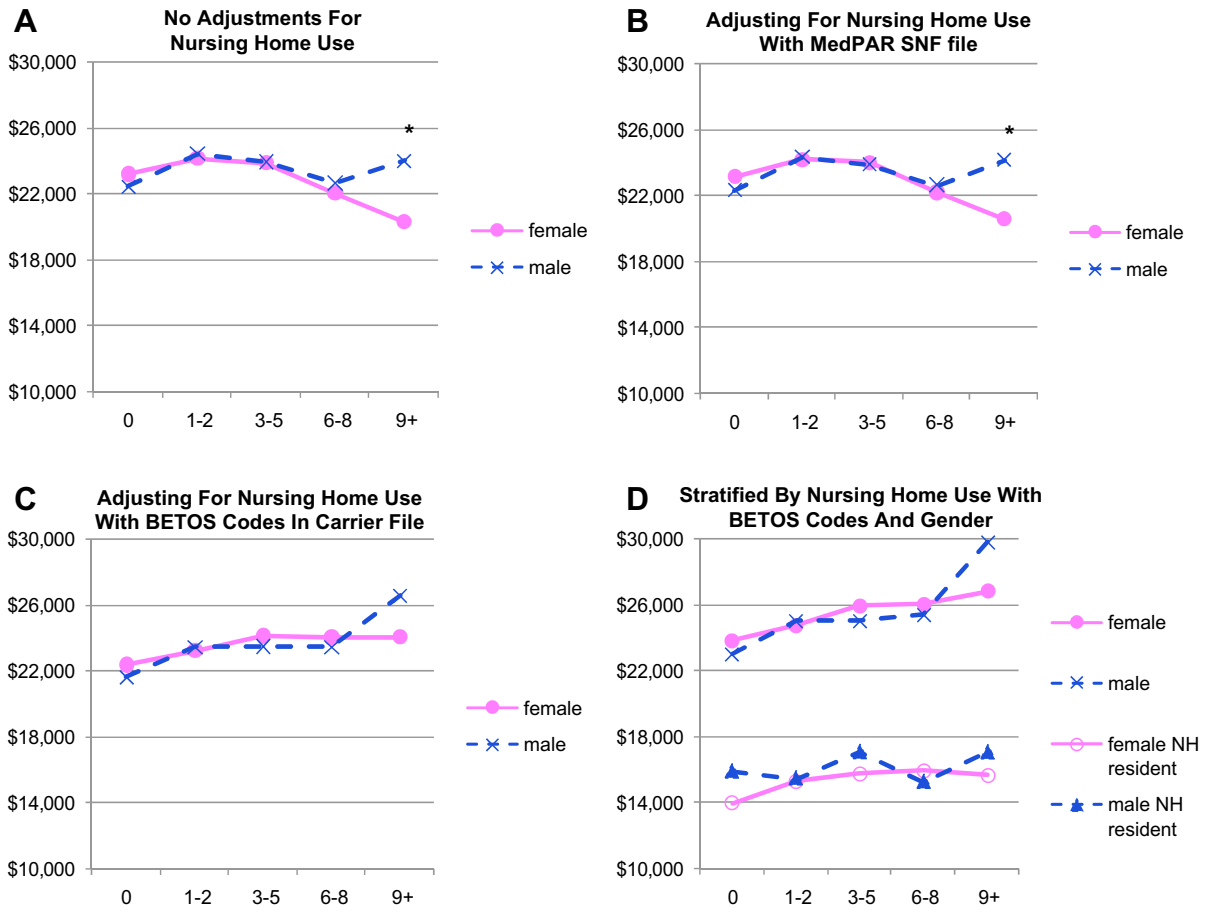

Figure 2. Preceding primary care visits‡ and ** total costs at the end of life***, by gender. **A**, No adjustments for nursing home use. **B**, Adjusting for nursing home use with MedPAR SNF file. **C**, Adjusting for nursing home use with BETOS codes in carrier file. **D**, Stratified by nursing home use with BETOS codes and gender. *Abbreviations*: NH, nursing home; BETOS, separated health care encounters in nursing facility based on Berenson-Eggers-Type-of-Service code 4B in the Medicare Carrier file; SNF = nursing home use based on bills in Medicare MedPAR Skilled Nursing Facility file. *$p < .05$, difference between genders; **Pre-period, months 18–7 before death; ***measured during final 180 days of life, adjusted for age, race, Medicaid use, comorbidity, geographic variation (hospital service area).

The decedent follow-back method that we used has been criticized for studying health care utilization before death (Bach, Schrag, & Begg, 2004). However, unlike Bach et al.'s study of cancer patients, 80% of our subjects did not die of cancer, meaning that there was likely not a well-defined moment at which such patients enter into a cohort with the expectation of a steady trajectory toward death (Lunney, Lynn, Foley, Lipson, & Guralnik, 2003). Most of our subjects have a vacillating trajectory of generally declining functional status resulting from chronic diseases such as heart failure and diabetes. So, although the prospective cohort approach may be more fruitful than the follow-back method for cancer patients, it is less clear how it might usefully be applied to a general population of elderly patients, with highly variable survival expectations.

In conclusion, when using Medicare data to examine gender-specific differences in health care utilization, it is important to account for nursing home use based on nursing home residence to avoid erroneous conclusions. Nursing home residence is highly confounded by gender because nursing home residents are predominantly female (Spillman, Liu, & McGilliard, 2002). We found that Medicare's MedPAR data does not identify nursing home residents, which can confound the interpretation of gender differences, even when studying only MedPAR (hospital or SNF) outcomes. However, we have shown how the potential confounding can be solved by using Medicare carrier file data, as described in this paper.

Author Descriptions

Andrea C Kronman, MD, MSc, is an Assistant Professor of Medicine in the Women's Health Unit in the Section of General Internal Medicine at the Boston University School of Medicine. She is a clinician-investigator whose research experience includes using large databases to examine disparities in primary care and healthcare utilization at the end of life, as well as examining the relationship between depression and cancer screening behavior.

Amresh Hanchate, PhD, is a Health Economist at the VA Boston Healthcare System, and Research Assistant Professor in the Healthcare Research Unit in the Section of General Internal Medicine at the Boston University School of Medicine. He has many years of research experience in estimation of health costs, economic evaluation of health interventions, risk adjustment and health disparities.

Karen M. Freund, MD, MPH, is a Professor of Medicine, Chief of the Women's Health Unit, and Executive Co-Director of the Women's Health Interdisciplinary Research Center at the Boston University School of Medicine. She is a clinician-investigator whose research has focused on disparities in health outcomes for minority, low-income, and underserved women, focusing on cancer outcomes.

Ezekiel J. Emanuel, MD, PhD, is Head of the Department of Bioethics at The Clinical Center of the National Institutes of Health and a breast oncologist. He is currently acting as special advisor for health policy to the director of the White House Office of Management and Budget. He has published widely on the ethics of clinical research, health care reform, international research ethics, end-of-life care issues, euthanasia, the ethics of managed care, and the physician-patient relationship.

Arlene. S Ash, PhD, is Professor in the Department of Quantitative Health Sciences at the University of Massachusetts Medical School and Chief of its Division of Biostatistics and Health Services Research. She is adjunct Research Professor of Medicine and Chief of the Healthcare Research Unit at the Boston University School of Medicine. A health services research methodologist, she has studied health care delivery financing; patient safety; and racial and gender differences in medical utilization and health outcomes.

Extensive efforts have been aimed at understanding the genetic underpinnings of complex diseases that affect humans. Numerous genome-wide association studies have assessed the association of genes with human disease, including the Framingham Heart Study (FHS), which genotyped 550,000 SNPs in 9,000 participants. The success of such efforts requires high rates of consent by participants, which is dependent on ethical oversight, communications, and trust between research participants and investigators. To study this we calculated percentages of participants who consented to collection of DNA and to various uses of their genetic information in two FHS cohorts between 2002 and 2009. The data included rates of consent for providing a DNA sample, creating an immortalized cell line, conducting research on various genetic conditions including those that might be considered sensitive, and for notifying participants of clinically significant genetic findings were above 95%. Only with regard to granting permission to share DNA or genetic findings with for-profit companies was the consent rate below 95%. We concluded that the FHS has maintained high rates of retention and consent for genetic research that has provided the scientific freedom to establish collaborations and address a broad range of research questions. We speculate that our high rates of consent have been achieved by establishing frequent and open communications with participants that highlight extensive oversight procedures. Our approach to maintaining high consent rates via ethical oversight of genetic research and communication with study participants is summarized in this report and should be of help to other studies engaged in similar types of research.

Key words: epidemiology; genetics; genome-wide association; medical ethics; population study

INTRODUCTION

Since the beginning of the twentieth century, advances in the prevention and treatment of infectious diseases have led to a steady increase in childhood survival and in life expectancy. Today with people in developed and developing countries living longer, we have entered an era in which the greatest threats to global health are heart disease, cancer, stroke, and other adult chronic diseases. Most of these diseases are believed to be the result of interactions between genetic factors and environmental exposures. Extensive efforts are underway to understand the genetic underpinnings of complex diseases that affect the lifespan and quality of life of humans. Marked advances in technology, however, have ushered in new challenges to the appropriate use of genetic science to promote improvements in public health.

Genome-wide association methods have been applied selectively to individual diseases. Numerous genome-wide association studies of 100,000 to 1,000,000 or more single nucleotide polymorphisms (SNPs) are now underway in a range of sample sizes from a few hundred to up to tens of thousands of people to assess the association of common genetic variants with human diseases. Numerous novel genetic associations have recently been reported for scores of traits and diseases, including some that hitherto were resistant to genetic discoveries (http://www.genome.gov/gwastudies/).

The Framingham Heart Study is a prospective epidemiology project that began recruiting participants in 1948 [Dawber et al., 1951]. In recent years, study investigators have collected DNA samples and have prepared immortalized cell lines—to establish and maintain a renewable DNA resource—in study participants from three generations within families. Because of its wealth of data, multigenerational structure, and extensive DNA resources, the Framingham Heart Study is an attractive research setting for genome-wide association studies (GWAS). The National Heart, Lung, and Blood Institute initiated a GWAS in the Framingham Heart Study. This new project, the SNP Health Association Resource (SHARe), genotyped approximately 550,000 SNPs in over 9,000 study participants (approximately 5 billion genotypes) (http://public.nhlbi.nih.gov/GeneticsGenomics/home/share.aspx). This detailed characterization of common human genetic variation across the entire genome has helped pinpoint common genetic signatures of disease and thereby identified new pathways related to health and disease [Dehghan et al., 2008; Köttgen et al., 2009; Levy et al., 2009]. The success of this effort is dependent on high rates of consent by study participation for collection of biosamples and for the conduct of genetic research. High rates of consent are closely linked to the implementation of procedures for ethical oversight of genetic research, informed consent, access to data by outside investigators and for-profit companies, protection of privacy and confidentiality, and participant notification of genetic results. Left unaddressed, participants' concerns about the oversight of genetic research could impact rates of participation in the study. Accordingly, for this investigation, we calculated the rates of participant consent from 2002 to 2009 to various uses of their DNA and genetic information.

MATERIALS AND METHODS

Description of the Framingham Heart Study

In 1948, the Framingham Heart Study, under the auspices of the US Public Health Service, embarked on a prospective population-based study [Dawber et al., 1951]. A central objective of the study was to identify factors that contribute to cardiovascular disease by following its development over a long period of time in a large group of community residents who were extensively evaluated. The researchers recruited an original cohort of 5,209 men and women between the ages of 28 and 62, including 1,644 spouse pairs, from the town of Framingham, Massachusetts, and began the first round of physical examinations, lifestyle interviews and laboratory tests that they would later analyze for common patterns related to cardiovascular disease development [Dawber et al., 1951]. Since 1948, the original cohort participants have continued to return to the study every 2 years for a detailed medical history, physical examination, and laboratory tests. In 1971 the study, with the formal involvement of Boston University, began the enrollment of a second-generation cohort consisting of 3,548 children of the original cohort along with 1,576 of their spouses [Feinleib et al., 1975]. Offspring cohort examinations were similar to those of the original cohort and were repeated approximately every 4–8 years. Between 2002 and 2005, 4,095 adults with at least one parent in the offspring cohort enrolled in the third generation cohort and underwent a clinic examination [Splansky et al., 2007]. The second examination of that cohort began in 2008.

Consent for Genetic Research

At the start of the clinic visit, study participants provide written informed consent as part of a process that is administered by clinic staff trained to answer questions and seek a senior investigator to address participant questions they cannot answer. For the initial visit of the third generation cohort (2002–2005), separate check boxes were created to obtain consent (or refusal) for DNA extraction and sharing of DNA and genetic data with researchers, cell line creation, and access to DNA and data by for-profit companies (http://www.framinghamheartstudy.org/research/pdfs/consent/gen3_exam1_consent.pdf). The consent process and the consent document have evolved in response to ongoing discussion with ethicists and study participants. Additional check boxes were included in the offspring cohort Examination 8 consent document (2005–2008) to determine participants' preferences for the use of their data for specific research areas, including some that might be viewed as sensitive or not part of the historic core mission of the Framingham Heart Study (e.g., reproductive health, mental health and alcohol use) (http://www.framinghamheartstudy.org/research/pdfs/consent/exam8_offsite_consent.pdf). The third generation cohort's second examination consent form (in use since 2008) similarly includes a check box regarding the conduct of studies of potentially sensitive areas of research, as described above (http://www.framinghamheartstudy.org/research/pdfs/consent/gen3_exam2_consent.pdf). In both cohorts, permission was also explicitly obtained to notify participants (and with their permission, a designated personal physician) about the results of genetic tests that have important health and treatment implications. The notification

procedures are under development. Participant notification of genetic results will occur only when prespecified criteria are met: a genetic result has established analytic validity, the genetic variant poses significant and replicable risk for an important health condition, and proven therapeutic or preventive interventions exist for that condition [Bookman et al., 2006]. After initial consent was obtained to collect a cell line, the question was not repeated on subsequent consent forms. Similarly, when consent has been previously provided, questions are often removed from subsequent forms, in order to avoid unnecessary length and complexity.

For both cohorts, the right to withdraw from the study at any time is stated explicitly. It is important to note, however, that data sets have been created and distributed for public use (www.nhlbi.nih.gov/resources/deca/datasets_obv.htm). After they have been distributed we cannot go back and destroy data on participants who have withdrawn consent. We can only do so prospectively, by deleting their data from subsequent data sets. In addition, there has been continuous tracking of the level of permission for use of DNA samples and genetic research, especially protecting participants who have not been able to return for a recent examination. An annually updated database has been developed to track the most recent consent document provisions given by each participant as well as withdrawals of consent. The informed consent documents were reviewed and approved by the Institutional Review Board of Boston University Medical Campus. Based on our most recently updated consent information, we have recorded the consent preferences for each of the consent provisions at each examination and calculated the percentage of participants who consented to each provision.

RESULTS

Preferences About Participation in Genetic Research

Tables I–III summarize the number (and percent) of offspring and third generation cohort participants who granted or refused permission for each of multiple informed consent preference fields. This analysis is based on 2,980 offspring cohort participants, who attended their eighth clinic examination from 2005 to 2008, 4,095

TABLE I. Consent for Various Uses of DNA and Data in the Offspring Cohort (2005–2008)

Check box	Answer	Participants consented (%)
I agree to participate in the Framingham Heart Study examinations described above to study the frequency of and factors contributing to heart and blood vessel diseases, lung and blood diseases, stroke, memory loss, and other diseases and health conditions	Yes	2,980 (100)
	No	0 (0)
I agree to provide a blood sample from which DNA and other components can be extracted. The DNA will be made available to researchers studying the diseases listed above	Yes	2,891 (99.9)
	No	3 (0.1)
If a cell line has not already been collected, I agree to allow a cell line to be made from a sample of my blood to provide a renewable supply of DNA. (A cell line is a frozen sample of specially processed white cells from your blood that allows us to grow more white cells and get more DNA from them in the future as needed for research projects.)	Yes	2,969 (99.7)
	No	10 (0.3)
I agree to participate in the genetic studies of factors contributing to heart and blood vessel diseases, lung and blood diseases, stroke, and memory loss	Yes	2,978 (99.9)
	No	2 (0.1)
I agree to participate in genetic studies of other diseases and health conditions including but not limited to joint disease, bone loss, and cancer	Yes	2,974 (99.8)
	No	5 (0.2)
I agree to participate in genetic studies of reproductive conditions and mental health conditions such as alcohol use and depressive symptoms	Yes	2,970 (99.7)
	No	10 (0.3)
I agree to allow researchers from private companies to have access to my DNA and genetic data which may be used to develop diagnostic lab tests or pharmaceutical therapies that could benefit many people. (Note: You or your heirs will not benefit financially from this, nor will your DNA be sold to anyone.)	Yes	2,739 (91.9)
	No	240 (8.1)
If a genetic condition is identified that may have potentially important health and treatment implications for me, I agree to allow the Framingham Heart Study to notify me and with my permission to notify my physician	Yes	2,964 (99.5)
	No	16 (0.5)

Differences between the 2980 eligible individuals and the sum of responses for any check box reflect missing values.

TABLE II. Differences between the 4095 eligible individuals and the sum of responses for any check box reflect missing values.

Check box	Answer	Participants consented (%)
I agree to participate in the physical examination and genetic studies of factors contributing to heart and blood vessel diseases, lung and blood diseases, stroke, memory loss, joint disease, bone loss, deafness, cancer, and other major diseases and health conditions	Yes	4,095 (100)
	No	0 (0)
I agree to provide a blood sample from which DNA and other components can be extracted. The DNA will be made available to researchers studying the diseases listed above	Yes	4,092 (99.9)
	No	3 (0.1)
I agree to allow the creation of a cell line from my blood sample to provide a renewable supply of DNA. (A cell line is a frozen sample of specially processed white cells from your blood that allows us to grow more white cells and get more DNA from them in the future as needed for research projects.)	Yes	4,082 (99.7)
	No	12 (0.3)
I agree to allow researchers from private companies to have access to my DNA and genetic data which may be used to develop diagnostic lab tests or pharmaceutical therapies that could benefit many people. (Note: You or your heirs will not benefit financially from this, nor will your DNA be sold to anyone.)	Yes	4,000 (98.0)
	No	95 (2.0)

Differences between the 4095 eligible individuals and the sum of responses for any check box reflect missing values.

third generation cohort participants who attended their baseline clinic visit in 2002–2005, and 1,141 third generation cohort participants who attended their second clinic examination, which began in 2008 and is ongoing. Data from the two third generation cohort examination cycles were analyzed separately due to slightly different consent forms. More than 99% of participants attending the examination affirmatively selected check boxes for participation in the clinical examination and genetic studies, extraction of DNA and sharing of DNA with researchers, creation of a cell line for generating renewable DNA resource, use of genetic information for other purposes, including research that might be regarded as sensitive, and notification of genetic findings with health implications that might be discovered as a result of research. A total of 240 offspring participants and 17 third generation participants (8.1% and 1.5% respectively) did not permit sharing their DNA or genetic data with private companies. Data from the first generation

TABLE III. Consent for Various Uses of DNA and Data in the Third Generation Cohort Exam 2 (2008–2010)*

Check box	Answer	Participants consented (%)
I agree to participate in the FHS clinic examination and studies of the factors contributing to heart and blood vessel diseases, lung and blood diseases, stroke, memory loss, cancer, and other major diseases and health conditions	Yes	1,141 (100)
	No	0 (0)
I agree to provide a blood sample from which genetic material (DNA and other components) can be obtained. I agree to allow my data and blood samples to be used in the genetic studies of factors contributing to heart and blood vessel diseases, lung and blood diseases, stroke, memory loss, cancer, and other diseases and health conditions	Yes	1,140 (99.9)
	No	1 (0.1)
I agree to allow my data and blood samples to be used in genetic studies of reproductive conditions, and mental health conditions such as alcohol use and depressive symptoms	Yes	1,141 (100)
	No	0 (0)
I agree to allow researchers from commercial companies to have access to my DNA and genetic data which may be used to develop new lab tests or treatments that could benefit many people. (You or your heirs will not benefit financially from this, nor will your DNA be sold to anyone.)	Yes	1,123 (98.5)
	No	17 (1.5)
If a genetic condition is identified that may have important health and treatment implications for me, I agree to allow the FHS to notify me, and then with my permission to notify my physician	Yes	1,134 (100)
	No	0 (0)

Differences between the 1141 eligible individuals and the sum of responses for any check box reflect missing values.

[a]Exam cycle is still underway.

cohort was not obtained contemporaneously, so it was not analyzed for this study. However, they provided nearly universal approval at the last examination at which consent for DNA and genetic research were sought.

As of March 31, 2009 two individuals in the third generation cohort have withdrawn consent to participate in future clinic visits but maintained permission to use their previously collected data and DNA samples. Nine offspring cohort participants withdrew participation in further clinic examinations after examination cycle 7, which took place between 1998 and 2000. Two offspring participants withdrew consent to use their DNA. No offspring cohort participants have withdrawn after attending their eighth examination cycle (2005–2008).

DISCUSSION

This report found that more than 99% of offspring cohort participants at their eighth clinic examination and third generation cohort participants attending their first and second examination granted permission for DNA extraction and the creation of cell lines for genetic research. This is considerably higher than the 85% of participants in the National Health and Nutrition Examination Surveys who consented to genetic research in 2000 [McQuillan et al., 2003]. In telephone interviews of 489 randomly selected people from Pennsylvania, 25% said they would not be willing to participate in medical research and 29% indicated uncertainty about participation [Trauth et al., 2000]. The Multiethnic Study of Atherosclerosis recently reported its rates of consent for genetic research and, in that study, full consent was granted by 79% of participants [Green et al., 2006]. The higher rates of consent for genetic research in Framingham Heart Study participants may be due in part to the nearly 60 years legacy of the program and the family-based design of the offspring and third generation cohorts. Before they arrived in clinic for their baseline examinations, eligible participants were aware of the history of the Framingham Heart Study from local media coverage and from their family members. The study's focus on familial patterns of disease and the genetic aims of the study were described in recruitment materials. Thus, it is possible that eligible participants who strongly objected to genetic research declined study participation and their objections to consent for genetic research are not reflected in our data.

It is our belief, however, that our participants' high consent rates are also due in large part to our ongoing efforts to maintain communications with participants and to keep them informed about research activities and procedures including ethical oversight. We assert that the steps we have taken are vital to fostering the trust that is essential to maintain high rates of participation and retention in a prospective study. Beskow and Dean [2008] conducted a survey that confirmed our proposed explanation for the Framingham Heart Study's high rates of consent and retention. It was determined through communication with potential research subjects that when investigators take steps to protect participants' privacy and confidentiality and keep them updated and informed, participants develop increasing trust for the research institution; these steps in turn favorably affect rates of consent.

The sole area with more than nominal unwillingness of Framingham participants to grant consent was for sharing of DNA and genetic data with private companies. Active restrictions to private sector access to data or DNA by Framingham Heart Study offspring cohort participants occurred in 2000–2001 when considerable publicity about a for-profit company's attempt to sell Framingham Heart Study data resulted in participant concerns about such efforts [Ready, 2001]. That private venture did not move forward, in large part because of inconsistency with informed consent provisions.

It is clear from our close interactions with participants that they enrolled in the Framingham Heart Study and continue to attend periodic clinic visits out of a strong desire to contribute to a scientific effort to improve public health. Sharing data and DNA with the outside research community is critical to maximizing the scientific knowledge gained from participation in the study. There remains inherent tension, however, between measures to maximize sharing of data and DNA with the outside research community to promote scientific discovery and restrictive measures to protect participants' privacy and confidentiality. Acknowledging this balance, we have developed procedures to achieve both aims, but recognize that they will evolve over time. Several of these procedures are described below. For example, we distribute datasets free of charge via the National Heart, Lung, and Blood Institute (http://www.nhlbi.nih.gov/resources/deca/directry.htm), and distribute genetic and phenotypic data at no charge via dbGAP (http://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/study.cgi?study_id=phs000007.v6.p3). Simultaneously, we protect privacy by removing identifiers, requiring IRB approval, and executed data distribution agreements for investigators requesting DNA and databases.

Despite the belief of some scientists and ethicists that identifiable DNA should not be used for any research purpose other than that specifically stated in the consent document [McGuire and Gibbs, 2006], such restrictions of scientific use would have a chilling effect on discovery, because many questions that can be addressed in the long term using banked specimens are not apparent at the time of study inception. Recently, Kaye et al. [2009] described the importance of data sharing in genomics and the challenges that researchers face in maintaining the highest ethical standards and participant/donor privacy when they share their data with other investigators. They provided several recommendations including specific oversight of data sharing by a committee *other than* an Institutional Review Board and accurate and complete consent forms that cover all possible uses of DNA at recipient institutions without overwhelming participants. Framingham has been taking steps towards these ends for several years.

In 2003 a panel of medical ethicists convened by the Framingham Heart Study recommended that the study establish an ethics advisory board to make recommendations on ethics issues as they arise, and that, "the board include study participants as well as local clergy, physicians, genetic counselors and an ethicist." In response, we sent a newsletter to all study participants summarizing the panel recommendations and announcing plans to form an ethics advisory board with participant membership (http://www.framinghamheartstudy.org/participants/newsletters/spring2004.pdf). In early 2004 the Framingham Heart Study Executive Committee established the Framingham Ethics Advisory Board, chaired by a medical ethicist (GK), and comprised of a genetic counselor, two attorneys, two physicians and a clergyman from the community, as well as several Framingham Heart Study participants

representing each of the study cohorts. The Board has met approximately four times per year and the Framingham Heart Study has published its recommendations in newsletters sent to participants. Our approach is consistent with that of the Marshfield Clinic Personalized Medicine Research Project, which initiated conversations with participant focus groups, and formed an advisory board to improve communication and dialogue with study participants [McCarty et al., 2008].

The topic of large-scale genetics research studies, including a genome-wide association study, was discussed at several Ethics Advisory Board meetings. Participants have been regularly informed via newsletters about the rationale for and conduct of a number of genetic research projects. In November 2005, as more details about a potential genome-wide association study became known, the Ethics Advisory Board expressed its approval in concept for such a project and recommended convening a focus group of study participants to review the study aims and obtain feedback. Such a meeting was held in December 2005 and a list of general questions was generated by the study participants (see supporting information which may be found in the online version of this article). These were assembled with answers and included in the February 2006 newsletter to all study participants along with a general article about genome-wide association studies (http://www.framinghamheartstudy.org/participants/newsletters/winter2006.pdf). The questions raised by participants related to communicating study plans, protections of privacy and confidentiality, informing participants about genetic results, withdrawal of consent, sharing data with the scientific community, and commercial access to data and DNA. Timed to coincide with a national press release (http://www.nhlbi.nih.gov/new/press/06-02-06.htm), the February 2006 Framingham Heart Study newsletter also included a letter from the director of the National Heart, Lung, and Blood Institute describing plans to pursue a genome-wide association study in the three Framingham Heart Study cohorts in a manner consistent with participants' preferences. In addition, Framingham staff received educational session on the same topics.

Already in existence at this time was a system by which Framingham Heart Study participants' DNA and genetic or non-genetic data are distributed free of charge to outside investigators with several safeguards to protect privacy and confidentiality: (1) the investigator must submit and receive approval of a DNA application (http://www.framinghamheartstudy.org/univapp/index.php), which is reviewed by a DNA Committee composed of four members including a chairperson with no scientific relation to the Framingham Heart Study, (2) the investigator must obtain project approval from the applicant's Institutional Review Board and, (3) the investigator and host institution must execute a Data and Materials Distribution Agreement (http://www.framinghamheartstudy.org/research/proposal.html) with the National Heart, Lung, and Blood Institute and Boston University. The distribution agreement prohibits investigators from redistributing data or DNA to any third party and it prohibits any attempt to identify participants. After these three conditions are met, DNA and data are distributed to the investigator with a new and unique set of random identifiers. Although DNA for distribution is stripped of participants name and other identifying information (to prevent outright identification), it is not completely ''de-identified.'' In other words, it is theoretically possible for participants to be linked to their DNA, but attempting to do so violates the Distribution Agreement.

Similarly, once genome-wide association study planning was underway, we began to develop a set of procedures to provide broad data sharing while maintaining the security of participant data. To address these needs, we deposited our genotype and phenotype data in dbGaP, a secure online data-sharing repository that grants investigators access to genotype and phenotype data with various safeguards (http://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/study. cgi?study_id=phs000007.v1.p1). In order to protect the confidentiality and privacy of participant data that are stored in dbGaP a Data Access Committee (DAC) was formed. In order to access genetic and phenotypic data, investigators must submit a Data Use Certification (DUC) application, in which they agree to abide by dbGaP rules not to share participants' information with third parties or make any attempt to identify participants. This application is then reviewed by the DAC, which reserves the right to terminate access upon breach of dbGaP policy. Institutional Review Board approval from the investigators' institution is also required for access to Framingham dbGaP data.

From our discussions with Framingham Heart Study participants about genetic research, we have learned that key among their concerns are (a) the need for protections of privacy and confidentiality, (b) a desire that data and biological specimens be shared at no cost with the scientific community to maximize discoveries and improve public health, and (c) a need to honor restrictions of access to DNA and data by for-profit companies. These concerns, however, are likely to be universal and not exclusive to the Framingham Heart Study. Similar concerns about genetic research emerged in the deCODE genetics study in Iceland, including opposition by the Icelandic Medical Association [Annas, 2000]. Icelandic dissent centered on protections of privacy, for-profit use of DNA and data, lack of voluntary participation, restricted access to the data by the scientific community and inclusion of medical records in a for-profit database without specific individual consent. In addition, similar concerns were expressed by residents of British Columbia participating in a study of the public's attitudes towards informed consent in genetic research. Participants were most concerned with balancing their own confidentiality and privacy with ensuring that their DNA and data be available for useful research to promote the public good [Secko et al., 2009].

Whereas characterization of genetic variation across the human genome is now technically feasible and in widespread use, large-scale genetic studies must be carried out in a manner consistent with the preferences expressed by study participants in the informed consent process. This report describes the procedures implemented for ethical oversight of genetic research in the Framingham Heart Study, including the informed consent process, access to data by outside investigators and for-profit companies, and protections of privacy and confidentiality. We are engaged in ongoing communications with study participants to inform them about the goals of our genetic research program and seek their comments and concerns. Importantly, we established an Ethics Advisory Board that includes Framingham Heart Study participants to review genetic research and ensure its consistency with their consent and their wishes.

Moreover, given the myriad of questions that can be addressed via genetic studies, the Framingham Heart Study specifies multiple general areas of use in our current informed consent document (Tables I–III), while not specifying hundreds of potential areas of scientific inquiry. This practice educates our participants about the potential areas of research without overwhelming them with each and every conceivable possibility. Caulfield et al. [2008] recommended that whenever genome-wide association studies are conducted, participants should have the ability to withdraw consent at any time should they change their mind. The Framingham Heart Study has consistently notified participants of their right to withdraw consent for future distribution of any sample they have donated and has made a concerted effort to keep each participant's consent information up to date. The number of withdrawals of consent among Framingham Heart Study participants has been very low.

The Framingham Heart Study has succeeded in obtaining high rates of consent for genetic research and has taken multiple steps outlined above to implement ethical oversight of the large-scale genetic research that it is currently conducting. Lessons from the Framingham experience described in this report should be considered by other studies engaged in human subjects' research to assist in the development of procedures to ensure ethical oversight of genetic research in a manner consistent with participants' preferences. By developing detailed consent procedures and the ability to track decisions, means for communicating study plans with participants, and participant involvement in ethical oversight of genetic research, we have been able to maximize rates of participation in and consent for research, and we are hopeful that this pattern will be continued in the future.

ACKNOWLEDGMENTS

We would like to acknowledge the members of the Framingham Heart Study Ethics Advisory Board who volunteer their free time to make ours a better and more responsive study; the Framingham Heart Study participants who are the key to our past success and our future aspirations; and the Framingham Heart Study participant coordinators who administer our informed consent process. Abstract: This study examined characteristics associated with prescription drug use disorder (PDUD) in primary-care patients with chronic pain from a cross-sectional survey conducted at an urban academically affiliated safety-net hospital. Participants were 18 to 60 years old, had pain for ≥3 months, took prescription or nonprescription analgesics, and spoke English. Measurements included the Composite International Diagnostic Interview (PDUD, other substance use disorders (SUD), Posttraumatic Stress Disorder [PTSD]); Graded Chronic Pain Scale, smoking status; family history of SUD; and time spent in jail. Of 597 patients (41% male, 61% black, mean age 46 years), 110 (18.4%) had PDUD of whom 99 (90%) had another SUD. In adjusted analyses, those with PDUD were more likely than those without any current or past SUD to report jail time (OR 5.1, 95% CI 2.8–9.3), family history of SUD (OR 3.4, 1.9-6), greater pain-related limitations (OR 3.8, 1.2-11.7), cigarette smoking (OR 3.6, 2–6.2), or to be white (OR 3.2, 1.7–6), male (OR 1.9, 1.1–3.5) or have PTSD (OR 1.9, 1.1–3.4). PDUD appears increased among those with easily identifiable characteristics. The challenge is to determine who, among those with risk factors, can avoid, with proper management, developing the increasingly common diagnosis of PDUD.

***Perspective:** This article examines risk factors for prescription drug use disorder (PDUD) among a sample of primary-care patients with chronic pain at an urban, academic, safety-net hospital. The findings may help clinicians identify those most at risk for developing PDUD when developing appropriate treatment plans.*

***Key words:** Primary care, substance abuse, pain.*

Chronic noncancer pain affects one-fifth of primary-care patients.[23] One pain treatment is opioid analgesic medication, which has been increasingly prescribed over the last decade[28,39,59] despite controversy about effectiveness.[20,36] Notwithstanding questions of efficacy, one risk to prescribing these medications is the potential of opioid addiction.[26,36,57]

The increase in prescribing has co-occurred with increasing misuse and abuse. This phenomenon ranges from misuse (nonmedical use, or for reasons other than prescribed) to the prescription drug use disorders (PDUDs) defined as abuse (misuse with consequences) or dependence (abuse with withdrawal or tolerance and/or uncontrolled use).[4] Rates of opioid misuse have increased since the 1990s, when lifetime misuse of pain relievers was less than 10%.[53] The 2007 National Survey

doi:10.1016/j.jpain.2009.10.012

on Drug Use and Health (NSDUH) found that, among people over the age of 12, lifetime misuse of pain relievers increased to 13.3%. While 18.1% of the misused opioid analgesic medication came from legitimate physician prescriptions, 81% came from a friend or relative who was originally prescribed the medication by a physician.[16] Consequently, law enforcement efforts to stop opioid diversion have extended to physicians prescribing opioids for pain, adding fear of legal prosecution to provider concerns.[47] A further correlate of an increase in prescribing of opioids has been an increase in overdose, both intentional and unintentional.[21,40]

In this atmosphere, physicians report discomfort when prescribing opioid analgesics,[2,42,52] with particular concerns over the potential addiction risks and legal implications.[6,44,45,52] When patients have a known substance use disorder (SUD), physician discomfort about prescribing opioid analgesics increases, primarily due to suspicions that patient medication requests are motivated by addiction rather than pain.[37] Given these concerns about prescribing opioids, it would be useful to identify patient characteristics that are associated with prescription drug use disorder (PDUD).

Past research on the prevalence of and risk factors for PDUD among primary-care patients with chronic pain is limited by a number of factors: focus on a population referred for specialized pain treatment or who had been successfully maintained on more than 6 months of opioid therapy; diagnostic measures that have not been validated; or administrative databases. Ives et al[26] reported that 32% of patients referred to a primary-care-based chronic-pain disease management program were misusing opioids, similar to other studies.[10,43] Racial and ethnic minorities were a small fraction of patients studied.

Among patients treated with opioid analgesics risk factors for opioid misuse include SUDs,[26,34,38,43,56] family history of SUDs,[34,38] cigarette smoking,[10,38] legal problems,[26,38] younger age,[19,34,36,43] and higher doses of opioid medication.[38] Evidence of psychiatric comorbidity and higher pain severity were associated with opioid misuse in some studies,[19,34-36,38,56] but not others.[26]

Other studies have examined the risks for all substance use disorders for patients on opioids.[19] While national surveys have found that persons with PDUD often have overlapping polysubstance use disorders,[11,13,49,50] clinical samples have not examined how patients with PDUD may be similar or different from those with SUDs other than PDUD.

We therefore conducted a study to examine the clinical characteristics of individuals with lifetime PDUD, using validated measures among a population of primary-care patients with chronic pain drawn from an urban safety-net hospital setting. We also explored whether those with PDUD differ from those with SUDs other than PDUD. We hypothesized that factors similar to those identified in prior clinical studies of referral pain patients as well as epidemiological surveys would be present in an urban, minority sample. If clinicians are aware of relevant risk factors for PDUD in this population, they may be able to provide more informed clinical care.

Methods

Study Design

This was a cross-sectional study of primary-care patients with chronic pain, designed to examine characteristics of those with PDUD. Participants were recruited from waiting rooms of an academic, urban, safety-net[7] hospital primary-care practice that has 80,000 visits and 32,000 unique patients annually. Eligible patients were 18 to 60 years of age, spoke English, reported pain of 3 months or more, reported use of any analgesic medication (over-the-counter or prescription in the prior month), and had a scheduled primary-care appointment. Interviewers included both bachelor- and master-level research assistants, each trained for 2 weeks with ongoing quality control and principal-investigator supervision. Interviewers approached patients in primary-care waiting rooms per a predetermined pattern based on location in the waiting rooms and asked potential participants if they were interested in participating in a study on pain and health and to complete written screening questions. Eligible patients were told that the study interview would include questions about pain history, feeling sad or nervous, being hurt by someone, and using health care services. Informed consent was administered to eligible patients. Interviews lasted 45 to 90 minutes and participants were compensated $10. Recruitment occurred between February 2005 and August 2006. The Boston University Medical Center Institutional Review Board approved the study and Certificate of Confidentiality was obtained from the National Institutes of Health.

Participants

Of the 2,194 patients who answered the screening questions, 822 (37.4%) were eligible for the study, of whom 620 (75.4%) agreed to participate. Twenty-three participants did not complete enough of the interview due to time constraints including the SUD and PDUD assessment, and were excluded, leaving a sample of 597. When comparing those who enrolled with those who declined, enrollees were more likely to be black (61% vs 54.9%, $P = .04$), less likely to take over-the-counter pain medication (66.4% vs 78.5%, $P < .001$), and more likely to take opioid pain medication (41% vs 29.7%, $P = .002$).

Key Variables

Unless otherwise noted, all variables were obtained from subject interview.

Dependent Variables

Prescription Drug Use Disorder (PDUD) was defined as meeting DSM-IV criteria for lifetime sedative and/or opioid analgesic prescription drug abuse or dependence as measured by the Composite International Diagnostic Interview (CIDI) v.2.1 module on Drug Disorders.[4,58] Sedative was explicitly described, and included benzodiazepines and barbituates. Criteria for abuse included social, physical or legal consequences from use. The criteria for dependence additionally included compulsive use, health consequences, and physical dependence

(ie, tolerance or withdrawal). Physical dependence alone would not suffice to meet the diagnosis. Participants with PDUD could also have another SUD.

Other Substance Use Disorder (Other SUD) was defined as meeting DSM-IV criteria for any lifetime drug (excluding prescription) abuse or dependence measured using CIDI v 2.1 module on Drug Disorders, and/or past year alcohol dependence measured with the CIDI-short form (CIDI-SF) for alcohol dependence.[58] Current alcohol abuse and past alcohol use disorders were not measured as the CIDI-SF was used to reduce respondent time burden. Nicotine dependence was not included among other SUDs. We coded the mutually exclusive 3-level outcome variable as PDUD ± SUD, Other SUD (SUD alone), or no PDUD or SUD.

Independent Variables

We examined factors that we anticipated would be associated with PDUD or SUD, based on review of literature from clinical and epidemiological studies. We prioritized assessment of variables from a range of potential options based on strength of association with PDUD and SUD. For example, we chose to measure 2 major mental health disorders: depression and PTSD. Both are associated with pain, and PTSD is strongly associated with SUD. Other anxiety disorders were not measured because of the overlap with PTSD in a prior study in the same population.[33]A variety of specific violence measures were included to examine whether the independent associations with PDUD or SUD would be eliminated when PTSD or depression were considered. High pain severity and physical health-related quality of life have been suggested as predictors of PDUD,[34] as have prior incarceration,[26,38] cigarette smoking,[10,38] and family history of SUD.[38] The following independent variables were defined as: 1) sociodemographics including age (in years), gender, race/ethnicity (black, Hispanic, white, other), income (≥ or <$20,000), employment (unemployed or receiving disability payments vs other), education (< high school, high school+), marital status (partnered, divorced, single), health insurance (Medicaid/Medicare vs others, including private and uninsured); 2) pain-related limitations (high vs others) from the Graded Chronic Pain Scale, a 10-item validated measure of pain and disability;[54] 3) posttraumatic stress disorder (PTSD) diagnosis from the CIDI v. 2.1 PTSD module;[58] 4) major depression from the Patient Health Questionnaire (PHQ) for Depression, a 9-item validated measure correlated with past 2-week major depression;[30] 5) high adverse childhood experiences (ACE) (≥3 vs <3 experiences) as adapted from Felitti;[18] (Examples of ACE are physical abuse, neglect, sexual abuse, parental mental illness, single-parent household, parental incarceration, witnessing domestic violence); 6) intimate partner violence (IPV) —1 or more affirmative responses to questions adapted from the AddHealth Home Questionnaire;[1] 7) family history of SUD (single question about first-degree relatives with alcohol or drug problems); 8) jail time (single question about having spent time in jail); 11) SF-12 health-related quality-of-life physical- and mental-health composite scores;[55] 10) current cigarette smoking (taken from the Electronic Medical Record (EMR) visit closest to the interview date); and 11) opioid, benzodiazepine or sedative prescription in the past year (from the EMR).

Analysis

Bivariate analyses examined associations between 3 mutually exclusive groups: 1) lifetime PDUD (with or without other SUD); 2) lifetime other SUD (not including PDUD); and 3) no lifetime SUD or PDUD. If significant associations were found, then pair-wise comparisons were conducted. A multinomial, multivariable logistic regression model was then constructed predicting PDUD, other SUD and no lifetime SUD or PDUD, entering all independent variables found to be significant at the $P < .05$ level in the bivariate analyses. The results of this model are not shown here. We also included interaction terms which we suspected based on independent correlations and clinical intuition. We tested interactions between every possible pairing of variables within the 2 groupings: 1) Disability-related (3 pairs tested—insurance status, employment status, pain limitation); 2) Mental health/violence exposure (10 pairs tested—depression, SF-12 mental component summary score, PTSD, high-ACE, IPV-victimization. We then fit a subsequent parsimonious model which included all the independent predictors and the single significant interaction (IPV and depression). We also fit a separate logistic regression model with the same independent variables comparing only PDUD to other SUD. We then calculated the number and percentage of participants with each number of the variables found significant in the multinomial regression analysis in 3 mutually exclusive groups; PDUD, other SUD (ie, without PDUD), and no SUD or PDUD. We also calculated the sensitivity and specificity of number of factors for PDUD.

Results

Participant characteristics are shown in Table 1. Overall, a majority of the study sample was unemployed or disabled, poor, nonwhite, and experienced high pain disability. Forty percent had received an opioid prescription in the prior year. One hundred and ten (18.4%) met criteria for lifetime PDUD, of whom 99 (90%) had another SUD, and 61 (55.5%) met the PDUD diagnostic criteria in the past year. Fifty-five had both lifetime sedative- and opioid analgesic-use disorders, 44 had opioid analgesic-use disorder only, and 11 had sedative-use disorder only. Seventy-one percent of those with PDUD reported addiction to medications not prescribed for them. One hundred and forty-six (24.5%) had lifetime SUDs other than PDUD.

Bivariate Comparisons Between PDUD, Other SUDs and No History of SUDs

Participants with PDUD and other SUDs both had higher percentages of participants with the following characteristics compared to participants without SUD: male gender, Medicaid/Medicare, unemployment/

*Other Substance Use Disorder includes participants with any substance use disorder, excluding prescription drug use disorder.

disability, severely limiting pain, PTSD, depression, intimate-partner victimization, family history of SUD, time spent in jail, and current smoking. Two measures showed differences between all 3 groups: mean SF-12 mental health component scores, and ≥3 ACEs. In both cases, the PDUD group had worse scores or greater exposures, respectively, compared to the other SUD group which in turn was worse than the no-SUD group. The PDUD group had a higher percent of whites compared to both other SUD and no SUD. The PDUD group had a higher percentage with current PTSD compared to those with no SUD but was not different compared to those with other SUD. No other factors differed significantly between the 3 groups (Table 1).

Independent Associations with PDUD and Other SUDs

In the first multinomial analysis, the following factors were found to be significantly associated with PDUD and/or other SUDs: time spent in jail, current smoking, family history of SUD, male gender, white race, higher limiting pain, PTSD, IPV, and depression. The interaction term between IPV and Depression was also statistically significant. In the final parsimonious model (which included only those 9 factors), time spent in jail, limiting pain, current smoking, family history of SUD, male gender, and PTSD were associated with a greater odds of both PDUD and SUD. White race was associated with PDUD. IPV and no depression, and No IPV with depression were associated with other SUDs (Table 2). In a logistic regression analysis comparing PDUD with other SUDs, the only significant association was white race (odds ratio 2.1, 95% CI 1.8–3.9) (other results not shown).

Table 3 shows the prevalence of PDUD and other SUD for each number of factors (0 through all 9). All patients with PDUD had 2 or more risk factors, and no person without SUD had more than 7 risk factors. The sensitivity and specificity of these combinations for PDUD are presented in Table 4.

Discussion

In the primary-care practice of an urban safety-net hospital, 18.4% of patients with chronic pain met criteria for a PDUD and an additional 24.5% had other SUDs. The vast majority of participants with PDUD had at least one co-occurring other SUD, and those with PDUD were virtually indistinguishable from those with other SUDs. Seven patient characteristics were independently associated with PDUD compared to those without any lifetime SUD: time spent in jail, high degree of

Table 2. Independent Associations With Prescription Drug Use Disorder and Other Substance Use Disorder Compared to Participants With no History of Substance Use Disorder* (n = 597)

Effect	PDUD Odds Ratio	95% CI	Other SUD Odds Ratio	95% CI
Time in Jail	5.11	2.8–9.34	3.82	2.22–6.57

pain-related limitations, current smoking, family history of SUD, white race, male gender, and PTSD. The only difference between SUD and PDUD was the higher prevalence of white race in PDUD.

The finding that PDUD is highly associated with other SUDs corroborates prior clinical studies which relied on proxy measures for the determination of PDUD.[15,17,26,38,43,51] Ives et al[26] found that prior cocaine or alcohol abuse predicted prescription opioid misuse among patients at a pain management clinic. Studies which included smoking status as a correlate for PDUD found a striking association, as did our study. This reflects the exceptionally high comorbidity of smoking with alcohol and illicit-drug dependence found in other studies.[38,46]

Table 3. Prevalence of Prescription Drug Use Disorder (PDUD) and Other Substance Use Disorder Among Primary Care Patients by Number of Risk Factors* for PDUD and Other SUD (n = 597)

*Risk Factors include: time spent in jail, family history of substance use disorder, smoking, white race, male gender, lifetime posttraumatic stress disorder, limiting pain, depression, intimate partner violence.

For physicians who prescribe opioid and sedative medications, a critical concern is differentiating individuals who take medications for the intended therapeutic purposes from those with current, or potentially future, misuse and addiction. This cross-sectional study does not permit a longitudinal analysis of persons prescribed opioid analgesics. However, it does suggest that a propensity toward addiction (other SUD, family history of SUD, cigarette smoking) is a strong correlate of PDUD. Fleming et al[19] found that positive urine-toxicology screening for cocaine or marijuana and aberrant drug behaviors were among the significant predictors of SUD in primary-care patients receiving opioids. Data in our study suggest that those with PDUD have similar characteristics to those addicted to illicit drugs and alcohol. The 2005 report from the Center on Addiction and Substance Abuse at Columbia University corroborates this association in a community sample: 75% of persons who misuse prescription drugs have at least one co-occurring other SUD.[11] Of note, a physician may consider screening patients with pain and other risk factors for PDUD even in the absence of prescribing controlled substances, as most participants with PDUD in this study obtained the medication from sources other than a treating clinician.

A strong association of both PDUD and other SUDs was having spent time in jail. Almost two-thirds of those with PDUD reported having spent time in jail, compared to 15.3% of those with no SUD. The relationship between criminal activity and prescription drug abuse has been suggested in prior studies.[11,26] Akbik et al[3] reported prior legal problems predict subsequent opioid misuse among patients starting opioids for chronic pain. It is not known whether the jail history was due to crimes related to drug use, possession, manufacture or sale, which would suggest a history of SUD. It also may be a proxy for antisocial behavior, which is associated with PDUD.[24]

The associations of white race and male gender with PDUD in this sample reflect findings in other clinical and population samples.[8,13,24] Whites are prescribed more opioid medications in Emergency Departments and primary-care practices, perhaps reflecting a cultural bias by patients and physicians toward use of prescription opioids.[12,41] Male gender predominance reflects epidemiology of SUDs in general, although some data suggest more gender balance in PDUD. These trends suggest that future research should explore the social context, including gender and racial differences, of these associations.

Patients with PDUD reported a greater degree of pain-related limitation. Others have found low pain intolerance among those with active[14] and past addictions[32] compared to nonaddicted controls. It may be that lower pain threshold is an increased risk for developing addiction, or that addiction itself lowers the pain tolerance. This may complicate pain management among those with PDUD.

Among this sample of urban primary-care patients with chronic pain, PTSD was associated with PDUD. PTSD is known to be associated with SUD in clinical and community samples,[9,27,29,33] but the relationship with PDUD has not been described. The scientific evidence for neurological and physiological changes in PTSD,[25,48] pain,[5,6,31] and substance use disorders[22] is growing. Exploring these overlapping phenomena may allow development of tailored interventions.

Intimate partner violence and depression appeared to be individually associated with SUD but not PDUD, when accounting for the interaction between these phenomena. These associations may function differently in gender-specific analyses, which should be explored in future studies. The fact that Adverse Childhood Experiences were not independently associated with either PDUD or SUD after controlling for other variables suggests that its effect is mediated through other variables such as PTSD which remained significant in the final model.

These data strongly suggest that physicians treating patients with pain should assess for SUD. This can help direct care, including treatment for pain and substance-use disorders. Specialty pain practices who commonly prescribe opioid analgesics are likely to screen for this, but primary-care settings may not be as aware of the overlap between pain and addictions. Furthermore, patients do not always admit to SUD, particularly if they are intent on deceiving the treating physician to obtain prescription medication. Potential screening questions for patients with chronic pain could include assessment of smoking,and specific questions used in this study: "Do you have a family history of alcohol or drug problems?" and "Have you ever spent time in jail?" Evaluations for pain disability and PTSD may be additional clinical tools to help identify those at highest risk for PDUD.

After identifying a patient with risk factors, should clinicians prescribe opioid medications? In an observational study, Wiedemer et al[57] examined the impact of a structured opioid clinic for patients with risk factors, including psychiatric and substance use problems. All patients with SUD but no aberrant behaviors were safely maintained on opioids.[57] Clinical trials testing methods of opioid medication monitoring could inform clinicians about how to safely prescribe them to high-risk patients.

This study adds to the literature in 3 ways. First, it examines an urban, largely poor, and minority sample, which is underrepresented in the literature. Secondly, validated measures of PDUD used in this study improve upon the use of proxy measures that most other studies have employed. Finally, subjects were primary-care patients with chronic pain, not limited to those being prescribed chronic opioid medication. This can illuminate issues about patients who may require opioid analgesics in the future and common clinical concerns of urban primary-care pain patients.

The study limitations include possible misclassification of PDUD in individuals with pseudo addiction, ie, behaviors that resemble addiction but result from inadequate treatment of pain.[15] We believe that this is not a significant limitation, as the diagnostic criteria demand social or physical problems and compulsive use, which are not characteristic of pseudo addiction. Furthermore, 71% had addictions to medications that were not prescribed for them, which lowers the probability of misclassification. Another limitation was that lifetime alcohol-use disorders were not measured, which should attenuate any associations found because of misclassification bias. Since numerous independent predictors of PDUD and SUD were found, it is not clear how information on lifetime alcohol disorders would change the associations. The cross-sectional design limits conclusions regarding cause and effect; the findings would be strengthened by studying a longitudinal cohort. The recruitment strategy may limit the generalizability of the findings. However, as this was a study of PDUD risk factors and not prevalence, the associations should remain stable in a similar sample. Another limitation is that no corroborating evidence of prescription drug misuse was obtained, such as urine toxicology screening. Such testing can be helpful as a supplement to self-report.

In an urban cohort of primary-care patients with high levels of pain disability, unemployment and psychosocial stressors, PDUD was concentrated among those with: a family history of SUDs, having spent time in jail, current cigarette smoking, male gender, white race, pain-related functional limitations, and PTSD. The vast majority had co-occurring other SUDs. This suggests that clinicians could gain clinical insight by carefully evaluating such patients for these risk factors when developing a comprehensive pain-management strategy. It may also suggest which patients would benefit from a structured program for use of opioid medications. Refining the knowledge base on co-occurrence of addiction and pain could maximize safe and effective pain relief strategies.

A Chasm Between Injury and Care: Experiences of Black Male Victims of Violence

Jane Liebschutz, MD, MPH, Sonia Schwartz, BA, Joel Hoyte, BA, Lauren Conoscenti, PhD, Anthony B. Christian, Sr., Leroy Muhammad, Derrick Harper, MSW, LCSW, and Thea James, MD, MPH

Background: Despite higher rates of stabbing and shooting violence among black men, healthcare systems have not demonstrated an efficacious response to these patients. This study describes challenges and promotive factors for engaging black male violence victims of violence with medical and mental healthcare.

Methods: Black male victims of stabbings and shootings were recruited through fliers and word of mouth, and were interviewed individually (n = 12) or in pairs (n = 4) using a semistructured guide. A racially diverse multidisciplinary team analyzed the data using Grounded Theory methods.

Results: Challenges to engagement with healthcare included the following: (1) Disconnect in the aftermath; e.g. participants reported not realizing they were seriously injured ("just a scratch" "poke"), were disoriented ("did not know where I was"), or were consumed with anger. (2) Institutional mistrust: blurred lines between healthcare and police, money-motivated care. (3) Foreshortened future: expectations they would die young. (4) Self-reliance: fix mental and substance abuse issues on their own. (5) Logistical issues: postinjury mental health symptoms, disability, and safety concerns created structural barriers to recovery and engagement with healthcare. Promotive factors included the following: (1) desire professionalism, open personality, and shared experience from clinicians; (2) turning points: injury or birth of a child serve as a "wake up call"; and (3) positive people, future-oriented friends and family.

Conclusions: For black male violence victims, medical treatment did not address circumstances of and reactions to injury. Policies delineating boundaries between medical care and law enforcement and addressing postinjury mental health symptoms, disability, and safety concerns may improve the recovery process.

Key Words: Black male, Community violence, Qualitative research.

(*J Trauma.* 2010;69: 1372–1378)

Hand gun and stabbing violence disproportionately affects young African American men in the United States.[1,2] Although homicides are the most extreme health effect of violence, injuries, with their attendant physical and psychologic morbidity, greatly impact survivors.[3,4]

Despite the burden of violence on young black males, limited literature describes effective healthcare responses to shooting and stabbing violence. An opportunity exists to engage those injured from violence while receiving care in acute hospital settings. Existing hospital-based programs focus on case management approaches when working with violence survivors, often referring them for community-based services,[5–8] such as education and vocational help.[9] These programs showed reduced criminal activity and re-injury compared with patients receiving care as usual.[6–8]

Although the literature specifically examining the effectiveness of healthcare response to black male victims of violence is limited, there is an extensive literature outlining disparities in healthcare treatment among different racial and ethnic groups. For instance, an Institute of Medicine 2002 report suggested that aspects of the clinical encounter, patient preferences, physician stereotyping, and system structure may contribute to these disparities.[10] Also, in a study to understand perceived barriers to and preferences for general healthcare among black men, Ravenell et al.[11] found that trauma survivors cited cultural differences, as well as a lack of awareness of medical concerns, as barriers to care. They also noted fear of serious conditions and fatalism ("I'm not going to make it anyway") as reasons to avoid medical care.

We performed a qualitative study using Grounded Theory methods to understand the experiences of survivors of gun shot and stab wounds, to gain insight for planning interventions in hospitals that treat victims of community violence. The data from the following study describes the potential challenges to and promotive factors for, engaging black male victims of gun shot and stabbing injuries with medical and mental healthcare.

MATERIALS AND METHODS

Study Design

This was a cross-sectional study of an urban, community-based sample of black male victims of gunshot or stabbing injuries. Qualitative data were collected through semistructured interviews and analyzed using a Grounded Theory approach.[12] This study obtained approval from the Institutional Review Board and a Certificate of Confidentiality from the National Institutes of Health.

Selection of Participants

Participants were recruited via fliers posted in the community and through word of mouth. Eligibility criteria included a history of emergency medical treatment for a stabbing or shooting injury, aged 18 years to 38 years, male gender, and self-identified black race. Eligible participants provided written informed consent before an interview and received $25 compensation following the interview.

Procedures

Trained interviewers conducted 14 semistructured interviews (12 individual interviews and 2 interviews with 2 participants each) from January 2008 to December 2008. The interviewers were two community-based, black, male, mental health professionals (seven interviews), a white female research assistant (three interviews), a black male research assistant (three interviews), and the principal investigator (one interview). The digitally recorded interviews lasted 45 minutes to 120 minutes. The interview guide was developed to include open-ended questions about the injury, experiences with healthcare after the injury, encounters with primary care, and views on mental health treatment, substance use, and research. Interviewers also inquired about experiences with race and gender if not spontaneously mentioned by participants. Audio-recordings were professionally transcribed and all identifying information was removed to protect the participants. The research team reviewed the interviews and then updated the interview guide so that future participants could clarify concepts found in earlier interviews. Participants also filled out a survey including demographics, posttraumatic stress symptoms (Posttraumatic Checklist-Civilian),[13–15] and alcohol use (AUDIT).[16]

Primary Data Analysis

The primary data analysis was conducted by an interdisciplinary and racially diverse research team consisting of two physicians (Emergency Medicine, Internal Medicine), two research assistants, a clinical psychologist, a mental health counselor, and two patient advocates working with victims of violence. Three members of the team were white and five were black. Additionally, one member of the team had a history of gun shot injury. The study used Grounded Theory[12] to analyze semi-structured interviews. Transcripts were read and audio-recordings listened to multiple times by the research team to identify common words and phrases of similar meaning to classify and create concepts. Researchers developed a coding scheme through discussion of each concept identified and placed excerpts from the transcripts into the codes with the aid of N-VIVO version 7 software.[17] At least two authors coded each transcript, and the research team discussion resolved coding discrepancies. The entire research team together grouped codes to create larger conceptual themes. For the final analysis, the research team generated theoretical constructs by examining these themes in the context of published literature from public health, medicine, social science, and psychology. The clinicians and advocates had extensive experience treating patients with stabbing and shooting injuries, which helped inform their interpretations of the themes. The findings were then placed into the context of published literature for the final analysis and presentation.

RESULTS

Characteristics of Study Subjects

Of the 16 participants enrolled in the study, the median age was 31 years (range, 25–38 years). Three were victims of gunshot, five of stab wounds, and eight of both injuries. The median length of time since the most recent injury was 5.5 years (range, 4 months–20.1 years). The median Posttraumatic Checklist-Civilian score was 43 (range, 22–69) and the median AUDIT score was 9 (range, 0–32).

Main Results

Researchers were struck by a lack of descriptions of interactions with healthcare clinicians, even when asked specifically about care after injury. For example, one participant described in exquisite detail all aspects of a stabbing assault. He summed up his medical treatment as, "let me see,… they took me to the emergency room. After that, for follow-up appointments…" This lack of detail in the narratives may indicate a sense of disconnection from the healthcare setting experienced by these men. Several themes, described in detail below, may elucidate the potential causes of this divide, and potential facilitators for future engagement with healthcare personnel. Table 1 provides illustrative quotations of the main themes.

Barriers to Care

Disconnect

Perceptions of the injury may be the source of a lack of participation and cooperation with clinicians. Eight participants reported not realizing they were injured in the moment of trauma or the extent of the injury. The language to describe the injury may also typify this disconnect: "scratch" (a liver laceration and a gunshot wound to the arm) and "poked" (multiple stabbings in abdomen).

Participants may not necessarily perceive the life-threatening aspect of injuries in the immediate aftermath. Their experience of the injury and the foreign environment of the hospital may lead to the development of a different injury awareness, which when considering the severity of the clinical observations, may cause both patients and clinicians to misinterpret each other. As described by one participant, "I know it's a real serious injury, but I saw I was alive, and ,. . . I didn't think it was a big deal at that time, 'cause I'm like, "I'm alive!"… And y'all over here, actin' like. . . it was real serious."

A range of emotions flooded participants once they realized what occurred. All participants described an overwhelming sense of anger in the immediate aftermath of the injury. For many, thoughts of anger, and possible retaliation, were all consuming, "But, when you first get stabbed, your mind goes blank. You don't think about anything but just revenge." One consequence of the anger was a desire to leave the hospital against medical advice to deal with their feelings. "[I was in the hospital] only three days, 'cause I was so mad that I wanted to leave." Furthermore, waking up from emergent surgery or lost consciousness, experienced by eight participants, contributed to the heightened emotional state by creating confusion and surprise.

TABLE 1. Barriers to and Promotive Factors for Engaging Black Male Community Violence Victims With Health Care

Theme	Subconcepts	Participant Quote
Physical and emotional disconnect	Not realizing that they had been injured	"I seen my cousin fall first, and I was askin' him, 'Are you a'right? And then I just noticed that he was bleedin, I was like, 'Yo, you know you're bleedin'?' He was like, 'No, I think that's you.' I checked myself, I didn't see nothin,' so I said, 'No, it must be you,' and it was . . . he got shot twice in his legs. I got up and I felt somethin' warm on my side, and he was like, 'Yo I think you (got) shot too,' and I looked and I was, I was hit in the side."
	Confusion after waking up	"When I first woke up out the coma, I didn't know what the f**k was goin' on, I didn't even know WHERE I was at. I woke up, like, 'Damn!' I'm lookin' around . . . can't even talk . . . and then I looked down at my stomach . . . 'Oh, what the f**k???' Now my heart's racin,' like, 'Damn!' I'm lookin' at my insides," and like, my f**kin' stomach's this wide . . . open!"
	Anger	"When I was in the hospital, there was nothin' nobody could tell me, like, "Naw, like f**k this. Like, I'm through with it. Like, I'm gonna kill everybody . . . like, anybody who have problems with me, I was gonna deal with, or if anybody looked at me wrong, I was gonna have . . . I was gonna do somethin' to."
Institutional mistrust	Police	"Well, the cops, as usual, were a**holes. Like it was our fault we got shot. First question they asked is, "Do you know who did it?" And then, "What did you do to the person that did it to you? Whose your enemies?" . . . they was actin' like you just don't get shot, it couldn't be an accident, that we was walkin' to the block and they got the wrong person; or they were lookin' for somebody else. And that was the case! The dude who shot us, it had nuttin' to do with us."
	Suspicion of clinician motives	"But they were happy to have people of color to patch up and profit off of. So, I guess they were grateful for that way. But, other than that, I was treated indifferently, especially by the nurses and the, um, after-care portion, the few days I spent in the hospital, I might as well have been a piece of meat."
Foreshortened future	Expect to die young	"When I was growin' up, lot of cats and neighborhood people used to say most kids wasn't gonna make it to see twenty-one."
Self-reliance	Mental health	"And, especially from the 'hood, if that's what you want to call the inner city, they think that the counselors don't care. They don't care about what's really goin' on in my life, or how I feel . . . Like, they're gettin' paid to sit here and play with my life like a yo-yo, and then people feel like, 'Oh, they don't care.'"
	Substance abuse	"Well, I cope with [PTSD symptoms] . . . through the grace of god, beer, and weed . . . (laughs). Well, that's not the right solution, but I told you, I ain't had no help, no counselin' or nothin' like that."
Preferred clinician characteristics	Race	"Like I said, I never had no problems with the doctors. It was just like they was . . . they was basically there for me It was just like . . . to me, it was a surprise, and like, different people, like . . . different colors, different race, you come through, they really don't care about you, but . . . these people showed me they're sorta like, 'We save everybody's life. Just not our own.'"
	Shared experience	"They need someone to relate. Again, they don't need to be an ex-drug addict; they don't need to be straight from the penitentiary; they don't need to be ANY of those things. Just be able to relate."
Wake-up call	Motivation for change	"If this didn't happen and, the way that I dealt with myself after it happened, if I didn't take that time to really put in work and to get myself to the point I am now, then I probably would have been in the streets with a gun right now, doing something ridiculous."
Positive person	Social support	"To have a positive person in your life can make a world of difference in it supports your belief in yourself and what you stand for, what you're tryin' to achieve. It's that affirmation that you can go on, despite tragedy and trauma. Now it's like your spirit is bein' ministered to. And, with anything that you do in life, you have to surround yourself with people who believe in you."

Institutional Mistrust

The context of "street culture" infused the injury and healthcare narratives of all participants to varying degrees. In particular, suspicion of dominant-culture institutions, such as police and healthcare, was common. The mistrust was exemplified by interactions with the police while receiving medical

care for the injury. The participants saw that healthcare personnel (e.g., ambulance, emergency department, or inpatient setting) would allow the police to question them while getting treatment. The police interrogation during medical treatment made some feel as if they were being treated as the perpetrator, and increased their sense of vulnerability. According to one participant, "…the only visitors I had was the police, comin' and talk to me. . . I felt like somebody was tryin' to murder ME, and I'm in jail, havin' all these cops comin' to see me and talk to me like (I'm the suspect in) a murder investigation."

Because this line between police and healthcare institution was blurred, in at least one case, it led to minimization of symptoms so that the healthcare personnel would not report this to the police. This participant discussed his presentation for treatment for a gun shot, "I just cut it short 'cause I wasn't too comfortable at tellin' 'em how I felt because if I tell 'em too much… next thing you know, the police is comin,' knockin' at my door."

Some of the institutional mistrust was based on a perception that healthcare clinicians are more motivated by money than by performing appropriate care, "… all the doctors and nurses and people in the healthcare field, when they first started out, they had genuine intentions. But, as years go on, big business corrupt their mind."

One manifestation of this mistrust was an unwillingness to give out accurate contact information to healthcare personnel. One participant explained this as, "the G-code," meaning gangster-code, a behavior in which the patient will be polite but not actually engage in the care, e.g. not give phone number, not attend follow-up appointments.

Foreshortened Future

Some participants reported that they had expected they would die at an early age. These feelings were reinforced by peers who were injured or died, and messages from adults, "A lot of my friends, they died when they were 15, 18 and, our teachers used to (say), "You guys, ya'll aint never gonna make it past 18 years old."

The injury reinforced expectations that getting shot or stabbed was inevitable. One participant said, "I left the hospital feeling like what happened to me is not a tragedy. It's just a way of life.'"

Participants heavily involved in street culture reported embracing this fate, "We had a gung-ho attitude about it. It's guns, violence, drugs. . . Today might be my day, so live it to the fullest." This apparent attitude suggests that clinicians appealing to self-preservation instincts in patients as motivation for treatment might not be successful.

Self-Reliance

Participants expected that individuals and families rely on themselves for help. "As a young Black male… I'm not one to go to somebody and say,…'I need some help, I need to talk." I rather. . . try to find out what to do, on my own. Get rid of my own stress." In particular, discussions of treatment for mental health issues were peppered with the language of stigma; one compared mental health treatment to putting a pacifier in a baby's mouth.

Others felt that mental health treatment is ineffective, partly because the therapist does not know the patient. One participant noted, "…spillin' your beans about everything personal to somebody who barely even knows you, and is giving you feedback and telling you what to do about YOUR situations…just 'cause it's their job."

Participants discussed forms of self-treatment, such as heavy use of substances, particularly alcohol and marijuana. "At times I cried, and then I started. . . breakin' up with my family, started usin' more drugs from alcohol to messin' with cocaine, with weed, then from there to messin' with heroin. . . to self-medicate myself. I figured if I self-medicate myself, I won't be in that mind."

Although 15 participants reported hazardous alcohol use or regular marijuana use, many reported that if they had a problem, they could stop on their own "My addiction is not so uncontrollable. . . I think my addiction is not worse than. . . quote/unquote 'hard core addicts'. . . I'm pretty much in control most of the time, when I make these bad decisions." While some participants did report mental health symptoms and a perceived need for treatment, few reported actively seeking or having received therapy. Some reported that they would have liked (or even now would like) therapy, but did not know how to obtain such help.

Logistical Issues

Several logistical barriers to obtaining medical and mental healthcare were noted. Participants discussed a lack of safety they felt after the injury, "I continued to work, but then I was always in the house, so it was like, I was hidin,' like I was a criminal…. And that's why, eventually, I just saved my money and moved on outside of the city."

Fear of public venues, such as public transportation, was common. This was particularly intense for those with newly acquired disabilities, including post-traumatic stress symptoms. "They wanted me to come to court and testify against him, … but, …after somethin' like this happen, there's no way you expect me just to get on the regular public transportation and come on down to the courthouse… That was like a death trap right there." Money struggles were common in the participants, including difficulty obtaining safe and affordable housing, and lack of employment.

Facilitators to Care

Desired Clinician Characteristics

All participants were specifically asked about racial and gender preferences for treating physicians and mental health professionals. None of the participants reported a need for the treating physician to be black. "If you're white, black, green, yellow, orange, as long as you're professional and you know how to do your job. . . It doesn't matter about race. I didn't have no black people on my team. A straight cracker saved my life." Medical competence, professionalism, and an "open-minded personality" that conveyed respect were cited as desirable characteristics of a clinician.

However, three did report wanting a mental health clinician to be black. One participant declared, "…she or he would definitely have to be the same color, hopefully, or

nationality… I'd definitely feel more comfortable with somebody in my, [background]." Five said they preferred clinicians to be one gender over another, with mixed opinions about which gender. Despite only a few requesting a black clinician, another eight participants wanted a mental health clinician who could relate to their experiences in the street, "It'd be nice to have someone who has experience,. . . like, they can say, 'Oh, I've been there,' or, 'I know someone who has been there.'"

Turning Point

Participants did report experiences and factors which promoted positive engagement with healthcare clinicians and motivated positive life changes. Despite feelings of a foreshortened future described by many participants, a number spoke about experiences which caused them to re-examine their lives. For some, the injury itself was a turning point in their life. It gave them time to think about past and future, and to see how their own actions might place them at risk. As one explains, "I was thinkin' about my future. I'm thinkin' about not doing the things that I had done in the past–sellin' drugs, doing drugs, goin' to jail, doing stupid stuff in the streets. . . God was tellin' me this was somethin' that may happen. It was a wake up call for me." More commonly the birth of a child or recognition of their importance to their children inspired personal change, "when (the baby) is yours and you're sittin' there, you're like, "Um, naw… I can't do this [street life] no more. I can't live like that."

Positive People

A number of participants used the phrase "positive person" to describe people who helped them with their mental recovery from the trauma (or other issues). These positive people included friends, neighbors, family members, bosses, religious communities, and a barber. Positive people focused on moving in a future direction, rather than dwelling in the past. It included people who spoke honestly and respectfully with the participant about their problems. According to one, "They need to be around a positive person, like a friend, and let them know like, 'Look, you need help, you need to, see somebody.'"

DISCUSSION

Among a group of black male victims of violence, the social environment strongly influenced engagement with medical and mental healthcare after an injury. These men perceived the importance of the medical treatment for their trauma. However, it did neither appear to integrate their reactions to the injury nor did it fully address the daily challenges they faced including mental health symptoms, disability, and safety concerns after the injury. Additionally, an underlying suspicion of institutions may interfere with taking advantage of potential resources of care. Beliefs about treatment for mental health and substance abuse may also have prevented them from accessing professional help. Engaging participants with supportive and forward social networks may best facilitate recovery.

The first sign of disengagement to healthcare may start at the moment of injury, with peritraumatic dissociation, a mental disconnect from the injury documented in studies of other violent injuries.[18,19] Just after the injury, thoughts centered on anger at the perpetrator and the circumstances of the injury. These two phenomena, and the foreign environment of the healthcare setting, may contribute to the patient being physically present but mentally and emotionally disconnected from the medical and surgical care. The narratives suggest that this chasm between the patient experience and medical care delivery has the potential to result in poorly planned discharges and preventable readmissions. While some factors may be beyond the control of medical personnel, knowledge of potential patient concerns, and challenges can facilitate development of potential responses.

While mistrust of healthcare institutions among black populations has been documented previously,[20–22] it has unique implications for victims of stabbing and shooting. Within inner-city black communities, suspicion of mainstream institutions may be explained in part by what sociologist Elijah Anderson calls, "The Code of the Street."[23] According to Anderson, this Code is a set of rules in response to the perceived failure of mainstream institutions to serve the needs of inner-city communities. The Code encourages an attitude of self-reliance, such as self-defense through neighborhood or gang affiliations, and aversion to asking for help, an attitude that may follow these youth into a healthcare setting. Cooperating with police may be interpreted as defying the Code and be a risk for further injury. Venkatesh,[24] in his book *Gang Leader for a Day*, substantiates the theme that poor black urban populations experience mainstream institutions as not serving their needs. Patients may view medical institutions as an extension of the legal system. For example, routine interviewing of patients by police detectives occurs during receipt of emergent treatment in both ambulances as well as Emergency Departments (EDs). Given this experience, patients may not view the postinjury care experience as a secure and trusting environment, rather- it has potential for worsening safety after discharge.

Emergency medical services should consider instituting policies about asking patient permission before allowing police to question patients. While this may not be possible before entering hospital EDs, instituting such policies could be considered in hospital EDs, in the same way that patients may refuse other visitors. In addition, medical personnel should clearly delineate what patient information is available to police (or others) and what is confidential.

Physical disabilities stemming from the injury increase the vulnerability already engendered by injury itself and subsequent encounters with police. This may lead to a decreased sense of safety, particularly heightened in venues such as public transportation. The fear of public transportation may be a major obstacle for these men to obtain postinjury care and to take advantage of available resources. Providing patients with private and safe transportation may help to improve follow-up care.

Appropriate and safe housing is also a challenge for a number of these men. Prior housing arrangements may not be appropriate due to physical limitations (e.g. not wheelchair accessible). They also may not feel safe from either gang-

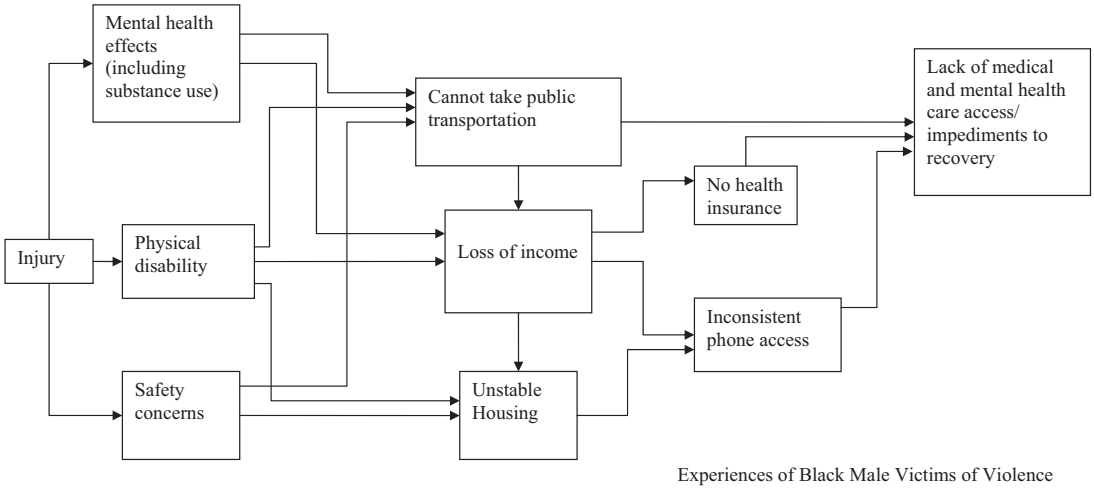

Figure 1. Postinjury barriers to medical and mental healthcare for black male victims of community violence.

related retaliation (to keep victim from disclosing to police), high family tensions, difficulty paying rent due to loss of income, or posttraumatic stress symptoms from fear of injury in the same neighborhood. These survival issues compete with medical needs, especially in a group of young men who hold self-reliance as a core value. Future programs on preventing further postinjury morbidity should consider providing supported and safe housing to allow the participant to recover. Figure 1 depicts a theoretical model of how logistical barriers stemming from injury may affect access to healthcare.

The easy availability of substances, particularly alcohol and marijuana, provided an escape from the emotional toll of stabbing and shooting for some study participants. As noted by Rich and Grey,[25] substance use is one link on the pathway to re-injury. Getting professional help for substance use or mental health symptoms would entail overcoming a variety of barriers for black male violence victims. The nature of treatment involves asking for help, acknowledging weakness and trusting of mainstream institutions, which contradicts a core value of self-reliance. Inaccurate information about effectiveness of treatment contributes to these barriers. Contradictorily, most study participants desired relief from mental suffering but did not know how to access such help, suggesting that a public health campaign about substance abuse and mental health treatment, along with expanded access, may decrease some barriers.

The power of the social network suggests another route that medical clinicians might draw on: working (with patient permission) on engaging a circle of positive people in the recovery plan. This may help encourage patients to engage in self-care and use the available treatments.

Limitations

Qualitative studies, by design, are meant to generate ideas and not provide conclusions generalized to other populations. A common drawback of qualitative research is related to bias, including bias of the interviewers who may have unknowingly influenced participant responses and bias of the researchers analyzing the data. To counter those biases, interviewers were extensively trained. As well, a large diverse, interdisciplinary team performed the analyses and formulated the conclusions with participation from all team members. It is not known whether this sample differed greatly from those unwilling to participate in research projects. Additionally, the participants' memories may have evolved since the actual events took place, and thus, the reporting may not reflect actual experiences. While interviews were scheduled with black male interviewers, participants who arrived at unscheduled times and did not have adequate phone access to reschedule were interviewed by available trained personnel. It is not clear how this affected study results.

CONCLUSIONS

Effective emergency care for black male victims of stabbing and shooting should go beyond stopping the acute bleeding, and encompass methods to build bridges to patients' needs. This would include delineating clear boundaries between patient rights and law enforcement needs, and then assessing for safety, transportation, and housing issues after discharge. Campaigns to educate and decrease stigma of mental and substance abuse care combined with facilitated access to such treatment may also improve outcomes.

Proton Pump Inhibitors and Risk for Recurrent *Clostridium difficile* Infection

Amy Linsky, MD; Kalpana Gupta, MD, MPH; Elizabeth V. Lawler, DSc; Jennifer R. Fonda, MA; John A. Hermos, MD

Background: Proton pump inhibitors (PPIs) are widely used gastric acid suppressants, but they are often prescribed without clear indications and may increase risk of *Clostridium difficile* infection (CDI). We sought to determine the association between PPI use and the risk of recurrent CDI.

Methods: Retrospective, cohort study using administrative databases of the New England Veterans Healthcare System from October 1, 2003, through September 30, 2008. We identified 1166 inpatients and outpatients with metronidazole- or vancomycin hydrochloride–treated incident CDI, of whom 527 (45.2%) received oral PPIs within 14 days of diagnosis and 639 (54.8%) did not. We determined the hazard ratio (HR) for recurrent CDI, defined by a positive toxin finding in the 15 to 90 days after incident CDI.

Results: Recurrent CDI was more common in those exposed to PPIs than in those not exposed (25.2% vs 18.5%). Using Cox proportional survival methods, we determined that the adjusted HR of recurrent CDI was greater in those exposed to PPIs during treatment (1.42; 95% confidence interval [CI], 1.11-1.82). Risks among exposed patients were highest among those older than 80 years (HR, 1.86; 95% CI, 1.15-3.01) and those receiving antibiotics not targeted to *C difficile* during follow-up (HR, 1.71; 95% CI, 1.11-1.64).

Conclusions: Proton pump inhibitor use during incident CDI treatment was associated with a 42% increased risk of recurrence. Our findings warrant further studies to examine this association and careful consideration of the indications for prescribing PPIs during treatment of CDI.

PROTON PUMP INHIBITORS (PPIs) are among the most commonly prescribed agents in outpatient and inpatient settings, but they are often used without a clear indication.[1,2] Although PPIs have been considered relatively safe, studies have demonstrated that PPI use and the use of other gastric acid suppressants are associated with a variety of infections, including *Salmonella* and *Campylobacter* gastroenteritis and community-acquired and nosocomial pneumonia.[3-7]

See also pages 747, 749, 751, 765, 779, and 784

Proton pump inhibitors have also been associated with *Clostridium difficile* infection (CDI).[8-11] *Clostridium difficile* is a spore-forming bacterium with a toxin that is associated with diarrheal illnesses. Symptomatic recurrence occurs in approximately 20% of patients after treatment, with even higher rates after subsequent episodes.[12-15] The incidence of CDI in the United States has nearly tripled in the past decade, with antibiotic and hospital exposures recognized as the preeminent risks for infection.[16,17] Other putative risk factors include older age, frailty, and environmental factors.[18]

Several observational studies have associated community-acquired and nosocomial CDI with PPI use, finding risks of CDI 2 to 3 times higher in PPI users compared with nonusers.[8-11,17,19,20] Other research has failed to associate PPIs with CDI.[21,22] The exact relationship between PPI use and incident CDI remains elusive, and no causative pathway has been demonstrated. The relationship between PPI exposure and the risk of recurrent CDI is even less clear, with fewer studies and conflicting findings.[23,24] To further address this question, we conducted a retrospective cohort analysis using data from the New England Veterans Healthcare System (VISN 1) to determine the association between PPI use and the risk of recurrent CDI.

METHODS

STUDY SETTING

We used linked pharmacy and administrative databases from VISN 1 from October 1, 2003, through September 30, 2008. The New England region consists of 8 Veterans Affairs (VA) medical centers and affiliated clinics, including 3 large, urban, tertiary care centers and 5 smaller facilities providing inpatient and outpatient care. The VISN 1 pharmacy files were obtained from Veterans Health Information Systems and Technology Architecture. The data elements of the outpatient and inpatient pharmacy files used in this study include patient identification, date of birth, drug name and dose, drug administration route, quantity, VA drug class, date of original prescription, number of days of medication supplied, and refill date. Laboratory data were obtained from the electronic medical record. Comorbidities were captured via the VA national patient care database located at the Austin Automation Center, Austin, Texas. Analyses were conducted at the Massachusetts Veterans Epidemiology Research and Information Center, VA Cooperative Studies coordinating center, VA Boston Healthcare System. The study was approved by the institutional review board of the VA Boston Healthcare System, which waived informed consent and Health Insurance Portability and Accountability Act of 1996 authorization.

STUDY POPULATION

From the data sets, we identified patients with a first positive finding of a *C difficile* toxin from October 1, 2004, through September 30, 2008. This search yielded the index date for 1549 patients. The laboratories of VISN 1 use enzyme immunoassay tests for toxins A and B, with a standard practice of testing only loose stool samples. This sample of incident cases was then restricted to 1546 patients with a minimum of 1 year of prior VA health care system use to establish their use of the VA system. We further limited the study population to 1408 patients for whom treatment was initiated within the VA system with metronidazole or oral vancomycin hydrochloride and then to 1166 patients whose treatment started within 3 days before or after the index CDI (**Figure 1**).

PRIMARY EXPOSURE AND OUTCOMES

The main exposure variable was the use of any oral PPI during the 14 days after incident CDI diagnosis, coinciding with the treatment window. For inpatients (n=981), PPI exposure was defined as any pharmaceutical dispensing of a PPI during this postdiagnosis window. For outpatients (n=185), the end date of the most recent antecedent prescription was extended by 10% (eg, 9 days for a 90-day prescription) to account for potentially missed doses. If the predicted prescription end date fell after the index date, then the subject was placed in the PPI-exposed group. For all outpatients, actual prescription end dates fell beyond the index date. With these exposure criteria, 527 patients (45.2%) were categorized as PPI exposed and 639 patients (54.8%) as non–PPI exposed (Figure 1).

The primary outcome measure was a positive finding for a *C difficile* toxin occurring 15 to 90 days after the incident CDI diagnosis date. We established a 15- to 90-day follow-up window to provide a period of observation that would capture the greatest number of possible recurrent cases based on clinical observations and previous studies.[12,24] Patients were censored at death or 90 days after the index date. We also calculated the time to recurrence, defined as the number of days from the later of either the index date or the start of incident CDI treatment until the recurrent diagnosis date. Thus, the calculated time to recurrence could be as short as 12 days.

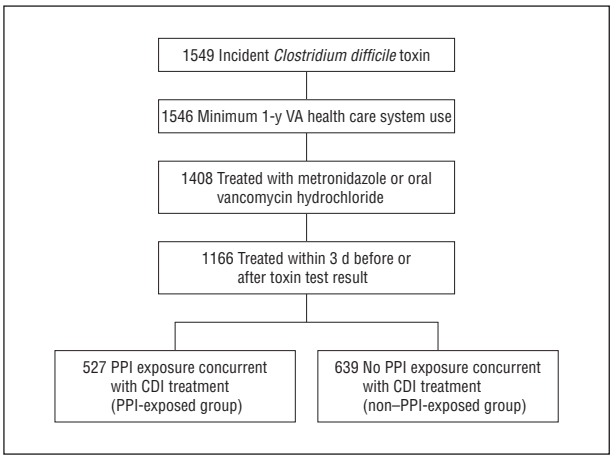

Figure 1. Determination of study population. CDI indicates *Clostridium difficile* infection; PPI, proton pump inhibitor; and VA, Veterans Affairs.

COVARIATES

Covariates that may influence the risk of recurrent CDI and those that may influence exposure to PPIs were included in our analysis. These variables were age, sex, comorbid conditions, medication used before the index date, initial incident CDI antibiotic treatment (metronidazole or vancomycin), non–CDI-targeted antibiotic exposure during follow-up, VA nursing home admission during the study period, and, for those who were inpatients, the duration of hospitalization after the index date.

Comorbidities were determined from administrative records using *International Classification of Diseases, Ninth Revision, Clinical Modification* (*ICD-9-CM*) codes, including selected diagnoses recorded in the 2 years before the index date. Comorbidities and their *ICD-9-CM* codes were hypertension (codes 401-404), diabetes (250), ischemic heart disease (410-414), chronic obstructive pulmonary disease (491, 492, and 496), esophageal disease (530), peptic ulcer disease (531-535), solid tumors (140-199), and rheumatologic disease (710, 714, and 720). Medication used in the 90 days before the index date was included to represent the acuity and severity of the comorbid conditions and those drugs that might directly increase susceptibility to infections. Specific medications were antibiotics, systemic and inhaled corticosteroids, chemotherapeutics, and immunomodulators. In addition, we recorded inpatient and outpatient prescriptions for H_2 receptor antagonists.

We determined the initial antibiotic treatment for CDI because differences in clinical severity may affect the choice of antibiotic. There may also be different treatment success rates.[25,26] We evaluated how many patients changed from metronidazole to vancomycin therapy within the 14 days after diagnosis. Because antibiotic exposure is a major risk factor for CDI,[20,27,28] we determined whether patients were exposed to non–CDI-targeted antibiotics during follow-up. Similarly, because hospital exposure is a major risk factor,[29,30] we determined the number of days patients were hospitalized after incident CDI diagnosis. We categorized this variable as 0 days, discharged fewer than 14 days after the index diagnosis, and discharged at least 14 days after the index diagnosis. To account for the possible effect of PPI exposure from day 15 to censorship, we determined whether patients were dispensed or prescribed PPIs by using the same criteria as during the treatment window.

Table 1. Characteristics of the Study Population[a]

Characteristic	PPI Exposure Concurrent With CDI Treatment (n=527)	No PPI Exposure Concurrent With CDI Treatment (n=639)	*P* Value
Patient demographics			
Age, median (IQR), y	74 (63-81)	74 (63-82)	.31

PPI exposure during days 15-90	434 (82.4)	41 (6.4)	<.001

Abbreviations: CDI, *Clostridium difficile* infection; IQR, interquartile range; PPI, proton pump inhibitor; VA, Veterans Affairs.

[a]Unless otherwise indicated, data are expressed as number (percentage) of patients.

STATISTICAL ANALYSIS

We used χ^2 tests to compare categorical variables between PPI-exposed and non–PPI-exposed groups, setting $\alpha = .05$. We compared age using Wilcoxon 2-sample tests. Rate ratios and 95% confidence intervals (CIs) were determined for recurrence during the follow-up period. To account for time to recurrence, we used survival analysis techniques, calculating Cox proportional hazards ratios (HRs) for additional positive findings of *C difficile* toxin. We included in the final model those variables that were statistically different between the groups or that were thought to be clinically relevant. We tested the proportional hazards assumption by including an interaction term in the final model between PPI exposure and the natural logarithm of time. Post hoc stratified analyses were conducted by patient age, non-CDI antibiotic exposure, and PPI exposure after treatment for incident CDI.

SENSITIVITY ANALYSIS

Positive toxin findings alone may not represent clinically relevant, recurrent CDI. Thus, we determined HRs excluding 34 patients (13.5% of 251 total cases of recurrence) with a new positive toxin finding for whom there was no VA pharmacy record of additional CDI antibiotic treatment. Because continued hospital exposure could favor CDI recurrence, we determined whether alternative categorization of inpatient time to discharge influenced hazard rates. We also analyzed to what extent patients with recurrent CDI had intervening positive toxin results. All analyses were performed using SAS statistical software (version 9.1.3; SAS Institute Inc, Cary, North Carolina).

RESULTS

STUDY POPULATION

The study population of 1166 veteran patients meeting criteria for recurrent CDI was predominantly male (97.2%), with a median age of 74 (interquartile range, 63-82) years. Overall, 527 (45.2%) of the patients were exposed to a PPI concurrent with antibiotic treatment (PPI-exposed group) and 639 (54.8%) were not exposed to concurrent PPI use (non–PPI-exposed group) (Figure 1 and **Table 1**). Almost all PPI-exposed patients (96.7%) were prescribed omeprazole, 20 mg once daily, or the equivalent dose of another PPI; the remaining patients received lower or higher PPI doses. Age and sex were similar among the PPI-exposed and non–PPI-exposed patients. The PPI-exposed group had a higher prevalence of *ICD-9-CM* coded ischemic heart disease, chronic obstructive pulmonary disease, esophageal disease, peptic ulcer disease, and rheumatologic disease. This group also had greater exposure to systemic corticosteroids. Metronidazole was the initial antibiotic used for treatment of incident CDI in more than 90% of both groups. Similar proportions (11%) in each group were switched from metronidazole to oral vancomycin within the treatment window. However, patients in the PPI-exposed group were more likely to have been inpatients and were more likely to have inpatient stays exceeding 14 days than those in the non–PPI-exposed group. Also, those in the PPI-exposed group were more likely to have been exposed to non-CDI antibiotics during follow-up. Of those in the PPI-exposed group, 434 (82.4%) had continued exposure to PPIs during follow-up days 15 to 90. In the non–PPI-exposed group, there were only 41 patients (6.4%) exposed to PPIs during this follow-up. Similar proportions of each group had an admission to a VA nursing home during the study window.

RELATIONSHIP OF PPI TO RECURRENT CDI

The primary outcome of additional positive findings for *C difficile* toxin occurred in 251 patients (21.5%). The unadjusted incidence of recurrent toxin in the 15 to 90 days after incident CDI was greater in the PPI-exposed compared with the non–PPI-exposed group (133 of 527 [25.2%] vs 118 of 639 [18.5%]). Unadjusted Kaplan-Meier recurrence-free survival curves are seen in **Figure 2**, with an associated HR of 1.42 (95% CI, 1.11-

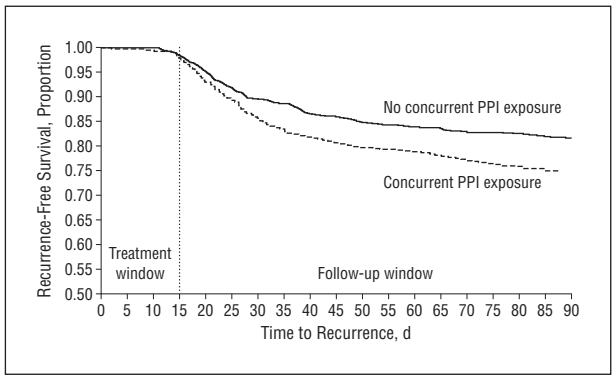

Figure 2. Recurrence-free survival in those exposed vs unexposed to proton pump inhibitors (PPIs) during treatment for incident *Clostridium difficile* infection. Time to recurrence started from the incident toxin finding or the start of antibiotic treatment (≤3 days after the diagnosis).

1.82; *P*=.006) for those in the PPI-exposed group compared with those in the non–PPI-exposed group. After adjusting for age, initial incident CDI antibiotic treatment (metronidazole or vancomycin), additional antibiotic exposure (yes or no), duration of hospital exposure (0, <14, or ≥14 days), and differing baseline comorbidities (ischemic heart, esophageal, peptic ulcer, pulmonary, and rheumatologic diseases) and medications (systemic corticosteroids), the HR associated with PPI exposure remained elevated at 1.42 (95% CI, 1.10-1.83; *P*=.008) (**Table 2**). The proportional hazards assumption was met for the adjusted model because the interaction term between exposure and the logarithm of time was not significant (*P*=.65).

EFFECT MODIFICATION

We evaluated potential effect modification by age, non-CDI antibiotic exposure during follow-up, and PPI exposure during follow-up. We found an increasing risk of recurrence associated with PPI use with increasing age (Table 2). Stratification by non-CDI antibiotic exposure in the follow-up window modified the association of PPIs and recurrent CDI on the ratio scale. Those exposed to additional antibiotics had a 71% greater risk of recurrence associated with PPIs, whereas those not exposed to antibiotics had a 30% greater risk of recurrence. However, we were not sufficiently powered to detect a statistically significant effect modification for age or non-CDI antibiotic exposure.

Most patients in the PPI-exposed group (434 of 527 [82.4%]) and very few of the non–PPI-exposed group (41 of 639 [6.4%]) received PPIs during the 15- to 90-day follow-up (Table 1). Patients prescribed PPIs during both treatment and follow-up had an increased risk of recurrence compared with those who were not exposed to PPIs in either time window (HR, 1.44; 95% CI, 1.09-1.89; *P*=.01). Greater risk for recurrence, although not powered for statistical significance, was also seen in the smaller subgroups who were exposed to PPIs in the treatment period only (41 patients; HR, 1.30; 95% CI, 0.68-2.51; *P*=.43) or in the follow-up period only (93 patients; HR, 1.51; 95% CI, 0.93-2.46; *P*=.10).

Table 2. Association of CDI Treatment-Concurrent PPI Exposure With Recurrent CDI Within 90 Days

Model	HR (95% CI)	*P* Value
Unadjusted	1.42 (1.11-1.82)	.006
Adjusted[a]	1.42 (1.10-1.83)	.008

Abbreviations: CDI, *Clostridium difficile* infection; CI, confidence interval; HR, hazard ratio; PPI, proton pump inhibitor.

[a] Adjusted for age, incident CDI treatment, additional antibiotic exposure, length of hospital exposure, ischemic heart disease, esophageal disease, rheumatologic disease, peptic ulcer disease, pulmonary disease, and systemic corticosteroid use.

SENSITIVITY ANALYSES

We determined the proportion of those classified as having recurrent CDI whose treatment with CDI-targeted antibiotics was documented in the VA pharmacy. Of the 251 cases meeting our criteria for recurrent CDI, 217 (86.5%) were prescribed metronidazole or oral vancomycin at the time of the additional positive toxin finding. Restricting our risk analyses to these patients did not change our estimates (adjusted HR, 1.52; 95% CI, 1.15-2.01; *P*=.003).

Because a change from metronidazole to vancomycin therapy may reflect more severe disease clinically or failure to respond to the original CDI treatment antibiotic, we evaluated the influence of any exposure to vancomycin on the association of PPIs and recurrence. Controlling for any vancomycin treatment within the first 14 days did not alter our findings (adjusted HR, 1.42; 95% CI, 1.10-1.84; *P*=.008).

We conducted adjusted analyses using varied categorical lengths of hospitalization following incident CDI diagnosis and found no differences in the HRs associating PPI exposure with recurrent CDI (data not shown).

Of the 251 recurrent cases, 121 (48.2%) had no intervening test for *C difficile* toxin, 100 (39.8%) had an intervening test with a negative result, and 30 (12.0%) had an intervening test with positive results, mostly within several days of the index date. There was no difference in PPI exposure among those with intervening negative test results or no intervening tests (*P*=.43).

COMMENT

Our findings indicate that PPI use concurrent with treatment for CDI was associated with a 42% increased risk of recurrent CDI in the subsequent 15 to 90 days. In stratified analyses, exposure during treatment and within the follow-up window was associated with a 44% greater recurrence, whereas patients prescribed PPIs in only 1 of the 2 exposure windows (ie, treatment only or follow-up only) demonstrated a higher but nonstatistically significant risk of recurrent infection.

Proton pump inhibitors have been linked to higher risks of community-acquired and nosocomial CDI,[8-11,19] but other studies have not shown this association.[21,22] Few studies have specifically focused on the association of PPIs with recurrent CDI. A retrospective medical record review of 140 patients in a single VA medical center demonstrated 4-fold increased odds of recurrence in those exposed to PPIs concurrently with CDI treatment, although HRs accounting for time to recurrence were not analyzed.[24] A small prospective medical record review of patients with endoscopically proved pseudomembranous colitis found higher relapse rates in those prescribed antiulcer medications but did not distinguish between PPIs and other gastric acid suppressants.[31] Similarly, a case-control study showed a slightly greater risk of recurrence in patients exposed to H_2 receptor antagonists, but the investigators did not assess the risk of PPIs.[13] Others have not found a difference in recurrence rates due to acid-suppressing medications[23]; however, those investigators did not distinguish between PPIs and H_2 receptor antagonists, which are generally less potent. The data presented herein represent, to our knowledge, the largest evaluation of this potentially modifiable exposure to PPIs and risk of CDI recurrence.

One potential mechanism to explain this association may be that elevated gastric pH levels facilitate the growth of potentially pathogenic upper and lower gastrointestinal tract flora.[3,32,33] Although *C difficile* spores are acid resistant, vegetative forms are susceptible to acidity.[34,35] Furthermore, elevated gastric pH levels may allow or facilitate conversion from spore to vegetative forms of *C difficile* in the upper gastrointestinal tract. Other potential mechanisms include impairment of leukocytes and other immune responses and antimicrobial properties of PPIs.[36-39]

Our study had several strengths, including use of data from the VA's large, multisite, integrated health care system. The ability to link information from laboratory, pharmacy, and administrative data enabled comprehensive assessment of multiple aspects of patients' health care. We also incorporated time to recurrence into our analyses, and stratified and sensitivity analyses supported the association of PPI use with recurrent CDI. Finally, our data are compatible with plausible biological mechanisms and with results from previous studies indicating increased risk of infections, including CDI, with PPI exposure.[4-11]

As with all studies using administrative and clinical data extracts, our findings should be viewed in the context of the following limitations. Use of observational databases allows for potential misclassification of exposure (eg, for outpatients, use of non-VA prescribed or over-the-counter PPIs or other gastric acid suppressants, and conversely, nonadherence to VA-prescribed PPI therapy). However, there exists significant financial incentive for most veterans to obtain prescriptions directly from the VA. Furthermore, because most of our sample initially had CDI treatment as inpatients, we are confident in the quality of our PPI exposure data.

A positive test result for a *C difficile* toxin by itself does not necessarily indicate a clinically relevant recurrence and could lead to potential misclassifications of the outcome. However, our findings remained robust when we assessed overdiagnosis of recurrent CDI by analyzing only the 217 subjects (86.5%) who had an additional positive toxin finding and additional documented treatment with CDI-targeted antibiotics. The hazards of recurrence in this restricted sample were similar to those of the entire study population (adjusted HRs, 1.52 vs 1.42, respectively).

Our data cannot, with certainty, determine to what extent the patients had recurrent CDI after a short period of treatment success or experienced treatment failure. Further examination revealed that 39.8% of the recurrent cases had an intervening negative stool toxin finding and 48.2% had no intervening tests. There was no difference in PPI exposure among these subgroups. From these data, there was little evidence to suggest that patients classified as having recurrent CDI had persistently positive toxin results between their index and recurrence dates. Nevertheless, to distinguish recurrent disease from treatment failure would require a prospective, systematic testing of subjects receiving treatment for CDI.

Patient frailty has been associated with CDI.[40] Although we controlled for differences in comorbid conditions, other than incorporating use of selected medications to treat these conditions, we did not directly assess the severity of illnesses. In addition, our study was conducted in a predominantly male veteran population, and our results may not generalize to all patients. Previous studies have found women to be at greater risk for CDI than men,[8] but other large investigations have associated PPIs with *C difficile* in both sexes.[10,40] Overall, these findings may be generalized to other elderly populations with similar access to PPIs.

After incident CDI diagnosis, our sample had other potentially important exposures increasing their risk of recurrent CDI. Although we controlled for patients' time in the hospital after incident disease, we were unable to incorporate *C difficile* pressure in specific settings such as hospital wards.[18] We also did not find any difference between groups for nursing home admissions during the study window. In our adjusted analyses, controlling for non-CDI antibiotic exposure during follow-up did not affect the risk associated with PPI exposure during treatment. When stratifying results, the risk associated with PPIs increased for those with additional antibiotic exposure, and statistical significance was no longer reached in those who received no further antibiotic treatment. Given the direction of the association, lack of further antibiotic treatment does not necessarily negate the effect of PPIs.

Most patients remained exposed or nonexposed to PPIs during the treatment and follow-up windows; very few received PPIs only during days 1 to 14 or only during days 15 to 90. Continued exposure to PPIs was associated with a risk of recurrent CDI similar to that found for the originally defined PPI-exposed group. Thus, to what extent the PPI exposure concurrent with CDI treatment, during follow-up, or during both periods is driving the association with recurrence is unclear.

The effect of any risk attributable to PPIs, regardless of magnitude, is increased owing to the high prevalence of use for this class of medication. Proton pump inhibi-

tors are often used without a clear indication. Studies of outpatients have found that of those receiving long-term acid-suppressive therapy, only 61% had a relevant gastrointestinal tract–related diagnosis.[2] Similarly, studies of inpatients found acid-suppressing medications frequently prescribed for stress ulcer prophylaxis in non–intensive care unit settings,[41-43] a practice contrary to the American Society of Health System Pharmacists guidelines.[44] Choudhry et al[45] studied patients with CDI and PPI use for prescription indication; an appropriate indication was not identified in 53.4% of the patients. We did not assess the indications for PPI use in our patients.

In conclusion, the study identified a 42% increased risk of recurrent CDI related to PPI use. Given the morbidity and cost associated with recurrent CDI and the lack of readily modifiable risk factors, our findings have important clinical implications. The data presented herein support the need for critical assessment of PPI use in patients being treated for CDI as well as further research to test this association.

Apixaban for Reduction In Stroke and Other ThromboembolLic Events in Atrial Fibrillation (ARISTOTLE) trial: Design and rationale

Renato D. Lopes, MD, PhD,[a] John H. Alexander, MD, MHS,[a] Sana M. Al-Khatib, MD, MHS,[a] Jack Ansell, MD,[b] Raphael Diaz, MD,[c] J. Donald Easton, MD,[d] Bernard J. Verheugt, MD, PhD,[j] and Lars Wallentin, MD, PhD[k] on behalf of the ARISTOTLE Investigators

Durham, NC; New York, NY; Santa Fe, Argentina; Providence, RI; Rochester, MN; Princeton, NJ; Adelaide, Australia; Boston, MA; Glasgow, United Kingdom; Nijmegen, The Netherlands; and Uppsala, Sweden

Atrial fibrillation (AF) is associated with increased risk of stroke that can be attenuated with vitamin K antagonists (VKAs). Vitamin K antagonist use is limited, in part, by the high incidence of complications when patients' international normalized ratios (INRs) deviate from the target range. The primary objective of ARISTOTLE is to determine if the factor Xa inhibitor, apixaban, is noninferior to warfarin at reducing the combined endpoint of stroke (ischemic or hemorrhagic) and systemic embolism in patients with AF and at least 1 additional risk factor for stroke. We have randomized 18,206 patients from over 1,000 centers in 40 countries. Patients were randomly assigned in a 1:1 ratio to receive apixaban or warfarin using a double-blind, double-dummy design. International normalized ratios are monitored and warfarin (or placebo) is adjusted aiming for a target INR range of 2 to 3 using a blinded, encrypted point-of-care device. Minimum treatment is 12 months, and maximum expected exposure is 4 years. Time to accrual of at least 448 primary efficacy events will determine treatment duration. The key secondary objectives are to determine if apixaban is superior to warfarin for the combined endpoint of stroke (ischemic or hemorrhagic) and systemic embolism, and for all-cause death. These will be tested after the primary objective using a closed test procedure. The noninferiority boundary is 1.38; apixaban will be declared noninferior if the 95% CI excludes the possibility that the primary outcome rate with apixaban is >1.38 times higher than with warfarin. ARISTOTLE will determine whether apixaban is noninferior or superior to warfarin in preventing stroke and systemic embolism; whether apixaban has particular benefits in the warfarin-naïve population; whether it reduces the combined rate of stroke, systemic embolism, and death; and whether it impacts bleeding. (Am Heart J 2010;159:331-9.)

Atrial fibrillation (AF) is a growing public health problem worldwide and is the most common arrhythmia requiring hospitalization in the United States.[1] The incidence of AF has increased over the past 2 to 3 decades. The number of people with AF in the United States is projected to exceed 10 million by 2050[2]; this will be accompanied by substantial morbidity and mortality.[2,3] Stroke is considered to be the most significant morbidity in patients with AF. Approximately 15% of strokes occur in those with AF and the risk of stroke in untreated AF patients averages 5% per year.[3,4] The annual risk of stroke in AF patients is related to age, increasing from 1.5% for patients aged 50 to 59 years to 23% for those aged 80 to 89 years.[5] When compared with stroke from other causes, ischemic stroke secondary to AF carries twice the risk of death.[5]

Warfarin

Warfarin, a vitamin K antagonist (VKA), reduces the risk of stroke by approximately 62%[6]; however, VKAs have major limitations and are underused in clinical practice.[7] Patients are frequently outside the optimal target anticoagulation range when VKAs are prescribed, exposing them to the risk of thrombosis or bleeding.[8,9] Clinical trial data show that among patients receiving

warfarin or other VKAs, even in the highly structured setting of a trial, the international normalized ratio (INR) is outside the therapeutic range (2.0-3.0) about one third of the time.[10-13] Moreover, a meta-analysis shows that the proportion of time outside the therapeutic INR range in community practice is 43%.[11] Thus, a large number of patients with AF who should be on warfarin are either not deriving full benefit from warfarin or are not receiving it at all. Not only do VKAs have a narrow therapeutic window but they also exhibit a highly variable dose response that is attributable to genetic, disease-related, and environmental factors. Their dosing can be particularly challenging among elderly individuals due to changes in the pharmacokinetics and pharmacodynamics that occur with age. Other factors influencing drug effect include prescription and nonprescription drugs, dietary vitamin K, and botanical products.[14,15] The need for regular and lifelong therapeutic monitoring is an inconvenience for many patients. These limitations of VKAs illustrate the need for new oral anticoagulants for the prevention of thromboembolism in patients with AF.

Current guidelines, including those from the American College of Cardiology/American Heart Association/European Society of Cardiology, recommend a risk-based approach for antithrombotic therapy for stroke prevention.[16] Aspirin or VKAs are recommended for patients with AF who have one moderate risk factor for stroke ($CHADS_2$ risk score of 1), and VKAs are recommended for patients with more than one moderate risk factor ($CHADS_2$ risk score ≥ 2) for stroke.[16] Vitamin K antagonists are efficacious at preventing stroke even in the lower risk AF population[17]; however, their routine use is not currently recommended because the overall net benefit in this low-risk group is uncertain. Because the oral factor Xa inhibitors avoid many of the limitations of VKAs, it is important to evaluate these new agents across the spectrum of risk including patients with a low to intermediate risk of stroke.

Another important issue is that in patients starting warfarin for the first time, the risk of thromboembolism and bleeding is high for the first year due in part to the time taken to establish an adequate and stable INR. In one observational study, patients starting warfarin had a 3-fold increased risk of bleeding in the first 90 days of treatment[7] compared with patients already on warfarin.[7] The ACTIVE-W study showed that, in patients with AF at high risk of stroke, warfarin was superior to clopidogrel plus aspirin for prevention of vascular events.[18] Additional analyses also showed that the rates of discontinuation of warfarin therapy during the first year of the trial were higher (15%) in the warfarin-naïve patients when compared with the warfarin-experienced patients (8%).[19]

In antithrombotic therapy for the prevention of thromboembolism in patients with AF, there is a need for an alternative to warfarin that has greater efficacy, greater convenience of use, and/or greater safety. When compared with warfarin in the SPORTIF III and V trials, the oral direct thrombin inhibitor ximelagatran was found to be effective with an acceptable bleeding risk,[10,12] but its development was stopped due to liver toxicity. A number of new anticoagulants, including factor Xa inhibitors and direct thrombin inhibitors, are now being developed and evaluated as alternatives to warfarin for stroke prevention in AF. The ideal agent should be oral and free from variation in absorption related to food intake and should have predictable pharmacokinetics, few drug interactions, and minimal toxicity. It would not require therapeutic monitoring and its efficacy and safety would be comparable with or superior to warfarin at preventing thromboembolism in AF subjects.

Apixaban

Factor Xa occupies a pivotal role in the clotting cascade because it promotes conversion of prothrombin to thrombin. Developed as an anticoagulant agent, apixaban is an orally active selective inhibitor of the coagulation factor Xa. The direct mechanism of this drug does not require the presence of antithrombin. It has a predominantly nonrenal (75%) clearance and a half-life around 12 hours in healthy volunteers. The effect is independent of vitamin K intake, and with the exception of strong CYP3A4 inhibitors, there is minimal potential for drug-to-drug interaction. This compound has shown efficacy in preclinical animal models for venous and arterial thrombosis and has no organ-specific toxicity in animal models of up to 12 months of exposure.[20,21]

In a phase II dose-ranging study of deep vein thrombosis (DVT) prevention in patients undergoing knee replacement surgery, pooling of all doses of apixaban showed a 21% reduction in venous thromboembolism (VTE) or all-cause death when compared with enoxaparin and a 53% reduction in VTE or all-cause death when compared with warfarin.[22] Importantly, the frequency of major bleeding events was low (0%-3.3%) and comparable among all apixaban arms. A dose-ranging trial in DVT treatment including 520 patients with proximal DVT also showed favorable efficacy and safety, including the 5 mg twice a day apixaban dose arm.[23]

The ADVANCE-1 study, a phase III VTE prevention trial, compared apixaban, 2.5 mg, twice daily with the Food and Drug Administration-approved dose of enoxaparin (30 mg twice daily).[24] The primary efficacy outcome was a composite of symptomatic or asymptomatic DVT, pulmonary embolism, and death from any cause. In a preliminary analysis, the rate of the primary efficacy endpoint in the apixaban arm was similar to that observed with enoxaparin (9.0% vs 8.9%, $P = .64$). The major bleeding rate for apixaban, however, tended to be

lower than for enoxaparin (0.7% vs 1.4%, $P = .053$), and the composite rate of clinically relevant nonmajor bleeding and major bleeding was significantly lower in patients assigned to apixaban than those assigned to enoxaparin (2.9% vs 4.3%, $P = .034$).

APPRAISE was a phase II, randomized, double-blind, placebo-controlled, parallel arm study that enrolled 1,715 patients with acute coronary syndrome (ACS) from Europe and North America.[25] This study demonstrated that the addition of apixaban to current antiplatelet therapy for 6 months after ST elevation or non-ST elevation ACS results in a dose-dependent increase in bleeding and a trend toward a reduction in ischemic events. Based on these data, apixaban at a total daily dose of between 5 and 10 mg is being tested in patients with ACS receiving aspirin or dual antiplatelet therapy in the phase III trial APPRAISE 2.

These findings indicate that oral factor Xa inhibition at a dose of 5 to 10 mg daily may be an effective and safe approach toward anticoagulation. Based on the experience in DVT prevention and treatment trials, a dose of 5 mg twice a day of apixaban was chosen for comparison with warfarin for prevention of stroke and systemic embolism in patients with AF in the ARISTOTLE trial.

Study objectives

Primary objective

The primary objective of this study is to determine whether apixaban is noninferior to warfarin (INR target range 2.0-3.0) at reducing the combined outcome of stroke (ischemic or hemorrhagic) and systemic embolism in subjects with AF and at least 1 additional risk factor for stroke.

Secondary objectives

The key secondary objectives are to determine if apixaban is superior to warfarin for the combined endpoint of stroke (ischemic or hemorrhagic) and systemic embolism, and for all-cause death. These will be tested after the primary objective using a closed test procedure.

Other secondary objectives are to compare apixaban and warfarin with respect to:

- The composite endpoint of ischemic stroke, hemorrhagic stroke, systemic embolism, and all-cause death,
- The composite endpoint (in warfarin-naïve patients) of ischemic stroke, hemorrhagic stroke, systemic embolism and major bleeding,
- The composite endpoint of ischemic stroke, hemorrhagic stroke, systemic embolism, and major bleeding,
- The composite endpoint of ischemic stroke, hemorrhagic stroke, systemic embolism, major bleeding, and all-cause death,
- The composite endpoint of ischemic stroke, hemorrhagic stroke, systemic embolism, myocardial infarction, and all-cause death,
- Major bleeding

Table I. Inclusion and exclusion criteria

Inclusion criteria

Age ≥18 y
Permanent or persistent AF or atrial flutter on ECG at enrollment; or AF or atrial flutter documented by ECG or as an episode ≥1 min on rhythm strip, Holter monitor, or intracardiac recording on 2 separate occasions at least 2 wk apart in 12 mo before enrollment
One or more of the following risk factors for stroke
  Age ≥75 y
  Prior stroke, TIA, or systemic embolus
  Symptomatic CHF within 3 mo or LV dysfunction with LVEF ≤40% by echocardiography, radionuclide study, or contrast angiography
  Diabetes mellitus
  Hypertension requiring pharmacologic treatment
Women of childbearing potential must use contraception to avoid pregnancy during treatment period or for 2 wk after last dose of study medication, whichever is longer
All subjects must provide signed written informed consent

Exclusion criteria

AF or atrial flutter due to reversible causes (eg, thyrotoxicosis, pericarditis)
Clinically significant (moderate or severe) mitral stenosis
Increased bleeding risk believed to be a contraindication to oral anticoagulation (eg, previous intracranial hemorrhage)
Conditions other than AF that require chronic anticoagulation (eg, prosthetic mechanical heart valve)
Persistent uncontrolled hypertension (SBP >180 mm Hg or DBP >100 mm Hg)
Active infective endocarditis
Planned major surgery
Planned AF or atrial flutter ablation procedure
Use of unapproved investigational drug or device in past 30 d
Required aspirin >165 mg/d
Simultaneous treatment with both aspirin and a thienopyridine (eg, clopidogrel, ticlopidine)
Severe comorbid condition with life expectancy ≤1 y
Active alcohol or drug abuse or psychosocial reasons that make study participation impractical
Recent stroke (within 7 d)
Severe renal insufficiency (serum creatinine level >2.5 mg/dL or calculated creatinine clearance <25 mL/min)
ALT or AST >2 × ULN or a total bilirubin ≥1.5 × ULN (unless an alternative causative factor [eg, Gilbert's syndrome] is identified)
Platelet count ≤100,000/mm^3
Hemoglobin level <9 g/dL
Inability to comply with INR monitoring

ECG, Electrocardiogram; *CHF*, congestive heart failure; *LV*, left ventricular; *LVEF*, left ventricular ejection fraction; *SBP*, systolic blood pressure; *DBP*, diastolic blood pressure; ALT, alanine transaminase; AST, aspartate transaminase; *ULN*, upper limit of normal; *wk*, weeks; *mo*, months.

Study population

In this double-blind study, we have randomized 18,206 patients with AF from over 1,000 centers in about 40 countries. Eligible subjects were randomly assigned in a 1:1 ratio to receive either apixaban or warfarin titrated to a target INR range of 2.0 to 3.0. Both warfarin-naïve and warfarin-experienced patients are being recruited, with a

special emphasis on the former. Our aim is for 40% of patients to be warfarin naïve. The inclusion and exclusion criteria are summarized in Table I.

Randomization and study drug

Subjects who were on warfarin before randomization discontinued the drug 72 hours before randomization and were not dosed with study drug until the INR was <2.0. Randomization is stratified by investigative site and prior warfarin use status (experienced or naïve). Patients are classified as warfarin naïve if they have never used warfarin (or other VKAs) or if they have used it for ≤30 consecutive days. Otherwise, patients are considered warfarin experienced.

To maintain blinding, study medications are packaged using a double-dummy design. The 2 sets of tablets each subject receives are distinguishable by color and size, but active apixaban tablets match placebo apixaban tablets and active warfarin tablets match placebo warfarin tablets to ensure blinding of the patient and investigator. After randomization, patients receive either apixaban and warfarin placebo or apixaban placebo and warfarin. During the titration phase, we recommend the use of a dosing algorithm with initial daily dose of up to 6 mg of warfarin (or warfarin placebo) (unless already on a stable dose of warfarin, in which case that may be continued) and dose of apixaban (or apixaban placebo) of 5 mg twice a day. For patients who are estimated to have higher apixaban drug exposure, we will use a lower dose of 2.5 mg twice a day of apixaban. Subjects who fulfill any 2 of the following criteria at baseline will receive the lower apixaban dose of 2.5 mg twice a day: age ≥80 years, body weight ≤60 kg, and serum creatinine level ≥1.5 mg/dL (133 μmol/L). Subsequent warfarin doses are recommended based upon an algorithm provided to the investigators; however, the final dose decision is left to the discretion of the investigator. Subjects, investigators, members of the steering and adjudication committees, and the sponsor's staff conducting the study do not have access to individual subject treatment assignments.

Study design and duration

The trial is event driven, thus, the number of subjects required and length of treatment were estimated based on event rates in similar trials. The final duration of the trial will be determined by the time required to accrue at least 448 primary efficacy events (see statistical methods). All subjects will be followed from randomization until the study end date.

The study includes a screening period of up to 14 days. Subjects with AF and at least ≥1 risk factors for stroke will be evaluated for study eligibility. The design of the study is shown in Figure 1.

INR monitoring

The INR monitoring for the warfarin-naïve patients begins on the fourth day after initiation of study drug and is performed twice a week for 2 weeks, once a week for 2 weeks, and monthly thereafter once a stable INR is attained. For the warfarin-experienced patients who have been on stable dosing of VKA for at least 3 months, INR monitoring visits are required on day 1, week 1, week 2, and then monthly. An investigator may increase the frequency of INR monitoring if it is considered clinically indicated.

Titration of the study drug is based on central monitoring of INR measurements using encrypted point-of-care (POC) devices, centralized dosing recommendations, and sham apixaban titration. The POC device delivers an encrypted result to the investigator who telephones or electronically transmits the result along with the subject's identification number, date, and time to a central response system. This system processes the information in a blinded manner and returns either a true INR value (if a subject is receiving warfarin) or a sham INR value (if a subject is receiving apixaban). Although investigators will need to obtain open label INR values when clinically indicated, efforts will be made to minimize nonstudy INR assessments. The final dosing decision rests with the investigator. Assessments of outcomes and study medication compliance are performed at each INR visit.

Follow-up

The follow-up period will last until the attainment of at least 448 primary study events. Follow-up of subjects who discontinue study drug will occur quarterly until the end of the study.

Outcome definitions

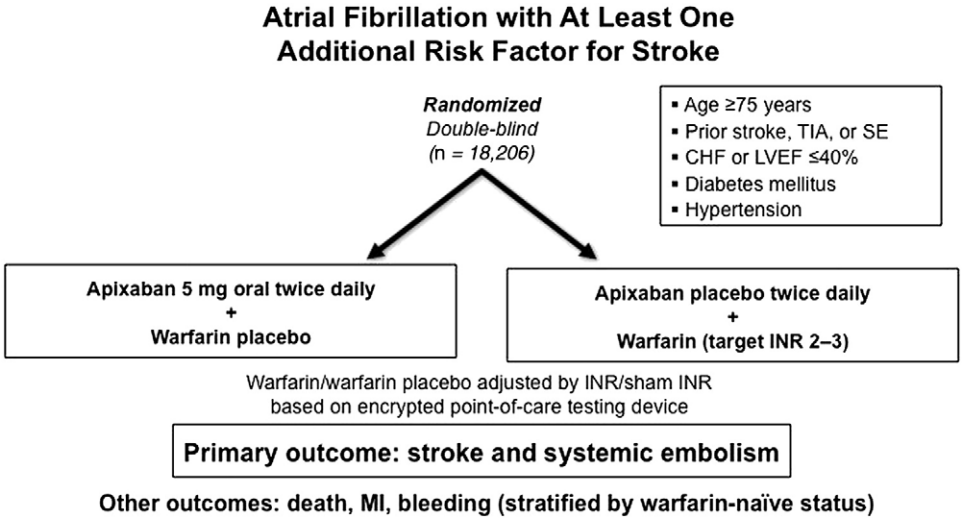
Efficacy outcomes

The primary efficacy outcome is the time to first occurrence of stroke (ischemic or hemorrhagic) or systemic embolism.

In this study, stroke is defined as a nontraumatic abrupt onset of a focal neurologic deficit lasting at least 24 hours. A retinal ischemic event (embolism or thrombosis) will be considered a stroke. A cerebral imaging study (computed tomographic scan or magnetic resonance imaging) is recommended for all suspected strokes. Strokes will be classified as ischemic, ischemic with hemorrhagic transformation, hemorrhagic, or of uncertain type. Hemorrhagic strokes will be subclassified as subdural, subarachnoid, or intraparenchymal.

A transient ischemic attack (TIA) is defined as a nontraumatic abrupt onset of a focal neurologic deficit lasting <24 hours. Stroke and TIA will be further subclassified based on whether there is imaging evidence of a new cerebral infarction that correlates with the clinical presentation of the subject.

Figure 1



Study design.

The diagnosis of systemic embolism requires a clinical history consistent with an acute loss of blood flow to a peripheral artery (or arteries) supported by evidence of embolism from surgical specimens, autopsy, angiography, vascular imaging, or other objective testing.

Safety outcomes

The primary safety endpoint is time to first occurrence of confirmed major bleeding.

The definition of major bleeding described below is adapted from the protocol and the International Society on Thrombosis and Hemostasis definition. The baseline hemoglobin level is defined as the closest hemoglobin level value before the bleeding event.

Major bleeding is defined as acute or subacute clinically overt bleeding accompanied by ≥1 of the following: (1) a decrease in hemoglobin level of ≥2 g/dL over a 24-hour period; (2) a transfusion of ≥2 U of packed red blood cells; and/or (3) bleeding that is fatal or occurs in at least 1 of the following critical sites: intracranial, intraspinal, intraocular, pericardial, intraarticular, intramuscular with compartment syndrome, retroperitoneal.

Clinically relevant nonmajor bleeding is defined as acute or subacute clinically overt bleeding that does not satisfy the criteria for major bleeding and leads to hospital admission for bleeding, physician-guided medical or surgical treatment for bleeding, or a change in antithrombotic therapy (including study drug) for bleeding.

All acute clinically overt bleeding events not meeting the criteria for either major bleeding or clinically relevant nonmajor bleeding are classified as minor bleeding. Bleeding events are also classified by the TIMI[26] and GUSTO criteria.[27]

The secondary safety outcome for this trial is a composite of major bleeding and clinically relevant nonmajor bleeding. Other safety outcome measures include minor bleeding, fractures, and other adverse events.

Clinical Events Committee adjudication

An independent, blinded, clinical events committee (CEC) adjudicates all suspected hemorrhagic and nonhemorrhagic strokes, TIAs, systemic emboli, major and clinically relevant non-major bleeding, myocardial infarction, and cause of death.

Using prespecified event definitions and agreed upon event adjudication criteria, the CEC adjudicates suspected events based on the preponderance of the evidence and the clinical knowledge and experience of the physician reviewers. Event adjudication in ARISTOTLE occurs in 2 phases. All suspected events are adjudicated in phase I. Each stroke, systemic embolism, and bleeding event are reviewed by 2 independent physician reviewers. Each myocardial infarction and death event are reviewed by 1 reviewer. Significant disagreements between phase I reviewers for stroke, systemic embolism, and bleeding cases are identified as needing phase II review. In addition, a quality control sample undergoes phase II review. All phase II reviews are conducted by committee with the final adjudicated result being a consensus of the committee members present. In both phase I and phase II reviews, all stroke events are evaluated by at least 1 neurologist.

Statistical analysis and sample size calculation

A meta-analysis of 6 AF studies estimated a relative reduction in the risk of stroke or systemic thromboembolism of 62% for warfarin versus placebo.[6] Based on historical trials, the primary noninferiority hypothesis of ARISTOTLE is that apixaban will preserve at least 50% of the benefit of warfarin in preventing stroke and systemic embolism. This gives an upper CI of 1.88 of the apixaban versus warfarin relative risk (Figure 2*A*). To be more certain that apixaban is noninferior to warfarin based on this single clinical trial, more stringent boundaries are defined. In response to different international regulatory bodies, 2 noninferiority tests will be applied. First, the 95% CI should not include ≥1.38 to declare noninferiority (Figure 2*B*). In addition, the 99% CI should not include ≥1.44 to declare noninferiority. Because the event rate is lower than initially expected, it is estimated that approximately 18,000 randomized patients with sufficient risk of stroke and sufficient treatment duration will result in 448 patients with primary outcome events needed for 90% power to meet the primary objective of the study. We originally estimated that the follow-up would be an average of 1.8 years, assuming a stroke or systemic embolism rate of 1.67 per 100 subject-years.

An independent Data Monitoring Committee is charged with monitoring the accumulating trial data. A formal interim analysis will be performed once 50% of the primary efficacy endpoint events have been confirmed by the CEC. The objective of this interim analysis is to determine whether apixaban is superior to warfarin for the primary efficacy endpoint. No interim testing for noninferiority will be performed.

Pharmacokinetic biomarkers

The main objectives of the biomarker and genetic substudy program are to correlate genetic polymorphisms and levels of biomarkers with clinical outcomes, to improve risk stratification for stroke among patients with AF, and to relate the effects of apixaban and warfarin to these disease biomarkers. Several biomarkers will be analyzed at baseline for as many of the 18,206 patients as possible (Table II), and a second blood sample will be collected for approximately 5,000 patients at 2 months. This will allow the analysis of changes in biomarker levels.

Organizational structure

The ARISTOTLE trial is led by an academic steering committee composed of 2 cochairs, national coordinators from each participating country, and a representative from the trial sponsor. This committee provides scientific direction and input, addresses policy issues regarding the protocol, and meets periodically to assess the trial progress.

The ARISTOTLE executive committee, composed of a subset of senior leaders from the steering committee, is responsible for evaluating the progress and safety of the trial and making decisions regarding early termination or continuation of the trial.

A subset of the steering committee will form the publications committee that will oversee the publication

Figure 2

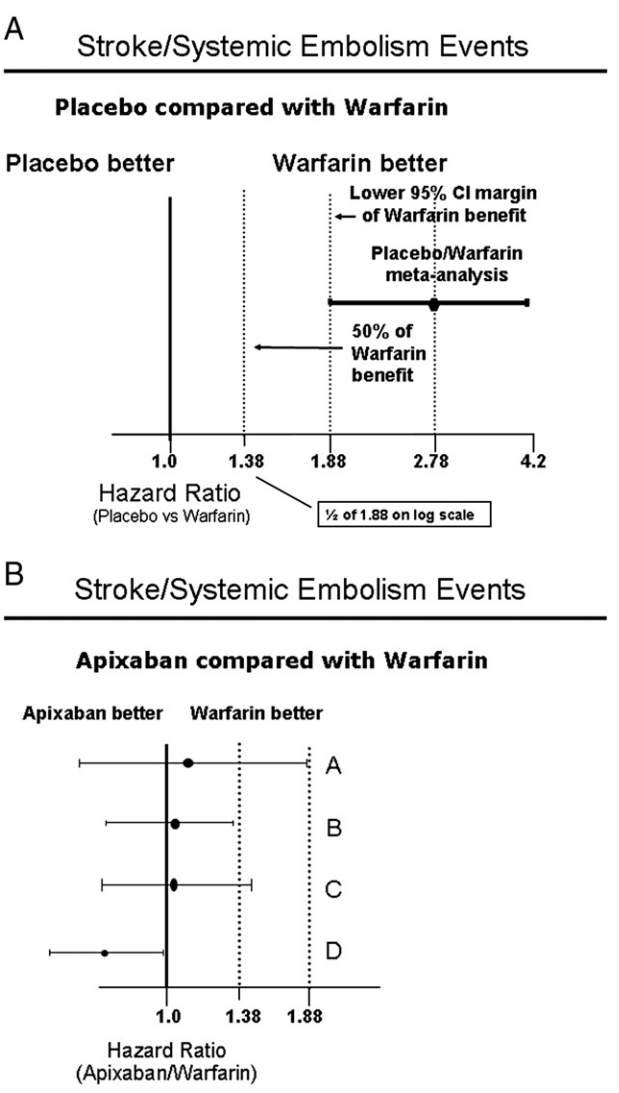


Illustration and interpretation of noninferiority boundaries for warfarin comparator AF trials. **A**, Noninferiority boundaries for warfarin comparator AF trials. **B**, Apixaban preserves some benefit (A), apixaban preserves >50% of warfarin benefit (B), apixaban preserves more than about 40% of warfarin benefit (C), and apixaban is superior to warfarin (D).

Table II. Biomarkers

Biomarkers	Area	Characteristic
hs-Troponin I	Myocardial necrosis, myocardial function	Strong predictor for raised mortality in ACS and in healthy elderly
NT-proBNP	Myocardial necrosis, myocardial function	↑ in patients with AF; high level indicates increased risk for thromboembolism
ADMA	Endothelial function	↑ in patients with vascular disease
vWF	Endothelial function	↑ levels in AF patients; predictor for vascular events
hs-CRP, IL-6	Inflammation	Associated with AF and risk of future CV events in healthy individuals
Soluble CD40 ligand	Platelet activity	↑ levels related to inflammatory activity, coagulation, and platelet activation
Fragment 1+2	Coagulation	↑ in patients with AF and related to risk factors for stroke; reduced with warfarin treatment
D-dimer	Coagulation	↑ in patients with AF and associated with new thrombotic events; reduced with warfarin treatment
Cystatine C	Renal function	↑ in patients with reduced renal function; poorer prognosis in patients with CV disease; better marker for endogenous GFR than creatinine clearance
HbA1C, Apo A, Apo B	Metabolism and lipoproteins	Lipoproteins and diabetes mellitus risk factors for CV disease; diabetes mellitus predictor of an increased risk for complications

BNP, Brain natriuretic peptide; *CV*, cardiovascular; *GFR*, glomerular filtration rate.

process for the main manuscript and all secondary presentations and manuscripts resulting from the trial.

The ARISTOTLE Trial is sponsored and funded by Bristol-Myers Squibb (Princeton, NJ, USA) and Pfizer (New York, NY, USA).

Discussion

Atrial fibrillation is a very common arrhythmia and is associated with an increased risk of mortality and morbidity, particularly stroke, which is the third most common cause of death in developed countries and the leading cause of serious long-term disability worldwide.[28]

The ACTIVE-W study included 6,706 patients with AF and at least ≥1 risk factors for stroke.[18] ACTIVE-W was designed to compare oral anticoagulation therapy with aspirin plus clopidogrel for prevention of vascular events in patients with AF at high risk for stroke. This study was not blinded. Moreover, there was no requirement for a certain proportion of warfarin-naïve patients. At study entry, approximately 76% of the patients were on warfarin. The study was stopped early because of the superiority of warfarin over aspirin plus clopidogrel for prevention of vascular events in patients with AF. These results were driven by the higher rates of stroke on clopidogrel plus aspirin.

Several oral direct thrombin inhibitors are being tested for stroke prevention in patients with AF such as ximelagatran and dabigatran.[29] This class of drug has a wider therapeutic range than warfarin, low potential for food and drug interactions, and no requirements for dose adjustments or regular monitoring. The SPORTIF III and V trials involving 3,407 and 3,922 patients, respectively, showed no difference in stroke prevention between ximelagatran and warfarin.[10,12] However, there was a significant increase in the level of liver enzymes in patients on ximelagatran. Moreover, major adverse cardiovascular events were observed in other studies,[30,31] and the drug was withdrawn from all markets in 2006. In addition, there was an unexplained higher rate of major bleeding in SPORTIF V when compared with SPORTIF III. Recently the RE-LY open label trial reported the results comparing 110 mg twice daily and 150 mg twice daily of the oral thrombin inhibitor dabigatran versus warfarin in 18,113 AF paitents with at least one risk factor for stroke. In this study dabigatran 150 mg twice daily was superior and 110 mg twice daily noninferior concerning stroke while simultaneously both doses reduced intracranial and life-threatening hemorrhage.[32] Therefore, there is now a larger focus on testing for potential superiority of apixaban over warfarin in the current trial.

Other phase III trials are testing inhibitors of factor Xa for stroke prevention in patients with AF. ROCKET-AF is comparing warfarin with rivaroxaban in a double-blind trial of 14,000 patients with AF at high risk for stroke.[33] AVERROES is another double-blind trial of apixaban in comparison with aspirin in 5,600 patients with AF and moderate risk of stroke or intolerance to warfarin.[34] BOREALIS-AF is testing subcutaneous weekly injections of biotinylated idraparinux, a subcutaneous indirect factor Xa inhibitor, in patients with AF and high risk of stroke.[35] This trial is designed as a double-blind comparison of idraparinux with warfarin in 9,600 patients.

ARISTOTLE will define whether apixaban is noninferior or/and superior to warfarin in the overall population and whether it may be superior solely in the warfarin-naïve population, which is more susceptible to complications until a stable warfarin dose has been established and more prone to warfarin discontinuation.

Important features of the ARISTOTLE trial include the investigation of a drug with a relatively long half-life and robust phase II to III data on safety and efficacy of the tested dose for DVT prophylaxis, the double-blind design with use of encrypted POC INR monitoring devices, good representation of warfarin-naïve patients, inclusion of the full risk-spectrum of patients ($CHADS_2$ score ≥1),

multinational representation of various health care systems and ethnic groups, and modification of dose of the study drug for patients with the highest drug exposure (2 criteria of older age, renal insufficiency, or low body weight). In ARISTOTLE, the protocol provides guidance on management of bleeding. Most bleeding can be managed by discontinuation of antithrombotic therapy (including study medication), local hemostatic measures, and fresh frozen plasma as needed. Patients with ongoing serious or life-threatening bleeding may require unblinding to guide reversal with vitamin K, and consideration of use of prothrombin complex concentrate, if on warfarin. For patients on apixaban, reversal of the anticoagulant effects will occur relatively rapidly over time given its half-life of around 12 hours. Apixaban has no specific antidote or reversal agent. Other agents, such as recombinant activated factor VII (NovoSeven, Novo Nordisk A/S, Bagsvaerd, Denmark), have not been studied in this setting and are not recommended.

Conclusion

In conclusion, the ARISTOTLE trial will answer many important questions related to stroke prevention in AF. Most importantly, it will compare apixaban with warfarin for stroke prevention in a wide range of patients with AF. It will provide information about the efficacy of apixaban both in warfarin-experienced and warfarin-naïve patients. Finally, it will generate a better understanding of this common disease and the risks of stroke and bleeding based on large scale substudies on genetic and protein biomarkers.

ABSTRACT

Associations between life course socioeconomic position (SEP) and novel biological risk markers for coronary heart disease such as inflammatory markers are not well understood. Most studies demonstrate inverse associations of life course SEP with C-reactive protein (CRP), interleukin-6 (IL-6) and fibrinogen, however little is known about associations between life course SEP and other inflammatory markers including intercellular adhesion molecule-1 (ICAM-1), tumor necrosis factor II (TNFR2), lipoprotein phospholipase A_2 (Lp-PLA_2) activity, monocyte chemoattractant protein-1 (MCP-1) or P-selectin. The objectives of this analysis were to determine whether three life course SEP frameworks ("accumulation of risk", "social mobility" and "sensitive periods") are associated with the aforementioned inflammatory markers. We examined 1413 Framingham Offspring Study participants (mean age 61.2 ± 8.6 years, 54% women), using multivariable regression analyses. In age- and sex-adjusted regression analyses, cumulative SEP ("accumulation of risk" SEP framework), for low vs. high SEP, was inversely associated with CRP, IL-6, ICAM-1, TNFR2, Lp-PLA_2 activity, MCP-1 and fibrinogen. We found that there were few consistent trends between social mobility trajectories and most inflammatory markers. Own educational attainment was inversely associated with 7 of 8 studied inflammatory markers, while father's education, father's occupation and own occupation were inversely associated with 4, 5 and 4 inflammatory markers, respectively, in age- and sex-adjusted analyses. The strengths of association between SEP and inflammatory markers were typically substantially accounted for by CHD risk markers (smoking, body mass index, systolic blood pressure, total:HDL cholesterol ratio, fasting glucose, medications, depressive symptomatology) suggesting these may be important mechanisms that explain associations between SEP and the studied inflammatory markers.

Introduction

Socioeconomic disparities in coronary heart disease (CHD) exist in many developed countries, where people of lower childhood or adulthood socioeconomic position (SEP) typically have higher risk for incident CHD (Galobardes, Smith, & Lynch, 2006; Gonzalez, Rodriguez Artalejo, & Calero, 1998). There is interest in investigating whether biological risk markers for CHD are related to life course SEP, as a way to evaluate if there is mechanistic evidence consistent with the inverse associations found between SEP and CHD in observational studies. Extensive progress has been made in recent decades on the

☆ The Framingham Heart Study is supported by National Institutes of Health/National Heart, Lung and Blood Institute contract N01-HC-25195. The research was supported by Canadian Institutes of Health operating grant MOP81239 (EBL), National Institutes of Health grants HL064753, HL076784, AG028321 (EJB), and a Canadian Institutes of Health New Investigator Award (EBL). We are grateful to the National Heart, Lung and Blood Institute for providing us with the limited access dataset, in conjunction with Framingham Heart Study investigators who provided other important variables for analyses.

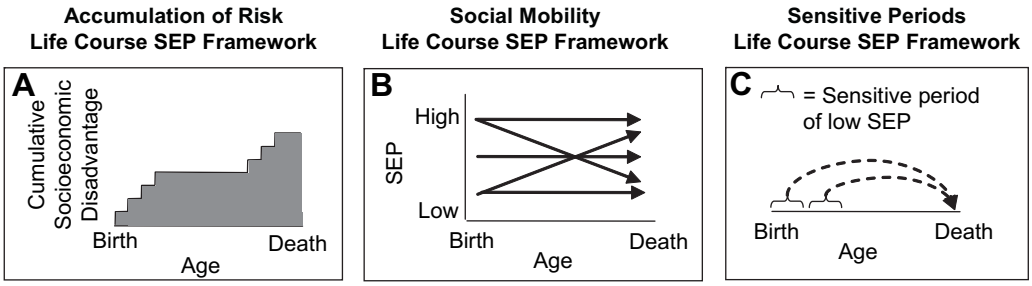

Fig. 1. Conceptual frameworks for three different frameworks to conceptualize socioeconomic position (SEP) across the life course: (A) Accumulation of Risk, (B) Social Mobility, and (C) Sensitive Periods.

involvement of inflammatory processes in atherosclerosis and subsequent risk for CHD, however little is known about associations between life course SEP and many inflammatory markers. Below we introduce major frameworks by which life course SEP is conceptualized, as well as evidence on roles of several inflammatory markers in specific atherosclerotic processes, leading to gaps in knowledge between life course SEP and inflammatory markers.

Galobardes et al. defined several phases for life course SEP including childhood SEP (e.g., parent's education or parent's occupation), young adulthood SEP (e.g., educational attainment), active professional life SEP (e.g., occupation or income), and retirement SEP (e.g., wealth or household conditions) (Galobardes, Shaw, Lawlor, Lynch, & Davey Smith, 2006). A number of frameworks to conceptualize life course SEP have been hypothesized (Fig. 1), including the "accumulation of risk" framework (which focuses on the total cumulative amount of exposure to SEP across the life course), the "social mobility" framework, which recognizes that people have evolving (e.g., increasing, decreasing or stable) SEP across their life span, and the "sensitive periods" framework which suggests that there are certain time periods in the life course when an exposure may have a stronger effect on disease risk than it would during other phases in life (Kuh & Ben-Shlomo, 2004; Kuh, Ben-Shlomo, Lynch, Hallqvist, & Power, 2003).

Novel risk markers for CHD include inflammatory markers. Substantial evidence suggests there is an important inflammatory component in the pathogenesis of atherosclerosis and the pathophysiology is becoming better understood (Libby, 2006). Several inflammatory markers are inversely associated with CHD, including interleukin-6 (IL-6) (Cesari et al., 2003), monocyte chemoattractant protein-1 (MCP-1) (de Lemos et al., 2003), tumor necrosis factor-α (TNF-α) (often measured as soluble tumor necrosis factor receptor II (TNFR2)) (Pai et al., 2004), C-reactive protein (CRP) (Danesh et al., 2004; Ridker et al., 2005), fibrinogen (Keavney et al., 2006), ICAM-1 (Malik et al., 2001), P-selectin (Armstrong, Morrow, & Sabatine, 2006) and lipoprotein-associated phospholipase A_2 (Lp-PLA_2) (Garza et al., 2007). Whether these inflammatory markers are causally related to CHD, rather than simply predictive of CHD, is still under investigation (Elliott et al., 2009; Keavney et al., 2006).

With regard to associations between life course SEP and inflammatory markers, most studies demonstrate inverse associations of life course SEP with CRP, IL-6, fibrinogen and white blood cell count (Brunner et al., 1996; Gimeno et al., 2007, 2008; Koster et al., 2006; Lawlor, Smith, Rumley, Lowe, & Ebrahim, 2005; Loucks et al., 2006; Nazmi & Victora, 2007; Pollitt et al., 2007, 2008; Tabassum et al., 2008), however little is known about associations between life course SEP and other inflammatory markers including TNFR2, MCP-1, ICAM-1, P-selectin and Lp-PLA_2.

The objectives of this study were to determine whether three life course SEP frameworks (i.e., "accumulation of risk", "social mobility", and "sensitive periods" SEP frameworks) are associated with several markers representing diverse inflammatory pathways and processes, including CRP, IL-6, ICAM-1, P-selectin, TNFR2, Lp-PLA_2 activity, MCP-1 and fibrinogen. Further objectives were to evaluate whether CHD risk markers (including smoking, body mass index, systolic blood pressure, total:HDL cholesterol ratio, fasting glucose, cholesterol-lowering medication use, anti-hypertensive medication use and depressive symptomatology) may be explanatory mechanisms for any observed associations between life course SEP and inflammatory markers. It should be emphasized, as discussed by Hallqvist et al. that it is likely not possible to critically test individual contributions of accumulation of risk *vs.* social mobility *vs.* sensitive periods due to mutual confounding between the three SEP frameworks (Hallqvist, Lynch, Bartley, Lang, & Blane, 2004). Consequently, we do not propose to statistically compare the contributions of each of these SEP frameworks to each other. As triangulation of methodological approaches enables a more thorough understanding of health determinants, we utilized the three life course SEP framework to offer three approaches to evaluate the potential association of life course SEP with inflammatory markers. Utilizing information from all three SEP frameworks will provide a more complete picture of life course SEP determinants of inflammatory markers than if findings were presented on only one of the life course SEP frameworks.

Materials and methods

Study sample

The Framingham Heart Study is a community-based observational cohort that was initiated in 1948. The Framingham Offspring Study began in 1971 with recruitment of 5124 men and women who were offspring (or offspring's spouses) of the Original Framingham Heart Study participants. The design and selection criteria of the Framingham Offspring Study have been described elsewhere (Kannel, Feinleib, McNamara, Garrison, & Castelli, 1979). All study participants received routine medical history and physical examinations, laboratory assessments of cardiovascular risk factors, and anthropometric measurements approximately every 3–4 years. Framingham participants signed informed consent and the Framingham Study is reviewed annually by the Boston University Medical Center Institutional Review Board.

Father's education was measured directly from fathers in the Original Cohort of the Framingham Heart Study. All other variables were measured in the Offspring Cohort. Own occupation was measured in Offspring Examination 2 (1979–1982) and Examination 7 (1998–2001). Own education was measured in Examination 2 and Examination 3 (1984–1987). Inflammatory markers and covariates were measured during Examination 7. There were 3475 Framingham Offspring Study participants in the National Heart, Lung and Blood Institute (NHLBI) data repository dataset who completed Examination 7. Of these, 1451 participants did not have fathers in the Original Framingham Study (362 participants had

only a mother in the Original Cohort, and 1089 participants were spouses of participants in the Offspring Cohort and had no father in the Original Cohort) from which measures of father's education were directly obtained. In order to be eligible for the Framingham Offspring study, participants needed to be offspring of a male or female Original Framingham Study participant, or a spouse of the offspring. An additional 78 participants had fathers who were missing the education variable. A further 180 participants were missing own education or occupation variables. We further restricted the participants to those ≥28 years when education and occupation were measured, resulting in 97 participants being excluded. Restricting participants to ≥28 years was done in order to allow at least 10 years from expected graduation of high school to obtain further education and become established in an occupational category. An additional 94 subjects with prevalent CVD were excluded, resulting in 1575 participants. Of these, the number of participants missing inflammatory marker variables were as follows: CRP: 62; P-selectin: 63; ICAM-1: 66; MCP-1: 99; interleukin-6: 65; TNFR2: 103; and Lp-PLA_2 activity: 64. As CRP is the most widely recognized inflammatory marker to date with regard to being a potential risk marker for CHD, analyses report sample sizes for CRP analyses ($n = 1513$).

Analyses on excluded versus included participants found that excluded and included participants were similar with regard to smoking, body mass index, fasting glucose, IL-6, TNFR, Lp-PLA_2 activity, P-selectin, fibrinogen, cholesterol-lowering medication use, and depressive symptomatology. Excluded participants were more likely to be older ($p < 0.001$), have higher systolic blood pressure ($p = 0.001$), CRP ($p = 0.008$), ICAM-1 ($p = 0.001$), MCP-1 ($p = 0.005$), and lower total:HDL cholesterol ratio ($p = 0.04$), compared with included participants. Furthermore, excluded participants were more likely than included participants to be taking anti-hypertensive medication ($p = 0.006$), have ≤high school education ($p < 0.0001$), have a manual occupation ($p = 0.001$), and have fathers with ≥high school education ($p = 0.009$).

Independent variables

Childhood SEP (father's education and father's occupation)

Childhood SEP was measured in primary analyses by father's educational attainment, obtained directly from Offspring cohort participants' fathers who were enrolled in the Original Framingham Heart Study. Father's educational level was measured at enrollment between 1948 and 1950 when their mean age was 44 years (range: 28–62), categorized into 3 groups: <high school ($n = 799$), high school ($n = 418$) and >high school ($n = 452$). Sensitivity analyses used father's occupation measured during Original Framingham Heart Study Examination 6 where all participants were greater than age 28 years. Father's occupation was categorized identically to Offspring occupation described below.

Young adulthood SEP (own educational attainment)

Own education was measured directly from Framingham Offspring Study participants at Examination 3 (1984–1987); if Examination 3 education was missing, then Examination 2 assessment (1979–1982) was used ($n = 197$). Education was categorized into 3 groups: ≤12 ($n = 612$), 13–16 ($n = 719$) and ≥17 ($n = 338$) years education. Pearson's correlation coefficient for associations between educational attainment at Examination 2 and Examination 3 was 0.89.

Active professional life SEP (own occupation)

Own occupation was measured from Offspring participants at Examination 7 (age range: 41–81 years). If participants were coded as missing, retired, unemployed, or housewife in Examination 7, then occupation from Examination 2 (1979–1982) was used ($n = 685$; age range: 28–67 years; mean age: 47.7 years). Those who were missing occupation at Examinations 2 and 7 were excluded from analyses. No participants were coded as retired or unemployed at both exams 2 and 7. Thus, 984 had occupation data from Examination 7, and the remaining 685 participants utilized occupation data from Examination 2. Included participants were age ≥28 years at the time of occupation assessment in order to allow at least 10 years between typical age of high school graduation to complete education and obtain an occupation. Occupation was categorized as laborer ($n = 306$), clerical/sales ($n = 203$), housewife ($n = 375$), technical/supervisor ($n = 195$), and executive/professional ($n = 590$). These occupation categorizations were broadened to only two or three categories for analyses, as detailed in the SEP Frameworks section below. Some misclassification of occupation is expected due to the wide age range for when it was measured, as described in more detail in the Discussion section.

SEP frameworks

Analyses that used an **accumulation of risk** framework used a cumulative SEP score (range: 0–6) including father's education (<high school = 0, high school = 1, >high school = 2), own education (≤12 years = 0, 13–16 years = 1, ≥17 years = 2) and own occupation (laborer = 0, clerical/sales/housewife = 1, executive/professional/supervisory/technical = 2). Higher cutpoints were used for own educational categories, compared with father's (i.e., own education categorized as: ≤12, 13–16 and ≥17 years education; father's education categorized as: <high school, high school and >high school) to account for secular trends of increased normative levels of education across generations. Analyses that used a **social mobility** framework utilized dichotomous categories of father's education (lower: <high school, higher: ≥high school) and own occupation (lower: laborer, higher: housewife/clerical/sales/supervisory/technical/professional/executive). Analyses tested the association of four possible types of social mobility across the life course: stable high SEP (high childhood and adulthood SEP), decreasing SEP (high childhood SEP and low adulthood SEP), increasing SEP (low childhood SEP and high adulthood SEP), and stable low SEP (low childhood and adulthood SEP). Using the occupation categorizations described above, we expect there will be SEP misclassification, however given the large variety of occupations in society, and the contributing factors to occupation-based SEP (such as income and social prestige), this appeared to be an acceptable approximation of occupation-based SEP that took into account factors such as income, social prestige and educational requirements. Analyses assessing the **sensitive periods** framework assessed associations between each individual SEP measure (i.e., father's education, own education, own occupation) and inflammatory marker concentrations, further adjusting for all SEP measures other than the independent SEP variable.

Dependent variables

Inflammatory markers were measured during Examination 7 (1998–2001). Fasting morning serum samples were collected then stored at −80 °C. Serum CRP was measured once using a high-sensitivity assay (Dade Behring BN100 nephelometer, Deerfield, IL; inter-assay CV 3.2%). IL-6, ICAM-1, TNFR2, MCP-1, and P-selectin concentrations were measured in duplicate and averaged using commercially-available Enzyme-Linked Immunoassay kits (R&D Systems, Minneapolis, MN) following previously described quality control procedures (Keaney et al., 2003, 2004). Lp-PLA_2 activity was measured by DiaDexus, Inc., San Francisco, CA. Biomarker measurement reproducibility was good (intra-assay coefficients of

variation for IL-6, 3.1%; ICAM-1, 3.7%; TNFR2, 2.2%; MCP-1, 3.8%; P-selectin, 3.0%, Lp-PLA$_2$ activity, 4.3%).

Covariates

CHD risk markers were measured at Examination 7 (1998–2001). Current cigarette smoking was determined by self-report if it occurred regularly in the past year. Systolic blood pressure was calculated as the average of the clinic physician's two seated systolic blood pressure measurements. Body mass index was calculated as the weight in kilograms divided by the square of the height in meters (kg/m^2). Fasting glucose was measured with a hexokinase reagent kit (A-gent glucose test, Abbott, South Pasadena, California); intra-assay coefficients of variation ranged from 2% to 3%. High density lipoprotein and total cholesterol concentrations were measured by automated enzymatic techniques (McNamara & Schaefer, 1987). Depressive symptomatology was measured using the Center for Epidemiologic Studies Depression (CES-D) scale, and was analyzed as a continuous variable. Medication use was classified by self-report.

Statistical analysis

Sex- and age-standardized descriptive statistics (means and proportions) were generated for CHD risk factors (systolic blood pressure, total:HDL cholesterol ratio, fasting glucose, body mass index, smoking and anti-hypertensive medication use) and prevalent CVD, according to cumulative SEP score.

Due to non-normality in the distributions, the inflammatory markers were natural log-transformed. Age- and sex-adjusted mean inflammatory marker concentrations were obtained using linear regression on natural log-transformed variables, then back-transformed to obtain estimates of the mean concentrations.

Multivariable regression analyses evaluated associations of life course SEP with log-transformed inflammatory marker concentrations. Analyses adjusted for potential confounders including age and sex, as well as CHD risk markers including smoking, body mass index, systolic blood pressure, total:HDL cholesterol ratio, fasting glucose, cholesterol-lowering medication use, anti-hypertensive medication use and depressive symptomatology. The three SEP variables (father's education, own education and own occupation) were not correlated highly enough to be of concern to simultaneously adjust for all three in a single multivariable model (correlation coefficients ranged from 0.27 to 0.51). Consequently, all three measures of SEP were simultaneously adjusted for in analyses testing the sensitive periods framework. Generalized Estimating Equations (GEE) were used to account for clustering of outcomes by family. There were 1051 clusters, with the minimum cluster size of 1 (indicating these participants are not part of a cluster) and maximum cluster size of 6. There was no evidence of effect modification by sex, consequently sexes were pooled. Analyses were conducted using the statistical program SAS version 9.1(SAS Institute, Cary, NC).

Results

Fifty-four percent of participants were women, and the mean age was 61.2 (8.6 SD) years. Higher cumulative SEP levels were associated with more favorable cardiovascular risk factors including smoking, body mass index, systolic blood pressure, fasting glucose, cholesterol-lowering medications, anti-hypertensive medications, and depressive symptomatology in age- and sex-adjusted analyses (Table 1). There were no associations between cumulative SEP score and total:HDL cholesterol ratio. Those with a low cumulative SEP score (0 or 1) were more likely to be older and more likely to be female (women tended to have lower educational attainment than men, and fewer females were in very high level occupations; data not shown) than participants with a high SEP score (4–6) (Table 1). Age- and sex-adjusted analyses describing the logarithmically back-transformed mean inflammatory marker concentrations showed inverse associations of cumulative SEP with CRP, IL-6, ICAM-1, TNFR2, Lp-PLA$_2$ activity, MCP-1 and fibrinogen (Table 1). There was an inverse U association between cumulative SEP and P-selectin. Effect sizes varied depending on inflammatory marker, shown in detail in Table 1. For example, participants with high cumulative SEP scores (SEP score = 4–6) had lower mean CRP concentrations (1.99, 95% CI: 1.81, 2.19 mg/L) than participants with low cumulative SEP scores

Bold values denote where the 95% confidence intervals do not encompass the reference category.
[a] CHD risk markers include smoking, body mass index, systolic blood pressure, total:HDL cholesterol ratio, fasting glucose, cholesterol-lowering medication use, antihypertensive medication use and depressive symptomatology.

(SEP score = 0 or 1; mean CRP concentration = 2.47, 95% CI: 2.22, 2.75 mg/L).

In regression analyses testing the **accumulation of risk SEP framework**, cumulative SEP was inversely associated with CRP, IL-6, ICAM-1, TNFR2, Lp-PLA_2 activity, MCP-1 and fibrinogen after adjusting for age and sex (Table 2). There was an inverse U association between cumulative SEP and P-selectin. Further adjustment for CHD risk markers substantially reduced effect sizes.

In analyses testing the **social mobility SEP framework**, participants with declining SEP across their life course (as measured by father's education and own occupation) had elevated concentrations of IL-6, ICAM-1, and TNFR2, compared with participants who had high SEP in childhood and adulthood after adjusting for age and sex (Table 3). Furthermore, participants who had low SEP in both childhood and adulthood were more likely to have elevated CRP and TNFR2 compared with those who had high SEP in childhood and adulthood in age- and sex-adjusted analyses. Participants who experienced low childhood SEP and high adulthood SEP were more likely to have elevated ICAM-1, TNFR2, and Lp-PLA_2 activity compared with participants who had high SEP in childhood and adulthood, after adjusting for age and sex (Table 3). Further adjustment for CHD risk markers typically accounted for a substantial amount of the strength of the associations of SEP with inflammatory markers.

For multivariable regression analyses evaluating the **sensitive periods SEP framework**, there were inverse associations of own education with 7 of the 8 investigated inflammatory markers (CRP, IL-6, ICAM-1, TNFR2, P-selectin, MCP-1 and fibrinogen) after adjusting for age and sex (Table 4). Father's education an down occupation were inversely associated with 4 of the 8 explored inflammatory markers (father's education inversely associated with CRP, ICAM-1, TNFR2 and Lp-PLA_2 activity; own occupation inversely associated with CRP, IL-6, ICAM-1 and TNFR2). Adjustment for all SEP measures demonstrated that educational attainment had evidence of inverse associations with several inflammatory markers (CRP, ICAM-1, P-selectin, MCP-1 and fibrinogen) independently of other SEP measures (Table 4). There was little evidence of associations of father's education or own occupation with most inflammatory markers independent of other SEP measures. Further adjustment for CHD risk markers typically accounted for a substantial amount of the strength of association between SEP measures and inflammatory markers (Table 4).

Sensitivity analyses evaluated associations of the life course SEP frameworks with inflammatory markers, where father's occupation was used as a measure of childhood SEP instead of father's education. Findings were generally similar, with point estimates typically somewhat stronger when using father's occupation (Tables S1–S3). Father's occupation was inversely associated with CRP, IL-6, ICAM-1, TNFR2 and MCP-1 in analyses adjusted for age and sex. Associations remained for father's occupation with CRP, IL-6 and TNFR2 after further adjustment for own education and occupation (Table S3). Additional adjustment for CHD risk markers typically accounted for a substantial amount of the association strength between father's occupation and inflammatory markers (Table S3).

Discussion

This study provided evidence that cumulative life course SEP is inversely associated with many inflammatory markers including CRP, IL-6, ICAM-1, TNFR2, LP-PLA_2 activity, MCP-1 and fibrinogen in age- and sex-adjusted analyses. Own education was associated with almost all studied inflammatory markers (CRP, IL-6, ICAM-1, TNFR2, P-selectin, MCP-1 and fibrinogen), while father's education, father's occupation and own occupation were associated with several but not all inflammatory markers in age- and sex-adjusted

[a] CHD risk markers include smoking, body mass index, systolic blood pressure, total:HDL cholesterol ratio, fasting glucose, cholesterol-lowering medication use, anti-hypertensive medication use and depressive symptomatology.

analyses (father's education: CRP, ICAM-1, TNFR2, Lp-PLA_2 activity; father's occupation: CRP, IL-6, ICAM-1, TNFR2 and MCP-1; offspring occupation: CRP, IL-6, ICAM-1 and TNFR2). There were minimal consistent trends between social mobility trajectories and the most inflammatory markers, with evidence that low SEP at any time in the life course conferred risk for elevated inflammatory markers. The associations between the SEP measures and inflammatory markers were typically substantially accounted for by adjusting for CHD risk markers, suggesting these may be important mechanisms that explain some of the association between SEP and the studied inflammatory markers.

Prior literature

The association of adulthood SEP with inflammatory markers has been well studied for CRP and fibrinogen, and less so for other inflammatory markers addressed in this report. A systematic review showed that 20 of 21 studies demonstrated inverse associations between adulthood SEP and CRP in minimally adjusted analyses. Further adjustment for demographic, anthropometric and other covariates typically reduced strengths of association, and only 9 of 16 multivariate-adjusted studies showed significant inverse associations (Nazmi & Victora, 2007). Inverse associations of adulthood SEP with IL-6 and fibrinogen have been found in most studies using large sample sizes ($n > 1000$), with effect sizes typically substantially reduced after adjusting for variables that may be partly on the causal pathway, such as smoking and obesity (Brunner et al., 1996; Gimeno et al., 2007; Koster et al., 2006; Loucks et al., 2006; Ramsay et al., 2008). These findings are in general agreement with those reported in the present study. Little is known about the association between adulthood SEP and other inflammatory markers addressed in this article including TNFR2, MCP-1, ICAM-1, P-selectin and Lp-PLA_2. For associations of SEP with tumor necrosis factor, in two large studies ($n > 1000$), adulthood SEP was shown to be inversely associated with TNF-α concentrations in multivariable-adjusted analyses (Koster et al., 2006; Panagiotakos et al., 2005). We showed previously in the Framingham Offspring study that educational attainment was inversely associated with ICAM-1 and MCP-1 in multivariable-adjusted analyses (Loucks et al., 2006). Analyses reported in our current paper were in general support of other studies, which showed inverse associations of education and occupation with CRP, IL-6, ICAM-1, and TNFR2 concentrations after adjusting for age and sex, and general reductions in effect size after further adjusting for CHD risk markers.

With regard to associations between childhood SEP and inflammatory marker concentrations, less is known on this topic compared with adulthood SEP and inflammatory markers. However, a reasonable number of studies showed inverse

Bold values denote where the 95% confidence intervals do not encompass the reference category.

[a] For father's education, regression coefficients (β) represent the relative logarithmic change in biomarker units (95% confidence intervals) for participants with father's education of <high school, versus father's education of >high school. Multivariable regressions included category of high school education (results not shown). For own education, regression coefficients (β) represent the relative logarithmic change in biomarker units (95% confidence intervals) for participants with own education of ≤12 years, versus own education of >16 years. For own occupation, regression coefficients (β) represent the relative logarithmic change in biomarker units (95% confidence intervals) for laborers versus participants with supervisory/technical/professional/executive jobs.

[b] Other SEP measures correspond to the two SEP variables other than the independent variable. For example, if father's education is the independent variable, other SEP measures would include own education and occupation.

[c] CHD risk markers include smoking, body mass index, systolic blood pressure, total:HDL cholesterol ratio, fasting glucose, cholesterol-lowering medication use, anti-hypertensive medication use and depressive symptomatology.

associations of childhood SEP (typically measured as father's occupation or father's education) with CRP concentrations (e.g., (Lawlor et al., 2005; Tabassum et al., 2008)) and at least 2 studies demonstrated no association (Gimeno et al., 2008; Pollitt et al., 2007). Our findings supported others' demonstrated inverse associations between childhood SEP and CRP as well as fibrinogen in age- and sex-adjusted analyses (Brunner et al., 1996; Pollitt et al., 2007; Tabassum et al., 2008). Our findings demonstrated father's education and father's occupation were inversely associated with a trend in fibrinogen concentrations, but the 95% confidence intervals for the effect point estimates just encompassed the referent point estimate, suggesting a null or weak association. With regard to other inflammatory markers addressed in this report (i.e., IL-6, ICAM-1, TNFR2, Lp-PLA_2, P-selectin and MCP-1), very little is known about their associations with childhood SEP. Mendall et al. showed that father's occupational prestige was inversely associated with mean IL-6 concentrations in 198 British men aged 50–69 years after adjustment for several CHD risk factors; no association was found with TNF-α (Mendall et al., 1997). To our knowledge, very little is known about association of childhood SEP with ICAM-1, TNFR2, P-selectin, MCP-1 and Lp-PLA_2 activity. We found inverse associations of father's education with ICAM-1, TNFR2 and Lp-PLA_2 activity; strengths of association were reduced after adjusting for adulthood SEP and CHD risk markers, suggesting these may be mechanisms accounting for the association.

Cumulative SEP studies to date typically showed inverse associations between cumulative life course SEP with CRP and fibrinogen concentrations (Gimeno et al., 2008; Lawlor et al., 2005; Pollitt et al., 2008; Tabassum et al., 2008). Our findings are consistent with other observed inverse associations of cumulative SEP with CRP and fibrinogen concentrations. Little prior information is available on associations between cumulative life course SEP and concentrations of other inflammatory markers addressed in this report (i.e., IL-6, ICAM-1, TNFR2, Lp-PLA_2, P-selectin and MCP-1).

Furthermore, to our knowledge, there is very minimal information on associations between social mobility and most inflammatory marker concentrations reported here. In conjunction with findings from "accumulation of risk" and "sensitive periods" SEP frameworks discussed above, this paper's analyses found general evidence that low SEP at any time in the life course was associated with elevated inflammatory markers. For example, in social mobility analyses there were associations between declining life course SEP and elevated IL-6, ICAM-1 and TNFR2 in age- and sex-adjusted analyses. Further, participants with low childhood SEP and high adulthood SEP had elevated ICAM-1, TNFR2 and Lp-PLA_2 activity; participants with low childhood SEP and low adulthood SEP had elevated CRP and TNFR2. Findings were not as consistent for social mobility analyses as for the other two SEP frameworks, likely in part because only father's education and offspring occupation were used in these analyses, rather than all three sensitive

periods (including own education which was strongly associated with most inflammatory markers).

Mechanisms

For the observed associations between SEP and inflammatory markers in this study after adjusting for age and sex, further adjustment for CHD risk markers typically accounted for a substantial amount of the association. These factors may be substantial mediating pathways through which life course SEP influences inflammatory markers. There is evidence that SEP in childhood and adulthood may influence health behaviors and CHD risk markers, which could serve as intermediate mechanisms contributing to the emergence of altered concentrations of inflammatory markers. For example, childhood SEP is inversely associated with obesity in adult females (Senese, Almeida, Kittler Fath, Smith, & Loucks, 2009) and smoking in adult males and females (Lawlor, Batty, et al., 2005). With regard to adulthood SEP, those with low SEP tend to have higher smoking rates (Gilman et al., 2008), blood pressure (Colhoun, Hemingway, & Poulter, 1998), diabetes (Maty, Everson-Rose, Haan, Raghunathan, & Kaplan, 2005), and in the case of women, obesity (McLaren, 2007). Cigarette smoking and obesity have been shown to be associated with inflammatory markers reported in this cohort and may be mechanisms by which childhood SEP influences inflammatory marker concentrations. An additional potential mechanism is through psychological distress, such as depression or anxiety. Childhood SEP is associated with depression in youth and adulthood (Gilman, Abrams, & Buka, 2003). Adulthood SEP is also related to depression (Muntaner, Eaton, Miech, & O'Campo, 2004). Reports have demonstrated that depression is associated with elevated inflammatory markers including C-reactive protein, IL-6, and ICAM-1 (Empana et al., 2005). The causal direction between depression and inflammation is still being elucidated (Almeida et al., 2009; Dantzer, O'Connor, Freund, Johnson, & Kelley, 2008). Furthermore, low SEP is associated with chronic inflammatory conditions such as periodontal disease that can influence circulating levels of inflammatory markers including CRP (Borrell & Crawford, 2008; Linden, McClean, Young, Evans, & Kee, 2008).

Strengths and weaknesses

Strengths of the present investigation include the well-characterized community-based cohort in which a wide range of CHD risk markers were routinely measured using high quality methods, enabling us to adjust for a large number of covariates. Furthermore, childhood SEP was obtained directly from parents, which can limit recall bias compared to studies that asked participants to estimate parents' SEP.

With regard to weaknesses, because the historical design of the Framingham Offspring Study reflected the population of Framingham, Massachusetts at study onset in 1948, the Original and Offspring cohorts are largely composed of participants of European descent. Consequently, the generalizability of our findings to other races/ethnicities is uncertain. Additionally, excluded participants were more likely to be of low SEP, and have elevated CHD risk markers, certain inflammatory markers and CHD, compared with included participants. We expect this could have induced bias in the reported findings likely towards the null as the excluded participants tended to have extreme values for both the exposures and outcomes. Furthermore, our primary analyses on life course SEP included only 3 measures: father's education, own education and own occupation. Other studies that have additional measures of life course SEP (such as *in utero* SEP, or multiple measures of occupation throughout the life course) will provide richer data as to the potential contribution of sensitive periods, accumulation of risk and social mobility SEP frameworks to inflammatory marker concentrations as well as further limit misclassification of SEP categories. Furthermore, education and occupation exposures were categorized as three-level variables, consequently socioeconomic misclassification is expected. In addition, for the measure of own occupation, the minimum age used for occupation assessment was 28 years in order to allow at least 10 years from the typical age of high school graduation to complete education, and obtain an occupation. Most participants were middle-aged or older when occupation was assessed. There was an approximately 40-year age range in participants at each measurement time, and approximately 20 years between Examinations 2 and 7 when occupation was assessed. Ideally all participants would be of similar ages when occupation was assessed, however these data were not available in this study. Given that occupation was categorized using only two or three broad categories, and that the mean age of assessment for the exam when participants were youngest (Examination 2) was 47.7 years, we felt this was a reasonable approximation of occupation. Misclassification of occupation is expected in this study, and other studies with occupation measured at narrower aged ranges will provide more precise information on the role of occupation in relation to inflammatory markers. Finally, the primary analyses represented potential risk for multiple statistical testing where there were 64 individual point estimates presented for age- and sex-adjusted regression analyses (Tables 2–4). Given an alpha of 0.05 used for the 95 percent confidence intervals, we would expect the reference categories' point estimates to be outside of comparison groups point estimates' 95 percent confidence intervals for 3 of the 64 tests simply due to chance. Given that the analyses demonstrated 35 of the 64 tests to have a reference category point estimates outside of the comparison groups point estimates' 95% confidence intervals, we feel that the overarching findings in this report are consistent with a relation between SEP and inflammation.

Conclusion

This study provides evidence that cumulative SEP across the life course is inversely associated with several inflammatory markers including CRP, IL-6, ICAM-1, TNFR2, LP-PLA_2 activity, MCP-1 and fibrinogen in age- and sex-adjusted analyses. Own education was associated with almost all studied inflammatory markers (CRP, IL-6, ICAM-1, TNFR2, P-selectin, MCP-1 and fibrinogen), while father's education, father's occupation and own occupation were associated with several but not all inflammatory markers in age- and sex-adjusted analyses (father's education: CRP, ICAM-1, TNFR2, Lp-PLA_2 activity; father's occupation: CRP, IL-6, ICAM-1, TNFR2 and MCP-1; offspring occupation: CRP, IL-6, ICAM-1 and TNFR2). There were few consistent trends between social mobility trajectories and most inflammatory markers, with general evidence that low SEP at any time in the life course conferred risk for elevated inflammatory markers. The strengths of association between the SEP measures and inflammatory markers were typically substantially accounted for by CHD risk markers, suggesting these may be important mechanisms that explain a reasonable amount of the association between SEP and the studied inflammatory markers. These data provide potential biological mechanistic evidence of inverse associations between life course SEP and CHD found in observational studies.

Clinical Case Study

Interpretation of HIV Serologic Testing Results

Vinay S. Mahajan,[1] Christine A. Pace,[2] and Petr Jarolim[1*]

CASE

A 33-year-old male patient visited the outpatient clinic at Brigham and Women's Hospital for a routine follow-up for obesity, obstructive sleep apnea, allergic rhinitis, and depression. He was maintained on a nocturnal continuous positive airway pressure device, loratadine, duloxetine, and fluticasone nasal spray. He was a resident of Boston and had not traveled outside the country. He denied intravenous drug use or high-risk sexual behavior, and he had not received any blood products. He had received his most recent influenza vaccine about 6 months earlier. He was screened for type 2 diabetes and hyperlipidemia. As a part of routine clinical care, he was also offered HIV screening in accordance with the current CDC recommendations *(1)*. The HIV assay [HIV 1/O/2 Enhanced (EHIV)], which was performed on the ADVIA Centaur analyzer (Siemens Healthcare Diagnostics), yielded a reactive result. As per the assay protocol developed by the manufacturer, the initially reactive sample was retested in duplicate after centrifugation; both results were reactive. The positive screen was followed up with a confirmatory western blot (WB)[3] analysis, which yielded an indeterminate result. The presence of an isolated p24 band in the WB (GS Western HIV-1; Bio-Rad Laboratories) was of concern regarding possible early HIV seroconversion.

QUESTIONS TO CONSIDER

1. What factors are known to cause false-positive HIV serologic test results?
2. What factors are known to cause an indeterminate WB result?
3. What further testing or clinical history would be of help in evaluating a patient with an indeterminate WB result?

DISCUSSION

The Siemens EHIV screen performed in this case is a double antigen-bridging microparticle chemiluminometric immunoassay that detects antibodies against p24, gp41, gp120 (from HIV-1), gp36 (from HIV-2), and a synthetic peptide from group O HIV-1 (Fig. 1). A positive result indicates the presence of antibodies that recognize any of these antigens, regardless of their isotype or subclass. Although such third-generation HIV immunoassays have greatly improved analytical sensitivity and specificity, false-positive results have not been eliminated completely. A common cause of false-positive serologic screens for HIV is recent influenza vaccination or an incidental viral infection *(2, 3)*. In addition to flu vaccination and viral infections, false-positive HIV-1 immunoassay results have been reported in a variety of other conditions, such as autoimmune disease, renal failure, cystic fibrosis, multiple pregnancies, blood transfusions, liver diseases, parenteral substance abuse, hemodialysis, and vaccinations against hepatitis B and rabies *(4)*. Thus, a positive result in an HIV screening test must be followed up with a more specific confirmatory test.

WB is routinely used to confirm a reactive HIV serologic screening result. These assays, which contain either viral lysate or recombinant HIV proteins, allow the determination of the antigenic specificity of the antibodies in the patient's serum. The predominant type of HIV in the US is HIV-1. A confirmatory test for HIV-1 infection was recommended because this patient had not traveled to any part of the world with a high prevalence of HIV-2, such as West Africa. The major antibody specificities detected in HIV-1 WB analysis include gp160, gp120, p65, p55, gp41, p40, p31, and p24. To be reported as positive, the WB assay requires reactivity against the gp41 and gp120/160 bands encoded by the *env*[4] (gp160, envelope glycoprotein) gene or against either one of these *env* bands plus the p24 band encoded by *gag* [Pr55(Gag)]. Such a result is highly specific for the presence of HIV infection *(5)*. A negative result implies the absence of any of the above bands. The result is called indeterminate when the band profile does not meet the criteria for a positive

[4] Genes: *env*, gp160, envelope glycoprotein [HIV-1 gene]; *gag*, Pr55(Gag) [HIV-1 gene].

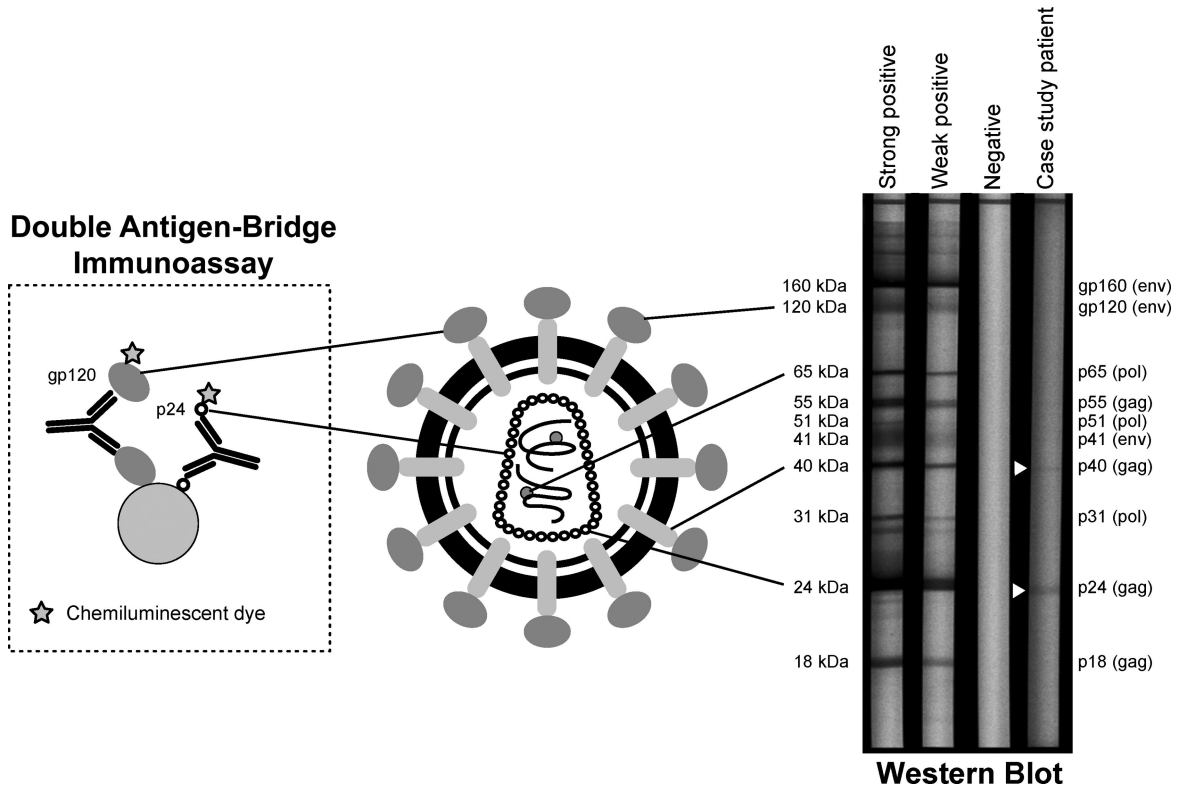

Fig. 1. Serologic tests for HIV.

The diagnosis of HIV infection is based on the detection of HIV antibodies against multiple HIV antigens. Antibodies against HIV are screened with an assay such as a double antigen-bridge microparticle immunoassay (left) and individually confirmed with a WB (right). The HIV WB from the patient in this case study is shown in the far right lane.

result. The patient's WB yielded an indeterminate result. In this case, the result was reported as indeterminate because a sharp p24 band and a weak p40 band were observed (Fig. 1).

After exposure to HIV, it usually takes an individual at least 3 weeks to build up an antibody titer sufficient to be detectable by a third-generation HIV immunoassay. This period is called the "seroconversion window." Because antibodies to p24 develop early during the course of infection, an indeterminate WB pattern seen during this window is often associated with an isolated p24 band *(6)*. Qualitative reverse-transcription PCR analysis for HIV is used to screen for or confirm the presence of HIV infection during the seroconversion window, and the screen can become positive as early as 10 days after exposure *(7)*. Nucleic acid testing (NAT) for HIV is also used when a rare HIV genotype is suspected; such testing plays a critical role in neonatal HIV screening, owing to interference from maternal antibodies. Besides early seroconversion, other causes of indeterminate HIV-1 WB results in the setting of HIV infection include infection with HIV-2 and advanced AIDS *(6)*. An indeterminate WB result can also arise from antibodies that are cross-reactive to HIV antigens, such as those associated with HTLV infection; with vaccination against influenza, hepatitis, or rabies; or with animal handlers exposed to unusual viruses. Nonspecific antibody binding to nonviral cellular components in the WB HIV antigen preparation can also produce an indeterminate WB result. Such results may be associated with frequent transfusions, injection drug use, liver disease, multiple pregnancies, rheumatoid factor, lymphoma, multiple sclerosis, various autoimmune disorders, a positive result in the rapid plasma reagin test, and chronic hemodialysis *(6)*.

The patient was contacted for follow-up of his HIV test results and possible NAT. Upon further questioning, however, he recalled that he had received an experimental HIV vaccine >5 years earlier. HIV vaccines may include either *gag*- or *env*-encoded proteins or both. Vaccines designed to induce cell-mediated immunity can also elicit a humoral response and produce vaccine-induced seropositivity. A majority of *gag* vac-

cine recipients have p24, p40, and/or p55 bands in their WB *(8)*. *env* vaccine recipients can have gp41, gp120, and gp160 bands. Such WB results are often reported as indeterminate, but some HIV vaccine recipients can meet the criteria for a positive HIV WB result. These patients can pose a true diagnostic challenge.

The results of HIV testing of vaccine recipients can be easily misinterpreted and can have a negative social impact *(9)*. Because of the blinding procedures of many vaccine trial designs, neither the patients nor the researchers may know whether a placebo or an experimental vaccine was administered. Vaccine-induced seropositivity can potentially lead to unblinding of the study participants as well as researchers, with a risk of compromising the study data. Therefore, HIV testing of vaccine trial participants is usually performed in designated laboratories with appropriate anonymization protocols that can provide interpretation of results without the risk of unblinding. The results of HIV testing in vaccine recipients need to be confirmed with NAT.

Vaccine trial participants are counseled to undergo HIV testing exclusively with the vaccine research group. Follow-up periods in such trials extend for decades, however, and patients may not recall all of the details. Therefore, the National Institute of Allergy and Infectious Diseases has provided participants in NIH-supported HIV vaccine trials with both a toll-free number for assistance and identification cards that document study participation *(9)*. A large number of experimental HIV vaccine trials have been undertaken over the last 2 decades, and there is a steadily increasing population of recipients of experimental HIV vaccines who present for HIV screening. This trend is likely to continue, especially considering the encouraging results of the recent HIV vaccine trial in Thailand *(10)*. Misinterpretation of the results of off-site HIV tests in vaccine trial volunteers may best be avoided through better communication between HIV vaccine researchers and local providers of diagnostic tests.

The decision for confirmatory NAT was deferred, and the vaccine research group was notified for appropriate interpretation, follow-up, and counseling regarding the patient's HIV screening result, in accordance with the study protocol. This procedure ensured that both the patient and the researchers remained blinded to whether the patient received a placebo or a test dose of the experimental vaccine.

POINTS TO REMEMBER

- False-positive HIV serologic screens can be caused by recent influenza vaccination, incidental viral infections, autoimmune disease, renal failure, cystic fibrosis, multiple pregnancies, blood transfusions, liver diseases, parenteral substance abuse, hemodialysis, or vaccinations against hepatitis B and rabies.
- An indeterminate WB result can be caused by a weak titer of anti–HIV-1 antibodies (as seen in early seroconversion), advanced AIDS, infection with an unusual HIV type, or recipients of experimental HIV vaccines. It can also be caused by the presence of antibodies cross-reactive against HIV antigens (incidental viral infection; vaccination against influenza, hepatitis, or rabies; or HTLV infection) or reactivity to the nonviral components of the WB (various autoimmune disorders, multiple pregnancies, and recipients of multiple blood transfusions).
- An indeterminate WB result should be followed up with qualitative NAT if early seroconversion is suspected, with a repeat immunoassay and WB analysis performed in 2–4 weeks. Although the US Food and Drug Administration has not cleared the use of quantitative viral load for HIV diagnosis, the viral load is unlikely to be $<$5000 copies/mL during acute HIV infection. Persistent reactivity of the antibody screening assay with a simultaneous lack of any change in the WB pattern suggests the absence of HIV infection.
- An increasing number of recipients of experimental HIV vaccines, which can cause false-positive results in HIV serologic tests, are being offered HIV screening. Whenever possible, testing for HIV in such patients is best performed in consultation with the vaccine research group responsible for the trial. This procedure will ensure proper interpretation of test results without compromising the study data.

Commentary

Frederick S. Nolte*

This case report adds HIV vaccination to the list of well-known causes of false-positive results in HIV antibody–screening tests and illustrates the problems often associated with the interpretation of WBs. Timely and effective means of confirming HIV screening tests have become increasingly important as more centers integrate HIV screening into routine clinical care as recommended by the CDC.

In many laboratory settings, NATs for HIV-1 RNA are more widely available and less costly than WB and are not subject to indeterminate results. Although quantitative HIV-1 NATs have not been cleared by the US Food and Drug Administration (FDA) for diagnosis, they have been used for years for evaluating patients thought to be acutely infected. These patients typically have high viral loads ranging from 10^5 to 10^6 copies/mL, and the results present no problems with interpretation. The reports of false-positive results in viral load tests all occurred with a single method (Versant bDNA test; Siemens Healthcare Diagnostics); results were $<10^4$ copies/mL.

The APTIMA HIV-1 RNA Qualitative Assay (Gen-Probe), currently the only NAT that has been FDA-cleared for diagnosis of infection, can be used to diagnose neonatal and acute infections, confirm positive results in antibody-screening tests, and resolve indeterminate WB results. As the authors point out, a NAT was the next step in the diagnostic work-up, but it was deferred when the vaccination history was obtained.

The rare individuals who are infected with HIV-1 but who progress to AIDS either very slowly or not at all pose another diagnostic dilemma. In these long-term nonprogressors, HIV-1 antibody is easily demonstrated, but these individuals show low or undetectable HIV-1 RNA loads in the assays available to clinical laboratories. Viremic controllers have low but readily measurable virus loads. Elite controllers suppress HIV to extremely low concentrations, which are measurable only with the most analytically sensitive laboratory techniques.

Understanding Racial Disparities in Treatment Intensification for Hypertension Management

Meredith Manze, MPH[1,2], Adam J. Rose, MD, MSc[3,1], Michelle B. Orner, MPH[3], Dan R. Berlowitz, MD, MPH[3,2], and Nancy R. Kressin, PhD[4,3,1]

[1]Section of General Internal Medicine, Boston University School of Medicine, Boston, MA, USA; [2]Health Policy & Management Department, Boston University School of Public Health, Boston, MA, USA; [3]Center for Health Quality, Outcomes, and Economic Research, Bedford VA Medical Center, Bedford, MA, USA; [4]VA Boston Healthcare System, Boston, MA, USA.

BACKGROUND: Disparities in blood pressure (BP) control may be a function of disparities in treatment intensification (TI).

OBJECTIVE: To examine racial differences in TI, understand modifiable factors that may mediate this relationship, and explore the relative effects of TI and race on blood pressure.

DESIGN: Prospective cohort study.

PARTICIPANTS: Participants were 819 black and white patients with hypertension from an urban, safety-net hospital

MAIN MEASURES: We sequentially explored the effects of patient race, sociodemographic and clinical characteristics, beliefs about BP/medications, perceptions of provider/discrimination, sodium intake, medication adherence, and provider counseling on TI, performing a series of random effects analyses. To assess the effects of race and TI on BP, we performed linear regressions, using systolic BP (SBP) as the outcome.

KEY RESULTS: Unadjusted analyses and those including sociodemographic and clinical characteristics revealed that black patients had less TI than whites (−0.31 vs.−0.24, p<0.001), but adjustment for patient beliefs and experiences eliminated the effects of race (β= −0.02, p=0.5). Increased patient concerns about BP medications were related to lower TI, as was more provider counseling (β=−0.06, p=0.02 and β= −0.01, p=0.001, respectively). In the unadjusted analysis, black race was a significant predictor of SBP (134 mm/Hg for blacks vs. 131 mm/Hg for whites, p= 0.009), but when both race and TI were included in the model, TI was a significant predictor of SBP (final SBP 2.0 mm/Hg lower for each additional therapy increase per 10 visits, p<0.001), while race was not (Blacks 1.6 mm/Hg higher than whites, p=0.17).

CONCLUSIONS: Improved patient–provider communication targeted towards addressing patient concerns about medications may have the potential to reduce racial disparities in TI and ultimately, BP control.

BACKGROUND

Racial disparities in hypertension control and hypertension-related outcomes persist despite efforts to improve control and reduce disparities.[1–5] Approximately 34% of non-Hispanic blacks have hypertension, the highest prevalence of any racial/ethnic group.[5] Black individuals also have more severe hypertension with an earlier age of onset, compared to non-Hispanic whites.[6] For these reasons, blacks have an increased rate of adverse hypertension-related health outcomes and mortality.[6,7] Identifying contributing factors responsible for this disparity is crucial in improving health outcomes.

We have only a limited understanding of the reasons why blood pressure (BP) control is worse in blacks. Increasingly, clinical inertia, the phenomenon by which providers do not always initiate or intensify therapy in response to uncontrolled BP, is recognized as a major barrier to BP control.[8–10] Treatment intensification (TI) for hypertension occurs when providers initiate and intensify therapy for patients with elevated BP. TI has been linked to improved BP control.[9,11,12] TI is complex and often involves discussions between patients and providers. Patient beliefs about hypertension and their medications, as well as their adherence to antihypertensive medications and their experiences with care, are likely to be critical factors in these decisions to intensify therapy. TI is best viewed as something that patients and providers accomplish in collaboration. Therefore, addressing insufficient TI is likely to involve factors related to patient–provider communication, and patients' experience of the process of care, including perceptions and experiences of discrimination. A more complete understanding of relational determinants of TI may help in designing interventions to increase TI and thus improve BP control.

Few studies have examined the issue of racial disparities in TI, or whether this disparity may also explain racial disparities in BP control.[13,14] Therefore, our objectives are to 1) explore the extent of racial disparities in TI in hypertension care, 2)

elucidate the contributions of patient characteristics, beliefs and behaviors, and patient–provider interactions to racial disparities in TI, and 3) examine the relative effects of race and TI on BP control.

METHODS

Study sample

We identified all white and black patients ages 21 and older with primary care clinic visits at an urban safety-net hospital, diagnosis of hypertension, and prescribed at least one antihypertensive medication. (The term "black" includes patients of black race born in Africa, Caribbean or U.S.A.) We enrolled 869 patients, as part of a larger study, and collected baseline data on BP control and patient beliefs and attitudes about and experiences with BP care and medications. We then implemented an intervention where providers were randomized to receive an educational workshop aimed at improving communication about hypertension care. Patients were approached for participation during their regular clinic visit. After consenting, recruited participants completed a survey, and clinical information was abstracted from the medical record.[15] Of the patients enrolled in the parent study, 50 were excluded from the present analysis because they had ≤ 2 BP values, too few to characterize TI. Therefore, 819 patients with hypertension constituted our study population. This study was approved by our Institutional Review board.

Measures

Independent Variables.

Sociodemographic and Clinical Characteristics. Patient sociodemographic characteristics including race, education and income were obtained through self-report. Patients' clinical data was extracted from the electronic medical record (EMR), including age, gender, height, weight, number of BP medications and diagnosis of hypertension. The EMR was also used to obtain diagnoses of comorbid conditions which pertain to hypertension management, including benign prostatic hypertrophy, cerebrovascular disease, chronic kidney disease, congestive heart failure, coronary artery disease, diabetes mellitus, hyperlipidemia, nicotine dependence, obesity, and peripheral vascular disease.[6] A patient was considered obese if s/he had either a diagnosis of obesity in the EMR or a body mass index of at least 30.

Health Beliefs and Illness Perceptions. We examined patient beliefs and perceptions about high BP and antihypertensive medications, using the Beliefs about Medicines Questionnaire (BMQ-specific). The BMQ-specific includes ten items to evaluate patients' *concerns* about potential adverse effects from their BP medications and eight items to measure patients' beliefs regarding the *necessity* of their medications (five point scale ranging from Strongly Agree to Strongly Disagree).[16,17] Scores were summed within each of these scales to create an overall scale score ('necessity' scale alpha=0.81 and 'concerns' scale alpha=0.80). Each score was divided by the number of items to obtain a mean summary score, where a higher number indicated either greater concerns about or beliefs in the necessity of medications. Scale scores were created only if 75% of the items were answered.

To assess the degree of seriousness with which patients perceived hypertension and its sequellae, we utilized four additional items (Table 2; ranging from "extremely serious" to "not at all serious"). We used five separate dichotomous items to assess patients' beliefs about BP medications. These items were first created and utilized in our prior work with a similar patient population.[18]

We included ten items from the "cause" scale of the Illness Perception Questionnaire. These items were analyzed separately to examine patients' subjective beliefs about the etiology of their high BP (five point scale ranging from Strongly Agree to Strongly Disagree).[19]

Perceptions of Provider and Experiences of Discrimination. To assess patients' perceptions of their providers, we used three items from the Commonwealth Fund 2001 Health Care Quality Survey [20]. We created an additional question about the patients' perception of their providers' understanding of their cultural background and how it affects their health. Each item was scored individually.

To measure perceived discrimination in health care, we included the seven item measure developed by Bird and Bogart,[21] creating a dichotomous variable for anyone who answered 'yes' to any question compared to patients who responded 'no' to all questions.

Sodium Intake. Because dietary sodium is an important contributor to BP, we assessed patients' sodium intake using the three-item subscale within the previously validated Hill-Bone Compliance to High Blood Pressure Therapy Scale, with responses ranging on a four point Likert scale from "None of the time" to "All of the time",[22] summing the items to create one sodium intake score.

Medication Adherence. We assessed medication adherence because better adherence to antihypertensive medications is associated with improved BP control. Patients used an electronic recording device (MEMS cap), that recorded each time a patient opened the medication bottle to take his/her BP medication, for approximately 90 days following their enrollment into the study. We calculated the proportion of days in this period on which the patient took at least the number of doses prescribed. We used this data to categorize patients as having "poor adherence" (defined as less than 50% adherent), "fair adherence" (50–80% adherent), "excellent adherence" (greater than 80% adherent), or having missing MEMS cap data.

Provider Counseling. We assessed the content of the patient–provider discussion regarding hypertension care and management, following earlier work from Kressin and Pbert.[18,23] We included a series of 12 dichotomous items that assessed whether or not the provider asked or advised patients about various issues related to antihypertensive medication adherence.

We summed the items from this measure to create a summary scale score, where higher scores indicate more discussion of hypertension related issues. Scale scores were created only if 75% of the items were answered (alpha=0.86).

Dependent Variable.

Treatment Intensification. TI was our main dependent variable. One author (AJR) performed a manual chart review to measure TI scores. A subset of patients, representing 5% of all clinic visits, were randomly selected for blind reabstraction by another author (DRB). Agreement between the reviewers was good (k=0.93 (95% CI, 0.87 to 0.98)).[15] We used the following formula to measure TI: (visits with medication changes–visits with elevated BP) / number of clinic visits.[12,15] A TI score of zero signifies that treatment was intensified once for each visit with elevated BP. A score greater than zero signifies that treatment was intensified at more visits than there were visits with elevated BP, while a score less than zero signifies that there were more visits with elevated BP than episodes of TI. A unit of 0.1 on this scale indicates one more or less TI than expected per 10 visits. This definition of TI, known as the Standard-Based method, is the preferred measurement of TI in hypertension care.[15]

The expected number of medication increases was the number of occasions on which the recorded BP was elevated, defined as 140/90 mm/Hg or higher. BP values were taken from the medical record at the clinic visit. In prior work using this data set, we found that using the threshold of >= 130/80 for uncontrolled BP, for patients with diabetes or chronic kidney disease, yielded similar results as using the same threshold (>= 140/90) for all patients.[15] Therefore, we used the single threshold of >= 140/90 mm/Hg for all patients in our sample. TI for each subject was calculated using BP values from visits between their respective dates of enrollment until December 2007.

Statistical Analyses. We first assessed distributions for each variable by racial group, performing univariate analyses (t-tests and chi-square, as appropriate). Next, we investigated the effect of race upon TI with and without controlling for patient-level covariates. In these analyses, we used random effects analyses to account for clustering of patients-within-providers. Our multivariate model also included patient race, age, gender, education level, income, number of BP medications and comorbid conditions. For the final model, we added the variables for health beliefs and illness perceptions, perceptions of providers and experiences of discrimination, medication adherence, sodium intake, and provider counseling, keeping only variables that had been significant at the $p \leq 0.10$ level in Model 2. We also performed these regressions without eliminating any variables and found similar results.

To assess the effects of race and TI score on BP, we performed two linear regressions, using systolic BP (SBP) (at the final clinic visit) as the dependent variable. Because uncontrolled BP is mostly a problem of poorly controlled SBP, we used this as our outcome (supplemental analyses found that there were only 166 (1.3%) visits in which patients had a SBP greater than or equal to 140 and diastolic BP less than or equal to 60).[24] The first model included only patient race and the second model also included TI score. All analyses were conducted using SAS 9.1.3 (SAS Institute, Cary, NC).

RESULTS

Black patients were significantly younger, more likely to be female, less educated, had a lower income, prescribed more BP medications compared to white patients, and were more likely to have diabetes, chronic kidney disease, congestive heart failure, and obesity (Table 1). Black patients had significantly more concerns about their BP medication (mean score 2.5 vs. 2.1, p<0.001; Table 2), and believed their BP was more serious, given their current use of medication (mean scores 2.8 vs. 3.3, p<0.001; lower scores indicate greater seriousness). More black patients believed that taking their BP medication would help them to feel better (p<0.001), but fewer of them believed that it would help them live longer, compared to whites (p=0.001).

In the bivariate analyses, important racial differences were noted with regard to almost every hypertension-related belief that we examined, with blacks having less accurate or more negative perceptions (Table 2). For example, black patients were more likely to report that a germ or virus, chance, other people, and poor medical care in the past contributed to causing their high BP. While all patients generally agreed that their provider understood their background and values, black patients agreed less strongly (p=0.03). Also, while all patients disagreed that their provider looks down on them and the way they live their life, white patients disagreed more strongly (p< 0.001). Blacks were more likely to have missing adherence data, generally due to failure to return MEMS caps. They were also more likely to have fair or poor adherence and less likely to have excellent adherence.

Table 1. Sociodemographic and Clinical Characteristics

Patient Characteristics	All patients (n=819)	Black (n=476)	White (n=343)	p-value
Mean age	59.6	58.3	61.4	<0.001
Gender (% male)	33.9	26.7	44.0	<0.001
Education (% less than 12th grade completed)	54.2	65.1	39.2	<0.001
Income (% less than $20,000/year)	48.4	57.4	36.1	<0.001
Mean number of blood pressure medications	2.3	2.4	2.3	0.003
Benign Prostatic Hypertrophy	3.7	1.7	6.4	<0.001
Cerebrovascular Disease	5.6	4.4	7.3	0.08
Chronic Kidney Disease	6.7	8.4	4.4	0.02
Congestive Heart Failure	3.5	5.0	1.5	0.006
Coronary Artery Disease	12.8	9.2	17.8	<0.001
Diabetes	33.2	39.1	25.1	<0.001
Hyperlipidemia	53.6	48.3	60.9	<0.001
Nicotine Dependence	7.5	8.6	5.8	0.14
Obesity	58.9	63.9	52.2	<0.001
Peripheral Vascular Disease	5.3	3.9	7.0	0.057

Table 2. Patient Beliefs and Experience Variables by Race

Patient Variables	Total	Black	White	p-value
Health Beliefs & Illness Perceptions				
Concerns about BP Medication (mean)[a]	2.3	2.5	2.1	<0.001
Beliefs about necessity of BP Medication (mean) [b]	3.7	3.7	3.7	0.15

[g] *Higher score indicates more discussion; range from 0–12*
[h] *Higher score indicates more treatment intensity*

Black patients reported more provider counseling about BP (7.2 vs. 5.7, p<0.001), and were much more likely to report at least one experience of discrimination in the health care setting than whites (29% vs. 8%, p<0.001). Finally, black patients had significantly higher baseline and final systolic BP compared to whites (135.1 mm/Hg vs. 131.4 mm/Hg, p<0.01; 134.2 mm/Hg vs. 131.0 mm/Hg, p=0.009, respectively).

In unadjusted analyses, black patients had less TI than whites, equivalent to approximately one fewer therapy increase per 14 clinic visits (−0.31 vs.−0.24, p<0.001) (Table 2). After including patient sociodemographic variables and clinical characteristics in our regression model, black patients had significantly lower TI, equivalent to approximately one fewer therapy increase per 17 clinic visits (Model 2, β=−0.06, p=0.01; Table 3). In the final model, after adding patient beliefs, perceptions of provider, experiences of discrimination, sodium intake, provider counseling and medication adherence, race was no longer a significant predictor of TI (Model 3, β=−0.02, p=0.5).

This final model revealed several determinants of TI. Patients with hyperlipidemia had increased TI, equivalent to approximately one more therapy increase per 13 clinic visits (β=0.08, p<0.001). Increased patient concerns about BP medications and more provider counseling were each related to lower TI, equivalent to approximately one fewer therapy increase per 17 clinic visits for each unit increase on the concerns scale and one less therapy increase per 100 visits for each unit increase on the provider counseling scale (β=−0.06, p=0.02 and β =−0.01, p=0.001, respectively). Two marginally significant findings indicated that more BP medications were associated with reduced TI (β=−0.02, p=0.054) and more disagreement with the item about

feeling one's provider looks down on them was associated with increased TI (β=0.04, p=0.05).

To assess the effects of race and TI on BP, we performed two linear regressions, using the final systolic BP as the outcome. When race was examined alone as a predictor, black patients had a higher final systolic BP (134 mm/Hg for blacks vs. 131 mm/Hg for whites, p=0.009; Table 2). In a model containing race and TI as independent variables, TI was a significant predictor of final BP (final SBP 2.0 mm/Hg lower for each additional therapy increase per 10 visits, p<0.001; Table 4), but race was no longer significant (blacks 1.6 mm/Hg higher than whites, p=0.17).

DISCUSSION

In this effort to understand racial disparities in BP control, we found that black patients had significantly lower rates of TI compared to whites, even after accounting for differences in their clinical and sociodemographic status. However, racial disparities in TI were explained by the inclusion of patient characteristics, health beliefs, and provider counseling. This finding differs from prior work finding that African Americans were treated more intensively for their hypertension,[14,25] but which did not account for patient health beliefs or interactions with providers. One study defined TI as the number of classes of BP medications,[14] a measure which is likely to be confounded by disease severity.[15]

In our study, having hyperlipidemia was the only significant predictor of increased TI. Patient concerns about BP medications and more provider counseling were associated with reduced TI, suggesting that providers may hesitate to intensify treatment when patients express concerns, or that providers may substitute counseling for TI. This conclusion is consistent with other findings indicating that more discussion between providers and patients about medication issues was associated with a lower likelihood of changing treatment.[26] Patient concerns may be related to being on an increased number of BP medications or lack of trust in providers whom patients may feel look down on them. The racial differences in BP control in our sample suggest that substituting counseling for TI is not an effective strategy to minimize disparities in BP control.

Black patients had a higher systolic BP in unadjusted analyses, but this effect was much attenuated and no longer significant after controlling for TI, suggesting that increasing TI may help to resolve disparities in uncontrolled BP. This notion is partly consistent with prior findings that TI was associated with increased odds of having controlled BP; however, in that study, no interactions were found between race and TI.[13] Our results add to this literature by revealing determinants of TI by race and demonstrating that patient concerns and beliefs about BP and provider counseling are associated with differential rates of TI, and thus are a target for intervention, along with increasing provider awareness about intensifying hypertension therapy.

Our findings should be interpreted within the limitations of our study. As part of the parent study, a subset of providers received an educational intervention, which may have affected provider-patient communication and, in turn, patient beliefs about BP medication. However, our analyses adjusted for nesting of patients-within-providers and thus controlled for differential practice styles that may have been associated with providers' exposure to the intervention. In addition, separate analyses indicated no significant effect of the intervention on counseling or BP (not shown). Our sample is comprised of only white and black patients receiving care at a single urban, safety-net hospital and our findings may therefore not be generalizable to other populations. We do not have information about provider attitudes and beliefs, which have also been shown to also be a key factor in clinical inertia.[26,27] Again, our analysis may account for some of this variability, but not all.

Disparities in hypertension control can be minimized by identifying and addressing modifiable factors that contribute to these differential rates in health outcomes. This study found that patient concerns about antihypertensive medications play a significant role in reducing necessary TI. These results provide some support for a model to explain disparities in BP outcomes. In this model, race contributes to racial differences in beliefs and experiences, which contributes to racial differences in TI, which contributes to racial differences in BP control. Future qualitative research to determine the causes of concerns about BP medications and how those concerns impact TI may be helpful.[28] Such findings could be incorporated into a patient or provider intervention, to help address patient concerns about BP medication. In the ongoing struggle to diminish racial disparities in health outcomes, this study offers insight to potential targets for interventions. Improved patient–provider communication and patient health education may have the potential to reduce racial disparities in TI and ultimately, BP control.

The Path to Physician Leadership in Community Health Centers: Implications for Training

Jeffrey F. Markuns, MD, EdM; Bruce Fraser, PhD; Jay D. Orlander, MD, MPH

Background and Objectives: *Community health centers are facing a shortage of primary care physicians at a time when government plans have called for an expansion of community health center programs. To succeed with this expansion, community health centers require additional well-trained physician leadership. Our objective was to ascertain how medical directors obtain leadership skills in an attempt to identify the best methods and venues for providing future leadership training programs.* Methods: *Using recorded interviews and focus group data with community health center medical directors, we identified patterns and themes through cross-case content analysis to determine leadership training needs in underserved settings.* Results: *Medical directors often enter positions unprepared and can quickly become frustrated by an inability to make system improvements. Medical directors seek multiple ways to obtain the leadership skills necessary, including conferences, peer networking, mentorship, and formal degree training. Many directors express a desire for additional training, preferring flexibility in curriculum and hands-on components.* Conclusions: *Additional leadership training opportunities for active and future medical directors are needed. Academic medical centers and other training sponsors should consider innovative ways to develop effective physician leadership to provide quality care to underserved communities.*

(Fam Med 2010;42(6):403-7.)

Community health centers (CHCs) take a lead role in providing quality care to the underserved. The Health Resources and Services Administration (HRSA) Bureau of Primary Care's Community Health Center Program provides care for more than 16 million underserved people and has undergone rapid expansion.[1-3] CHCs provide high-quality cost-effective care to underserved communities, improve access to care, and reduce health care disparities.[4]

For CHCs to continue to expand in the face of limited resources, strong physician leadership is needed. However, there may not be a sufficient qualified workforce.[5-8] Many active CHC medical directors may also lack sufficient training in practice management and the specific skills such leadership requires.[9-14]

Although medical directors play an important role in direct patient care and CHC management, there is limited research elucidating their basic characteristics, such as roles and responsibilities, relationships with other administrators, retention, and satisfaction levels.[10,11,15] Some studies suggest administrative inexperience and insufficient training may lead to poor retention of medical directors.[10,11] Further, increased training correlates with improved leadership skills, as reported by CHC executive directors,[13] and leadership skills play a significant role in achieving exemplary CHC practices.[16] Guidance on how medical directors should obtain such leadership training, however, is lacking.

Our primary objective was to ascertain the need for leadership training programs for medical directors of CHCs. This included determining how medical directors obtain skills in practice management and leadership as well as the most appropriate methods and venues for this training.

From the Department of Family Medicine (Dr Markuns), School of Education (Dr Fraser), and Evans Department of Medicine (Dr Orlander), Boston University; and VA Boston HealthCare System, West Roxbury, MA (Dr Orlander).

Methods

We performed a qualitative study analyzing key informant interviews with current and former CHC medical directors. Semi-structured interviews, audio recorded and later transcribed, were performed over a period of 12 months during 2006–2007 by the same interviewer using a standardized question guide. The validity of the insights gained from these interviews were then evaluated through a focus group of a separate sample of medical directors. The study was approved by the Boston University School of Medicine Institutional Review Board.

Samples

We recruited a purposeful sample of 11 current and former medical directors through a hospital-affiliated urban network of independent CHCs in Boston. We specifically chose participants based on current and previous experience and community demographics to achieve a diverse group. All medical directors approached for interviews agreed to participate except one.

For the focus group, four current and former medical directors were recruited from a training program sponsored by the Massachusetts League of Community Health Centers. All were affiliated with CHCs outside of the Boston-based hospital-affiliated network that served as the source of key informants.

Instruments

We developed an initial question guide based upon literature review, personal experience of the authors, and discussion with individuals who provide medical director training, including leaders from state and national CHC organizations. After the first three recorded interviews with medical directors, the question guide was further refined to better address the core objectives of the study.

Analysis

All transcripts were coded and analyzed for common themes and higher-order categories using the qualitative research software NVivo 7 to perform cross-case content analysis. We performed pattern and theme recognition based on inductive and deductive processes using grounded theory principles in an iterative process and performed interviews until data saturation was achieved.[17] Coded data was reviewed by the coauthors, neither of whom is affiliated with CHCs. Focus group responses were analyzed in a similar manner.

Results

Participant Demographics

Of the 15 medical directors participating, 12 were active medical directors at the time of the interviews. The remaining medical directors were previous medical directors now involved in administrative roles outside of CHCs; however, all continued to work closely with CHC medical directors. Ten of the medical directors were men. Although a majority were Caucasian, the sample did include physicians of multiple racial and ethnic backgrounds, not specifically identified so that we could maintain confidentiality.

Medical directors interviewed had a range of experience in the position, ranging from 1 month to 35 years (median 3 years). Time since graduation from residency ranged from 5 to 35 years (median 14.5 years). All were primary care physicians: nine were family physicians, three were pediatricians, three were internists, and one was trained in both internal medicine and pediatrics.

Content Analysis

Three prominent themes emerged in relation to leadership training: (1) motivation for improvement as the path to leadership, (2) inexperience as a barrier to achieving change, and (3) training as a facilitator for success.

Theme 1: Path to Leadership: Motivation for Improvement

Our subjects typically followed a path to leadership driven by a desire for health care improvement. Although some physicians were recruited to the medical director position immediately upon completing postgraduate training, most were not. More often, directors were recruited to leadership positions after becoming established in an initial clinical role either in a CHC or elsewhere. Most directors accepted their first clinical position in a CHC or other underserved setting, citing motivators such as a desire to participate in social change or community health. Respondents express a desire to make system improvements in care and as a result evolved into leadership positions. Some felt recruited or pulled into a leadership position by other CHC administrators. One director said:

> I started off just being a pediatrician, but because of my nature of being a busybody and wanting to improve things, I sort of got sucked into the administrative thing. (Director A)

Another stated that:

> I always felt that I would pay back the community for its investment in me, and so I had always planned to be involved in community medicine…A position opened up as medical director, and I thought I would like to try that…I was looking for a way to kind of have some influence beyond individual treatment…so I thought, you know, I might be able to do that being a medical director. (Director G)

Theme 2: Inexperience: A Barrier to Achieving Change

Once established, medical directors almost universally describe feeling unprepared for a poorly defined role. Many report little prior knowledge of CHCs, and only a few report a clear understanding of the role of a medical director. Job descriptions are often absent or considered outdated or inadequate. Even highly experienced medical directors have difficulty providing a focused, concise summary of their role. They cite extremely broad areas of responsibility encompassing multiple areas of leadership, sometimes overlapping the supervisory duties of other CHC administrators. One director reported that:

> I remember telling him, 'Do I get a job description on this?' I mean, I had a sense. He said, 'Ah, we can—it won't help.' He probably would have been right, because I don't think he had a great idea. (Director F)

Another said:

> I don't even know, I don't know what my job is, if I tell you the truth. (Director J)

While some medical directors accepted their position without formal leadership training, others had participated in fellowships or earned additional graduate degrees prior to becoming medical directors. Regardless of prior experiences, almost all frequently felt unprepared in the early phases of their careers as medical directors. The combination of inexperience and lack of direction in this period often acted as a barrier to achieving improvements within their CHCs.

As desire for improvement is a primary motivator, the ability to effect successful change within a CHC appears to play a large role in the satisfaction of medical directors. Medical directors unable to achieve successful CHC improvements express considerable frustration, often including a desire to leave the position, potentially contributing to troubles with retention and turnover. As one director said:

> I took over one of the sites as the local site director and burned out in about a year. Just totally flamed out. Cause I wasn't really ready. My skills weren't really at the level that they needed to be. I couldn't do it. (Director C)

Another reported that:

> This is a place I see right now, as we stand, if we don't make changes, it's a place that you go the last five years before you retire. When you don't give a damn about anything. So that's what's bothering me right now. And that's a big issue. At least for me. Because I need to move on. I need to move on. (Director J)

Theme 3: Training: a Facilitator for Success

To address the barrier of inexperience, we explored the role of subsequent administrative education. Training fell into four main categories: conferences, peer networking, mentorship, and formal degree programs. Most medical directors attended at least one management conference designed specifically for CHC medical directors. One of the focus group participants stated that:

> I can't do this without some training, or I'm just gonna fail right away.

Medical directors frequently referred to peer networking as a potential method for skill enhancement. It is not clear, however, if medical directors use this primarily to discuss mutual areas of inexperience or if they actively benefit from each others' experiences as surrogate knowledge. Peer networking takes place primarily through conferences and electronic mail. A sample comment was that:

> So we can sit and just sort of talk about things in general, and get a sense of where each other are, call each other and ask for help or advice, or to discuss a topic. We have a listserve…where people put out questions to the whole medical director group, and people are very good about responding. To me, that's been very powerful... (Director H)

The guidance of a mentor is often mentioned as a highly effective training method. Those with mentors often praise the relationship. Some participants describe trying to provide mentoring for others, even when they lack such assistance themselves. When available, mentoring appears to be one of the most effective methods for achieving success and satisfaction in the position. Director A stated that:

> Mentors are the only way I have survived.

Director C said that:

> He was just a senior person, and…he was very helpful in terms of commenting on how the world works…I would say, 'This thing just seems funny' and he would say, 'Well, this is why it's not funny. This is why it really is how it is...' And it was really useful to get reality checks from people like him.

Several of the medical directors interviewed pursued graduate degrees. In general, these are felt to be very helpful, particularly those focusing upon business or health care administration. A formal degree seems most helpful when obtained after acquiring some experience as a physician administrator, rather than prior to any such work experience.

> I started working as the site director again a little while after I started business school. And I was much better able to do it after a while…the job just came at me slower. And so that was a much more enjoyable year. (Director C)

When asked about the types of training they would desire most, subjects preferred programs with a practical approach. Medical directors feel programs should allow them to directly apply training to problems in their own health centers. They also seek flexibility in adapting such training to fit their personal needs and commitments. Sample comments included:

> It'd be nice to be able to take that [conference] stuff home, work on it, and get more feedback…later on. (Director D)

> It could be, spend three hours on a Saturday morning… do that once a month, and then have time between courses where you live your life…Folks'll learn this interesting concept, and then carry it back to where they work, and then have enough time to noodle around with it while they're doing their life. (Director C)

In the focus group, core themes from the individual interviews were confirmed. There was a particular focus on preferred training approaches.

In summary, medical directors entered leadership roles motivated by a desire to make improvements in CHC care. Many quickly found themselves unprepared and unable to achieve improvements they desired. Many sought training through conferences, peer networking, mentoring, and formal degree programs. In general, medical directors believe that additional training programs would be useful, especially if programs included longitudinal project work with direct application, components of peer networking and mentorship, and flexibility in interacting with the curriculum.

Discussion

In recent years, the medical community has focused attention on health care quality, patient safety, chronic disease management, operational improvement, and information management. The complexity of these tasks demands a higher level of leadership skill than ever before,[18] yet many new physician leaders of CHCs feel unprepared. Our results show this to be compounded by poorly defined roles, lack of mentorship or peer networking opportunities, and medical directors' own inexperience.

A resulting lack of success by medical directors in achieving CHC improvement may contribute to human resource issues of retention and turnover. To be successful, medical directors must provide transformative leadership to their institutions: training can assist in achieving this goal.[13]

Our findings suggest training methods that may be most useful. Longitudinal programs that provide mentoring and project work are preferred by our participants. A number of conference training opportunities are available, but these 1-day to 1-week courses do not suffice. The Health Disparities Collaboratives developed by HRSA and the Institute for Healthcare Improvement is one model that includes longitudinal project work and provides a number of helpful resources.[19] It has the broad mission of health care system improvement focused on health disparities but does not focus specifically on the needs of CHC medical directors. We believe our findings demonstrate that additional accessible and comprehensive leadership training opportunities are needed specifically for the clinical leaders of these institutions.[20]

Although our data are limited by the urban nature of our sample, we expect these themes remain similar in other settings. While it is possible that physician leaders in rural CHCs have a different set of experiences and preferences, given inherent challenges in rural areas of accessing educational resources, it seems likely that rural medical directors would share many of the same frustrations regarding training and overall leadership preparedness. It also is important to note that our sample is recruited almost entirely from Massachusetts, an area with a high number of tertiary care medical centers and robust funding mechanisms of health care for the uninsured relative to many other areas of the country. These differences would seem to make it more likely, however, that our participating medical directors would have good access to postgraduate leadership training opportunities and fewer financial, recruitment, and other challenges relative to counterparts in other areas of the nation.

This research has important implications for medical education as well as public policy. At a time when comprehensive health care reform is being discussed, the fate of the medically underserved becomes inextricably entwined with the health of the entire nation, and CHC medical directors are a key group of primary care physician leaders necessary for providing high-quality health care to underserved populations. The struggles of these physician leaders may signal a more significant deficit in medical education regarding issues of physician leadership, particularly in primary care. Our results suggest further training is needed both to prepare new medical directors and successfully retain those currently serving in this role. Government, health centers, and academic and postgraduate training institutions will need to work together to generate adequate funding and develop and coordinate this important leadership training to provide the highest quality health care to all.

Acknowledgments: Our thanks to the medical directors and the staff from the Massachusetts League of Community Health Centers who assisted in our research.

This study was presented at the 2008 Society of Teachers of Family Medicine Annual Spring Conference in Baltimore.

ABSTRACT

Background The internet can contribute to improved access to information and services among underserved populations. Little is known about veterans' use of the internet for health, and how it is affected by socio-demographic characteristics. This knowledge gap is acute given the US Department of Veterans Affairs' (VA's) deployment of a major patient portal/personal health record system.
Objectives To assess the frequency and correlates of veterans' use of the internet and identify personal characteristics impeding veterans' health-related internet use.
Methods Survey of 12 878 randomly selected adults from a panel of 60 000 US households. Veterans were oversampled.
Results Of the 3408 veterans responding, 54% had used the internet and 29% had used the internet specifically for health. In multi-variable analyses, general internet use was positively associated with younger age (OR = 0.03, CI = 0.01–0.06, oldest versus youngest group), higher income (OR = 3.12, CI = 2.10–4.63, ≥$75 000 versus <$25 000), more education (OR = 4.2, CI = 2.92–6.02, most versus least educated group), and better health (OR = 0.59, CI = 0.42–83, fair/poor versus very good/excellent). Health-related internet use was positively associated with more education (OR = 2.32, CI = 1.45–3.74, most versus least educated group), urban location (OR = 2.41, CI = 1.66–3.50), and worse health (OR = 1.85, CI = 1.16–2.95, fair/poor versus very good/excellent).
Conclusions In the first large, systematic survey of veterans' internet use we found that more education and urban location were strongly, and positively, associated with veterans' health-related internet use, even after controlling for multiple socio-demographic characteristics. Interventions may be needed for less educated and rural veterans, e.g. by providers discussing internet use with their patients, or by the VA training veterans in health-related internet use.

Keywords: disparities, health information, internet, veterans

Introduction

Access to health information helps patients to make health-related decisions, communicate with their providers and enhance their self-care skills.[1–3] The internet is a promising means of delivering health information to patients[4] and allowing them better access to healthcare systems.[5] Additionally 70–80% of Americans use the internet.[6,7] Studies examining health-related internet use estimate wide differences in use. The Pew Internet and American Life Project has estimated that 63% of Americans have looked for health information online.[6] A recent study, however, looking at use in past 30 days, found that only 13% of Americans had sought health-related information.[8] Additionally, while some disparities seem to consistently emerge, e.g. females and those more educated being more likely to search the internet for health information,[9] there is less consensus about race/ethnicity[10] and very little information about the role of rural location.[11]

Understanding patterns of internet use for health are important for the healthcare organisations that are making the internet an integral component of communication, services and information for patients, i.e. through personal health record (PHR) systems. Two well known examples of PHRs are 'My Health Manager' at Kaiser Permanente and 'MyGroupHealth' at Group Health Cooperative, both of which allow patients to view parts of their electronic medical record and to complete transactions, such as ordering prescription refills or sending secure emails to their doctor or nurse.[5,12] These types of internet-based systems, while they may improve access in general, do not necessarily overcome existing disparities. A study of the Kaiser Georgia PHR found, for example, that African Americans are less likely to register for the Kaiser PHR than white Americans, even after controlling for education, income and internet access.[10]

The Veterans Health Administration (VHA), one of the largest healthcare systems in the USA, also invested substantially in a PHR called My HealtheVet. My HealtheVet provides veterans with health information, allows them to create and maintain health logs, enables online refilling of prescriptions and sends electronic reminders for preventive tests and screening. Despite outreach efforts only about 15% of the approximately five million veterans who receive care in the VHA have registered for My HealtheVet.[13] The reasons are not well understood, and to date there have been no large systematic surveys of veterans' use of the internet for health, though studies of select subgroups of veterans have found that between 54 and 77% have access to the internet.[14,15] We sought to examine the characteristics of veterans and their use of internet, both in general and for health-related purposes. We had access to data from a large national survey conducted in 2002 that oversampled veterans and included questions about health-related internet use.

The survey provides important baseline data for the development of My HealtheVet and similar PHR efforts in other healthcare systems. Rates of general internet use will have assuredly increased since the survey was conducted, but socio-demographic disparities in use of technologies tend to persist for long periods of time.[16] Knowledge of such disparities is crucial for health planners interested in expanding healthcare access through PHRs to hard to reach groups. We were particularly interested in rural–urban disparities in use of the internet and use of the internet for health because serving rural veterans remains a challenge, and a priority, for the VA.[17] We conducted this study first to examine rates of general internet use among veterans, and the socio-demographic characteristics associated with that use; and second to examine, among those veterans who used the internet, the characteristics associated with health-related internet use.

Methods

The study data were collected as part of a larger national survey of internet use for health which reported findings about the general population's use of the internet for health,[18,19] and about internet use among persons with stigmatised illness[20] and among persons with chronic conditions.[21] The study was based on a research panel of 60 000 US households created and maintained by Knowledge Networks Inc., Menlo Park, California. Potential households were contacted using random digit dialling. As part of study participation, every panel household received WebTV internet hardware and software.

For this study, a survey was sent via the internet to 12 878 randomly selected panel members aged 21 years or older, including oversampling of veterans and persons of 50 years of age and older. The survey sample was comparable to the National Health Interview Survey and the Census Bureau's Current Population Survey.[18] Data were collected between December 2001 and January 2002. A total of 8935 persons (69.4%) completed the survey. Additional details of the research panel and sampling have been previously reported.[18]

Respondents were asked about their use of the internet for health-related purposes. All were asked, at the time they joined the panel, whether they had ever used the internet prior to receiving WebTV; those who said yes were classified as 'internet users'. Of the 8935 survey respondents, 3408 were US veterans and formed the analytical sample for this study. Figure 1

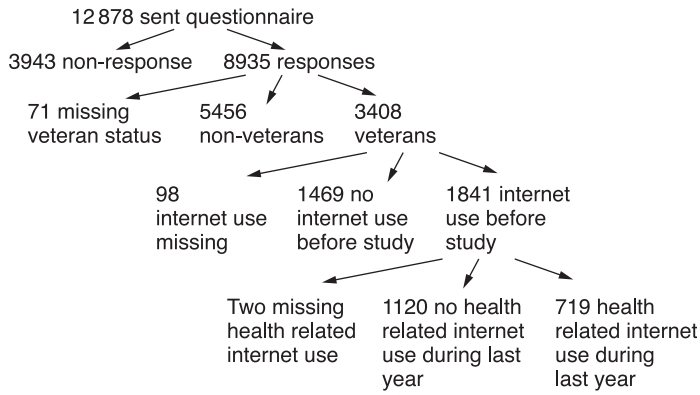

Figure 1 Diagram of analysis of veterans' use of internet for health-related behaviour

shows how the veteran sub-sample is associated with the overall study sample.

Respondents were surveyed about a range of socio-demographic, behavioural and health characteristics, as well as about their use of the internet. Full text of specific items is available from the authors on request. Veterans were identified by a question about being discharged from active duty in the US Army, Navy, Air Force, Marine Corps or Coast Guard. Internet use referred to respondents reporting ever having used the internet prior to the start of the study. Health-related internet use was use of the internet for information or advice about health or health care (possible responses: more than once a week, about once a week, once a month, every two to three months, less than every two to three months or never). For regression analysis we dichotomised this variable with 1 = yes (had used the internet for health in the past year), and 0 = no (had not used the internet for health in the past year).

Race/ethnicity categories were White non-Hispanic, Black non-Hispanic, Hispanic, other non-Hispanic (which included Asian, American Indian or Alaska Native and Pacific Islander). In logistic analyses it was dichotomised (1 = white, 0 = other) due to the small percentages of non-white respondents. Health status was assessed with an item asking, 'Would you say your health in general is ...?', with possible responses of excellent, very good, good, fair or poor, which we recategorised to excellent/very good, good, or fair/poor because of the small percentages in the excellent and poor categories.

Urban location was based on the federal government's categorisation of Metropolitan Statistical Areas, which are urbanised areas of high population density. Travel time to medical care was determined by the item, 'When you need medical care, how long does it take you to get to the place you usually go for care?', with responses of <15 minutes, 15 to 29 minutes, 30 to 60 minutes, and >60 minutes. In logistic analyses we dichotomised this variable (1 = 30 or more minutes, 0 = less than 30 minutes).

Marital status, originally given five categories, was dichotomised (1 = married, 0 = single/divorced/widowed/separated). Number of chronic conditions refers to diagnoses of hypertension, diabetes, cancer, depression and heart problems. We created a dichotomous variable for these (1 = one or more; 0 = none). Use of a VHA hospital or clinic was determined by an item that asked 'Have you received any medical care at a VA hospital or clinic in the last two years?' (1 = yes, 0 = no).

We compared veterans to non-veterans on a number of demographic, health services and internet-related characteristics using chi-square analysis. Among veterans we compared health-related internet use between users and non-users of VHA services. We used multivariable logistic regression to examine, among all the veterans in the study, the characteristics associated with internet use. Next, among the subset of veterans who were internet users, we examined the characteristics associated with health-related internet use. We reported adjusted odds ratios and 95% confidence intervals. In all analyses we used post-stratification weights to match the respondents to the known distribution of the US population on age, sex, race, education, region, metropolitan residence and veteran status, and to account for the oversamples and for non-response. We corrected the standard errors for the complex survey design using PROC SURVEYFREQ and PROC SURVEYLOGISTIC procedures in SAS 9.1 (SAS Institute, Inc., Cary, NC). Chi-square estimates were based on Rao–Scott chi-square tests which adjust for the complex survey design. The study was approved by the Institutional Review Boards at Stanford University and at the Edith Nourse Rogers Memorial VA Hospital, Bedford, MA.

Results

Table 1 compares the demographic and health-related characteristics of veterans and non-veterans. Veterans and non-veterans were equally likely to have used the internet (53.9 vs. 52.5%, $P = 0.41$). Veterans were older, and more often white, married and male ($P<0.001$ for each). They had higher incomes and more education ($P<0.001$ for each). Although more likely to have a chronic health condition, veterans reported similar overall health status to non-veterans.

Nearly one-third of all respondents nationally reported using the internet to search for health information, with veterans reporting similar health-related internet use (29.2%) to non-veterans (32.5%, $P = 0.18$) (Table 2). About 7–8% of both veterans and non-veterans used the internet frequently (monthly or more often) for health-related information. Among veterans, both users and non-users of VHA care were equally likely to use the internet for health-related information ($P = 0.63$).

To understand the factors associated with veterans' internet use, we constructed multivariate regression models to identify independent predictors of internet use in general, and of internet use for health in particular (Table 3). Age was important for general internet use, with the oldest veterans significantly less

[a] Not equal to 3408 due to missing internet use
[b] Not equal to 1841 due to missing health-related internet use
[c] Single refers to never married, divorced, widowed or separated
Urban = resident of metropolitan statistical area (MSA)
Adj. = adjusted OR = odds ratio
CI = confidence interval
VA = Department of Veteran Affairs
Frequencies weighted to correct the distribution of respondents to match the known distribution of the US population on age, sex, race, education, region, metropolitan residence, veteran status and to account for oversamples and non-response.

likely than the youngest veterans to use the internet (OR = 0.03, CI = 0.01–0.06). Among internet using veterans there was no effect of age on health-related internet use. Higher income was positively associated with internet use (OR = 3.12, CI = 2.10–4.63, highest versus lowest income groups), but, like age, among internet using veterans income was not associated with health-related internet use. More education was associated with greater likelihood of internet use (OR = 4.20, CI = 2.92–6.02, most versus least educated group), and among internet using veterans it was associated with greater likelihood of health-related internet use (OR = 2.32, CI = 1.45–3.74, most versus least educated group). Health status had opposite effects in the two regression models. Worse health was associated with a smaller likelihood of general internet use (OR = 0.59, CI = 0.42–0.83, for fair/poor vs very good/excellent), but among internet using veterans, worse health was associated with greater likelihood of health-related internet use (OR = 1.85, CI = 1.16–2.95, for fair/poor vs very good/excellent health). Urban location was associated only with health-related internet use (OR = 2.41, CI = 1.66–3.50).

Discussion

Principal findings

This study represents the first large-scale, systematic report of veterans' use of the internet for health. It sheds light on socio-demographic characteristics that may substantially affect health organisations' ability to provide electronic, health-related information and services to patients with lower education levels and/or living in rural locations. We found that 29% of veterans had used the internet to search for health related information in the past year. Correlates differed between general internet use and health-related internet use. Younger age, higher income, more education and better health status were positively associated with general internet use, while education, living in urban areas and worse health status were positively associated with health-related internet use. The findings about education and rural location are each noteworthy. Education level was a barrier in two ways. First, those with less education were less likely to use the internet in general, and second, even among those who were internet users, less education was associated with less likelihood of using internet for health. Secondly, our study is among the first to document the importance of rural location on internet use for health, even after controlling for internet access and multiple socio-demographic variables. The potential rural barrier is particularly relevant today as the VA strives to improve access and quality of care for rural veterans.[22–24]

Implications of the findings

Our findings demonstrate that patient access to the internet does not guarantee their use of the internet for health-related information and services. Unless health-care organisations make special efforts to include disadvantaged groups, such as the less-educated and those in rural areas, the digital divide will persist. As organisations increasingly digitise they may inadvertently

erect barriers for some groups of vulnerable patients. This suggests that outreach may be needed. Healthcare organisations that intend to reach patients through the internet could provide direct training to vulnerable patients (e.g. those in rural areas, the less educated and those with stigmatised health conditions) to provide them with PHR and internet skills. Healthcare organisations should also consider sensitising and educating clinicians regarding patient internet use, and encourage clinicians to ask their patients if they use the internet for health. For patients who do not, clinicians could motivate them to do so by providing them with the URLs of informative, trustworthy and user-friendly health-related websites. Our findings about education suggest that website developers should carefully consider literacy and health literacy when designing content and layout. Less educated patients may be left behind as healthcare organisations digitise unless health-related websites are tailored to meet the needs of less literate patients. Finally, these data suggest that the VA's special focus on rural veterans is well placed.

Comparison with the literature

Our findings have similarities to, but also differences from, prior studies of internet use. General US population studies have shown that being female, being younger and having more education are positively associated with health-related internet use.[18,25] A recent study of users of a web-based personal health record found that white race and higher income were associated with greater use of the system.[26] Rice (2006) found that being female, being in worse health and having chronic health conditions were associated with health-related internet use.[9] Our results for veterans were similar but with two important distinctions. After controlling for being an internet user (i.e. analysis among veterans who were using the internet prior to the study start) age was not a statistically significant correlate of health-related internet use. Additionally, among the internet using veterans we found that rural respondents were less likely to use the internet for health. This is noteworthy because prior research shows that rural veterans have less contact with the VA, and worse health outcomes, than urban veterans.[22,27] Rural residents' use of the internet for health is an understudied area. Studies to date have been limited by their use of patient populations,[28] small scale qualitative designs[29] and use of convenience samples.[11,30]

Limitations of the method

Our cross-sectional study design precluded inferences of causality. Additionally, the data were collected in 2001 and 2002, so given the rapid development and adoption of online technologies more recent data are clearly desirable. However, because there has been little systematic research to date on veterans' use of the internet and use of the internet for health purposes, this study provides important insights about the socio-demographic characteristics that were barriers at the time of the study, and are likely to still be barriers today, though potentially attenuated. Even the most recent general population studies show that socio-demographic characteristics are still important determinants of health-related internet use.[10] Our results provide important additions to the knowledge about how socio-demographic characteristics affect electronic access to health information.

Call for further research

New surveys of veterans' use of the internet are needed to see if strides have been made in narrowing the gaps in health-related internet use based on education and rural–urban location. Additionally, to encourage greater use, research is needed to better understand physicians' views of patient use of the internet and PHRs. Such research could help healthcare organisations to enlist physicians to encourage their patients to use the internet and PHRs.

Our results provide a baseline against which future research can be compared, to determine whether gains have been made in providing health information and health services through the internet to a greater percentage of veterans. Future research will also evaluate whether disparities have been reduced, especially those based on education and urban–rural location. Additionally, research should examine the possibility that educational and urban–rural differences in internet use are not related to disparities in health information and health outcomes, but that they merely signify that different socio-demographic groups use different (but equally good) health information sources. Finally, additional research is needed to understand what aspects of rural locations might explain the lower rates of health-related internet use. It may be that innovations, such as the positive attributes of the internet for health information, do not diffuse as rapidly in rural locations as in urban locations due to less face-to-face contact.

Conclusions

Younger age, higher income and more education were associated with greater internet use. Among those who used the internet, using it for health-related purposes was strongly associated with education level and with

urban location, even after controlling for multiple socio-demographic characteristics. Healthcare facilities and systems need to recognise that there is unequal use of the internet for health, and that some groups will continue to be disadvantaged in terms of information and online services unless measures are taken to include such groups by tailoring services to their needs, providing training and tutorials and encouraging clinicians to learn about their patients' use of internet.

Jodie A. Trafton, Ph.D.
Steven M. Asch, M.D., M.P.H.
Allen L. Gifford, M.D.

Objective: **This study examined whether organizational characteristics and quality improvement initiatives were related to HIV and hepatitis C (HCV) testing rates in veterans' substance use disorders programs.** ***Methods:*** **Data were collected by surveying 232 program directors at all U.S. Department of Veterans Affairs (VA) substance use disorder programs.** ***Results:*** **Program directors (N=223) reported that, on average, 35% of their patients were tested for HIV (median=10%) and 57% were tested for HCV (median=80%). Of the quality improvement initiatives examined, computerized reminders to clinicians (p=.02) and a designated clinician for screening (p=.01) were positively associated with HCV testing, and computerized templates that guide clinicians through ordering of testing were positively associated with HIV testing (p=.06).** ***Conclusions:*** **Despite national emphasis on HIV testing, rates of testing were lower for HIV than for HCV in programs serving veterans with substance use disorders and at risk of both illnesses. System-level quality improvement initiatives may be effective at increasing rates of infectious disease screening. (*Psychiatric Services* 61:90–94, 2010)**

Dr. McInnes is affiliated with the Center for Health Quality Outcomes and Economic Research (CHQOER), Edith Nourse Rogers Memorial Veterans Hospital, 200 Springs Rd. (152), Bldg. 70, Bedford, MA 01730 (e-mail: keith.mcinnes@va.gov). He is also with the Department of Health Policy and Management, Boston University School of Public Health, Boston. Dr. Hyun is with the National Center for PTSD, Department of Veterans Affairs (VA) Palo Alto, Palo Alto, California. Dr. Trafton is with the VA Center for Health Care Evaluation, Menlo Park, California. Dr. Asch is with the HIV Hepatitis Quality Enhancement Research Initiative, VA Greater Los Angeles Health Care System, and the Department of Medicine, David Geffen School of Medicine at the University of California, Los Angeles. Dr. Gifford is with the HIV Hepatitis Quality Enhancement Research Initiative, VA New England Health Care System, Bedford, Massachusetts, and Boston University Schools of Public Health and Medicine.

HIV and hepatitis C virus (HCV) infections are leading causes of death and disability in the United States. Much of the morbidity and mortality from these conditions is due to late detection and late entry into care (1,2), which could be addressed by more widespread screening and testing. The Department of Veterans Affairs (VA) is the largest provider of HIV and HCV care in the United States. Despite efforts to increase testing among veterans (3,4), rates of HIV and HCV testing remain suboptimal, even among those with known risk factors. Substance use disorders increase the risk of infection by HCV (5) and HIV (6,7). Despite this increased risk, a recent study in the Pacific Northwest found that only 19% of VA patients with substance use disorders had been tested for HIV and only 60% had been tested for HCV (8).

Beginning in 1999 the VA mandated its health facilities to conduct universal screening for HCV risk factors (and to conduct antibody testing if risk factors were present), created a computerized clinical reminder in the electronic medical record, which prompts providers to screen and test their patients for HCV, and made HCV risk screening a quality performance measure (3). The VA has also devoted resources to increasing HIV screening rates (4). Recent research has shown that quality improvement initiatives such as provider feedback and provider activation can increase HIV testing rates among at-risk patients (4). Little is known, however, about how these policies and characteristics of substance use disorder programs may affect infectious disease testing rates in substance use disorder programs.

The Drug and Alcohol Program Survey (DAPS) collects data about the VA's substance use disorder programs, which treat over 120,000 patients annually. In 2006 all VA substance use disorder clinics (N=232) responded to the DAPS survey, which for the first time included questions about HIV and HCV testing and about system-level initiatives to increase testing rates (for example, computerized reminders and provider feedback). We describe

HIV and HCV testing rates by substance use disorder program type. We also evaluate whether quality improvement systems are related to HIV and HCV testing rates.

Methods

We surveyed every VA program that was designed to treat patients who have substance use disorders, had at least two full-time staff, and could be distinguished from other programs on the basis of unique staffing, patients, clinical services, or policies. The survey response rate was 100% (N=232). Of these, nine programs did not meet the above inclusion criteria, resulting in 223 programs in our analyses.

The survey was mandated in all VA substance use disorder programs, was conducted between October 1, 2006, and January 31, 2007, and was completed by the substance use disorder program director or designee. It covered patient characteristics, treatments, staffing, continuity of care, HIV and HCV screening and testing, and quality improvement systems in use. For most items, respondents were asked to describe programs and characteristics in place during September 2006. Program directors were asked about services directly delivered within their substance use disorder programs. Information gathered included the outcome measures of the percentage of clinic patients who, between October 1, 2005, and September 30, 2006, received HIV testing and HCV testing from program staff. We combined conceptually related items into indices.

The six quality improvement systems assessed were provider education, computerized reminders, computerized templates to guide test orders, provider performance profiling and feedback, presence of a clinical champion to promote and monitor the progress of testing, and presence of a designated clinician for testing. All of these variables were dichotomous. They were selected because they are commonly used quality improvement methods that have been used to increase infectious disease testing (4,9,10).

Treatments and services provided in the substance use disorder programs were assessed through two variables. Supplementary services referred to smoking cessation and vocational training, and the variable was calculated by summing the percentages of patients engaged in a smoking cessation program or in vocational training and then dichotomizing at the median (a code of 1 indicated more patients receiving services). Evidence-based medication therapy was a dichotomous variable, where 1 indicated use of any of five treatments (methadone, buprenorphine, or naltrexone for opioid use, and naltrexone or acamprosate for alcohol use) and 0 indicated that none of these treatments were used.

Six variables described program characteristics, such as program type (such as inpatient or residential), staffing, patients, and emphasis on infectious disease testing. The priority a clinic places on infectious disease testing was assessed by asking respondents to compare HIV testing (for the first regression model) and HCV testing (for the second regression model) with the "assessment and treatment of other common conditions (mental health care, diabetes monitoring, cancer screening, chronic pain management)," scored as 0, not important; 1, somewhat important; and 2, very important. Substance use disorder programs were uniquely assigned to one category according to type of treatment and services they provided (11). Inpatient programs provided 24-hour acute care. Residential programs provided round-the-clock care but without 24-hour medical staff. Intensive outpatient programs provided at least three hours of programming three days per week, and standard outpatient programs (the reference category in multivariate models) provided care that did not meet the frequency criteria of intensive treatment for outpatients. All programs provided psychosocial rehabilitation.

Medical staff was assessed by the number of physicians, physician assistants, and nurses divided by total staff and then dichotomized at the median; social welfare staff was quantified as the sum of psychologists, social workers, addiction therapists, and psychiatric technicians or aides divided by total staff and then dichotomized at the median (with 1 indicating more staff). Number of unique patients represented patients admitted to the program during the 2006 fiscal year. Patients with complex needs represented five summed variables—percentages of patients who were homeless (or in unstable living arrangements), nicotine dependent, opioid dependent, or not married (or in a long-term relationship) or who had a major psychiatric disorder, with results dichotomized at the median (with 1 indicating more patients with complex needs).

Descriptive statistics were estimated for total respondents and for each program type (inpatient, residential, intensive outpatient, or standard outpatient). We compared program types by organizational characteristics by using analysis of variance and chi square tests. Next, we estimated differences in the use of quality improvement systems for HIV testing versus HCV testing using chi square tests.

Multivariate regression analyses were conducted with HIV and HCV testing rates as the dependent variables. In the models, we retained variables that in bivariate analyses were significantly associated ($p \leq .05$) with either HIV testing or HCV testing. In addition, despite bivariate nonsignificance, for conceptual reasons we retained clinical champion, inpatient program, intensive outpatient program, and number of patients in multivariate models. We examined interactions between designated clinician for screening and medical staffing levels, between designated clinician for screening and number of patients, and between evidence-based medication treatments and medical staffing levels. We conducted sensitivity analyses to see whether our results differed when the outcome variables (HIV and HCV testing rates) were dichotomous instead of continuous. We used three cut points for dichotomization: 75%, 50%, and 25% of patients tested. This study was approved by the Stanford University Institutional Review Board and Veterans Affairs Palo Alto Health Care System Research and Development Committee.

Results

In all programs combined (N=223), mean±SD reported testing rates were lower for HIV (35%±40% of patients in the program, median 10%) than for HCV (57%±44%, median 80%) (t=8.61, df=222, p<.001 for difference of means). Residential programs (N=65) reported testing the largest proportion of patients for HIV and HCV. For HIV, residential programs tested 51%±44% of patients, versus 23%±35% for outpatient programs (N=97) (F=6.52, df=3 and 219, p<.001). For HCV, residential programs tested 73%±39% of patients, versus 45%±45% for outpatient programs (F=5.63, df=3 and 219, p=.001). Inpatient programs (N=19) tested 40%±42% and 63%±43% of patients, on average, for HIV and HCV, respectively, whereas intensive outpatient programs (N=42) tested 36%±39% and 55%±44% of patients, respectively. About one-third of programs (N=77 or 35%) tested more than half of their patients for HIV, 131 programs (59%) tested more than half for HCV, and 74 programs (33%) tested more than half of their patients for both HIV and HCV. The Pearson correlation between HIV and HCV testing was .61 (p<.01). Residential programs, compared with the other types of program, rated the importance of HIV testing (F=5.29, df=3 and 217, p=.002) and HCV testing (F=4.75, df=3 and 216, p=.003) highest compared with testing for other conditions, and outpatient and inpatient programs rated the importance of HIV and HCV testing lowest.

On average, of the quality improvement systems, programs used computerized reminders most frequently (91 programs, 41%, for HIV and 164 programs, 74%, for HCV) (χ^2=22.28, df=1, p<.01), followed by provider education (122 programs, 55%, for HIV versus 131 programs, 59%, for HCV), computerized templates (92 programs, 41%, for HIV versus 106 programs, 48%, for HCV), designated clinician for testing (78 programs, 35%, for HIV versus 84 programs, 38%, for HCV), performance profiling (32 programs, 14%, for HIV versus 41 programs, 18%, for HCV), and clinical champion for testing (19 programs, 9%, for HIV versus 34 programs, 15%, for HCV). These systems were used more for HCV than for HIV, although the difference was significant for computerized reminders only.

Results of multivariate models are shown in Table 1. Computerized templates were positively associated with HIV testing, although the association was not quite significant (p=.06). For HCV testing, use of computerized reminders (p=.02) and use of a designated clinician for screening (p=.01) were significant. Provision of supplementary services (smoking cessation services and vocational training) was positively associated with HCV testing (p=.001), and use of evidence-based medication therapy was positively associated with both HIV testing (p=.01) and HCV testing (p<.001). Among program characteristics, priority placed on infectious disease testing was significantly associated with HCV testing (p=.002), residential programs (compared with standard outpatient programs) were more likely to test for both HIV (p<.001) and HCV (p=.01), and the variable patients with complex needs was positively associated with HIV testing (p=.03). None of the interactions we examined (between designated clini-

[a] Analysis of testing rates in the Veterans Affairs (VA) system was by multivariate ordinary least-squares regression.
[b] Adjusted R^2=.16, F=3.51, df=16 and 200, p<.001
[c] Adjusted R^2=.32, F=7.42, df=16 and 199, p<.001
[d] Separate items were used for program priority for HIV testing (used in the HIV testing model) and for HCV testing (used in the HCV testing model).
[e] Reference group is standard outpatient setting.

cian and medical staffing levels, between designated clinician and number of patients, and between evidence-based medication treatments and medical staffing levels) were statistically significant. Our sensitivity analyses with dichotomous outcome variables produced substantially the same results as with continuous outcomes.

Discussion

In the first nationwide survey of HIV and HCV testing in VA substance use disorder programs, 223 program directors reported testing, on average, 35% of patients for HIV and 57% for HCV. The highest rates of testing were in residential programs (51% for HIV and 73% for HCV), and the lowest rates were in standard outpatient programs (23% for HIV and 45% for HCV). Computerized templates to guide test orders were associated with higher reported HIV testing rates, although the relationship did not achieve statistical significance (p=.06). Computerized reminders and designated clinician for screening were associated with higher reported HCV testing rates. There was substantial variation in the use of the quality improvement systems, ranging from computerized reminders used by 91 (41%) and 164 (74%) programs, respectively for HIV and HCV testing, to clinical champions for testing used by 19 (9%) and 34 (15%) programs, respectively.

Reported testing rates for both HIV and HCV are strikingly low, especially given that patients with substance use disorders are at high risk for both conditions and that guidelines supporting testing of these groups are widely endorsed and disseminated. There are several possible explanations for low testing rates. Providers with many demands may focus on their immediate job of treating substance use disorders. Especially with opioid-dependent patients, providers may feel a sense of urgency to stabilize their patients above all else, in order to prevent relapse and possible death from overdose. Other providers may not be aware of the importance of viral screening. Also, patients' refusal of testing could contribute to low testing rates.

The 22% gap we found between mean reported HIV and HCV testing rates may reflect HIV testing policies in the VA at the time that made HIV testing more of a clinical burden than other blood tests by requiring written informed consent and pre- and posttest counseling. Also, until recently, VA policy strongly emphasized HCV testing by mandating computerized clinical HCV testing reminders. Also, the greater prevalence of HCV infection among veterans may lead to greater provider awareness and higher priority for HCV testing and treatment. The positive association between percentage of patients with complex needs and HIV testing rates may similarly reflect greater interest in infectious disease screening when clinicians and managers perceive, on the basis of patient characteristics, that HIV prevalence may be high in their patient population.

Of interest is that use of evidence-based medication therapies for opioid and alcohol use was significantly associated with both HIV and HCV testing rates. We suspect that programs using evidence-based medication therapies are more medically (versus behaviorally) oriented and thus may order more medical diagnostic tests, such as those for HIV and HCV. Also noteworthy, computerized templates were positively associated with only HIV testing, whereas computerized reminders were significantly associated with only HCV testing. The former may indicate that computerized templates were well suited for HIV testing in the VA because of the multiple steps and forms required when we conducted our survey (the process in the VA has been streamlined since then), and the latter may reflect the VA's implementation of the HCV testing reminder in the electronic medical record (3). The association of a designated clinician for HCV screening may indicate that providers are more likely to order tests if they know that a responsible clinician will ensure their implementation.

Our study has several limitations. Data were collected cross-sectionally, which limits our ability to make causal inferences. We used reports from program directors to assess HCV and HIV testing rates. The rates we observed may be subject to reporting bias (such as inflated estimates). Our findings for HIV testing, however, are similar to recent, separate analyses of VA administrative data that suggest that about 28% of veterans treated in substance use disorder programs receive HIV testing (12). Thus it is likely that the rates of testing shown here, although generally low, may have been even lower if we used different methods. Our independent variables were also based on respondent report and were not independently verified. It is important to note, however, that substance use disorder programs are the only repository of information about services and testing provided to patients in those programs. VA administrative data structures do not allow unambiguous matching of patients to specific substance use disorder programs. Thus this survey represented the most efficient means of examining system-level issues in substance use disorder programs and enabled the comparison of program-level testing rates with program-level characteristics, such as services provided and staffing levels.

Conclusions

Despite limitations, these national survey results suggest strikingly low rates of testing in VA substance use disorder programs, with 35% of patients tested for HIV and 57% tested for HCV. The gap between the rates may reflect differences in VA policies (at the time of the survey, written informed consent was required for HIV testing) or greater awareness, among providers, of HCV because of its higher prevalence. Our finding of an association between quality improvement systems and higher testing rates is encouraging for substance use disorder programs interested in increasing testing rates. Most promising were computerized templates for HIV testing and computerized reminders and designated clinicians for HCV testing.

Are Residents' Decisions Influenced More by a Decision Aid or a Specialist's Opinion? A Randomized Controlled Trial

Mitchell A. Medow, MD, PhD[1], Hal R. Arkes, PhD[2], and Victoria A. Shaffer, PhD[3]

[1]Section of General Internal Medicine, Boston University School of Medicine, Boston, MA, USA; [2]Department of Psychology, The Ohio State University, Columbus, OH, USA; [3]Department of Psychology, Wichita State University, Wichita, KS, USA.

BACKGROUND: Physicians are reluctant to use decision aids despite their ability to improve care. A potential reason may be that physicians do not believe decision aid advice.

OBJECTIVE: To determine whether internal medicine residents lend more credence to contradictory decision aid or human advice.

DESIGN: Randomized controlled trial. Residents read a scenario of a patient with community-acquired pneumonia and were asked whether they would admit the patient to the intensive care unit or the floor. Residents were randomized to receive contrary advice from either a referenced decision aid or an anonymous pulmonologist. They were then asked, in light of this new information, where they would admit the patient.

PARTICIPANTS: One hundred eight internal medicine residents.

MEASUREMENTS: The percentage of residents who changed their admission location and the change in confidence in the decision.

MAIN RESULTS: Residents were more likely to change their original admission location (OR 2.3, 95% CI 1.04 to 5.1, P=0.04) and to reduce their confidence in the decision (adjusted difference between means −12.9%, 95% CI −3.0% to −22.8%, P=0.011) in response to the referenced decision aid than to the anonymous pulmonologist. Confidence in their decision was more likely to change if they initially chose to admit the patient to the floor.

CONCLUSIONS: In a hypothetical case of community-acquired pneumonia, physicians were influenced more by contrary advice from a referenced decision aid than an anonymous specialist. Whether this holds for advice from a respected specialist or in actual practice remains to be studied.

KEY WORDS: decision aid; judgment; choice behavior; internship and residency.

J Gen Intern Med 25(4):316–20
DOI: 10.1007/s11606-010-1251-y

Physicians are reluctant to use medical decision aids, despite their documented ability to improve the quality of patient care[1–6]. For example, Garg's systematic review[1] found that clinical decision support systems improved performance in 64% of the 97 studies identified. Yet physicians do not use decision aids. Only 4% of physicians in a recent national survey of ambulatory physicians had access to a fully functional electronic health record that offered rudimentary decision support (medication warnings, out-of-range laboratory indications and guideline-based reminders).[7] Even physicians exposed to a helpful aid in a randomized controlled trial and who experienced its benefits did not continue to use it after the trial [8]. Factors relating to this underutilization are commonly classified as pertaining to the clinical problem, patient factors, provider traits, system characteristics and the health-care environment [9]. We have been exploring issues affecting the psychological perspective of the provider on the use of decision aids [10,11]. Perhaps physicians simply do not put as much credence in the recommendation of a decision aid compared with the advice of a colleague. Dreiseit and Binder [12] found that dermatologists changed their decisions in only a quarter of the cases when a decision aid contradicted them. To ensure conflict between the physicians and the decision aid, their system purposefully gave an incorrect diagnosis in about a third of the cases presented.

To further test the hypothesis that physicians may not believe decision aids as much as they believe colleagues, in the present study we gave internal medicine resident physicians a case scenario of a patient with pneumonia and asked them whether they would admit the patient to the floor or the intensive care unit (ICU). We then presented them with contradictory advice from either a referenced decision aid or an anonymous pulmonologist and again asked, in light of the new advice, to which location they would admit the patient. No subterfuge was needed in this scenario—two validated decision aids made different recommendations based on the same data.

METHODS

Research Question

Do physicians, when confronted with contradictory advice, lend more credence to a referenced decision aid or an anonymous specialist?

Subjects

One hundred eight residents in The Ohio State University (OSU) Medical Center's internal medicine residency program (preliminary, categorical, combined Medicine/Pediatrics and chief residents) were recruited in November 2007. Subjects were recruited through a written letter and an oral request at a conference. They were e-mailed occasional reminders if they did not complete the survey and a thank-you note when they completed the survey. To augment our enrollment we used a convenience sample of internal medicine residents from MetroHealth Medical Center, recruited by one of their chief residents with a single solicitation in June 2008. They completed the survey in July. All participants were paid $50.

Procedure

The study was conducted electronically over the World Wide Web. Each resident was presented the case of community-acquired pneumonia (CAP) and asked if the patient should be admitted to the floor or the ICU (figure in online-only Appendix). The case was carefully constructed such that the two major decision aids for CAP offer different recommendations. The PORT (Pneumonia Patient Outcomes Research Team) Score[13] suggests a floor admission, while the CURB-65 (Confusion, Urea, Respiratory Rate, Blood Pressure and age 65 or older)[14] suggests an ICU admission. After reading the case subjects were asked:

(a) Do you feel that Ms. J should be admitted to the intensive care unit (ICU) or to the floor? (Please choose one option.)
(b) Please indicate your confidence in your decision by selecting a level below from 50% (no confidence) to 100% (complete confidence).

After answering these two questions, subjects were then presented with contradictory advice. For example, if they decided to admit the patient to the floor, they were presented with advice to admit the patient to the ICU. Each subject was randomized by computer to get this contradictory advice from either (a) a referenced decision aid (DA) or (b) an anonymous pulmonologist.

An example of the advice from the decision aid is "A severity score has been developed for community acquired pneumonia (Fine MJ, Auble TE, Yealy DM, et al., "A Prediction Rule to Identify Low-Risk Patients with Community-Acquired Pneumonia." N Engl J Med. 1997 Jan 23;336 (4):243–50). The community-acquired severity score classifies this case as Class IV, for which hospital admission is advised, but ICU admission is not necessary."

An example of the advice from the anonymous pulmonologist is, "As you are getting ready to admit the patient, you run into a pulmonologist and decide to ask their advice. After you present the patient, you ask the pulmonologist whether Ms. J should be admitted to the ICU or to the floor. The pulmonologist suggests a floor admission."

After reading the contradictory advice, the subjects were again asked whether the patient should be admitted to the intensive care unit (ICU) or to the floor, and for their confidence in that decision.

Analysis

The primary endpoint was the comparison of the number of subjects that switched their decision about the admission location (e.g., floor to ICU) when given the decision aid or pulmonologist's advice (randomized), stratified by their initial decision (self-selected, i.e., floor or ICU). We used a logistic regression model to check the independent statistical significance of the change in the admission location with respect to (1) the source of the advice (randomized) and (2) the initial admission location (self-selected). We used a full model with all interaction terms among the initial admission location, source of advice and residency program to determine if any of the interaction terms were statistically significant.

The secondary endpoint was the change in confidence in the decision. Confidence change was calculated as the change in confidence between the final and initial confidence indicated by the subjects, adjusted for changes of location. The change in confidence was analyzed with an analysis of variance (ANOVA) model including the source of advice (randomized) and the initial admission location (self-selected). A full model, with all the interaction terms, was also tested.

All statistical tests were two-sided with α=0.05. The analysis was done with R version 2.9.2[15].

Sample Size

We would need 65 subjects in each group (130 total subjects) to have 90% power to detect a difference in the proportion of residents who changed their admission location from 5% to 25%, with a two-sided α of 0.05. We had enough incentive funds to survey 110 subjects; therefore, that was our target enrollment with 84% power to find the hypothesized difference.

Institutional Review and Funding

The study was approved by The Ohio State Institutional Review Board.

RESULTS

Subjects

Of the 108 residents solicited from OSU, 85 responded, 2 with incomplete data (77% response rate). Twenty-five of 99 solicited residents from MetroHealth completed the survey. Thus, there was a total of 108 participants. The subjects were mostly categorical internal medicine (71) and combined internal medicine-pediatrics (24) residents. Fifty-two subjects were randomized to receive contrary advice from the decision aid and 56 from the pulmonologist (Table 1).

Location Change

Overall 48 of the 108 subjects (44.4%, 95% CI: 34.9–54.3%) changed the admission location in response to the contrary

advice (Table 2). When the resident received advice from the decision aid, the resident changed the admission location in 53.8% of the cases (95% CI: 39.5–67.8%). When the resident received advice from the pulmonologist, the resident changed the admission location in only 35.7% of the cases (95% CI: 23.3–49.6%). The unadjusted relative risk for a subject to change their admission location was 1.51, indicating that subjects were approximately 50% more likely to change their decisions in response to advice from the decision aid than from a specialist. The unadjusted odds ratio (OR) was 2.10. The adjusted OR from the logistic regression model including the initial admission location (the pre-specified primary endpoint) was 2.27 (95% CI: 1.04–5.08; P=0.04), indicating that the odds of changing the admission location if given contradictory advice from the decision aid were over two times the odds of changing the decision if given advice from the pulmonologist. In the full logistic regression model with all the interaction terms included, none of the terms (the source of advice, the initial admission and the interaction terms) showed significance. Significance of the interaction terms would have suggested that the effect of one of the terms (e.g., the source of advice) had different effects depending on the value of the other term (e.g., the initial admission location). There was no association between location change and either initial confidence (P=0.50) or year of training (P=0.33).

Confidence Change

In the ANOVA model exploring changes in confidence, both the subjects' initial admission location and the source of advice were statistically significant. Respondents were more likely to change their confidence in their initial decision towards the contrary advice after hearing the decision aid's recommendation (unadjusted mean, −36.0%; SD=29.7) than the pulmonologist's recommendation (unadjusted mean, −23.0%; SD=22.9; adjusted difference between means, −12.9%; 95% CI –3.0% to −22.8%, P=0.011), irrespective of their initial admission decision. Second, residents were more likely to lower their confidence in their initial decision if their initial admission location was to the floor (unadjusted mean, −32.8%; SD=26.0) than to the ICU (unadjusted mean, −22.2%; SD=28.1; adjusted difference between means −12.0%, 95% CI −1.5% to −22.4%, P=0.025). In the full model including all the interaction terms, the main effects of source of advice and initial admission location were significant ($P \leq 0.025$), whereas the program and the interaction terms were not statistically significant ($P > 0.13$).

DISCUSSION

Contradictory advice from a referenced decision aid was more effective in influencing resident physician decisions than contradictory advice from an anonymous specialist, as evidenced by the change in admission location and the change in confidence. Interpretation of this result is complicated by the asymmetry in the description of the alternatives. In designing the study we elected to provide the minimal necessary description of the decision aid, which we felt to be identifying information (i.e., its name and literature citation), and its recommendation (e.g., "The community-acquired severity score classifies this case as Class IV, for which hospital admission is advised, but ICU admission is not necessary."). We purposefully did not repeat data used by the aid (e.g., respiratory rate) or the aid's test characteristics (e.g., positive predictive value). We kept the human opinion anonymous since locally respected leaders can affect adherence[16]. Instead, we vested the human in the mantle of a specialist. Thus, the description of the decision aid, although minimal, was more elaborate than that of the human, which could have affected the results. It is unclear if using an anonymous decision aid or a locally respected human would have produced the same results.

This result is unexpected given the general reluctance of physicians to utilize decision aids[17]. One might have surmised that physicians do not find decision aid advice credible. Yet the physicians in our study were more likely to be influenced by the decision aid. In the clinic physicians might still eschew decision aids because of other problems, such as patient, provider, system and health-care environment factors. By design, we did not examine whether the resident would use a decision aid, the residents' opinions of decision aids or the residents' attitudes about physicians who use decision aids. In a previous study, Arkes et al.[10] showed that patients and

Table 2. Location Change Results

	Initial admission to the ICU		Initial admission to the floor	
	Switched	Did not switch	Switched	Did not switch
Decision aid	9 (9/20=45%)	11 (11/20=55%)	19 (19/32=59%)	13 (13/32=41%)
Specialist	4 (4/16=25%)	12 (12/16=75%)	16 (16/40=40%)	24 (24/40=60%)

ICU = Intensive care unit. Odds ratio for the source of advice (decision aid vs. pulmonologist) 2.3, 95% CI 1.0 to 5.1, P=0.04. Odds ratio for the initial admission location (ICU vs. floor) 0.5, 95% CI 0.2 to 1.2, P=0.15

medical students derogate physicians who use decision aids. This suggests that physician attitudes about using decision aids and their actions when given (unsolicited) decision aid recommendations diverge.

Only about half of the physicians in training were willing to change their decisions based on advice from a more qualified source. We cannot conclude that the physicians in our study who maintained their initial hypothesis were mistakenly preserving an incorrect one. First a decision to admit to either the ICU or the floor was justified by one of the two reputable decision aids on this topic. Second, assessing the accuracy of management decisions, such as the decision to admit to ICU, is more difficult than assessing the accuracy of diagnostic decisions, as the criterion for accuracy is less definitive. Thus, management decisions may not have an indisputably correct course of action that should resist the contrary guidance of a decision aid or colleague.

Although our research focuses on a management decision, parallels drawn from the literature on diagnostic decisions may inform this discussion. Berner and colleagues[18] found that residents often maintained an unquestionably incorrect diagnosis despite a decision support system's suggestion of the correct diagnosis. They suggested that their findings may have been due to overconfidence on the part of the residents. In support of Berner and colleagues' suggestion, Dreiseit and Binder[12] found in a study of dermatologists' decision making that there was a negative correlation between a physician's confidence and their propensity to change their decisions. These studies suggest that if a physician is highly confident in his or her diagnosis irrespective of its conformity to or the existence of any gold standard, then any recommendation, regardless of the source, may not be influential. Overconfidence is particularly troubling because confidence is often not highly correlated with accuracy[19,20]. As a result, a physician who uses his or her confidence as a basis for disregarding advice may be making an ill-advised decision.

There are a few limitations to our study. The major limitation is the asymmetry between the description of the decision aid and the specialist's advice. Absent from written scenarios is the potential social cost of defying a colleague with whom one might have subsequent interactions. Thus, these results may not generalize to cases where the specialist is highly respected or there is a large social cost to defying the advice of the specialist.

Another potential limitation is our use of hypothetical decisions. Hypothetical decisions may not map on to real decisions; however, using a hypothetical scenario allowed us to create a case where two credible decision aids provided contradictory advice. Also, our use of residents may limit our ability to generalize these results to more experienced physicians. However, approximately one third of the residents were at the end of their final year of training, and pneumonia is a common clinical problem that most house-staff become familiar with early in their first year. This suggests that the results might also pertain to more experienced clinicians.

Future studies can attempt to tease out the salient characteristics of the decision aid or human opinion that enhance their credibility.

CONCLUSIONS

Physicians in training treating a scenario depicting community-acquired pneumonia were more influenced by the recommendation of a referenced decision aid than the recommendation of an anonymous specialist, each of which provided advice that conflicted with the initial admission decision. This suggests that greater adherence to human over decision aid advice is not a cause of decision aid non-use. Future research should further evaluate physician attitudes to decision aid use, the response to respected specialists and how justifications might influence the physician's adherence to the decision aids, as well as confirming and extending the results to other clinical scenarios and physician populations.

Effectiveness of Policies Maintaining or Restricting Days of Alcohol Sales on Excessive Alcohol Consumption and Related Harms

Jennifer Cook Middleton, PhD, Robert A. Hahn, PhD, MPH, Jennifer L. Kuzara, MA, MPH, Randy Elder, PhD, Robert Brewer, MD, PhD, Sajal Chattopadhyay, PhD, Jonathan Fielding, MD, MPH, MBA, Timothy S. Naimi, MD, MPH, Traci Toomey, PhD, Briana Lawrence, MPH, the Task Force on Community Preventive Services

Abstract: Local, state, and national laws and policies that limit the days of the week on which alcoholic beverages may be sold may be a means of reducing excessive alcohol consumption and related harms. The methods of the *Guide to Community Preventive Services* were used to synthesize scientific evidence on the effectiveness for preventing excessive alcohol consumption and related harms of laws and policies maintaining or reducing the days when alcoholic beverages may be sold. Outcomes assessed in 14 studies that met qualifying criteria were excessive alcohol consumption and alcohol-related harms, including motor vehicle injuries and deaths, violence-related and other injuries, and health conditions.

Qualifying studies assessed the effects of changes in days of sale in both on-premises settings (at which alcoholic beverages are consumed where purchased) and off-premises settings (at which alcoholic beverages may not be consumed where purchased). Eleven studies assessed the effects of adding days of sale, and three studies assessed the effects of imposing a ban on sales on a given weekend day. The evidence from these studies indicated that increasing days of sale leads to increases in excessive alcohol consumption and alcohol-related harms and that reducing the number of days that alcoholic beverages are sold generally decreases alcohol-related harms. Based on these findings, when the expansion of days of sale is being considered, laws and policies maintaining the number of days of the week that alcoholic beverages are sold at on- and off-premises outlets in local, state, and national jurisdictions are effective public health strategies for preventing excessive alcohol consumption and related harms.

Introduction

Excessive alcohol consumption in the U.S. is responsible for approximately 79,000 deaths per year, making it the third-leading cause of preventable death.[1] Approximately 15% of U.S. adults aged ≥18 years and approximately 29% of high school students in the U.S. report binge drinking (consuming five or more drinks per occasion for men, and four or more drinks per occasion for women).[2,3] The direct and indirect economic costs of excessive drinking in 1998 were $184.6 billion.[4] The reduction of excessive alcohol consumption is thus a matter of major public health and economic interest; this objective is a central goal in the U.S. public health agenda for the year 2010.[5]

This review examines the utility of enacting or maintaining limits on the days of the week on which alcoholic beverages may be sold ("days of sale") as a strategy to prevent excessive alcohol consumption and related harms. The limitation of days of sale of alcoholic beverages is here defined as "applying regulatory authority to limit the days that alcoholic beverages may be sold at on- and off-premises alcoholic beverage outlets." *Limiting* may be either maintaining existing limits (e.g., on the sale of alcoholic beverages on Sundays) or extending current limits (e.g., eliminating Sunday sales by repealing current

authorization for such sales). Days of sale may be regulated at national, state, or local levels. *On-premises* retailing refers to the sale of alcoholic beverages for consumption at the point of sale (e.g., at bars, restaurants, or clubs); *off-premises* retailing refers to the sale (e.g., at package stores, liquor stores, grocery stores, or convenience stores) of contained alcoholic beverages for consumption elsewhere. Because most of the studies reviewed consider removing limits on days of sale (e.g., allowing sale of alcoholic beverages on Sunday when Sunday sales had previously not been allowed), the intervention of public health interest for the review is the study control condition (i.e., maintaining limits on days of sale).

In the U.S., policies restricting the days of sale currently apply to Sundays only. There are several variations on the regulation of Sunday alcohol sales in the U.S. including full bans, reduced hours relative to other days of the week, restrictions on the sale of alcoholic beverages with a high alcohol content, and the authorization of local decision making.[6] A total of fourteen states (Alabama, Arkansas, Connecticut, Georgia, Illinois, Indiana, Kansas, Kentucky, Minnesota, Nebraska, Oklahoma, South Carolina, Tennessee, and Utah), ban alcohol sales at off-premises retail alcohol outlets on Sundays. Fourteen states (Alaska, California, Colorado, Florida, Hawaii, Idaho, Kentucky, Montana, Nevada, New Hampshire, Oregon, Vermont, Wisconsin, and Wyoming) do not restrict Sunday alcohol sales. The remaining 22 states and the District of Columbia allow Sunday sales with restrictions regarding hours and/or types of alcoholic beverages sold. Outside of the U.S., current policies restricting the days of sale may apply to days other than Sunday (e.g., some countries prohibit alcohol sales on Saturdays).

In the U.S., the control of days and hours of sale at the local level is often pre-empted by state regulations prohibiting local authorities from enacting stricter alcohol control regulations in the state in general.[7,8] However, in some states, counties and other local jurisdictions are allowed to establish their own alcohol control policies. The nature of this authority varies by state and may allow cities or counties to have reduced hours from those stipulated by the state; have the same hours on Sunday as available during the rest of the week; or limit the sale of alcohol on Sundays to specific areas or locations. Fourteen states provide for local authority regarding days of sale, and four more allow Sunday sales in limited locations within the state.[6] In 1995, New Mexico repealed a ban on off-premises alcohol sales on Sundays, but also allowed local jurisdictions to hold referenda to restore a local ban on Sunday sales. Alaska and Kentucky also allow counties to independently restrict alcohol sales.

This review addresses the effects on excessive alcohol consumption and related harms of maintaining or increasing restrictions on the days of sale at on- or off-premises outlets.

Findings and Recommendations from Other Reviews and Advisory Groups

Several reviews conducted in the U.S. have concluded that restricting the days of sale is an effective strategy for reducing excessive alcohol consumption and related harms. For example, a narrative review conducted by Single[9] concluded that controlling the days (and hours) of sale may influence levels of impaired driving and other drinking problems. A systematic review published by the Substance Abuse and Mental Health Service Administration's Center for Substance Abuse Prevention[10] in 1999 found substantial evidence for harms associated with expanding the days (and hours) of alcohol sales. This finding was based on previous empirical research indicating that the expansion of the days (and hours) of sale increased prevalence of excessive alcohol consumption and alcohol-related problems. Other narrative reviews[11,12] generally concur with these findings.

Several international bodies have recommended the control of days (or hours, or both) of sale, as a means of reducing excessive alcohol consumption and related harms. The WHO has published a narrative review[13] that identifies the limiting of days of sale as an effective method for reducing alcohol-related harms. Similarly, the Western Australian Alcohol Plan[14] recommended that days and hours of sale should be considered as factors in the local regulation of alcohol availability. In Ireland, the Department of Health and Children's Strategic Task Force on Alcohol[15] concluded that "restricting any further increases in the physical availability of alcohol (number of outlets and times of sales)" is among the most effective policy measures that influence alcohol consumption and related harms.

The present review updates prior syntheses using the systematic approach of the *Guide to Community Preventive Services (Community Guide)*, as described below.

Methods

The methods of the *Community Guide* were used to systematically review scientific studies that have evaluated the effectiveness of limiting or maintaining existing limits on days of sale for preventing excessive alcohol consumption and related harms. More details on the *Community Guide* review process are presented elsewhere.[16] In brief, this process involves forming a systematic review development team; developing a conceptual approach to organizing, grouping, and selecting interventions; searching for and retrieving available research evidence on the effects of those interventions; assessing the quality of studies and abstracting information from

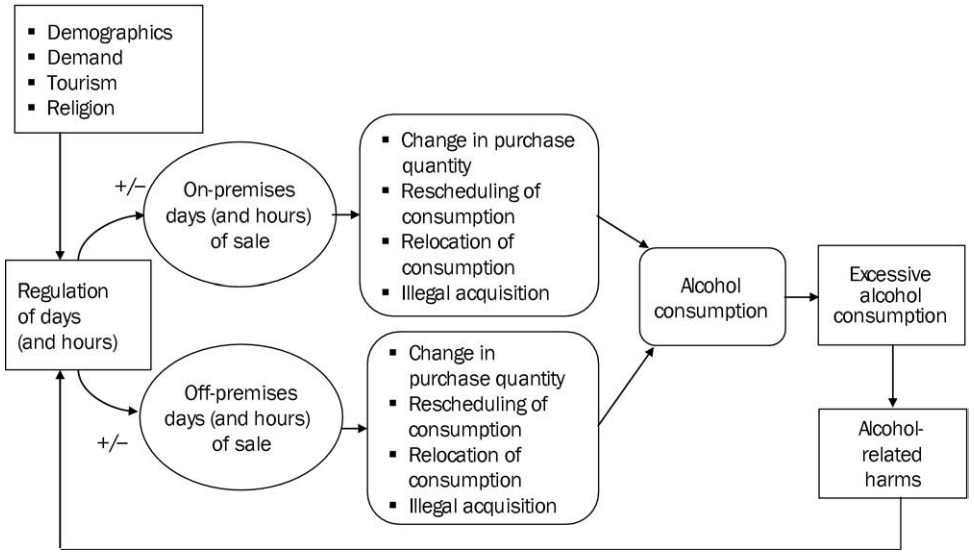

Figure 1. Effects of regulation of days (and hours) of alcohol sales on excessive alcohol consumption and related harms

each study that meets inclusion criteria; assessing the quality of and drawing conclusions about the body of evidence on intervention effectiveness; and translating the evidence on effectiveness into a recommendation or finding for each intervention reviewed. Evidence is collected and summarized on (1) the effectiveness of interventions in altering selected health-related outcomes and (2) positive or negative effects of the intervention on other health and nonhealth outcomes. To help ensure objectivity, the review process is typically led by scientists not employed by a program that might be responsible for overseeing the implementation of the reviewed intervention. When an intervention is shown to be effective, information is also analyzed on (3) the applicability of the evidence (i.e., the extent to which effectiveness data might generalize to diverse population segments and settings); (4) the economic impact of the intervention; and (5) barriers to implementation. The results of this review process are presented to the Task Force on Community Preventive Services (Task Force), a nonfederal independent scientific review board, which objectively uses specified guidelines to consider the scientific evidence on intervention effectiveness and determines whether the evidence is sufficient to warrant a recommendation.[16]

Conceptual Approach and Analytic Framework

Policies reducing or expanding days of sale (Figure 1) are hypothesized to affect alcohol consumption and alcohol-related harms through the following means: First, increases or decreases in the days of sale affect consumers' ability to purchase alcohol by changing its availability. Second, when access to alcoholic beverages changes, consumers may alter their purchasing habits in several ways, including changing their purchase volume per visit to the outlet, rescheduling their purchases, relocating their purchases, or obtaining alcoholic beverages illegally. Various characteristics of the affected population, including the demand for alcoholic beverages, the number of adult tourists the area attracts, and the religious affiliation and involvement of residents, may affect the establishment of the policies regulating days of sale.

Changes in days of sale may also affect alcohol-related outcomes by other means. For example, increases in the days of sale at on-premises outlets allow more opportunities for social aggregation, which in turn may increase aggressive behaviors that are exacerbated by alcohol consumption.[17] Increases or decreases in the days of sale may also alter travel patterns to areas where alcohol can be purchased, and thus influence the risk of injury or death in motor vehicle crashes that may be alcohol-related. It might be expected that added days of sale at on-premises outlets would be more likely to increase alcohol-related motor vehicle crashes than added days in off-premises facilities because patrons who have drunk at an on-premises facility may drive after excessive consumption, whereas patrons of off-premises outlets are not supposed to drink at that facility. It is also possible that when available days at on-premises facilities are reduced, motor vehicle crashes might be increased if consumers drove to more distant on-premises facilities and then returned after excessive consumption.

Inclusion and Exclusion Criteria

To be included as evidence in this review, studies had to

- evaluate long-term policy changes related to days of sale; studies that assessed short-term changes in alcohol availability (e.g., alcohol sales related to a special event) were not included;
- assess the impact of changes in days of sale alone on excessive alcohol consumption or related harm, as opposed to evaluating the effect of this change only in combination with other interventions;
- be conducted in a high-income country[18,a];
- present primary research findings, and not just review other research findings;
- be published in English;
- have a comparison group, or at a minimum, compare outcomes of interest before and after a change in the policy related to days of sale.

Table 1. Evidence of the effects of limits of days of alcohol sale on excessive alcohol consumption and related harms

Study Design description (suitability) Study execution (no. of limitations)	Population Study time period	Intervention comparison
Days of sale: On-premises		
Ligon (1996)[22] Interrupted time series: before-and-after with comparison (greatest) Fair (2)	Athens GA January 1992 –December 1993	Intervention: On 12/8/1992, Athens-Clarke County amended the Alcoholic Beverage Ordinance. Previously, Sunday sales of liquor were banned. After the change, restaurant patrons were able to purchase alcoholic beverages with food, but bars and taverns remained closed and off-premises sales were still prohibited. Comparison: Other days of the week
Smith (1978)[28] Interrupted time series: before-and-after with comparison (greatest) Fair (2)	Perth, Western Australia 3 years before and 3 years after new law (used midpoint of June 30, 1970)	Intervention: On 7/7/1970 the sale and supply of alcoholic beverages on Sundays in the Perth Metropolitan area of Western Australia became legal. In general, two 2-hour drinking sessions were permitted. Prior to the change, alcohol sales at on-premises facilities were permitted between 10 AM and 10 PM only, Monday to Saturday. Comparison: Remainder of the state
Smith (1988)[30] Before-and-after with comparison (greatest) Fair (2)	Brisbane, Australia Before period: April 1, 1968–March 31, 1970 After period: April 1, 1970–March 31, 1973 3-year After period: April 1, 1973–March 31, 1976	Intervention: On April 3, 1970, Sunday alcohol sales were introduced in Brisbane, Australia. Sunday drinking was allowed from 11 AM to 1 PM and 4 PM to 6 PM Comparison: Other days of the week and the rest of Queensland
Smith (1987)[29] Before-and-after with comparison (greatest) Fair (3)	New South Wales, Australia Before period: December 7, 1976–December 6, 1979 After period: December 7, 1979–December 6, 1981	Intervention: In 1978, Select Committee of the New South Wales Parliament considered the issue of hotel alcohol service hours in that state. Subsequently it was recommended on December 7, 1979 that the hotel service hours of 12 NOON to 10:00 PM on Sundays be introduced. Comparison: Other days of the week and the rest of the Queensland state
Smith (1990)[31] Before-and-after with comparison (greatest) Fair (3)	Victoria, Australia Before period: January 1, 1980–December 31, 1983 After period: January 1, 1984–December 31, 1984 The following 12 months were used as the "after" period for the 8-hour Sunday drinking permit.	Intervention: Two legislative changes that increased the Sunday availability of alcoholic beverages in Victoria. Prior to July 13, 1983, on Sunday, hotels and licensed clubs in Victoria could sell alcoholic beverages for consumption only with a meal. After that date, hotels and clubs were allowed to obtain a permit that permitted them to open for two 2-hour periods on Sunday between 12 NOON and 8PM. The two drinking periods had to be at least 2 hours apart. Following an amendment to the Victorian Liquor Control Act, as of November 1984, hotels and clubs could apply for a permit that enabled them to open between 12 NOON and 8 PM on Sundays. The 1984 amendment also allowed for hotels to obtain a permit to continue Monday to Saturday ordinary bar trading from 10 PM to 12 MN. The amendment also introduced Sunday restaurant hours of 12 NOON to 11:30 PM. Previously, the Sunday restaurant opening hours were 12 NOON to 4PM and 6 to 10 PM. Comparison: Other days of the week
Knight (1980)[21] Before-and-after study design without comparison (least) Fair (4)	Four major cities and central belt of Scotland Before: March 1977 After: October 1977	Intervention: In 1973, Scottish Licensing Law changed. The two main changes were the extension of evening hours on weekdays to 11 PM (previously 10 PM) and the provision for special licenses to allow pubs to open regularly on Sundays. Sunday licenses were not issued for approved public houses until October 1977. Comparison: No comparison group

Table 1. *(continued)*

Analysis Outcome	Reported findings	Review Effect size
Chi-square DUI arrests	Following the change in law, the incidence of DUIs was lowest for Sundays. The frequency of DUI arrests made on Sundays were statistically lower than every other day of the week, except for Monday	Relative % change (95%CI): 39.8 (–21.9, 150.4)
Chi-square Traffic crashes: people killed in motor vehicle crashes	Significant increase in the proportion of people killed and the number of motor vehicle crashes on Sundays, compared with the other 6 days of the week in Perth. No increases in the proportions of people killed or in the number of motor vehicle crashes occurring on Sundays in comparison with the other days of the week for the rest of the state. 11% of the 453 people killed in Perth traffic crashes were killed on Sundays: after the new law, 16.9% of 486 people were killed on Sundays (χ^2= 6.134, p>0.02). Rest of the state proportions were 18 and 17.4% before and after (χ^2= .0318, p>0.80). Motor vehicle crashes occurring on Sundays in the Perth area increased from 12.4% of 11,598 before the new law to 14.2% of 11,870 afterward (χ^2=16.85, p<0.001). In the rest of the state the proportion of motor vehicle crashes occurring on Sunday decreased from 19.7% to 18.4% (χ^2 = 15.95, p>0.20)	Relative % change: People killed: 58.9; motor vehicle crashes: 22.6
Chi-square Motor vehicle crashes	First follow-up period: Only the segment from 6:00 PM to 7:59 PM gave a significant result for Brisbane. In comparison to the other 6 days of the week, and after allowing for the slight change in the control data from the before to the after period, the annual increase was 129.8%. No significant differences in Brisbane motor vehicle crashes on Sundays between 8:00 PM and 10:59 AM. No significant increases in Queensland Sunday motor vehicle crashes occurred for any of the time segments. 3-year follow-up available, but data incomplete	Relative % change (95%CI): 65.0 (30.49, 108.65)
Chi-square Motor vehicle fatalities Traffic crashes	After the introduction of a 10-hour hotel session in New South Wales, for the 12-hour period from 12:00 NOON to 11:59 PM, there was a 22.2% increase in Sunday fatal crashes. None of the analyses for the control period of 12:00 MN to 11:59 AM gave significant results in the same direction as for motor vehicle fatalities or traffic crashes.	Relative % change (95%CI): Motor vehicle Fatalities 15.5 (–0.13, 33.59) Traffic crashes 6.7 (0.56, 13.21)
Chi-square Motor vehicle traffic crashes	The introduction of the two 2-hour drinking sessions on Sundays did not adversely affect the number of motor vehicle crashes, so information on 8-hour drinking not included.	Relative % change (95% CI): 9.9 (3.27, 16.98)
Percentage changes Consumption and patterns of consumption	Increase in consumption among men aged <45 years. Virtually no change in drinking among women.	Average change in consumption for men: 6.82 Average change in consumption for women: 1.85

Alcohol-related Sunday crash fatalities (relative % change [95% CI]): 26.8% (3.3, 44.2)
ARIMA and parametric models Alcohol sales, assaults, drunken driving, and positive breath analyzer test results	Effects appear uniform across three experimental areas, tendency toward weaker effect in Northern Sweden not sign. Phase I consumption (relative % change): ● Beer (7.6%) ● Wine (2.5%) ● Spirits (3.7%) ● Total alcohol (3.7%) Phase II consumption (relative % change): ● Beer (1.8%) ● Wine (1.2%) ● Total alcohol (3.6%)	Relative % changes (95% CI): Drunk driving: 11.3% (4.2, 18.4) Alcohol sales (liters pure alcohol per capita per year): 3.6% (2.6, 4.6) Assaults, women (indoors): 0.6% (–6.5, 7.7) Assaults, total: –1.3% (–5.6, 3.0)
Police interventions Intoxicated people Domestic disturbances Outdoor assaults	Sales of alcohol: Slight decline could not be attributed to effects of Saturday closing. Illegal trading: (Police judgment) % of districts reporting: ● No change: 69% ● Increase: 24% ● Decrease: 7% Overall declines in: ● Drunkenness ● Domestic disturbances ● Public disturbances (not attributable to policy) ● Assaults declined	Relative % changes (95% CI): Outdoor assaults: –17.7% (−45.8, 25.0) Domestic disturbances –17.3% (–34.8, 4.8) Police interventions against intoxicated people –35.7% (–43.8, –26.4)
Time-series analysis of state-level variables, including Sunday bans. Controlled for pre-repeal trends	Per capita beer sales in gallons ● –2.4 relative % change due to Sunday bans controlling for pre-repeal trends ● –4.1 relative % change due to Sunday ban not controlling for pre-repeal trends Per capita spirits sales in gallons ● –3.5 relative % change due to Sunday ● –5.2 relative % change due to Sunday ban not controlling for pre-repeal trends.	Beer sales: 2.4% relative change due to repeal of bans Spirits sales: 3.5% relative change due to repeal of bans Note: Although authors coded for presence of Sunday bans, all policy changes during the study period were in the direction of repeal, so the signs have been reversed in reporting effect (above).
Customer calls Cash turnover Liters pure alcohol Liters total sale all outlets Arrests for drunkenness Reports of drunkenness Reports domestic trouble Reports of violence	Customers made fewer trips to vinmonopolets (i.e., state alcoholic beverage monopoly stores). Total sales at these outlets declined, but the total sales at all outlets went up slightly. Reports of drunkenness went down but not significantly, while drunkenness arrests declined significantly. Reports of domestic trouble went down a sizeable and significant 16%, whereas reports of violence went up 5%. General effects were consistent but small; ordinary drinkers consumed about the same total amount, purchased in fewer trips to the vinmonopolets with larger purchases per trip. Ultimately, the Saturday closing was repealed because of insufficient evidence of benefit.	Relative % changes: Liters pure alcohol: –3.1% Arrests for drunkenness: –5.8% Reports of drunkenness: –5.0% Reports domestic trouble: –15.9% Reports of violence: 5%

ARC, alchohol-related crashes; ARIMA, autoregressive integrated moving average; RR, relative risk

To be included in this review, studies also had to report on outcomes related to excessive alcohol consumption or related harms. Specific types of harm that were of interest included alcohol-related medical conditions (e.g., liver cirrhosis); alcohol-impaired driving; alcohol-related crashes; unintentional or intentional injuries; and violent crime.

Outcome measures that had the strongest known association with excessive alcohol consumption included binge drinking, heavy drinking, liver cirrhosis mortality, alcohol-related medical admissions, and alcohol-related motor vehicle crashes, including single-vehicle night-time crashes (which are widely used to indicate motor vehicle crashes due to drinking and driving).[19] Less-direct measures included per capita alcohol consumption, a recognized proxy for estimating the number of heavy drinkers in a population[13,20]; unintentional injuries; suicide; and crime, such as homicide and aggravated assault. When studies assessed multiple outcomes of interest, those outcomes with the strongest known association with excessive alcohol consumption were selected.

Search for Evidence

The following databases were searched from inception to February 2008: Econlit, PsycINFO, Sociology Abstracts, MEDLINE, Embase, and EtOH. Searches also were conducted of the reference lists of papers reviewed as well as lists in review articles. Government reports were considered for review, but other unpublished papers were not. In addition, experts were consulted to identify other studies that might have been missed.

Assessing the Quality and Summarizing the Body of Evidence on Effectiveness

Each study that met the inclusion criteria was read by two reviewers who used standardized criteria (available at www.thecommunityguide.org/about/methods.html) to assess the suitability of the study design and threats to validity. Uncertainties and disagreements between the reviewers were reconciled by consensus among the team members.

Studies were evaluated based on their design and execution. The current classification of the study designs accords with *Community Guide* standards[16] and may differ from the classification reported in the original studies. Those that collected data prospectively on exposed and control populations were classified as having the greatest design suitability. Those that collected data retrospectively or lacked a comparison group but that conducted multiple pre- and post-measurements on their study population(s) were rated as having moderate design suitability. Finally, cross-sectional studies, those without a comparison group, and those that involved only a single pre- and post-measurement in the intervention population were considered to have the least suitable design. Quality of execution was assessed by examining potential threats to study validity, including an inadequate description of the intervention or of the study population, poor measurement of the exposure or outcome, failure to control for potential confounders, and a high level of attrition among study participants. Based on these criteria, studies were characterized as having good quality of execution if they had at most one threat to validity, fair execution if they had two to four threats to validity, and limited quality of execution if they had five or more threats to validity. Only studies with good or fair quality of execution were included in the body of evidence; studies with any level of design suitability were included, other than those with cross-sectional design.

We calculated effect sizes as relative percentage change in the intervention population compared with the control population using the following formulas:

- For studies with before-and-after measurements and concurrent comparison groups:

  $$\text{Effect size} = [(I_{post}/C_{post})/(I_{pre}/C_{pre}) - 1] \times 100\%,$$

  where:

  I_{post} = last reported outcome in the intervention group after the intervention;

  I_{pre} = reported outcome in the intervention group before the intervention;

  C_{post} = last reported outcome in the comparison group after the intervention;

  C_{pre} = reported outcome in the comparison group before the intervention.

- For studies with before-and-after measurements but no concurrent comparison:

  $$\text{Effect size} = [(I_{post} - I_{pre})/I_{pre}] \times 100\%$$

  When there was a large enough number of studies of a single outcome, median effect size and interquartile intervals were reported.

Results

Intervention Effectiveness

Fourteen studies[21–34] that examined the effects of changes in days of sale met the inclusion criteria for the review. These studies assessed changes that took place in cities (Athens GA [two studies] and Perth and Brisbane, Australia); states (50 U.S. states, New Mexico [two studies], and Victoria and New South Wales, Australia); and countries or large regions of countries (Norway [one study], Sweden [three studies], and Scotland [one study]). The policy changes that were assessed took place between 1967 and 2004. (For a summary of all evidence included in this review, see Table 1.)

The studies used a variety of methods for estimating intervention effects, including chi-square statistics, percentage change, relative risks, and auto-regressive integrated moving average (ARIMA) time series; all except one study[21] had comparison populations or conditions. Thirteen studies[22–34] were of greatest design suitability and one[21] was of least design suitability. Four studies[25,26,32,33] were of good execution and the remainder[21–24,27–31,34] were of fair execution. Studies assessing changes in days of sale in off-premises settings were analyzed separately from those in on-premises settings. Four studies[28–31] were conducted by one researcher (Smith), and two studies each by Ligon and Thyer,[22,34] McMillan and colleagues,[23,24] and Norstrom and Skog.[25,26]

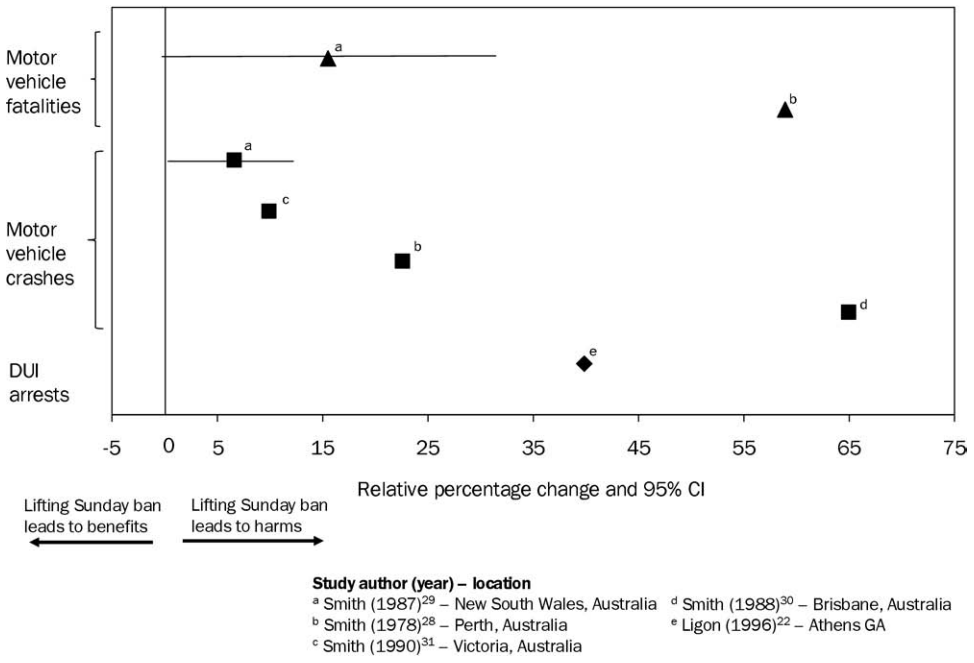

Figure 2. Relative percentage change in motor vehicle–related events after Sunday on-premises sales legalized
DUI, driving under the influence

The Effect of Changing the Number of Days That Alcohol Was Sold at On-Premises Outlets

Seven studies[21,22,28–31,34] assessed the effects of increasing days of sale at on-premises retail alcohol outlets. Only one study[21] assessed changes in consumption; the remainder assessed the effects of changes in days of sale on motor vehicle–related outcomes.

Effect on excessive alcohol consumption. The findings of Knight and Wilson[21] were reviewed in detail because only these authors examined excessive consumption among individuals (rather than per capita consumption or alcohol-related harms). This study assessed the impact on excessive alcohol consumption of a 1977 law allowing Sunday alcohol sales in the four major cities and within the central belt of Scotland. After Sunday pub sales were legalized in this area, there was a 1.3 (95% CI=−0.4, 2.8) standard unit of alcohol (a British measure equivalent to 0.6 of the U.S. standard drink) increase in the average weekly consumption by men who drank; a significant 2.4 standard unit (95% CI=0.6, 4.2) increase among men aged 18–45 years; and a nonsignificant −0.5 (95% CI=−2.6, 1.3) standard unit change in the average weekly consumption of men aged >45 years. Increases among men occurred across most levels of baseline drinking. The researchers reported a nonsignificant −0.6 standard unit change among women who drank (95% CI=−1.6, 0.5) that did not differ by age. Knight and Wilson also obtained information on the patterns of consumption among study participants. After the change, the percentage of people who reported having 1–8 standard units on Sundays increased from 27% to 29% (7.4%, 95% CI=−11.0, 31.1), and those who reported having >8 standard units increased from 4% to 5% (25%, 95% CI=−26.5, 100.1); neither increase was significant.

Effect on alcohol-impaired driving and motor vehicle crashes. Five studies[22,28–31] examined the impact of allowing Sunday on-premises sales on various measures of alcohol-impaired driving (e.g., arrests for driving under the influence [DUI]) and motor vehicle crashes [Figure 2]). An additional study in Athens GA[34] examined the impact of a December 1992 local law that allowed Sunday sales in restaurants (but not in bars). The investigators found that this change was followed by a 39.8% increase in DUI arrests (95% CI not calculable).

Two studies[28,30] assessed the impact of changes in days of sale in on-premises retail outlets in Perth and Brisbane, Australia, on deaths and injuries related to motor vehicle crashes; they compared outcomes on days when alcohol became newly available with outcomes on days when availability did not change. The city of Perth legalized Sunday alcohol sales in 1970, allowing two 2-hour periods when alcoholic drinks could be purchased. After this change, there was a 22.6% increase in motor vehicle crashes and a 58.9% increase in motor vehicle fatalities in Perth compared with the rest of the state. In the same year, Sunday sales were legalized in Brisbane also, resulting in an increase of 65% (95% CI not calculable) in motor vehicle crashes.

Finally, two additional studies assessed the effects on motor vehicle crashes of allowing Sunday sales in different regions of Australia. In 1979, the state of New South Wales began allowing hotels to serve alcoholic beverages between 12 NOON and 10 PM on Sundays.[29] This change was followed by an increase of 6.7% (95% CI=0.6%, 13.2%) in traffic crashes and an increase of 15.5% (95% CI=−0.1%, 33.6%)

in motor vehicle fatalities, compared with other days of the week in which hours did not change. Lastly, a study by Smith[31] assessed the influence of newly legalized Sunday sales in clubs and hotels on motor vehicle injury crashes in the state of Victoria. Before the law changed in 1983, hotels and licensed clubs could sell alcoholic beverages only with a meal. After the law changed, a meal was no longer required for the consumption of alcohol, and two 2-hour drinking periods were introduced. In the following year, there was a 9.9% increase in motor vehicle crashes on Sundays compared with days of the week in which hours had not changed (95% CI=3.3%, 17.0%).

Effect of Changing the Number of Days That Alcohol Was Sold at Off-Premises Outlets

Effect of repealing bans on days of sale. Four studies[23,25,26,32] examined the impact of increasing the days of sale at off-premises locations (Figure 3), by removing existing restrictions. Two of these studies[25,26] examined the two-phase reinstatement of Saturday sales in Sweden between 2000 and 2003 (Sunday sales remained banned). Another study[23] examined the repeal of a ban on Sunday sales in New Mexico. Lastly, a time-series study[32] examined the impact of bans across U.S. states over a period of 15 years, during which policies on off-premises Sunday sales changed in 13 states.

One study[25] examined the effect of removing a nearly 20-year ban on Saturday alcohol sales at off-premises locations in Sweden. Researchers collaborated with the Swedish government to implement a national experiment. In the first phase, to assess possible harms, Saturday sales were allowed only in select counties for an experimental period of 1 year. The intention was to repeal the ban on Saturday sales in the rest of the country if harms did not increase significantly when the repeal was in place in the experimental counties. To limit confounding by cross-border sales, buffer zones were designated between the experimental areas and the control areas. The experimental areas were noncontiguous, and included several rural areas, as well as Stockholm, encompassing about 43% of the population. The control area covered seven contiguous counties and another eight counties not contiguous with those, with a total of about 34% of the population. The buffer counties had approximately 22% of the population.

During Phase I, alcohol sales in the experimental area increased 3.6% (95% CI=2.6%, 4.6%) and incidents of drunk driving arrests increased by 11.3% (95% CI=4.2%, 18.4%) compared with that in the control areas. Both findings were significant. However, the researchers noted that along with repeal of the ban, there was increased police surveillance for alcohol-related motor vehicle incidents in the experimental region, which may have contributed to the increase in the number of drunk driving incidents reported. Assaults against women indoors (a proxy for domestic violence) increased 0.6% (95% CI=−6.5%, 7.7%) and total assaults declined by 1.3% (95% CI=−5.6%, 3.0%); neither result was significant.

During Phase II, the repeal of the ban on Saturday sales was extended to the whole country.[26] Alcohol sales increased by 3.5% (95% CI=3.0%, 4.0%) in what had been the control and buffer regions in Phase I—an increase similar to that which had occurred in experimental counties in Phase I. The 1.7% (95% CI=−7.0%, 10.0%) in-

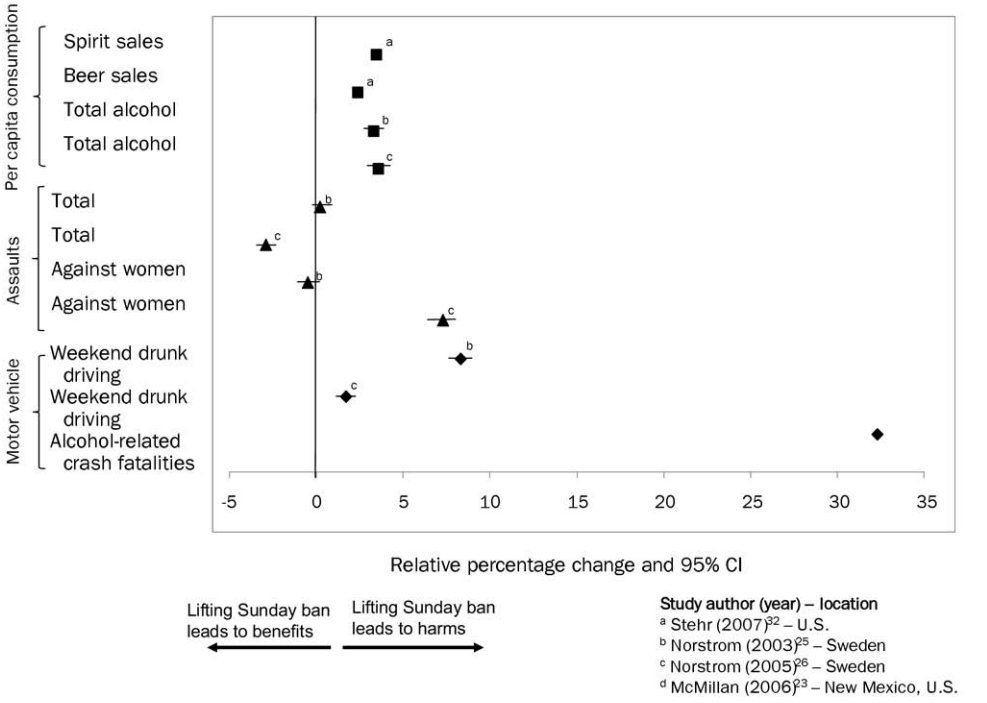

Figure 3. Relative percentage change in three categories of alcohol-linked effects attributable to an increase in days of alcohol sale in off-premises establishments

crease in drunk driving arrests in the rest of the country was not significant in Phase II (unlike in Phase I).

McMillan and others[23] examined the impact of the repeal of a ban on Sunday alcohol sales at off-premises retail outlets in New Mexico in 1995. (On-premises consumption of alcohol on Sundays was allowed already in New Mexico at that time, and was not changed by the law.) The study evaluated the impact of this change on deaths in alcohol-related motor vehicle crashes. Crashes were considered to be alcohol-related if one of the drivers involved in the crash had a blood alcohol concentration (BAC) >0.0%. To assess the impact of the repeal on alcohol-related crash fatalities, the researchers calculated the relative risk of dying in an alcohol-related crash, by day of the week, after alcohol sales were allowed on Sundays compared with the period prior to the change. They then compared the relative risk of death in an alcohol-related crash on Sundays (RR=1.4) to the mean relative risk of death in an alcohol-related crash on other days of the week (RR=1.1). Thus, the risk of death in an alcohol-related crash on Sunday increased 26.8% (95% CI=3.3%, 44.2%) relative to the risk of death in a crash on other days of the week after the ban on Sunday alcohol sales was repealed.

Finally, one study[32] examined state-level U.S. data to determine the impact on beer and liquor consumption of laws repealing bans on Sunday alcohol sales in states. The authors used a time-series analysis to compare changes from 1990 to 2004 in per capita alcohol consumption in 13 states that repealed bans on Sunday alcohol sales relative to changes in consumption in other states that maintained existing state policies on Sunday sales. Controlling for other variables such as income and taxes, as well as trends in alcohol consumption in the 13 states before the bans were repealed, the researchers found that per capita spirits consumption was 3.5% higher in states that allowed Sunday sales of spirits than in states that did not. In six states that allowed Sunday sales of beer, beer consumption was 2.4% higher.

Effects of imposing bans on days of sale. Three studies[24,27,33] examined the effect of imposing bans on days of sale of alcoholic beverages for off-premises purchase. One of these[27] examined the impact of the 1981 imposition of the Saturday ban on off-premises alcohol sales in Sweden that was discussed above. A second examined the impact of the 1984 imposition of a Saturday ban on alcohol sales in Norway.[33] The third examined the local referendum-based re-imposition of a previously repealed state ban on Sunday sales, described above, in several New Mexico counties.[24]

Olsson and colleagues[27] compared outdoor assaults, domestic disturbances, and police interventions against intoxicated people during the ban with the same 3-month period in the previous year when the ban was not in place. They also compared the number of these events that took place on Saturdays with the number of events that took place during the rest of the week over these two 3-month periods. During the ban, outdoor assaults on Saturdays declined by 17.7% (95% CI=−25.7%, –8.9%) relative to the rest of the week from a mean of 71.0 assaults per Saturday in the nation before the policy change to 53.2 after, compared with a mean change from 27.8 to 25.3 for the rest of the week. Domestic disturbances similarly declined by 17.3% (95% CI=−22.0%, –12.4%) relative to the rest of the week from a mean of 205.6 domestic disturbances per Saturday prior to the policy change to 154.9 per Saturday after, compared with a mean change of 104.5 to 95.3 for the rest of the week. During the ban, police interventions against intoxicated people declined by 35.7% (95% CI=−37.8%, –33.5%) relative to the rest of the week from 659.8 per Saturday before to 401.1 per Saturday after the policy change, compared with a mean change of 453.6 to 428.8 for the rest of the week.

In 1984, the Norwegian government initiated a similar experimental ban to determine whether closing state-run spirits and wine monopoly stores on Saturdays would reduce alcohol-related harms.[33] Because it was available from other sources, beer remained available on Saturdays during the experimental period. Six pairs of Norwegian communities in similar settings and with similar demographics were selected, with one community in each pair randomly selected for the intervention, and the other for the control. Nordlund evaluated changes in consumption and alcohol-related harms in October 1984, before completion of the experimental intervention year. Compared with the control communities, the consumption of ethanol (from wine and spirits) decreased by 3.1% in the experimental communities. However, the consumption of beer increased by a relative 6.4%, for a combined relative increase of total alcohol consumption of 0.7% in the experimental settings. In addition, there were relative declines of 5.8% in arrests for drunkenness and 15.9% in domestic trouble, but a relative increase of 5.0% in reports of violence in experimental communities compared with control communities. In sum, there was little net change in alcohol consumption associated with the ban and mixed results in terms of other alcohol-related outcomes. The Norwegian government concluded that the closing had little substantial effect and reverted to the prior policy allowing Saturday retail sales.

Finally, in addition to their analysis of repeal of the New Mexico ban on Sunday alcohol sales, described above, McMillan and colleagues undertook an analysis of data on the effects of local reinstatement of the ban.[24] The 1995 New Mexico law allowed local communities to re-

instate the Sunday sales ban following a community referendum (mounted at community expense). The towns of Gallup, Clovis, and Portales reinstated the ban within 3 months after the statewide repeal. Each of these cities is the county seat, and each comprises a sizable proportion of the total county population (70%, 27%, and 62%, respectively), such that county-level data can be taken as a gross measure of the impact of the local decision passed by these cities. Each of the three counties that rapidly reversed the state policy locally had a relative risk of Sunday alcohol-related motor vehicle crashes (comparing crash levels in each county after the policy change to levels before the change) between 1 and 1.13, the lowest reported relative risks among counties in the state. Of 33 total counties in New Mexico, only one other county had a relative risk in that range. Three other towns passed local policies somewhat later. One, Roswell, which makes up 74% of its home county, had a relative risk of <1.30. The remaining two towns had populations <2000, and would therefore not be expected to show a stable effect at the county level.

In sum, the findings from these three studies indicate that local decisions to reinstate a 1-day off-premises sales ban protected against the alcohol-related harms observed in areas that maintained the state (no ban) policy. The researchers note that these findings were based on a small number of communities and few years of data.

Conclusion

This review found that increasing days of sale by allowing previously banned alcohol sales on either Saturdays or Sundays increased excessive alcohol consumption and related harms, including motor vehicle crashes, incidents of DUI, police interventions against intoxicated people, and, in some cases, assaults and domestic disturbances. Thus, *maintaining* existing limits on Saturday or Sunday sales—the control condition in these studies—can prevent alcohol-related harms that would be associated with increased days of sale. A study of the imposition of a Saturday ban in Norway showed mixed effects, whereas one study of the imposition of a Saturday ban in Sweden and one study of the reversal of a lifted ban in New Mexico found a decrease in alcohol-related harms. Thus, some evidence suggests that *imposing* limits on the days of sale will reduce alcohol-related harms.

According to the *Community Guide* rules of evidence, there is strong evidence for the effectiveness of maintaining limits on days of sale for the reduction of alcohol-related harms. Of the qualifying studies on the *repeal of weekend-day sale bans* evaluated by *Community Guide* criteria, there were nine of greatest design suitability, three of which were of good execution and six of fair execution; there was one study of least-suitable design and fair execution. Most findings in this body of evidence indicated harms associated with an increased day of sale; effect sizes were of public health significance.

There were three studies of greatest design suitability and fair execution that assessed the impact of *imposing bans* on weekend days of sale. Two of these studies indicated that restricting days of sale is associated with a decrease in excessive alcohol consumption and related harms, and the third did not. By *Community Guide* standards, there is not sufficient evidence on which to base a determination of effectiveness. However, these studies support the overall conclusion that increasing days of sale is directly associated with excessive alcohol consumption and related harms.

Other Harms and Benefits

In association with fewer days of sale and reduced consumption, community quality of life—evaluated through such factors as reduced levels of public drunkenness—may improve on days when alcohol outlets are closed. Although it is possible that crimes such as illicit alcohol production and sales may increase in localities in which days of sale are reduced, no evidence of such effects was found.

Applicability

The studies in this review were conducted in a variety of settings in the U.S. and in other countries and during a wide range of time periods. The association between restrictions on days of sale and excessive alcohol consumption and related harm was consistent across most geographic locations and time periods. Moreover, three of the studies of greatest design suitability were conducted in the U.S. and were published within the past 10 years. Thus, the findings of this review are relevant for examining the potential impact of current proposals to modify days of sale in the U.S.

Barriers

Reductions in days of sale and resulting reductions in excessive alcohol consumption and related harms may affect overall alcohol sales; thus those restrictions may be opposed by firms involved in manufacturing, distributing, or selling alcoholic beverages. Indeed, the alcohol industry has tended to support policies removing restrictions on days of sale,[35] although some industry groups or individual businesses have supported the maintenance of Sunday sales bans.[36]

State pre-emption laws (i.e., laws that prevent the implementation and enforcement of more restrictive local alcohol sales laws) can also undermine efforts by local governments to regulate days of sale.[7] The elimination of

pre-emption laws related to the sale of tobacco products was one of the health promotion objectives in *Healthy People 2010*[5]; however, *Healthy People 2010* had no similar objective related to eliminating pre-emption of the local regulation of alcohol sales.

Economics

We identified one study[37] that assessed the economic impact of reducing days of sale. This study modeled the cost effectiveness of restricting alcohol sales for a 24-hour period over the weekend in 12 global health regions, as defined by the WHO. The costs associated with this intervention included the cost of passing the legislation itself, and the cost of administering and enforcing the laws once passed. Effectiveness was assessed using Disability-Adjusted Life Years (DALYs), a standard measure of global health impact that considers the impact of an intervention on healthy years of life lost due to either death or disability. For the region most relevant to this review, the America's A region composed of the U.S., Canada, and Cuba, the estimated cost for limiting weekend days of sale was $175,616 (converted to 2007 dollars using the Consumer Price Index) per 1 million population per year, based on a 10-year implementation period and discounted at 3%. At the same time, this restriction was estimated to prevent the loss of 250 DALYs per 1 million population per year, yielding an average cost-effectiveness ratio for this intervention of approximately $700 per DALY averted, which is much less than the average annual income per capita in these three countries, a threshold for an intervention to be considered very cost effective that was proposed by the Commission on Macroeconomics and Health.[38] To obtain country-specific estimates of the DALYs saved per country as a result of this intervention, the regional analysis needs to be adjusted using country-specific data. Such estimates are limited by data available and based in part on assumptions made.

We found no study that specifically estimated the magnitude of commercial losses in sales and tax revenues resulting from a policy of restricting days of sale. Regarding the economic burden of such a policy in terms of premature mortality, the one study that examined the impact of lifting a Sunday packaged alcohol sales ban in New Mexico[23,24] showed that this policy resulted in an estimated increase of 41.6 alcohol-related fatalities on Sundays for the 5-year period from 1995 to 2000, which translated to more than $6 million of additional cost per year for the state when the team applied the approximate unit cost of $745,285 (in 2007 dollars)[39] per motor vehicle fatality.

Research Gaps

The research on days of sale conducted in the U.S. was primarily at the state level. However, additional research is needed to assess the effectiveness of local restrictions on days of sale in preventing excessive alcohol consumption and related harms.

It would be useful to better understand the effect of differential policies regarding days of sale across neighboring jurisdictions. Does more ready access in a neighboring region lead to increased travel to this region, allowing the possibility of motor vehicle crashes, especially with intoxicated drivers?

Additional research is also needed to more fully assess the costs and benefits of restricting the number of days of sale. From a societal perspective, these should include intervention costs; loss in sales and tax revenues and employment; reductions in fatal and nonfatal injuries, crime, and violence; gains in safety and public order; and averted loss of household and workplace productivity.

Discussion

We found strong and consistent evidence that limiting alcohol availability by maintaining existing limits on the days of sale is an effective strategy for preventing excessive alcohol consumption and related harms. In addition, there is some direct evidence that the imposition of increased limits on days of sale may reduce alcohol-related harms. However, further scientific evidence is needed to fully assess the symmetry between maintaining existing limits and implementing new restrictions on days of sale, specifically as regards the impact of the latter on excessive alcohol consumption and related harms.[b]

In addition to the small number of studies that assessed the effect of new restrictions on days of sale, the studies in this review had several other limitations. First, some studies did not directly assess the impact of restrictions on days of sale on excessive alcohol consumption and related harms, but rather relied on proxy measures of these out-

[b]A reviewer of this manuscript indicated two studies of the effects of expanding days of sale published after the close of our reference search in February 2008: Carpenter 2009 and Stehr 2010. (Carpenter CS, Eisenberg D. Effects of Sunday sales restrictions on overall and day-specific alcohol consumption: evidence from Canada. J Stud Alcohol Drugs 2009;70(1): 126—33; Stehr M. The effect of Sunday sales of alcohol on highway crash fatalities. B.E. Journal of Economic Analysis & Policy 2010;10.1.) Both studies assess the effects of expanded days of sale in off-premises facilities, for which we hypothesize smaller effects. In a cross-sectional study, Carpenter finds increased consumption on Sundays in Canadian provinces with newly allowed Sunday sales, compared with provinces which maintain Sunday sales prohibition; however, there are also reductions in consumption on other days, yielding no net effect. Stehr, who in an earlier study included in our review indicated increased consumption associated with newly allowed Sunday sales in U.S. states, in this recent study finds increases in automobile crashes in New Mexico, but not in other states. These recent studies are not entirely consistent with earlier research and suggest a need for additional research.

comes (e.g., motor vehicle crashes not specifically related to alcohol). In these cases, focus was placed on measures for which the links between proxy and health outcome have been well established. Second, these studies were often unable to control for some potential confounding factors. However, they generally assessed changes in the same geographic area and within a fairly short time period before and after the implementation of changes in days of sale. Consequently, other contextual factors that could influence alcohol sales and consumption (e.g., changes in alcohol excise taxes) at the country, state, or community levels were likely to have remained fairly constant during the study periods, thus allowing for a more valid assessment of the impact of changing days of sale on excessive alcohol consumption and related harms.

One issue not addressed in this review is the potential consequence of neighboring regions having differing policies. For example, if one community restricts access to alcohol by not allowing sales on certain days, although the neighboring community lacks these restrictions, it is possible that harms (e.g., crashes from driving, drunk or sober, over longer distances) may result when those in the restricted neighborhood travel to the other community.

The findings in this review also support the potential value of allowing local communities to maintain restrictions on days of sale independent of state policies preemptively regulating days of sale. If further research supports the effectiveness of local restrictions on days of sale, it would also argue for eliminating state pre-emption laws that prohibit local governments from enacting alcohol control policies that are more restrictive than those that exist statewide.

BACKGROUND: Little evidence exists to determine whether depression predicts hospital utilization following discharge among adult inpatients on a general medical service.

OBJECTIVE: We aimed to determine whether a positive depression screen during hospitalization is significantly associated with an increased rate of returning for hospital services.

DESIGN: A secondary analysis was performed using data from 738 English-speaking, hospitalized adults from the Project RED randomized controlled trial (clinicaltrials.gov Identifier: NCT00252057) conducted at an urban academic safety-net hospital.

MEASUREMENTS: We used the nine-item Patient Health Questionnaire (PHQ-9) depression screening tool to identify patients with depressive symptoms. The primary endpoint was hospital utilization, defined as the number of emergency department (ED) visits plus readmissions within 30 days of discharge. Poisson regression was used to control for confounding variables.

RESULTS: Of the 738 subjects included in the analysis, 238 (32%) screened positive for depressive symptoms. The unadjusted hospital utilization within 30 days of discharge was 56 utilizations per 100 depressed patients compared with 30 utilizations per 100 non-depressed patients, incident rate ratio (IRR) (confidence interval [CI]), 1.90 (1.51–2.40). After controlling for potential confounders, a higher rate of post-discharge hospital utilization was observed in patients with depressive symptoms compared to patients without depressive symptoms (IRR [CI], 1.73 [1.27–2.36]).

CONCLUSIONS: A positive screen for depressive symptoms during an inpatient hospital stay is associated with an increased rate of readmission within 30 days of discharge in an urban, academic, safety-net hospital population. ***Journal of Hospital Medicine* 2010;000:000–000.** © *2010 Society of Hospital Medicine.*

KEYWORDS: depression, hospital discharge, patient safety, readmission, rehospitalization.

Fully 19% of Medicare patients are readmitted to the hospital within 30 days of discharge.[1] This represents a large amount of potentially avoidable morbidity and cost. Indeed, projects to improve the discharge process and post-hospital care have shown that as much as one-third of hospital utilization in the month after discharge can be avoided.[2] Consequently, the rate of early, unplanned hospital utilization after discharge has emerged as an important indicator of hospital quality and the Centers for Medicare and Medicaid Services (CMS) has proposed a policy to decrease payments to hospitals with high rates of early unplanned hospital utilization. Thus, there is great interest in identifying modifiable risk factors for rehospitalization that could be used to refine intervention models and lead to improvements in quality of care, patient outcomes, and cost savings.

To date, known predictors of readmission include: lower socioeconomic status,[3] history of prior hospitalization[4] and advanced age,[5] length of stay greater than 7 days,[6] a high burden of comorbid illnesses (based on Charlson score),[7] poor social support,[8] and specific diagnoses (eg, congestive heart failure, chronic obstructive pulmonary disease [COPD] and myocardial infarction).[5,9,10] In addition, unplanned readmissions and emergency department (ED) visits have been linked to polypharmacy and adverse drug events related to treatment with medications such as warfarin, digoxin and narcotics.[11,12] Another characteristic that has also been linked to readmission is depression;[13] however[5]

Published online in wiley InterScience (www.interscience.wiley.com).

reports supporting this association are from studies of elderly patients or with patients who have specific diagnoses (eg, congestive heart failure [CHF], COPD, myocardial infarction).[14–16]

Depression is common, affecting 13% to 16% of people in the US, and is recognized as an important risk factor for poor outcomes among patients with various chronic illnesses.[17–19] The mechanisms by which depression can be linked to health outcomes and health service utilization have been studied in age-specific or disease-specific cohorts such as cardiac patients or frail elders and include both physiologic factors such as hypercoagulability and hyperinflammatory conditions, as well as behavioral factors such as poor self-care behaviors and heightened sensitivity to somatic symptoms. How these mechanisms link depression to health outcomes and hospital utilization in a general medical population is not clearly understood. Kartha et al.[13] reported findings indicating that depression is a risk factor for rehospitalization in general medical inpatients, but the study sample was relatively small and the study design methodology significantly limited its generalizability.[12] It would be useful to provide supporting evidence showing depression as an important risk factor for readmission in the general medical in-patient population using more rigorous study methods and a larger cohort.

We hypothesized that depressive symptoms would be an independent risk factor for early unplanned hospital utilization after discharge for all medical patients. Therefore, we conducted a secondary analysis of the Project RED clinical trial dataset to assess the association between a positive depression screen during inpatient hospitalization and the rate of subsequent hospital utilization.

Methods

Data from the Project RED clinical trial were reviewed for inclusion in a secondary analysis. Complete data were available for 738 of the 749 subjects recruited for Project RED.

Project RED Setting and Participants

Project RED was a two-armed randomized controlled trial of English-speaking adult patients, 18 years or older, admitted to the teaching service of Boston Medical Center, a large urban safety-net hospital with an ethnically diverse patient population. A total of 749 subjects were enrolled and randomized between January 3, 2006 and October 18, 2007. Patients were required to have a telephone, be able to comprehend study details and the consent process in English, and have plans to be discharged to a US community. Patients were not enrolled if they were admitted from a skilled nursing facility or other hospital, transferred to a different hospital service prior to enrollment, admitted for a planned hospitalization, on hospital precautions, on suicide watch, deaf or blind. The Institutional Review Board of Boston University approved all study activities. A full description of the methods for the Project RED trial has been described previously.[2]

Outcome Variable

The primary endpoint was rate of hospital utilization within 30 days of discharge from the index admission, defined as the total number of ED visits and readmissions per subject within 30 days of the index discharge. Hospital utilization rates within 60 and 90 days of the index hospitalization discharge were also analyzed as secondary outcomes. Any ED visit in which a subject was subsequently admitted to the hospital was only counted as a readmission. Outcome data were collected by reviewing the hospital's electronic medical records (EMRs) and by contacting subjects by telephone 30 days after discharge. Dates of hospital utilization occurring at Boston Medical Center were obtained from the EMR, while those at other hospitals were collected through subject report. Subjects who could not be reached within 60 days of discharge were assumed alive.

Primary Independent Variable

The primary independent variable of interest was depressive symptoms defined as a positive score for minor or major depression on the nine-item Patient Health Questionnaire (PHQ-9) depression screening tool.[20] A dichotomized variable was created using a standardized scoring system to determine the screening cut-off for major or minor depressive symptoms.[19]

Statistical Analysis

Demographic and other characteristics of the subjects were compared by depression status (Table 1). Potential confounders were identified a priori from the available literature on factors associated with rehospitalization. These included age, gender, marital status, health literacy score (rapid estimate of health literacy in adult medicine tool [REALM]),[21] Charlson score,[22] insurance type, employment status, income level, homelessness status within past three months, hospital utilization within the 6 months prior to the index hospitalization, educational attainment, length of hospital stay and Project RED study group assignment. Bivariate analyses were conducted to determine which covariates were significant confounders of the relationship between depression and hospital utilization within 30 days of discharge. Chi-square tests were used for categorical variables and *t*-tests for continuous variables.

Age, length of stay, and Charlson score were used as continuous variables. Gender, marital status, frequent prior utilization (0–1 vs. 2 or more), and homelessness were treated as dichotomous variables. Categorical variables were created for, educational attainment (less than eighth grade, some high school, high school graduate, some college, college graduate), insurance type (Medicare, Medicaid, private insurance or free care), income level (no income, less than $10,000 per year, $10,000–20,000, $20,000–50,000, $50,000–

Abbreviations: PCP, primary care provider; PHQ9, Patient Health Questionnaire-9; REALM, Rapid Estimate of Health Literacy in Adult Medicine tool; SD, standard deviation.

*Positive depressive symptom screen determined by PHQ9 screen tool, a nine-item 4-point Likert scale, standard scoring algorithm to screen for major and minor depression. A score of 5 or higher indicates a positive depression symptom screen.[17]

†Free Care is a Massachusetts state program for uninsured patients.

‡Health literacy categories correspond to total score as determined by REALM.[18]

§"Have PCP" refers to subject self-identifying PCP at time of Project RED study enrollment.

‖"Unmarried" marital status includes subjects identified as divorced, widow, single, partnered.

¶Charlson Comorbity Index Score reflects the cumulative increased likelihood of 1-year mortality. The higher the score the more severe the comorbid condition. A 33% increase in risk for death is reflected in a 1-point increase in weights. The minimum score is 0. There is no maximum score.[19]

#Project RED study intervention group refers to subjects who received the 3-armed discharge intervention.

**Frequent Utilizer is defined as a subject with 2 or more hospital utilizations in 6 months prior to Project RED clinical trial index admission.

100,000, no answer), level of health literacy (grade 3 and below, grade 4–6, grade 7–8, grade 9 or above) and employment status(working full-time, working part-time, not working, no answer).

The 30-day hospital utilization rate reflects the number of hospital utilization events within 30 days of discharge per subject. The same method was used to calculate hospital utilization rates within 60 and 90 days of discharge respectively. The unadjusted incident rate ratio (IRR) was calculated as the ratio of the rate of hospital utilizations among patients with depressive symptoms versus patients without depressive symptoms. Data for hospital utilization at 30, 60, and 90 days are cumulative.

Poisson models were used to test for significant differences between the predicted and observed number of hospitalization events at 30 days. A backward stepwise regression was conducted to identify and control for relevant confounders and construct the final, best-fit model for the association between depression and hospital reutilization. A statistical significance level of $P = 0.10$ was used for the stepwise regression. To evaluate potential interactions between depression and the Project RED intervention, interaction terms were included. Two-sided significance tests were used. *P* values of less than 0.05 were considered to indicate statistical significance. All data were analyzed with S-Plus 8.0 (Seattle, WA).

In addition, a Kaplan-Meier hazard curve was generated for the first hospital utilization event, ED visit or readmission, for the 30-day period following discharge and compared with a log-rank test.

Results

A total of 28% of subjects were categorized as having a positive depression screen. More women (36%) had positive depression screens than men (28%). Among patients with a positive depression screen, 58% had a history of depression and 53% were currently taking medications at the time of enrollment, compared with 25% and 22% respectively for subjects with a negative depression screen. Table 1 presents the means or percentages for baseline characteristics by depression status in the analytic cohort. Subjects with Medicaid for insurance had a higher rate of depression (61%) than subjects with Medicare (13%), private insurance (9%), or those who qualified for the Free Care pool (17%) which is the Massachusetts state funding for healthcare to uninsured persons. Subjects who were unemployed, unmarried, or who reported earnings less than $10,000 per year were also more likely to screen positive for depression. In addition, depressed subjects had a higher severity of co-morbid disease and longer length of stay for the index hospitalization. Patients categorized as frequent utilizers (2 or more prior admissions) for the 6 months prior to the index hospitalization were also more likely to be depressed. Of further note, is the relatively younger average age among both depressive

§Refers to Project RED study group assignment.

‖Charlson Comorbity Index Score reflects the cumulative increased likelihood of 1-year mortality. The higher the score the more severe the comorbid condition. A 33% increase in risk for death is reflected in a 1-point increase in weights. The minimum score is 0. There is no maximum score.[19]

¶Interaction term of Project RED study group assignment and depressive symptom category (positive or negative).

patients (49.6 years) and non-depressive patients (49.9) of these study subjects.

The unadjusted hospital utilization rate at 30, 60, and 90 days post-discharge by depression status is shown in Table 2. At 30 days post-discharge, those with depressive symptoms had a higher rate of hospital utilization than those without depressive symptoms (0.563 vs. 0.296). In other words, 56 utilization events occurred per 100 patients with depressive symptoms, compared with 30 utilization events per 100 patients without depressive symptoms. The unadjusted 30-day post-discharge hospital utilization rate among those with depressive symptoms was higher compared with those without symptoms (IRR, 1.90, 95% confidence interval [CI], 1.24–2.71). A similar trend was found among subjects at 60 and 90 days post-discharge.

Poisson regression analyses were conducted to control for potential confounding in the relationship between depressive symptoms and hospital utilization rate within 30 days after discharge (Table 3). After controlling for relevant confounders, including age, gender, employment status, frequent prior hospitalization status, marital status, Charlson score, Project RED study group assignment and the interaction variable for RED study group assignment and depression, the association between symptoms of depression, and hospital utilization rate remained significant (IRR, 1.73; 95% CI, 1.27–2.36).

Figure 1 depicts the Kaplan-Meier hazard curve generated for time to first hospital utilization, stratified by depression status. While 21% of participants without symptoms of depression had a hospital utilization within 30 days, fully 29% of participants with symptoms of depression had a hospital utilization within 30 days ($P = 0.011$).

Discussion

Our study shows hospitalized patients who screen positive for depressive symptoms are significantly more likely to have a hospital visit (emergency room or rehospitalization) within 30 days of discharge than those who do not screen positive for depressive symptoms among medical patients admitted to an urban, academic, safety-net hospital. These findings are consistent with, and extend, prior reports regarding depression and rehospitalization in specific populations (ie, geriatrics) and specific diagnoses (ie, cardiovascular disease [CVD] and COPD).[10–12] We observed a 73% higher incidence rate for hospital utilization within 30 days of discharge for those with symptoms of depression. This puts symptoms of depression on par with frequent prior rehospitalization, advanced age and low social support, as known risk factors for rehospitalization.[4,5,23]

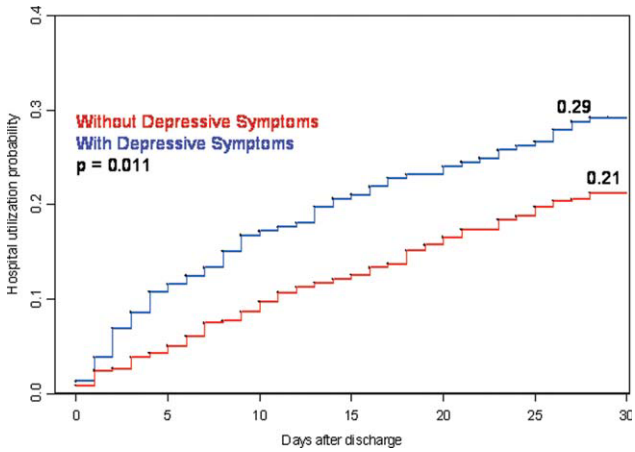

FIGURE 1. Hazard for hospital utilization among subjects with and without depressive symptoms in 30 days following hospital discharge.

Also of significance is the relatively young age of this study population (49.9 years non-depressive patients and 49.6 years for depressive patients) compared with the study cohorts used for research in the majority of the existing literature. The chief reason for the young age of our cohort is that potential subjects were excluded if they came from a skilled nursing facility or other hospital. This may limit the generalizability of our findings; however, it seems likely that interventions relating to depression and transitions of care will need to be quite different for patients that reside in long-term care facilities vs. patients that live in the community. For example, patients living in the community may have significant barriers to access post-discharge services due to insurance status and are more likely to be sensitive to variations in social support.

Early rehospitalization is associated with significant morbidity, mortality, and expense. It is also a potential marker for poor quality of care.[24] Concerns for patient safety, escalating healthcare costs, and possible change in hospital reimbursement mechanisms are fueling the search for modifiable risk factors associated with early rehospitalization. Our data provide evidence that symptoms of depression may be an important focus of attention. We do not know, however whether treating hospitalized patients who screen positive for depression will decrease early rehospitalization and emergency room utilization rates.

Various physiologic and behavioral mechanisms may link symptoms of depression to hospital utilization after discharge. For example, depressed patients with features of somatization may be more likely to experience worrisome physical symptoms after discharge and present prematurely for reevaluation. Patients who are sicker in some fashion not captured by our measured confounders may have symptoms of depression related to chronic, debilitating disease warranting early return to the hospital. Depression may also yield nonadherence to aspects of the discharge treatment plan leading to rehospitalization as a result of poor post-discharge disease management. For example, research shows that patients with depression following coronary artery bypass surgery are less likely to adhere with cardiac rehabilitation programs.[25] Likewise, depression among chronically ill patients such as diabetics, asthmatics, or human immunodeficiency virus (HIV)-positive patients impairs medication adherence and self-care behavior which may lead to disease relapse or recurrence.[26–28] One study examining depression effects on hypertensive medicine adherence in African Americans identified self-efficacy as a mediating factor between depression and nonadherence.[29] This implies that interventions such as self-management education, a program through which chronically-ill patients learn to better manage their illnesses through enhanced self-confidence and problem-solving strategies (including mood disorder challenges) may reduce early rehospitalization among depressed patients.[30]

There is also evidence that depression may have direct physiologic consequences. In patients with CVD, depression is associated with poor outcomes possibly related to decreased heart rate variability, hypercoagulability, high burdens of inflammatory markers, and severity of left ventricular dysfunction.[31–34] Similarly, depression among HIV/acquired immune deficiency syndrome (AIDS), diabetics and multiple sclerosis (MS) patients is linked to heightened levels of proinflammatory markers and less favorable outcomes that may signal a more severe form of the disease or an impaired response to treatment.[35–38] Indeed, MS investigators now hypothesize that the proinflammatory environment associated with the neurologic manifestations of MS are also causing depression symptoms among MS patients.[34] This theory contrasts the common belief that depression in the chronically ill manifests independent of the chronic illness or in response to living with chronic disease.

A major strength of the current study is the large dataset and the broad range of covariates available for analyses. However, several limitations should be noted. First, data on hospital utilization outside Boston Medical Center were determined by patient self-report and were not confirmed by document review. Second, we do not know the direction of the associations we report. If symptoms of depression are merely the consequence of having a higher disease burden, treatment of the underlying disease may be the most important response. While this is possible, our model does include several variables (eg, Charlson score and length of stay) that are likely to adjust for disease severity, pointing to the likelihood that symptoms of depression truly predict hospital utilization in a fashion that is independent of disease severity. Third, our results may not be generalizable to populations other than those served by urban safety-net hospitals or other populations excluded from the Project RED trial (eg, non-English speaking patients and patients from nursing homes). Finally, social factors such as substance use and social support system variables may residually confound the relationship between depression and hospital reutilization

2010 Society of Hospital Medicine DOI 10.1002/jhm.673
Published online in wiley InterScience (www.interscience.wiley.com).

demonstrated in this study. While this dataset does not include a measure of social support other than marital status and housing status, data is available on substance use. Analyses conducted by our colleagues using Project RED data found that in this study population depression was significantly more prevalent among substance users (29% vs. 14%) compared with non-users and that substance use is an independent risk factor for hospital reutilization (unpublished data).

Our findings linking depression to increased hospital utilization also warrant further consideration from healthcare policymakers. Central to the Obama Administration's February 2009 healthcare reform proposal is the pursuit of cost savings through reductions in unplanned hospital readmissions.[39] Thus, identifying potentially modifiable risk factors for readmission, such as depression, is of great concern to healthcare providers and policymakers across the nation. If, through testing of interventions, depression proves to be a modifiable risk for readmission, policymakers, while negotiating healthcare reform measures, must provide for the services required to address this comorbidity at the time of discharge. For example, if a patient screens positive for depressive symptoms during a hospitalization for COPD exacerbation, will the proposed payment reforms allow for mental health services during the immediate post-discharge period in order to reduce the likelihood of hospital readmission? Will those mental health services be readily available? Payment reforms that account for all necessary transitional care services will indeed help reduce readmission costs with less risk for untoward consequences.

In conclusion, our results indicate that a positive depression screen is a significant risk factor for early post-discharge hospital utilization among hospitalized adults on a general medical service, even after controlling for relevant confounders. Screening for depression during acute hospitalizations may be an important step in identifying patients at increased risk for readmission. Future research should focus on further characterizing and stratifying populations at highest risk for depression. Efforts should also include developing and evaluating targeted interventions for patients with symptoms of depression among hospitalized patients as part of discharge planning. Timely depression therapy during the hospitalization or following hospital discharge might reduce costly readmissions and enhance patient safety.

BACKGROUND: In 2000 a diverse group of clinicians/educators at an inner-city safety-net hospital identified relational skills to reduce disparities at the point of care.

DESCRIPTION: The resulting interviewing and precepting model helps build trust with patients as well as with learners. RESPECT adds attention to the relational dimension, addressing documented disparities in respect, empathy, power-sharing, and trust while incorporating prior cross-cultural models. Specific behavioral descriptions for each component make RESPECT a concrete, practical, integrated model for teaching patient care.

CONCLUSIONS: Precepting with RESPECT fosters a safe climate for residents to partner with faculty, address challenges with patients at risk, and improve outcomes.

KEY WORDS: health care disparities; cultural competency training; cross-cultural medicine; learning climate; physician-patient relationship; communication; professionalism.

INTRODUCTION

The need to reduce health care disparities at the point of care raises urgent challenges for training of medical professionals. Each clinical encounter offers an opportunity to decrease risk for disparate care and poor outcomes. To succeed in this effort, clinicians must transform knowledge and awareness into action and skills; we must partner effectively with patients whose backgrounds may differ dramatically from our own. An expanding literature has identified patient-centered and culturally competent interpersonal skills as critical to maximizing patient satisfaction, trust, adherence, and outcomes.[1] The challenges for clinical faculty are twofold. How do we establish the trust and safe learning climate trainees need to discuss openly their challenges in interactions with patients at risk for disparities? Secondly, if our learners do identify barriers to effective relationships with their patients, what skill set should we teach to help them be more effective? The well-documented decline in medical trainees' empathy during the clinical years means that house staff may be at particular risk for erosion of the interest and personal skills essential to maximize their patients' care[2,3]. Attention to learning climate and supportive training relationships may help restore some of residents' empathy, while skills training remains important given the often pragmatic orientation of trainees and the need to sustain their motivation and self-efficacy.

In 2000 a racially and culturally diverse group of clinician-educators at Boston Medical Center, a large urban safety net hospital, worked to address this training need, identifying the communication skills we use to relate effectively with our patients, a population with great diversity by race/ethnicity, culture, language, and class. We sought ways to address disparities within each individual doctor-patient encounter and new methods to teach these skills to busy trainees in clinical settings. The resulting RESPECT model is an integrated instrument for teaching, evaluation, and expansion of faculty skills. It provides a guide for what to do and how to teach it. By addressing relations with learners as well as patients, it offers help aligning the powerful hidden curriculum with the explicit curricular goals of compassionate patient care, sensitivity to diverse populations, interpersonal communication, professionalism, life-long learning, and

This article is dedicated with gratitude and respect in memory of Samuel Morse Putnam MD, MPH.

 The RESPECT model was developed by members of the Diversity Curriculum Task Force in 2000 originally led by Carol Mostow, Peter Gonzalez, and Julie Crosson including Sandra Gordon, Sheila Chapman, Oranti Aladessamni, Thea James, Eric Hardt, Charles Brackett, and Sandhya Wahi. The model was further elaborated and implemented in the 2004-2005 faculty development project, which in addition to Mostow, Gordon and Crosson included Leyda Delgado, Michele David, Sondra Crosby, Danru Lee, and Sam Putnam.

practice-based improvement. These are all core residency training requirements for accreditation by the American Council of Graduate Medical Education (ACGME)[4].

What is the RESPECT Model?

The RESPECT model is an action-oriented set of communication and relational behaviors designed to build trust across differences of race/ethnicity, culture, and power[5]. Clinicians can use RESPECT to target documented disparities in doctor-patient relationships[6]. Medical educators can use the model as an integrated instrument for teaching, observation, and evaluation. Finally, preceptors can also apply the RESPECT model to their own relationships with learners to facilitate more effective training. The specific component skills for this interviewing model and educational framework are:

*R*espect
*E*xplanatory model
*S*ocial context, including Stressors, Supports, Strengths and Spirituality
*P*ower
*E*mpathy
*C*oncerns
*T*rust/ *T*herapeutic alliance/ *T*eam.

See Table 1 for details on the use of RESPECT for patient care.

Why Another Model?

A review of the literature reveals important early contributions regarding how to elicit and negotiate differences of culture, health beliefs, and practices. Valuable attention to social context helps to understand some issues of the poor, but we did not find the same attention to matters regarding race, power, and distrust apparent to our racially/ethnically diverse patients and clinician group. We also noted that teaching models initially focused on the traditional information-gathering function of the interview rather than a relational guide addressing the affective domain. In the context of an emotional climate of potential distrust, racial, ethnic, and economic inequities, and risk for disparate outcomes, we were looking for a model that teaches physicians how to respond, not just what to ask. What should the physician do to build trust across differences of power, race, ethnicity, and class? Finally, we knew as preceptors that these issues felt sensitive and difficult to address in busy clinical settings with harassed residents trying to handle patients with challenging medical as well as social problems. What in the literature could help us build the relationships with residents that allowed these important conversations, so important to help them better meet the needs of the patients they serve?

A review of the literature on cross-cultural interviewing identified Kleinman's tool to elicit diverse health beliefs and practices. This widely used set of questions targets the patient's explanatory model, concerns about the illness, and goals of treatment[7]. Building on this work, Berlin and Fowkes proposed the LEARN Model, a framework for cross-cultural care[8]. This model contributes the skills of *L*istening, *E*xplanation of provider perceptions, *A*cknowledgement of differences, treatment *R*ecommendations, and *N*egotiation of plans. The *ETHNIC* mnemonic, designed by Levin et al., adds helpful attention to the way that cultural beliefs and practices may differ and be addressed. Model components include: seeking *E*xplanations of the patients' understanding of illness; asking what *T*reatments patients use and expect; inquiring about alternative *H*ealers; *N*egotiation of options incorporating patients' beliefs; designing culturally appropriate *I*nterventions; and *C*ollaboration with patients and their support systems[9]. Betancourt et al. developed the *ESFT* model, which added to the *E*xplanatory model the expanded *S*ocial context of illness including economics, literacy, and other important constraints[10]. This model also included attention to the patient's *F*ears and concerns about therapy and advocates *T*herapeutic contracting with patients around medication issues.

These valuable models all facilitate the gathering of relevant information related to cultural issues and introduce the skill of negotiation. However, they focus more on negotiating difference than addressing the power dynamics involved with differences of race, ethnicity, and class, or the relational and affective dimensions of the clinical encounter. These models do not themselves suggest or describe direct provider responsiveness to the emotional climate and potential distrust often operative in encounters across differences of race, ethnicity, and power in our society.[11]

Since 2001 additional cross-cultural interviewing models have been developed, including the *BELIEF* model by Dobbie et al., that do recognize the importance of addressing the affective domain in conversations across cultures.[12] Its components are: health *B*eliefs, *E*xplanation, *L*earn, *I*mpact, *E*mpathy, and *F*eelings. Still, little attention is given to the dynamics of power and historic oppression important for addressing differences of race, ethnicity, and class in contemporary America. According to a recent critique of multicultural education, too many cultural competence curriculae fail to provide direction in these dimensions.[13]

In 2008, scholars conversant with the literature regarding cultural competence and patient-centered communication called for the two fields to build on each others' contributions to increase effectiveness in both domains[14]. Teal and Street furthered this effort by publishing a comprehensive model using a complex array of communication skills.[15] Their important work further supports the elements distilled and prioritized in the RESPECT model while suggesting curricular elements for an in-depth and intensive physician training process.

Why RESPECT the Patient?

Reduction of disparities in clinical practice requires strategic action to bridge differences of race/ethnicity, culture, and power. The RESPECT model can help medical professionals develop the practical skills needed to build trust actively. It expands on earlier models by adding the components of respect, empathy, and power specifically to target documented areas of disparity in interracial and cross-cultural encounters.[16] In the context of inequity, stigma, and power differentials, proactive demonstrations of respect seek to mitigate patients' prior negative experiences and possible expectations of disrespect.[17] In the RESPECT model, the provider actively conveys empathy to the patient rather than simply collecting data. Since so much of trust-building is affective and relation-

Table 1. How (and why) to RESPECT the Patient

Skill	Definition	Behavioral description	Examples	Relevant evidence
Respect: *show*	A demonstrable attitude communicating the value and autonomy of the patient and the validity of his/her concerns	Non-verbal: Maintain attentive posture, appropriate eye and personal contact; follow cues regarding personal space, physical contact, and appropriate greetings	"Hi, I'm Dr. X, and I'm looking forward to working with you"	Disparity: African American, Hispanic, and Asian patients reported feeling less respected by their doctors than did White patients[17]
		Verbal: Welcome patient to encounter; introduce self and explain role on team; ask the patient how they want to be addressed; recognize and affirm strengths and efforts	"What would you like me to call you?" "You overcame a lot to get here today!"	
Expanatory model: ask	The patient's understanding of what causes their illness, or what will help it	Non-verbal: Give patient space to share their ideas by listening without judgment Verbal: Ask patient what they think is causing or will alleviate their symptoms	"What do you or your family think is causing your symptoms?" "Why do you think this started when it did?" "What do you think will solve the problem?"	Patients and doctors often have different ideas that remain unexplored unless elicited. Without discussion, patients leave less satisfied[20]
Social context: ask	Impact of patient's life upon illness and of illness on his/her life. Include stressors, supports, strengths, spiritual resources that influence patient, health or care	Nonverbal: Show interest and pay attention Verbal: Ask how patient's illness affects their life and how their life affects illness	"What should I know about you to care for you best?" "What is hardest for you?" "Who helps you the most?" "What keeps you going?" "What about religion?"	Low social support predicts higher mortality post MI [21] Negative health consequences follow death of spouse alleviated by presence of confiding figure[22]
Power: *share*	Access to status, control, resources, options, and ability to produce desired outcomes Power gradient favors doctors[11]	Non-verbal: Reduce physical barriers. Don't dominate the interaction. Sit Verbal: Listen. Limit interruptions. Build history rather than take it.[24] Use EMR to share information with patient via graphs, etc. Invite open discussion of disagreement. Negotiate agenda/treatment plan by eliciting preferences. Empower patient, recognize strengths	"Beside your diabetes, what else should we talk about?" "What would make your medications easier?" "Thanks for telling me that you don"t agree. What do you think?"	Disparity: White physicians dominate conversation more with non-white patients[36] Self-efficacy needed to make healthy choices[23]
Empathy: *show*	Verbal and nonverbal responses that validate patients' emotions and cause them to feel understood.	Non-verbal: Listen attentively and respond accordingly Verbal: Name and validate patients' emotions. Put significance of patient's experience into words to convey specific understanding	"That must be hard, anyone would feel that way." "This can be scary. Let's talk about it." "The injury changed everything for you"	Disparity: Doctors display less warmth with African-American patients[36]
Concerns/ fears: ask	Worries about symptoms, diagnosis, or treatment, often unexpressed	Nonverbal: Head nods, etc., to encourage patient to give details Verbal: Ask open-ended questions about fears/concerns	"What worries you the most?" "What scares you about the medication?" "Are you worried about sex after your heart attack?"	Unvoiced concerns lead to unmet needs and patient dissatisfaction[25]
Trust/team-building/ therapeutic alliance	Relationship built on understanding, power-sharing and empathy; patient confident that doctor acts on his behalf	Trust: Notice/respond to signs of distrust. Elicit and respond to expectations. Reassure and clarify follow-up. Follow through	"People in my family have had the same thing." "Should we get your family involved to help us?" "We"re here when you need us." "Let's make sure we answer all your questions so you feel comfortable making your decision"	Disparity: 62.8% Blacks vs. 38.4% Whites believe their doctors have or would experiment on them without their consent.[26] Black patients receive less support, partnering and information[27]
Build: don't assume		Therapeutic alliance: Find specific common goals, negotiate differences Team building: Identify, enlist, and collaborate with potential members of health care team		

al, these empathic skills are particularly important.[18,19] Providers need skills to counterbalance power differentials through verbal and nonverbal behaviors, actively seeking patients' concerns, potential disagreements, and barriers to treatment.

Accumulating evidence supports the validity of the RESPECT components as critically related to disparities in care (see Table 1: refs [16,20–27,36]). For example, disparities were identified in patients' experience of respect and trust in surveys of patients and providers conducted by the Kaiser Family Foundation and the Commonwealth Fund.[17,28–34] Trust in doctors among African-American patients continues to be diminished by the legacy of the Tuskegee experiment, often reinforced by more contemporary racial experiences.[35,36] The components of power and empathy are also supported by evidence regarding disparate experiences of non-white patients. White physicians dominate speech more with non-white patients and display less warmth and patient-centered behaviors.[16,36] Another study documented that black patients received less support, partnering, and information from their doctors and have lower levels of trust in their physicians.[27]

Collaborative empowerment and empathy assume even greater importance given recent findings that physician dominance reduced patient engagement while demonstrations of caring elicited more emotional sharing by the patient and increased activation in the interview[37]. Another study found that the majority of patients do have the explanatory models of illness described by Kleinman as so pivotal in health-related behaviors, but did not disclose them unless specifically invited to share them.[20]

The contribution of social factors to health and patients' approach to health care has also been well established.[38] The RESPECT model offers a helpful tool to focus quickly and prioritize elements of the social context most salient to the patient. Physicians can focus on matters of greatest importance to the patient rather than squandering time on less relevant closed-ended demographic information. (see Table 1). The value of identifying the patient's stressors is supported by clinical studies.[39,40] By eliciting strengths, supports, and spiritual resources as well as stressors, the RESPECT model replaces a focus on social deficits with an appreciation of the internal, family, and community strengths fostering self-efficacy, a critical element for health behavior change.[23] Recent literature on patient-centered approaches suggests that prompt attention to patients' emotions and perspective may add to, not diminish efficiency.[41]

Why RESPECT the Trainee?

Recognizing the learning climate and working to improve teaching relationships addresses the implicit "hidden curriculum" within medical education.[42–44]. Much learning occurs by selective reinforcement of behaviors that may not be consciously examined.[45] Effective teaching must address the persisting decline in empathy documented during the clinical years of medical school and residency.[2,3,46] Caring for the socially disadvantaged adds to the personal stressors of residency training.[47] Explorations of residents' errors suggest a reluctance to discuss them with faculty.[48] The Institute of Medicine reports on patient safety indicate that rigid hierarchies and atmospheres of fault-finding and blame are antithetical to a safe culture for patient care. A "flattened hierarchy" promotes honesty and reduces defensiveness.[49] Growing attention to the implicit curriculum suggests the importance of using methods to train residents that are congruent with learning objectives and content.[50,51]

Our explicit application of the RESPECT model to both patients and learners is similar to an innovative contribution by Kern et al. teaching residents an approach to psychosocially sensitive care of patients while applying the same approach to the residents.[52] As they note, empathic listening skills may wither in residents whose own concerns are routinely ignored. A similar call to address power dynamics in the teaching of prospective doctors recently came from educators focused on the elimination of health disparities.[13] We must create a safe learning climate for the open dialogue that learners need to internalize professional values and commit to social justice goals. The call for a wholesale "reorientation of the traditional teacher-student paradigms" requires faculty development related to these new teaching methods.

RESPECT: A Versatile Teaching Tool

Ten years using RESPECT has persuaded us that it is an effective model promoting generalizable skills for a wide range of health care providers working in varied clinical settings. In addition to its utility in clinical practice, the RESPECT model has proven to be a versatile tool for teaching, evaluation, and faculty development.

For pre-clinical learners, didactic presentations and experiential approaches provide exposure to the relational process of clinical care. We adapted RESPECT as an observational tool for students to observe their attendings at work with patients (Looking for RESPECT, BOX 1). Following a lecture introducing the framework and an exercise about difference and power, all first year medical students at Boston University School of Medicine use the tool in their first patient contacts as they observe faculty in diverse clinical settings. They use Looking for RESPECT to guide their observations and write-ups of physician-patient encounters with a focus on patient concerns and relational elements beyond the classical data-oriented approach. Through the lens of the model, students see the clinical relationship and watch doctors build trust and understanding across differences.

Looking for RESPECT:

An observation exercise or assessment tool for demonstrating ACGME competencies

The RESPECT model conveys a value essential to clinical practice and required for all effective communication. It also offers a handy list of essential components to optimize health care encounters for both patient and physician, especially important when facing additional differences of culture, race, ethnicity, class, etc. between the parties.

R	Did the physician convey Respect? If so, in which ways? What seemed to be the patient's reaction?
E	What did the doctor learn about the patient's Explanatory model of the illness and ideas of what might help? (e.g. what's wrong with me? what do I think will make me better?)
S	What did the doctor learn about the Social context of the patient including Stressors, Supports, Strengths, Spiritual beliefs and practices which might affect health, treatment, expectations, or relationships with the doctor and healthcare system? How does the patient's life affect his illness? How does his illness affect his life?
P	What expectations and preferences did the patient and doctor each seem to have for the Power relationship? Notice both non-verbal and verbal cues. Pay attention to displays of deference, control, hierarchy. Who does the talking? Who determines the agenda ? What did the doctor or patient do or say during the encounter which seemed to empower or disempower either party? Does the doctor seek the patient's input and preferences or simply announce to the patient what will happen?
E	What opportunities were there for the doctor to convey Empathy? What did the doctor do or say to which conveyed an understanding of the patient's experience and its significance to the patient? What were the patient's responses?
C	Are there any Concerns and fears which underlie or coexist with the patient's presenting problems? What prompted the patient to share these? What did the physician do to elicit or facilitate this fuller, possibly more emotional disclosure?
T	What seemed to be the patient's initial level of Trust? What did the doctor say or do during the interview which seemed to modify the patient's level of Trust? What verbal and non-verbal indicators did you notice? Was a Therapeutic plan created? Did the doctor and patient reach common ground regarding the problem and the approach to diagnosis and treatment? Are there any indications that there might be obstacles to and/or disagreements about the next steps? If there remained divergent preferences at the end of the interview, was the doctor able to negotiate a partnership based on other shared goals?

NOTE: Make sure to observe non-verbal as well as verbal behaviors regarding the above.

To teach these concepts to residents and practicing clinicians, we use case-based learning in discussions, role plays, and trigger tapes. This approach has worked well in interactive didactic presentations with medical residents and clinicians in a variety of settings. As the model is easily generalized, faculty have used it to train substance abuse screeners and health care workers providing breast cancer outreach.[53] It has also been adopted for the didactics, discussion, and video demonstration for Alcohol Clinical Teaching, a web-based alcohol training program.[54] In a training for experienced eye care professionals and faculty, we solicited problematic cross-cultural clinical encounters cases and addressed them using RESPECT-based role play.[55]

For residents, we use an inductive exercise designed to help them discover the RESPECT model actively. In case-based preclinic conferences at continuity clinics, we encourage them to think through their own cases with challenging communication issues. They then identify the elements contributing to a past success bridging differences and distrust, which combine to form the RESPECT model. The residents then reflect and strategize with peers and faculty about how to apply the model to their other challenging cases, identify skills and behaviors to try in future encounters.

We have found the observation tool designed for medical students, Looking for RESPECT (BOX 1), to be equally useful for preceptors in resident primary care clinics. The model provides a framework that helps faculty go beyond evaluation of standard bedside skills to assess critical competencies of interpersonal communication and professionalism including sensitivity to the needs of diverse populations[4]. We can use the same teaching tool to stimulate residents' reflections and self-assessments as well as for more structured performance evaluation as has been suggested.[56]

Effective teaching in this area requires that residents disclose the challenges that they face in order to reflect on what they're doing and consider new approaches. A top-down approach is unlikely to succeed in promoting development of this level of 'critical consciousness.'[13] Simply telling learners to be culturally

sensitive and respectful does not assure that they can and will do so. We realized that we needed to apply the RESPECT model skills to build relationships with our learners as well as with our patients. We have translated those skills into a precepting guide that helps faculty improve their skills. By explicitly addressing issues of power, Precepting with RESPECT (BOX 2) addresses the implicit curriculum and harnesses parallels between educational and clinical encounters.[52] The model incorporates relational and cognitive elements from recommended precepting models that elicit the resident's model of understanding, encourage independent thinking, and facilitate targeted educational interventions.[57,58]

Precepting with RESPECT:

Application of the RESPECT model to preceptor-learner relationships

RESPECT	Approach the learner with respect. Builds resident confidence, preceptor resident relationship. Reduces defensiveness. "I know how hard you've been working to try and get his diabetes under control".
EXPLANATORY MODEL	Elicit the resident's thoughts about the patient and interest in the patient's perspective. Helps preceptor learn what resident knows and has asked as starting point for further discussion. Conveys interest in resident's perspective while supporting resident's interest in patient's perspective "What do you think is going on with the patient?" "What does patient think is causing his symptoms?"
SOCIAL CONTEXT	Check re residents' well-being and context . Explore possible professional and personal stressors. Builds preceptor-trainee relationship. Models how to act with patients. " How are things going for you these days?" "What clinical rotation are you on?"
POWER	Find ways to share power and support resident self-efficacy. Resist the temptation to take over in the face of learner's uncertainty. Helps assess clinical judgment, build problem-solving ability and increase investment in solution. "How might you find out why this patient has a hard time taking his medicines daily?"
EMPATHY	Let resident know their frustrations and emotions are heard Documented decline in residents' mood and empathy for patients as well as differences from their patients' background make this step essential. Faculty support may enable residents to engage more effectively with patient. "After all your effort, I can imagine how frustrating it is that she didn't fill her prescription." "Particularly when I'm tired, it can be hard to put aside my own frustration to find out what's going on from the patient's perspective."
CONCERNS	Elicit and address residents' concerns about situations they don't feel confident handling or fear will make visit too long. Help residents strategize about possible solutions and educate about relevant data Replaces anxiety with information to improve quality and efficiency " I know you were worried about eliciting more of the patient's concerns but eliciting them doesn't mean you or the patient can tackle them all in one visit." " Let's discuss how to identify your and the patient's top priorities, come up with a plan for today and bring him back for follow-up and to address the other issues."
TRUST	Building on all the skills above fosters trust in the preceptor-resident relationship. Learners may become more willing to identify areas of challenge. "I admire your openness and ability to share with me that your patient was so frustrated that she wanted to change doctors." "How can I help you?"

We discovered some of these approaches during a year-long faculty development project at our institution in 2004-2005, funded by BCBS of Massachusetts Medical Foundation.[59] We applied the RESPECT model in resident clinics and other settings. We sought to make cultural competence, prevention of health care communication disparities, and more effective relationships between residents and patients a routine part of precepting and clinical care. Faculty sought increased comfort and effectiveness precepting residents to connect more effectively with their diverse patient population. A group of ten experienced clinician-educators of diverse racial/ethnic backgrounds joined together in monthly 3-h sessions. The faculty group included four blacks, four whites, one Asian, and one Latina; four participants were born outside of the USA. Participants included clinic preceptors, in-patient attendings, an emergency room attending, and a medical educator, all involved with resident and/or medical student teaching. Most of them had participated in the ongoing Diversity Curriculum Task Force that had originally developed the RESPECT model. Despite our extensive experience, like our learners, we needed the opportunity to reflect and develop skills on how best to approach sensitive subjects and resident interactions that made us uncomfortable. While our commitment to the goals of cultural competence was clear, how to be most effective with our learners in getting there was not. Using Looking for RESPECT (BOX 1), preceptors identified residents' learning needs and then designed interventions for individual residents using Precepting with RESPECT (BOX 2). Preceptors often role-played these interactions to practice and get feedback from other faculty using faculty development strategies developed by the American Academy on Communication in Healthcare.[60] This protected learning environment allowed us to experiment with teaching methods, strategize about challenging teaching encounters, and share resulting observations of resident behaviors and attitudes.

Evaluation

In an effort to test, refine, and disseminate our RESPECT model into the clinical setting, we developed a self-administered questionnaire to evaluate its impact on teachers and trainees. In 2004-2005, we surveyed a diverse group of internal medicine residents at our hospital before and after implementing the RESPECT model as a teaching tool in resident primary care clinic sessions. Ten precepting faculty underwent structured interviews at the end of the intervention. Forty-four residents completed the baseline questionnaire and 20 the post-intervention questionnaire.

The ten precepting faculty all reported increased comfort and skill precepting regarding cross-cultural care in resident continuity clinics. In particular, some expressed a willingness to address racial issues affecting patient care that they had previously regarded as "taboo." Another theme noted was that faculty members also improved their own interviewing skills. Among the residents surveyed, 88% felt that the RESPECT-based training was useful. We found differences in several survey items pre- and post-training. Residents reported greater comfort when interacting with diverse groups (60% pre, 80% post). Residents seemed more convinced that cross-cultural training might improve health care delivery (57% pre, 93% post). Some reported major improvement in skills related to culturally sensitive interviewing (10% pre, 20% post). The number of residents reporting no skills in this area declined (12% pre, 0% post). Small numbers and limited response rates precluded more statistical analysis of survey results. Changes in preceptor and resident schedules along with variation in the frequency of contact also limited the data.

DISCUSSION

The RESPECT model was a product of a highly diverse group of clinician-educators working together for 10 years at a large urban medical center that cares for racially and ethnically diverse patients from the US and abroad. It is notable that diversity of the faculty group itself allowed us to draw upon personal and clinical experience and to share insights about the role of differences and of race in particular. Together we were able to derive a model of broad clinical utility to the care of our patients. A diverse faculty group's access to clinical and personal experience outside of majority culture may foster insights less apparent to others[28,62]. However, in the 2004–2005 evaluation of the project to improve faculty participants' teaching skills by precepting with RESPECT, our faculty preceptors also noted with interest improved interactions with their own patients by using the RESPECT model. The relational elements in the RESPECT model for interviewing and teaching have a lot to offer even a very sophisticated faculty and remind us that cultural competence and relationship-centered care of at-risk populations require ongoing efforts.

The RESPECT model can be useful to medical schools, residencies, and other health care organizations in meeting their training goals, core curricular competencies, and patient care standards, assuring that quality care is delivered equitably to all. To monitor and continually improve the quality of care and communication with all patients, evolving definitions by the ACGME[4] and others[44,63–65] of professionalism, practice-based improvement, and systems-based practice remind us that faculty and residents alike need to be lifelong learners. We must remain ever mindful of our ongoing impact on others and the value of teaming up with our patients, trainees, and colleagues. Respectful communication across power differentials among faculty, residents, and colleagues promotes positive professional communication and teamwork along with full and open disclosure.[49] This change of culture can promote a personal and systems-based examination of obstacles to optimum care and patient safety, especially important for patients at risk for poor outcomes.

One of the limitations of the RESPECT evaluation is that because of small resident numbers in the pilot clinics and the large number of them unavailable to complete the post-intervention survey, we could not perform tests of statistical difference. However, to date one study of the efficacy of the teaching model has been published.[55] Cultural competence training based on the RESPECT model was conducted for faculty at The New England Eye Institute and New England College of Optometry. A follow-up study demonstrated measurable positive impact that persisted 3 months post-intervention, using a cultural competency scale validated by Campinha-Bacote.[61]

It has been 10 years since we initially derived our interviewing and teaching model from the insights of our racially, ethnically diverse group of clinician educators. During that time empirical data as well as consensus recommendations

from the fields of patient-centered communication and cultural competence have been published that support the elements in our model.[1,6,15,16] For patients already at risk for disparities, a doctor who dominates the encounter or withholds warmth or empathy is a threat and a lost opportunity to partner for better health.[5,6,36] By addressing barriers to trust posed by power differentials, RESPECT may be a helpful part of the solution. What we offer is an easily remembered mnemonic that prioritizes elements linked to documented disparities in a clear, readily applied model. Attention to the power dynamics within our own relationships with residents has helped us precept our learners with RESPECT. Designed to improve communication with patients at risk for disparities, the RESPECT model provides a flexible, practical, and widely applicable teaching model targeting documented disparities in health care communication while promoting relational skills needed to build trust and partner for better health care.

Addiction
COMMENTARY

Commentary on McCaul *et al.* (2010): Observational studies about average alcohol consumption and health - closing time for a limited evidence base

Positive attitudes about 'moderate' drinking may weaken efforts designed to reduce alcohol misuse and its terrible consequences. For many, it is dogma that alcohol is good for the heart, if not one's overall health. The study by McCaul *et al.* [1] about the relationship between alcohol consumption, mortality and coronary heart disease (CHD) death among older Australians will not change those convictions. Although studies about drinking and mortality are mixed, this study's findings for CHD are generally consistent with those from other studies [2]; and although it is rarely emphasized, this study is also consistent with others in demonstrating that, among drinkers, drinking less alcohol generally results in better health outcomes than drinking more [3]. However, this study suffers from the same limitations that afflict other observational studies about average alcohol consumption and chronic disease outcomes. While these limitations are sometimes overlooked or dismissed, they are worth reviewing in depth and with a frequency matching the feverish publicity heralding new alcohol studies.

While confounding is an important theoretical consideration in any observational study, evidence suggests that confounding is a serious problem in alcohol studies conducted among western populations. First, many traditional CHD risk factors are more prevalent and intense among non-drinkers [4,5], and many analyses attempt to control for these differences statistically. In this paper, smoking was one of the few confounders controlled for in statistical analyses. However, smoking is one CHD risk factor that is typically more prevalent among drinkers, so its inclusion in analytical models, coupled with a failure to control for other confounders, probably led to overestimates of the protective effect of alcohol. Even in more carefully controlled studies, however, residual confounding would probably bias studies in favor of moderate drinkers. Furthermore, those with more risk factors have more possible combinations of risk factors that could be synergistic in terms of CHD risk. To the extent that this synergistic risk is not captured in observational studies, this would also bias studies in favor of moderate drinkers. Finally, because CHD risk factors tend to cluster in certain individuals and populations, it seems plausible that unknown or unmeasured confounders would also be more prevalent among non-drinkers, further biasing studies in favor of moderate drinkers.

In addition to the distribution of traditional cardiac risk factors, moderate average alcohol consumption appears to be a marker of affluence, leisure, education, social advantage, good mental health and having nice teeth (literally) [5]. These psycho-socio-economic markers, many of which are also considered 'non-traditional' cardiac markers are, in turn, major determinants of mortality [6]. Because there is not a plausible causal relationship between, for example, alcohol and higher educational attainment, it seems particularly likely that moderate drinking is merely a reflection of prosperity and wellness, not its genesis.

The second set of limitations—especially important among studies of older people—could be grouped under the heading of selection bias (i.e. when there is a systematic error in the selection or enrollment of study subjects that distorts the relationship between alcohol and outcomes). Of these, the 'sick quitter' bias is discussed most frequently. Those who are ill or frail often stop drinking, thus contaminating non-drinking study groups with unhealthy people who were exposed previously to alcohol [4,7]. In this paper, information about former drinking status was unavailable for women and was not utilized to separate former-drinking from non-drinking men. While most researchers mitigate the sick quitter problem by excluding former drinkers from their analyses altogether, this still biases results against non-drinkers as it selectively removes a frail population whose poor health outcomes would have otherwise accrued to the drinking group in a randomized trial with an intention-to-treat protocol.

In addition, established moderate drinkers enrolled in observational studies are undoubtedly different than non-drinkers who might be randomized to drink in a trial: they self-selected to drink alcohol; they tolerated or enjoyed its effects; they did not die or stop drinking due to health or social problems (alcohol-related or otherwise) prior to the inception of the survey or study cohort; they continued to drink moderately in order to meet enrollment criteria; and they were of sufficient physical and mental capacity to be study respondents. Finally, rates of binge drinking (i.e. drinking at levels that typically result in impairment) may be considerably lower among study participants than the general population [8,9], and many with moderate average consumption also binge drink [10]. Because binge drinking is associated with increased mortality and CHD and a loss of any protective associations with moderate average alcohol consumption [11,12], the associations observed in studies may not be realized in the general population.

The ultimate relevance of alcohol research lies in the domains of public health, clinical care and individual behavior. Many scientists and physicians have implicitly or explicitly framed low-dose alcohol consumption as a

potential therapeutic agent [13], and the public is similarly engaged. To date, however, there has not been a single randomized trial of low-dose alcohol and any mortality outcome. Such trials, which are typically required to evaluate new pharmaceutical agents, should be the standard to which low-dose alcohol is held, particularly as alcohol misuse is a leading public health problem world-wide [14]. In the recent past, numerous observational studies suggested that beta carotene intake was associated with reductions in CHD and cancer, that hormone replacement therapy and vitamin E supplementation were associated with reductions in CHD and dementia and that *Chlamydia* infection was associated with CHD. However, supplementation with hormones, beta-carotene and vitamin E and anti-microbial treatment for *Chlamydia* were found to be ineffective or harmful when subjected to randomized controlled trials [15–19].

While it is possible that low-dose alcohol may be beneficial for some or even many health outcomes, the appeal of possible health panaceas generally, and of alcohol in particular, may have resulted in a reduced scientific standard when considering low-dose alcohol as a potential therapeutic agent. Therefore, in the absence of evidence from randomized trials and weighing the real-world implications of public messages promoting alcohol consumption, we would be best served by aggressively implementing effective policy and clinical interventions to reduce excessive per-occasion alcohol consumption among those who already drink.

The Intensity of Binge Alcohol Consumption Among U.S. Adults

Timothy S. Naimi, MD, MPH, David E. Nelson, MD, MPH, Robert D. Brewer, MD, MSPH

Background: Binge drinking (consuming five or more drinks during a drinking occasion) is responsible for more than half of the 79,000 annual deaths due to excessive drinking in the U.S. Although studies show a strong dose–response relationship between the intensity of binge drinking (i.e., the number of drinks consumed per binge episode) and adverse outcomes, there are no population-based studies assessing this measure.

Purpose: This study aims to analyze population-based data from a module of questions on binge drinking among U.S. adults to assess the number of drinks consumed by binge drinkers and the associated independent risk factors for consuming more drinks.

Methods: Data were analyzed from 14,143 adult binge drinkers who responded to the Behavioral Risk Factor Surveillance System binge drinking module in 2003 and 2004. Total drinks were calculated by summing the total number of beer, wine, and liquor-containing drinks consumed during a respondents' most recent binge drinking episode.

Results: Binge drinkers consumed an average of 8.0 drinks (median 6) during their most recent binge drinking episode; 70.0% of binge drinkers consumed six or more drinks, and 38.4% consumed eight or more drinks. Men consumed more drinks during their last binge episode than women (M=8.3 vs 7.0, median=7 vs 6), and those aged 18–34 years consumed more drinks than those aged >34 years for both men and women. Independent risk factors for consuming eight or more drinks included being male; being aged <35 years; being other than white race/ethnicity; having less education; not being married; binge drinking three or more times in the past 30 days; and drinking mostly beer.

Conclusions: Most adult binge drinkers drink in excess of the five-drink threshold defining this risky behavior. The intensity of binge drinking should be monitored regularly by health agencies to improve surveillance and to better assess the impact of interventions designed to reduce binge drinking and its consequences.

(Am J Prev Med 2010;38(2):201–207) Published by Elsevier Inc. on behalf of American Journal of Preventive Medicine

Introduction

Excessive alcohol consumption is a leading preventable cause of death[1] that causes approximately 79,000 deaths annually in the U.S., and it shortens the lives of those who die by approximately 30 years.[2] Binge drinking, often defined as the consumption of five or more drinks on an occasion, typically results in acute impairment and is responsible for more than half of these deaths.[2,3] Binge drinking is also a leading risk factor for a variety of health and social outcomes, such as unintentional injuries, violence, unintended pregnancy, and cardiovascular disease.[4–8]

Studies have demonstrated that the risk of alcohol-related harms increases with the intensity of binge drinking—that is, with an increased number of drinks consumed per binge episode and with higher blood alcohol concentrations.[9–12] However, we are unaware of prior studies that have characterized the number of drinks consumed per binge episode on a population basis. Such information is crucial for characterizing the risks associated with binge drinking and for evaluating the impact of strategies to prevent this behavior. This study used population-based data from a module of questions on binge drinking among U.S. adults to assess the number of drinks consumed by binge drinkers and independent risk factors for consuming more

drinks during a person's most recent binge drinking episode.

Methods

Data for this study came from the CDC's Behavioral Risk Factor Surveillance System (BRFSS). Extensive detail about the BRFSS and its methods are available at www.cdc.gov/brfss/. In brief, the BRFSS includes state-based random-digit-dial telephone surveys of people aged ≥18 years, which are conducted monthly in all states, the District of Columbia, and some territories; survey instruments contain questions on a variety of health risk measures, including alcohol consumption. Data are weighted to be representative of states or other jurisdictions.

The current study was restricted to binge drinkers identified from the BRFSS core survey (i.e., the portion of the survey asked of all respondents in all states and territories) in 2003 and 2004. A binge drinker was defined as someone who consumed alcohol in the past 30 days who gave a nonzero response to the following question: *Considering all types of alcoholic beverages, how many times during the past 30 days did you have five or more drinks on an occasion?*

In 2003 and 2004, the CDC offered states an optional module of six additional questions for people who reported one or more occasions of binge drinking in the past 30 days; all the questions in the module pertained to a respondent's most recent binge drinking episode. These questions asked binge drinkers about the number and type of alcohol-containing beverages (beer, wine, or liquor) consumed during their most recent binge drinking episode; the physical location of their last binge episode; and whether the respondent drove during or within 2 hours of their binge drinking episode. The intensity of binge drinking—that is, the total number of drinks consumed during the most recent binge episode—was calculated by summing the number of beer, wine, and liquor-containing drinks.

Analyses were limited to 18 states that used the BRFSS Binge Drinking optional module in 2003–2004 (13 states in 2003 and 14 states in 2004). States using the module in both years were California, Maine, Michigan, Minnesota, Montana, Nevada, New Hampshire, Wisconsin, and Wyoming; states using this module in 2003 only were Nebraska, North Carolina, Pennsylvania, and South Dakota; and states using the module in 2004 only were Delaware, Idaho, New Mexico, North Dakota, and Virginia. Data were weighted for age, gender, and race to be representative of the states and years for which data were analyzed; state weights were divided by 2 for those states with data from both years. The median response rate to the BRFSS survey among these states across both years was 55.0% and included 121,172 respondents, including 16,496 people who reported one or more episodes of binge drinking in the past month. The weighted prevalence of binge drinking was 16.3%, which was approximately 1 percentage point higher than for the U.S. during 2003–2004. After excluding those with missing or incomplete information from the binge drinking module, data from 14,143 respondents were analyzed.

Data analyses were conducted using SAS, version 9.0, and SUDAAN, version 9.0. Analyses were conducted for demographic characteristics, social characteristics, and alcohol-related covariates. Demographics included age groups, gender, race/ethnicity, education level, income level, marital status, and employment status. Alcohol variables included number of binge episodes in the past 30 days, predominant beverage type consumed during the most recent binge episode, location of the binge drinking episode, and whether or not the respondent drove a motor vehicle during or within 2 hours of his or her most recent binge drinking episode.

We used logistic regression analysis to further explore the relationship between high-intensity binge drinking (i.e., consuming eight or more drinks per binge episode) and those demographic and alcohol variables that had a significant effect on the mean number of binge drinks consumed in bivariate analyses. Because of their important associations with alcohol consumption measures in other studies, more detailed information about age, race/ethnicity, and education were presented in Table 1. However, because of similarities among certain groups and sample size considerations, those categories were collapsed for regression analysis. Age categories were collapsed to those aged 18–34 years (mean number of drinks=8.7; 95% CI=8.5, 8.9); those aged 35–54 years (M=7.4 drinks, 95% CI=7.2, 7.6); and those aged ≥55 years (M=6.7 drinks; 95% CI=6.4, 7.1). Race/ethnicity categories were collapsed to white, non-Hispanic (M=7.7 drinks; 95% CI=7.6, 7.9) and other than white non-Hispanic (M=8.8 drinks; 95% CI=8.4, 9.2). Education categories were collapsed to being a high school graduate or less (M=8.7 drinks; 95% CI=8.4, 9.0) and having at least some college education (M=7.5 drinks; 95% CI=7.4, 7.7).

Results

The study population was 75.1% male, with 52.7% aged ≤34 years, 59.4% with at least some college education, and 72.8% of white non-Hispanic race/ethnicity. Overall, binge drinkers consumed an average of 8.0 (median=6) drinks during their most recent binge drinking episode (Table 1). Groups that consumed a significantly higher number of binge drinks included those who were male; aged 18–34 years; belonged to racial/ethnic groups other than white non-Hispanic (data not shown); had no college education (data not shown); earning <$50,000 per year; not married; those with five or more binge episodes in past 30 days; and those who consumed predominantly beer. Men consumed more drinks during their most recent binge drinking episode compared with women (M=8.3 vs 7.0, median=7 vs 6); however, stratification by gender did not significantly change the relative distri-

[a]Binge drinking was defined as consuming five or more drinks on at least one occasion in the past 30 days. Respondent information pertained to their most recent episode of binge drinking. Strata of respondent numbers may not add up to 14,143 because of nonresponse to selected questions (e.g., income).
[b]All results were weighted by age, gender, and race/ethnicity to be representative of people residing in the states and years for which data were analyzed.
[c]Not married included those who were never married, divorced, separated, or widowed.
[d]Not employed people included those who were unemployed, home makers, students, retired, or unable to work.
[e]Predominant beverage type referred to whether the respondent drank mostly beer, liquor, or wine or flavored beverages during their most recent binge drinking episode.
[f]Private residences included the drinker's own home or another person's home; licensed outlets included bars, clubs, or restaurants; others included all other locations.
[g]Driving after binge drinking refers to those who reported driving "during or within 2 hours" of their most recent binge drinking episode.

bution of drinks per binge episode for most characteristics. Those consuming alcohol in establishments licensed to sell alcohol (bars, clubs, or restaurants) consumed a similar amount (M=8.0 drinks, median=6.0 drinks) compared to those who drank in their own or another person's private residence (M=8.0 drinks, median=6.0 drinks).

During their most recent binge drinking episode, 70.0% of drinkers consumed six or more drinks, 38.4% consumed eight or more drinks, and 16.9% consumed 11 or more drinks (Table 2). Men and binge drinkers aged 18–34 years were more likely to consume larger numbers of drinks per binge episode than were women and people aged ≥35 years, respectively. For example, more than half (51.1%) of the male binge drinkers aged 18–34 years reported consuming eight or more drinks during their most recent binge drinking episode, as compared to 31.4% of women in this age group. Even so, a substantial proportion of male and female binge drinkers aged ≥55 years also reported consuming six or more drinks during their most recent binge episode (58.1% of men and 38.2% of women, although numbers are small).

In logistic regression analysis, independent risk factors for high-intensity binge drinking (i.e., consuming eight or more drinks per episode) included being male; being of younger age; being a member of a racial/ethnic group other than white non-Hispanic; having no college education; not being married; binge drinking on three or more occasions in the past 30 days; and drinking mostly beer (Table 3). Income level was not associated with consuming more drinks during the last binge episode.

Discussion

To our knowledge, this is the first study to examine the intensity of binge drinking, that is, the total number of drinks consumed during a discrete binge drinking episode. It was found that adult binge drinkers in the U.S. consumed an average of eight drinks per binge episode, and that 70% of binge drinkers consumed six or more drinks, including almost 40% who consumed eight or more drinks. Although drinking just five drinks on one occasion is associated with adverse outcomes in epidemiologic studies and typically results in blood alcohol concentrations of 0.08 mg/dL or higher,[3,10,13,14] the risk of adverse outcomes (e.g., unintentional injuries) increases with the number of drinks consumed or with progressively higher blood alcohol concentrations.[9,11,12] As such, these findings illuminate an important dimension of binge alcohol consumption, and emphasize the need to reduce the intensity of binge drinking among U.S. adults as well as its prevalence and frequency.

These findings are concordant with other results[15] demonstrating that men and younger people are more

Table 2. Distribution of number of drinks consumed during most recent binge drinking episode,[a] by gender and age

Characteristic	No. of drinks consumed by binge drinkers,[b] % (95% CI)			
	5 drinks	6–7 drinks	8–10 drinks	≥11 drinks
All binge drinkers	30.0 (28.5, 31.4)	31.7 (30.2, 33.2)	21.5 (20.1, 22.9)	16.9 (15.5, 18.2)
Men by age (years)

[c]CIs were not reported because there were less than 50 respondents.

likely to binge drink compared with women and older people. However, it was interesting that non-Hispanic whites and those with higher educational attainment consumed fewer drinks per binge drinking episode compared with people with lower educational levels who were of a race/ethnicity other than white, in view of the fact other studies[16] have shown that the prevalence of binge drinking does not differ dramatically based on educational levels and that the prevalence of binge drinking among white non-Hispanic people is comparable to that of white Hispanics and higher than that for blacks. These inconsistencies emphasize the importance of assessing multiple measures of binge drinking, including intensity, to obtain a more complete picture of binge drinking behavior.

In terms of other findings with relevance to health policy, it was surprising that people binge drinking in establishments licensed to sell alcohol (bars, clubs, and restaurants) consumed as many drinks as those drinking in private residences. Because state laws generally prohibit the sale of alcohol to intoxicated people, our findings underscore the need for better enforcement efforts.[17] However, these results are not surprising in light of studies demonstrating that most pseudo-intoxicated patrons are served alcohol, including approximately half of the instances when the server appears to notice that the patron is intoxicated.[18–20] In addition, the current study found that those drinking mostly beer consumed more drinks compared with those drinking predominantly wine or distilled spirits. This is consistent with the fact that beer accounts for most binge drinks consumed by adults, and that beer is generally taxed, distributed, and marketed more permissively than other beverage types.[21]

This study is subject to several limitations that make it likely that our estimates of the number of drinks consumed per binge episode were conservative. Survey data were from self-report, and survey respondents may under-report how much they drink.[22] Excessive drinking may also be associated with nonresponse,[23,24] and therefore the response rate may have resulted in a conservative estimate of the number of drinks consumed per binge episode. Furthermore, respondents who were unable to recall how many drinks they consumed were excluded from our analyses, and it is possible that these individuals were more likely to have consumed more drinks compared with those who were able to recall the number of drinks they consumed.

Although this was a study that included data from multiple states, these data may not be representative of the entire country, and the prevalence of binge drinking was slightly higher in the study states compared to the U.S. general population. This study examined those who reported binge drinking at least once in the past month, and the number of drinks consumed would have likely been somewhat different if it had included those who binge drank more or less frequently (e.g., those who consumed five or more drinks in the past 2 weeks). Subsequent to this study, the definition of binge drinking has been modified to drinking five or more drinks for men and four or more drinks for women.[3] Were those thresholds used to define binge drinking in this study, women consuming only four drinks would have been included in the study population and their mean number of drinks consumed would have been lower. Finally, although standard drinks sizes contain similar

[b]OR was adjusted for all covariates listed in the table.
[c]Not married included those who were never married, divorced, separated, or widowed.
[d]Predominant beverage type referred to whether the respondent drank mostly beer, liquor, or wine or flavored beverages during their most recent binge drinking episode.

amounts of ethanol, the actual ethanol consumed per drink may vary by beverage type, drinking location, gender, or other factors.[25]

In light of the high intensity of binge drinking found in the current study, and because subgroups with higher numbers of drinks consumed per binge episode are not necessarily those with the highest prevalence of binge drinking, it is recommended that there be routine monitoring of the number of drinks per binge drinking episode in addition to the prevalence and frequency of this behavior. In addition, public health research is recommended to specifically evaluate the impact of effective policies to reduce binge drinking (e.g., increased alcohol excise taxes) on the number of drinks consumed per binge drinking episode.

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the CDC.

BACKGROUND: Personal health records (PHRs) are designed to help people manage information about their health. Over the past decade, there has been a proliferation of PHRs, but research regarding their effects on clinical, behavioral, and financial outcomes remains limited. The potential for PHRs to facilitate patient-centered care and health system transformation underscores the importance of embracing a broader perspective on PHR research.

OBJECTIVE: Drawing from the experiences of VA staff to evaluate the My HealtheVet (MHV) PHR, this article advocates for a health services research perspective on the study of PHR systems.

METHODS: We describe an organizing framework and research agenda, and offer insights that have emerged from our ongoing efforts regarding the design of PHR-related studies, the need to address PHR data ownership and consent, and the promotion of effective PHR research collaborations.

CONCLUSION: These lessons are applicable to other PHR systems and the conduct of PHR research across different organizational contexts.

KEY WORDS: personal health records; health information; health services research; PHR.

INTRODUCTION

Recent advances in information and communication technologies have enabled the development of comprehensive tools intended to support greater consumer participation in their healthcare.[1–3] The personal health record (PHR) is one such tool that has potential to dramatically shape the contemporary healtheare landscape. Whereas electronic health records (EHRs) and systems (EHR-S) are collections of health information that are managed by healthcare providers, PHRs are designed to address the health information needs of consumers. Although there is variability in functionality across

systems,[4–11] most PHRs share a basic goal: "to give patients better access to their own healthcare data and enable them to be stewards of their own information."[12]

According to the American Health Information Management Association (AHIMA), the PHR is "an electronic, lifelong resource of health information needed by individuals to make health decisions. Individuals own and manage the information in the PHR, which comes from healthcare providers and the individual. The PHR is maintained in a secure and private environment, with the individual determining rights of access. The PHR does not replace the legal record of any provider."[13] Currently there are more than 200 PHR systems available.[14] Many early PHRs were "static repositories,"[15] but more recently there has been a shift towards web-based PHRs that are integrated with or "tethered" to an EHR-S.[11] Tethered PHRs can bring together data created and stored by the individual with that from the EHR, thus offering a range of functionality.[11,16,17]

The enthusiasm surrounding the development of PHR systems can be attributed to the anticipated value that PHRs hold for consumers, healthcare providers, financers, and other stakeholders;[5,11,12,14,18] however, such perceived benefits extend beyond what is currently known about their use and effects. The perspectives of healthcare providers suggest both excitement over the potential benefits of PHRs and concerns surrounding their impact.[4,5,12,19–22] Trends in consumer survey research reflect limited access to electronic PHRs but suggest growing interest in using them.[23–26] Despite this expressed interest, it remains difficult to anticipate the manner in which different communities of users may ultimately choose to adopt PHRs.

Initiatives undertaken to inform the course of PHR development[27,28] and to articulate important architectural and policy recommendations[29] represent a foundational response to persistent calls for more substantive PHR research;[30] yet, the lack of research demonstrating the value of PHRs to stakeholders poses a threat to their long-term viability and sustainability.[16] Research regarding the effects of PHR use on patient and provider experiences, behavior, costs, and clinical outcomes remains underdeveloped.[11,16] Studies that move beyond a technical focus to embrace a broader health services research perspective on PHR systems are needed to promote further adoption, enhance patient-centered care, and realize the anticipated potential for health system transformation. Health services researchers are in a unique position to address this gap in the evidence base, but doing so will require careful attention to the formulation of research questions and study designs, the prioritization of research areas, and an accounting of the unique factors inherent in PHR research.

In 2003, the Department of Veterans Affairs (VA) introduced My HealtheVet (MHV), a web-based PHR intended to complement traditional services, improve co-managed care, and empower patients and their families to play a more active role in veterans' health. Below we describe the MHV PHR and efforts to evaluate the impact of its use on veterans and the VA healthcare system. Drawing upon the VA experience, we describe salient PHR research questions and potential study design issues. We identify important factors inherent to PHR research that we have thus far identified, and offer lessons learned that can inform research and evaluation efforts surrounding PHR systems across different contexts.

BACKGROUND

My HealtheVet System Overview

My HealtheVet (http://www.myhealth.va.gov) is an integrated PHR that includes health information entered by Veterans, data from VA's unified EHR-S, health education information, health management tools, and links to other resources.[31–36] The system represents collaborative work between multiple offices in VA. The Veterans and Consumers Health Informatics Office (V/CHIO), a division of the Chief Health Informatics Office (CHIO), identifies strategic priorities, coordinates with policy experts, and translates MHV goals into business, functional, and technical requirements, based on veteran and consumer needs and preferences. Other offices perform the technical lifecycle tasks of requirements management, system development, testing, and run-time operations. Hereafter, we refer to this partnership as the MHV Program Office, a functional model that represents the full range of strategic and technical activities. The MHV Program Office is advised by a multidisciplinary Clinical Advisory Board (MHV CAB). From an organizational perspective, this approach yields multiple benefits, including the direct alignment of program goals and resultant PHR design and development strategies with the overarching objectives of VA and its partners.

There are three levels of MHV access, with a progressive increase in functionality (see Table 1). First, portions of MHV can be accessed by anyone with an Internet connection. Second, veterans can create an account by performing an online registration, which provides them with functions not available to the general public. Third, veterans who choose to complete a onetime in-person identity verification at a VA medical center, referred to as "in-person authentication" (IPA), can also view a growing array of additional information extracted from the VA EHR-S. As of July 2009, MHV has been visited over 28 million times, more than 810,000 people have registered (16.3% of veterans currently receiving VA healthcare services), and over 130,000 veterans have completed the IPA process.[37,38] Veteran feedback obtained through the American Customer Satisfaction Index (ACSI) Survey, an industry standard tool for measuring satisfaction and prioritizing improvements,[39] is used to guide system redesign and the addition of new features.

Developing an Evaluation Approach for MHV

The MHV Program Office is working to pursue a robust PHR evaluation program that moves beyond studies focused solely on technological or system concerns to those that reflect a broader health services perspective. Inherent in this shift is a fuller accounting of the social, clinical, and organizational contexts in which PHRs are used. Each of these dimensions is important to identifying optimal PHR features and assessing system impact. Several MHV-related projects initiated by members of the VA research community were not formally designed as part of the Program Office's evaluation effort, but together reflect commitment to an encompassing approach. For example, the MHV Program Office has partnered with the Stroke Quality Enhancement Research Initiative (QUERI) to create age-appropriate, culturally relevant materials for caregivers

Table 1. My HealtheVet Personal Health Record Features

My HealtheVet Personal Health Record feature key: V = all site visitors R = registered users A = authenticated users (IPA)	V	R	A
General information and resources: Access information about Federal and VA benefits and resources, VA-related news and events. Link to additional resources	X	X	X
Research health: Browse and search collections of evidence-based health information including Healthy Living Centers, Condition Centers, and medical databases. Access health screening tools, mental health resources, and articles	X	X	X
My HealtheVet Learning Center: Take online courses to promote mental health	X	X	X
Personal information: Store and maintain contact information including emergency contacts. Manage account profile, preferences, and options		X	X
Get care: Store and maintain information pertaining to caregivers and providers, treatment facilities and locations, and health insurance coverage		X	X
Health information card: Print selected personal and medical information on a pre-formatted wallet card for a convenient reference		X	X
Personal health history: Record important health history information and events		X	X
Family health history: Record family member's health history and events that may affect health		X	X
Military health history: Record important events from military service including assignments related to health history, potential exposures, and treatments		X	X
Personal health summary: Select information to print out as a personal health summary report to share with providers		X	X
Health eLogs: Track and graph common health measures (blood pressure, blood sugar, cholesterol, body temperature, weight, heart rate, pain, pulse oximetry, INR)		X	X
Allergies: Record allergies by date, severity, reaction, diagnosis, and add comments		X	X
Immunizations: Record the immunization, date, method used, and any reactions		X	X
Tests: Record tests by test name, date of test, location where the test was performed, provider's name, results, and add comments		X	X
Medical events: Keep track of illnesses, accidents, or other events by logging the date, treatment prescribed, and any comments regarding the event		X	X
Food and activity journals: Record food intake to monitor diet or control weight, and keep track of exercise routines. Print journal worksheets for easy tracking		X	X
Health calendar: Add events, set reminders, utilize a to-do list		X	X
Medications, over-the-counter drugs, herbals, and supplements: Record the name, starting and ending date, prescription number, and dosage		X	X
Prescription refills: Request refills for VA prescriptions online (authenticated users can view medication names when ordering refills)		X	X
VA prescription history: View a record of all VA prescriptions			X
My complete medications: View and print a complete summary of both VA and self-entered medications to support medication reconciliation			X
Wellness reminders: View customized reminders for preventative care and screens			X
Secure messaging: Exchange secure electronic messages with your healthcare team for non-urgent needs (currently available at 8 sites with further expansion planned)			X

of stroke survivors.[40] Other research studies are currently underway, including studies focused on usability testing,[41] use of MHV as a communication tool for health screening,[42] development of a MHV Healthy Living Center dedicated to spinal cord injury,[43] and the integration of evidence-based tools to assess heart failure care according to published VA guidelines.[44] As we discuss below, close working relationships between PHR system providers and researchers can be instrumental in sustaining such efforts.

We recognized the need for a broader organizing framework in order for VHA to utilize its significant research expertise to optimize the MHV system. The Performance Evaluation Workgroup of the MHV CAB, whose task it is to guide system evaluation efforts, is currently using an extension of the RE-AIM (Reach, Efficacy/Effectiveness, Adoption, Implementation, and Maintenance) framework[45] as a model for assessing the impact of MHV on the veteran population. This framework supports a comprehensive evaluation effort and has resulted in the identification of a number of high priority research areas as shown in Table 2. These range from extending the reach of the program in the veteran population to examining cohorts of users with respect to utility, outcomes, and cost. Ongoing efforts to evaluate the MHV PHR have revealed a number of insights that can inform similar work regarding other PHR systems. In the remainder of this paper, we discuss these lessons and offer examples from our work with MHV, as appropriate.

LESSONS LEARNED FROM A HEALTH SERVICES RESEARCH PERSPECTIVE ON PHRS

Posing Research Questions and Designing Studies

Our experiences underscore the point that many kinds of research questions can be posed in relation to PHRs. Organizations that provide PHRs are generally interested in knowing who is using the system and for what purpose(s), how the design affects use, and whether the content has perceived value. Health services and other researchers, however, are likely to also be interested in additional aspects, including how PHRs can be used to improve patient outcomes, eliminate health disparities, and deliver interventions.

PHR-related studies may entail designs that require engaging PHR users as study participants, or, with their consent, accessing the data that they store in their PHR (e.g., blood pressure readings) as a means of monitoring outcomes. Delineating between research for the purpose of PHR evaluation and studies that utilize the PHR in the course of an intervention is critical. Each approach requires different methodologies and types of collaboration to ensure that goals are clearly identified, and that adequate safeguards are applied to support user needs and expectations. In the case of MHV, the Program Office has thus far emphasized research on users, expecting to address the issue of delivering evidence-based interventions through the system in the future. The scenarios

Table 2. MHV PHR Research Agenda by RE-AIM Domain

RE-AIM domain	MHV program goal	Research priorities
Reach: the number, proportion, and representativeness of individuals who utilize the MHV PHR	Increase enrollment of the veteran population served by the MHV program	• Assess level of awareness in the veteran population and identify effective improvement strategies • Characterize users in comparison with the veteran and VA patient populations • Identify target populations who can most benefit from use
Effectiveness: the impact of MHV PHR utilization on users, outcomes, performance, and organizational systems	Utilize MHV to enhance access to services, improve behavioral and health outcomes, improve quality, increase satisfaction, and enhance system efficiency	• Validate and extend initial analytic findings from user surveys • Examine cohorts of users to evaluate impact on utilization management (access), behavioral and clinical outcomes (quality), cost (value), and satisfaction • Identify how MHV can enhance access to services for rural or special populations • Evaluate impact on workflow, workload, VA performance measures, and organizational processes
Adoption: use of the MHV PHR by veterans and their caregivers, healthcare providers, and healthcare teams	Increase adoption of MHV by veterans, providers, and healthcare teams	• Elicit perceptions of veteran and provider nonadopters • Identify barriers to adoption and develop strategies to address • Examine the current authentication process and identify ways to improve
	Increase levels of engagement and activation with MHV among patients and providers	• Demonstrate clinical utility of MHV components • Compare clinical adoption across settings • Identify communication and process strategies for integration of MHV within clinical practice
Implementation: the efforts and costs involved in implementing the MHV Program	Implement the MHV program nationwide in the most equitable, effective, and efficient manner; enhance program value	• Examine how to prevent further health disparities by exploring issues of access, health literacy, and computer literacy • Evaluate cost/benefit impact of MHV use • Identify optimal implementation strategies
Maintenance: the long-term effects of MHV PHR use and program sustainability	Utilize MHV to enhance and sustain desirable long-term outcomes	• Track long-term impacts on targeted outcomes (access, quality, value, satisfaction) • Identify effective engagement strategies to support sustained MHV use • Explore program enhancements (usability) and expansion (interoperability) • Analyze MHV program sustainability

provided in Table 3 illustrate different ways that a PHR could be employed in intervention studies, either as a vehicle through which to deliver an intervention or as the intervention itself.

A related and particularly challenging issue that warrants mention is that most PHRs are "live systems" with corresponding populations of users. As such, researchers must develop innovative study designs to investigate continually evolving PHR systems and contexts of use. In the time it takes to publish study results, a PHR may have undergone significant changes in terms of content and functionality. Using a PHR to deliver an intervention may also have the effect of making the system even more dynamic and difficult to characterize.

Addressing Issues of Data Ownership and Consent

In contrast to EHR systems, which are predominantly owned and operated by the system provider, PHRs are based on consumer control and management of their own data. In the

Table 3. Potential Scenarios for Research Involving PHRs

Study type	Description
1. Accessing data stored within the PHR	A researcher would like to link information from the PHR with patient medical records. In particular, he is interested in looking at blood pressure rates over time, as entered by patients into the PHR, with patient consent, and linking this information to pharmacy and laboratory data for particular medications with the goal of relating patient outcome (blood pressure control) with medication use
2. Delivering an intervention through the PHR	A researcher is interested in improving patient self-management of diabetes through a healthy diet, regular exercise, and regular monitoring of blood sugar. She wants to provide a series of self-help exercises and educational materials through the PHR
3. Utilizing the PHR as an intervention	Through the use of secure messaging, the PHR could be used to facilitate adherence with requirements for elective surgery (e.g., details for arrival check-in, preoperative instructions such as stopping certain medications)

case of MHV, the overall system is managed by the VA, but the content of the PHR is the property of the veteran. Privacy and security are paramount, and researchers who design studies that include access to PHR data must explicitly obtain the informed consent of consumers. These consent processes must recognize the PHR user as the data owner, protect the integrity of PHR data, and still offer PHR users the opportunity to participate in research intended to enhance the system, improve user experience, or strengthen positive outcomes based on effective use.

Engagement of PHR users in research must also ensure that participation is voluntary and that participants have a clear understanding of the level of data-sharing expected. Organizational policy development must include a review of formal agreements between PHR providers and PHR users regarding the maintenance and protection of data, including the PHR terms and conditions, privacy policy, and system of records. From a technical perspective, the development of standardized processes to support access to data is crucial for future research efforts. For example, analysis of application activity logs could reveal patterns of activity independent of user identity, facilitating key insights about PHR usage. For studies that involve PHR users as consenting participants, user delegation of access to specific PHR data may allow researchers to draw upon patient self-reported data and link it to patient data from medical records and other sources to evaluate outcomes. At VA, this delegation functionality has been successfully piloted with an earlier prototype; however, it is not yet available in the national MHV PHR.

Promoting Effective Working Relationships

Efforts to foster PHR research reveal the importance of multidisciplinary collaboration. Processes and policies must attend to the varying objectives, needs, and requirements of PHR providers and researchers to enable effective collaboration. To the extent possible, approaches to collaboration should leverage existing institutional research policies, structures, and processes rather than recreating or duplicating them, accounting as necessary for nuances specific to PHRs. Development of a research agenda to identify high priority areas of study, similar to that shown in Table 2 for MHV, is one way to address this issue. Additionally, an organizational infrastructure is necessary to develop sustainable research collaborations. Such infrastructure can help guide and support research in ways that align with the vision of system designers and stakeholders while preserving the trust of PHR users.

Discussions with VA researchers have also identified practical tools which can further support research, such as the incorporation of a survey engine within MHV to efficiently host survey research. The development and dissemination of a standardized data dictionary has also been proposed. Such a tool would describe relevant data elements important to PHR research, along with any data-specific constraints. A study currently funded by VA is identifying the data elements and technical infrastructure needed to support MHV research.[46] For each type of PHR data, formal processes must be established in order to enable appropriate access for Institutional Review Board (IRB)-approved studies.

CONCLUSION

Significant further work is needed to understand the use of PHRs as integrated tools that complement traditional care, and to identify the impact of their use on patients, providers, organizations, and healthcare systems. In particular, identifying the effect of PHRs on clinical, behavioral, and financial outcomes will be critical in fostering the cultural transformation and uptake needed to make PHRs an integral part of the fabric of healthcare. These interests are well aligned with health services research. Organizations that offer a PHR or intend to develop one will benefit from elucidating specific PHR research priorities, identifying and addressing research barriers, and finding pragmatic ways to support research efforts.

The lessons that we have thus far learned from our efforts to study MHV are not unique to the system itself or to the VA as an institution. PHRs are new tools intended to support patient-centered healthcare. As such, priority must be given to issues inherent to PHRs, including data ownership, access, privacy, and confidentiality. Organizational policy development must be guided by emerging national privacy policy frameworks, provisions, and laws.[47,48] Technical solutions to foster effective research programs must be driven by organizational policy that ensures adequate protection for users while enabling rigorous investigations. Collaborative approaches that connect PHR system providers with the skills and expertise embodied in research communities are essential to support studies that will optimize PHRs and their use. At the center of this work is the PHR user. As researchers and PHR providers, we must offer clear information about data management policies, privacy and security policies, analysis procedures, and opportunities to participate in research, all while maintaining the integrity of consumer trust. Only in this way can we enable a deeper understanding of the PHR as a contemporary tool and a potentially transformative force in health care.

US state alcohol sales compared to survey data, 1993–2006

David E. Nelson[1,2], Timothy S. Naimi[2], Robert D. Brewer[2] & James Roeber[3]

Cancer Prevention Fellowship Program, Center for Cancer Training, National Cancer Institute, Bethesda, MD, USA,[1] Alcohol Team, Emerging Investigations and Analytic Methods Branch, Division of Adult and Community Health, National Center for Chronic Disease Prevention and Health Promotion, Centers for Disease Control and Prevention (CDC), Atlanta, GA, USA[2] and New Mexico Department of Health, Albuquerque, NM, USA[3]

ABSTRACT

Aims Assess long-term trends of the correlation between alcohol sales data and survey data. **Design** Analyses of state alcohol consumption data from the US Alcohol Epidemiologic Data System based on sales, tax receipts or alcohol shipments. Cross-sectional, state annual estimates of alcohol-related measures for adults from the US Behavioral Risk Factor Surveillance System using telephone surveys. **Setting** United States. **Participants** State alcohol tax authorities, alcohol vendors, alcohol industry (sales data) and randomly selected adults aged ≥ 18 years 1993–2006 (survey data). **Measurements** State-level per capita annual alcohol consumption estimates from sales data. Self-reported alcohol consumption, current drinking, heavy drinking, binge drinking and alcohol-impaired driving from surveys. Correlation coefficients were calculated using linear regression models. **Findings** State survey estimates of consumption accounted for a median of 22% to 32% of state sales data across years. Nevertheless, state consumption estimates from both sources were strongly correlated with annual r-values ranging from 0.55–0.71. State sales data had moderate-to-strong correlations with survey estimates of current drinking, heavy drinking and binge drinking (range of r-values across years: 0.57–0.65; 0.33–0.70 and 0.45–0.61, respectively), but a weaker correlation with alcohol-impaired driving (range of r-values: 0.24–0.56). There were no trends in the magnitude of correlation coefficients. **Conclusions** Although state surveys substantially underestimated alcohol consumption, the consistency of the strength of the association between sales consumption and survey data for most alcohol measures suggest both data sources continue to provide valuable information. These findings support and extend the distribution of consumption model and single distribution theory, suggesting that both sales and survey data are useful for monitoring population changes in alcohol use.

Keywords Alcohol abuse, alcohol drinking, cross-sectional studies, drinking behaviors, health surveys, statistics.

INTRODUCTION

Given the enormous health, economic and other costs associated with excessive alcohol use [1,2], monitoring alcohol consumption and other alcohol use behaviors on a population-wide basis is important for surveillance, epidemiological, programmatic and other purposes [1,3–6]. The two most common methods for obtaining population-level measures of alcohol use are per capita consumption estimates based generally on alcohol sales, taxation or product shipment data [1,3] (referred to hereafter as sales data), and self-reported measures based on surveys of individuals [3,4].

Per capita alcohol consumption based on alcohol sales is a widely used measure in alcohol research [1,3], and it is included as a key surveillance measure in the Healthy People 2010 objectives for the United States [6]. A substantial body of evidence from many countries has shown an association between population-based per capita alcohol consumption and adverse health effects of

Disclaimer: The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention or the National Institutes of Health.

alcohol use, including cirrhosis and other alcohol-specific conditions, motor vehicle crashes and suicide [7–17].

Alcohol sales data have several advantages: they are obtained readily and inexpensively; they are measured relatively uniformly across states; they are not affected by recall bias as survey data may be; and they can broadly measure the impact of policies or other interventions across an entire population [3,4,7,16,18,19]. The major disadvantage of sales data is that consumption is averaged across an entire population (including non-drinkers), making it impossible to characterize alcohol consumption patterns within a population or to compare alcohol consumption by factors such as age, sex, race/ethnicity or substate geographic area [4,18,19].

In contrast, survey data based on self-reports can identify drinking patterns readily among population groups and are useful for measuring the potential differential impacts of interventions, such as policy changes or educational programs, on these subgroups [3,4,19]. The major disadvantage is that survey data substantially underestimate alcohol consumption and other alcohol use measures, such as binge drinking and alcohol-impaired driving [3,4,19–21]; the extent of this underestimation may be increasing because of declining survey response rates and non-coverage bias, e.g. people in cellphone-only households are not included in landline-only telephone surveys [22]. For example, people in cellphone-only households are much more likely to be younger adults and to binge drink [22,23].

Somewhat surprisingly, relatively few US studies have directly examined the association between population-based per capita alcohol consumption based on state sales data with self-reported alcohol measures from state surveys [24–26], and none have done so using data collected within the past 10 years. Smith and colleagues [26] reported that survey data underestimated per capita consumption substantially based on sales data among 21 states participating in the 1985 Behavioral Risk Factor Surveillance System (BRFSS), with the median state alcohol consumption estimate averaging only 25% of per capita consumption based on sales data. Nevertheless, state sales data were correlated strongly with survey estimates of annual consumption, heavy drinking, binge drinking and alcohol-impaired driving.

Fitzgerald & Mulford [27] found that from 1985 to 1989, per capita alcohol consumption based on sales data and drinking frequency based on survey data both declined in most locations in Iowa. Rogers & Greenfield [28] pooled data from five US telephone surveys from 1989–94 conducted in 48 US states and the District of Columbia and performed state-specific analyses comparing sales with survey data. They found that, overall, survey data accounted for 35% of sales data (coverage rate), with state estimates ranging from 8% in Wyoming to 60% in North Dakota. They also reported that the correlation coefficient of state coverage rates with state current alcohol use prevalence was 0.33.

To our knowledge, Smart and colleagues [18] have conducted the only study examining the association between sales and survey data over time. Using data from Ontario, Canada from 1977 to 1997, they correlated sales data with survey measures for any drinking in the past year, average number of drinks per week; daily drinking; consuming more than five drinks at a sitting on a weekly basis; and experiencing two or more harmful effects from alcohol use. In contrast to Smith *et al.* [26], daily drinking was the only survey measure that correlated with alcohol sales data ($r = 0.94$) [18].

To assess the validity and utility of both types of population-based measures and to relate alcohol exposure to health outcomes at the population level, it is important to determine if any associations exist currently between state per capita alcohol consumption based on sales and alcohol survey measures, and whether such associations changed over time. To do so, we greatly extended and updated the original Smith *et al.* [26] study and correlated sales-based alcohol consumption data with self-reported survey measures of alcohol consumption, current alcohol use, heavy alcohol use, binge drinking and alcohol-impaired driving from adults aged ≥ 18 years for nearly all 50 US states using data from 1993 through 2006.

METHODS

Per capita alcohol consumption

We obtained state-specific estimates of apparent per capita alcohol consumption from the Alcohol Epidemiologic Data System (AEDS), which is maintained under the auspices of the US National Institute for Alcohol Abuse and Alcoholism (NIAAA). Detailed information about the AEDS is provided elsewhere [29]. Briefly, the AEDS collects and summarizes state and national data on apparent per capita alcohol consumption each year, with public data sets available from 1977 to 2006. Consumption data are based on state sales, state tax receipts or alcohol shipments from alcohol industry sources for beer, wine and spirits. In 2006, for example, the AEDS used sales and/or tax receipts reports from 30 states for beer, 29 states for wine and 26 states for spirits; all other state estimates were based on shipment data.

AEDS uses an estimate of average ethanol content for each type of beverage to convert sales data for the three types of alcohol-containing beverages into a single estimate of total gallons of pure alcohol consumed. To replicate the analyses used by Smith *et al.* [26], denominators

used to estimate per capita consumption from alcohol sales were based on US Census data for people aged ≥ 14 years. Data were not included for the District of Columbia because it is not a state. Analyses of per capita consumption data from the AEDS were limited to the same years for which BRFSS survey data were available.

Survey estimates

Survey data for adult alcohol measures were obtained from publicly available Behavioral Risk Factor Surveillance System data sets for 1993, 1995, 1997, 1999 and 2001–06 from the Centers for Disease Control and Prevention (CDC); details about the BRFSS are available elsewhere [30]. Briefly, the BRFSS obtains state-based estimates on a variety of health risk measures through random digit dial telephone surveys of non-institutionalized people aged ≥ 18 years each year. Overall, the median state sample sizes for the years studied ranged from 2045 to 6080. The state median response rate was 72% in 1993, 69% in 1995, 62% in 1997, 55% in 1999, 51% in 2001, 58% in 2002, 53% in 2003, 53% in 2004, 51% in 2005 and 51% in 2006 [30,31].

We chose 1993 as the starting year for this study for two reasons. First, from 1993 onwards, all 50 states participated in the BRFSS except for Wyoming in 1993 and Hawaii in 2004. Secondly, the wording of BRFSS alcohol-related questions and the definitions of alcohol measures has remained relatively consistent since 1993. The BRFSS contains alcohol questions that covered current use, alcohol consumption (frequency and quantity of alcohol use), binge drinking and alcohol-impaired driving [30]. Only people who reported current alcohol use were asked subsequent alcohol questions. All the alcohol-related questions were asked during each study year with the exception of alcohol-impaired driving, which was included in 1993, 1995, 1997, 1999, 2002, 2004 and 2006.

Current drinking was generally defined as having had at least one alcohol-containing beverage (e.g. beer, wine, wine cooler, liquor) within the past 30 days or past month. Alcohol consumption was based on the average number of days that alcohol was consumed in the past week or month (frequency) and the average number of drinks consumed on those days (quantity). Heavy drinking was defined as consuming an average of two or more drinks per day for men or one or more drink per day for women.

To 2005, binge drinking was defined as consuming more than five drinks on an occasion on one or more of the past 30 days or past month. In 2006, a gender-specific definition of binge drinking was adopted by the BRFSS, based on recommendations from NIAAA [32], and a binge drinking episode was defined as consuming more than four alcohol-containing beverages on an occasion for women (the more than five drinks cut-point remained unchanged for men). Alcohol-impaired driving was defined as having driven more than one time in the past 30 days or past month after having 'perhaps too much to drink'. There were few minor wording changes to questions over time, with the most common change being the use of past 30 days rather than past month as a referent period beginning in 2001.

Analyses

BRFSS state prevalence data were based on the entire population surveyed (i.e. alcohol and non-alcohol users) and were weighted to be representative of each state's adult non-institutionalized population based on the age, sex and race/ethnicity of each state's population using information available from the US Census Bureau. Alcohol consumption and heavy drinking data were not available from California for 1993, 1995 and 1997, because these alcohol-related questions used in that state were different from those used in all other states. For all other years, however, all states used identical alcohol-related questions.

Data from the frequency and quantity questions in the BRFSS were converted to average number of drinks consumed per month, and then multiplied by 12 to estimate the average number of drinks per year. We assumed that one drink of alcohol (regardless of beverage type) contained 0.6 ounces of alcohol [33], multiplied the average annual number of drinks per year by 0.6 ounces, and then divided this number by 128 (the number of ounces in a gallon) to determine per capita annual alcohol consumption in gallons. BRFSS alcohol consumption estimates were divided by AEDS sales data for each state and year to determine the proportion (percentage) of consumption estimated by surveys. We calculated state median, minimum and maximum proportions for each year; similar state data were also obtained on the prevalence of current drinking, binge drinking, heavy drinking and alcohol-impaired driving.

Linear regression models were created to assess the strength of association annually between sales and survey data on (i) average annual per capita alcohol consumption; (ii) current alcohol use prevalence; (iii) binge drinking prevalence; (iv) heavy alcohol use prevalence; and (v) alcohol-impaired driving prevalence. For each model, a β estimate, an *r*-value (correlation coefficient) and an R^2 value were determined, with sales data as the dependent variable and the BRFSS estimate as the independent variable. Correlations of 0.10–0.29 were considered weak, 0.30–0.49 moderate and ≥0.50 strong [34]. Finally, to gain an idea of within-state variability of

alcohol consumption estimates from sales and survey data, we calculated quintile rankings in 2006 for alcohol consumption based on both sources.

RESULTS

From 1993 to 2006, the relationship between estimates of per capita alcohol consumption from sales and survey data across states was generally consistent (Table 1), with median state estimates of alcohol consumption from surveys accounting for 22.3–31.6% of estimates based on sales data. However, there was a strong correlation between the two sources of state estimates over time, with correlation coefficients (*r*-values) ranging from 0.55 to 0.71, and β values ranging from 0.16 to 0.22.

The median state prevalence of current, binge and heavy drinking varied little over the study period (range: 52.1–59.3%; 14.1–16.5%; and 3.4–5.8%, respectively; data not shown in tables). We found consistently strong and similar magnitudes of β values and correlation coefficients between state sales-based consumption and survey estimates of current drinking, binge drinking and heavy drinking prevalence (Table 2). Correlation coefficients ranged from 0.57 to 0.65 for current drinking and from 0.45 to 0.61 for binge drinking, with slight yearly variations. There was somewhat greater variability in the correlation between sales data with heavy drinking prevalence (range: 0.33–0.70). The median state prevalence of alcohol-impaired driving also remained relatively unchanged over time (range: 1.9–2.5%; data not shown in tables). Although sales data were correlated with alcohol-impaired driving in all years (Table 3), coefficients were generally lower and had more yearly variation (range: 0.24–0.56).

State estimates and quintile rankings from sales and survey data on alcohol consumption for 2006 are shown

Table 3 Relationship between state alcohol sales data and survey data for alcohol-impaired driving, 1993–2006 based on linear regression models.

Year	*β Coefficient (95% CI)*	*P-value*	*r*	R^2

CI: confidence interval.

in Table 4. Consumption estimates from surveys as a percentage of sales data ranged from 17.3% in Kentucky to 34.8% in Ohio. States where alcohol consumption estimates from surveys averaged less than 22% from that based on sales were Nevada, Louisiana, Mississippi, New Hampshire and Kentucky. For most states, quintile rankings of alcohol consumption from sales and survey data were similar, but there were a few outliers. For example, Texas was in the 4th quintile based on sales but in the 1st quintile based on survey data; Iowa and Ohio were also in the 4th quintile based on sales but in the 2nd quintile from survey data. By contrast, states such as Louisiana, Idaho and South Dakota were in the 2nd quintile based on sales but in the 4th quintile based on survey data.

DISCUSSION

To our knowledge, this is the first study to examine the association between per capita alcohol consumption estimates from sales data with population-based survey estimates from all 50 states over time. We found that self-reported alcohol consumption from estimates from state surveys accounted for only 22–32% of per capita consumption based on alcohol sales, which was similar to the estimate of 25% found by Smith *et al*. using BRFSS data from 21 states in 1985 [26]. These findings confirm prior research that self-reports substantially underestimate alcohol consumption. However, our estimates were lower than 40–60% as reported by Rehm in a 1998 literature review [19], and 52% as reported by Kerr & Greenfield [35] based on a national comparison of sales data with the 2000 US National Alcohol Survey. They are also lower than the estimate of 35% reported by Rogers & Greenfield based on pooled data from 1989–94 [28]. The use of alcohol-focused surveys, and the inclusion of graduated frequency and other types of questions related to alcohol use, may account for the higher consumption estimates found in these other studies [36].

What was most notable about our results was the striking consistency of the correlations and regression

Table 4 State-specific sales and survey estimates of alcohol consumption, 2006.[a]

State	*Per capita sales (gallons)*	*Survey per capita consumption (gallons)*	*Survey-based consumption as a percentage of sales-based consumption (%)*

[a]Numbers in parentheses represent the quintile (from highest to lowest) of each state for alcohol consumption.

coefficients over time between estimates of state per capita consumption from sales data with survey data for current, binge and heavy drinking. Our study's findings were similar to those found in the Smith study for these measures (correlation coefficients of 0.81, 0.74 and 0.59, respectively) [26], although the magnitudes were slightly lower. State alcohol consumption sales data were also correlated with survey estimates of alcohol-impaired driving over time, although the relationship was less strong and consistent; by comparison, Smith *et al.* [26] found a correlation coefficient of 0.51. The consistency of our findings over time suggests that the declining survey response rate and increasing percentage of cellphone households had little effect on the observed correlations, at least to 2006 [37].

Our findings contrast with those of Smart and colleagues based on 1977–97 data from Ontario, who found little correlation between alcohol consumption based on sales data with most survey-based alcohol measures [18]. Reasons for these differences are unclear, but may be the result of different years of study; inclusion of different alcohol survey measures; differences in alcohol consumption patterns; or Smart *et al.*'s analyses of a more limited number of data points from a single province.

The quintile rankings of states for per capita alcohol consumption based on sales were generally similar to those based on survey data, although there were larger differences for a handful of selected states. Reasons for the within-state differences in sales versus survey data for alcohol consumption cannot be gleaned from these data. We speculate that they may stem from cross-border sales (i.e. where large differences in tax policies exist among neighboring states, such as New Hampshire), from non-resident purchases of alcohol-containing beverages in states with high levels of tourism or gaming (e.g. Louisiana, Mississippi, Nevada) or from relatively higher or lower consumption of non-commercially produced alcohol in some states.

The strong relationship we found between per capita consumption estimates based on sales data with specific patterns of alcohol use based on survey data (e.g. binge drinking), as well as the relationship between alcohol sales data with various alcohol-related outcomes observed in prior research [7–17], provide some support for the distribution of consumption model, the single distribution theory and similar frameworks [7,18,38–40]. These frameworks, despite their limitations, posit that alcohol consumption in populations occurs in a relatively fixed distribution such that per capita consumption based on sales data provide a useful proxy for excessive alcohol use and its related harms [18]. For example, in the United States the top 5% of alcohol users account for about 40%, and the top 20% of users for about 90%, of all sales of alcohol-containing beverages [41]. Empirical evidence for these theoretical frameworks is supported further because half the alcohol consumed in the United States is consumed during days where drinkers consume five or more drinks [42].

This study has limitations. For sales data, alcohol sold may not represent actual consumption because people may store beverages and alcohol wastage is not taken into account [3]. Assumptions were made about the average alcohol content for each type of beverage [29], but the volume and percentage of alcohol varies by type of beverage and has changed over time [36]. Alcohol brought into states from other places or made by individuals themselves (e.g. moonshine) is not included. Consumption by tourists or by people on military bases may affect estimates. There were differences in the age groups for denominators used in the two data sources, with sales data based on the population aged $\geq$ 14 years and BRFSS data based on people aged $\geq$ 18 years.

There were additional limitations associated with survey data [4,19], and the BRFSS in particular [30,43]. Under-reporting because of social desirability [44] is a well-known phenomenon. Usual quantity and frequency of alcohol use within the past week or 30 days (month) was projected over a 1-year period. Younger people, particularly men, are individuals who are at greater risk for heavier alcohol use but they are also less likely to have landline telephones or respond to surveys [23]. People on military bases are not part of the BRFSS sample. Estimates of alcohol consumption are based on average alcohol content in beverages. Similar to other telephone surveys [22], there have been declines in response rates to the BRFSS, although the impact of this decline on alcohol measures is not clear. There were slight variations in BRFSS survey questions over time, but this appears to have had little impact. Survey-based consumption estimates would probably have been higher if beverage-specific, graduated frequency or context-specific questions were used [4,19–21,45–47].

We did not use indexing to adjust average alcohol consumption and account for the number of drinks consumed during binge episodes [48,49]. In a study using 2003 BRFSS data on the quantity and frequency of alcohol consumption among US adults, Stahre and colleagues [48] found that indexing average daily alcohol consumption to account for binge drinking episodes increased per capita daily alcohol consumption by 14% and heavy drinking prevalence by 42%. Indexing BRFSS data for binge drinking using the Stahre *et al.* approach from 2003 to 2006 would have increased the median estimates of per capita alcohol consumption to 31–36% of sales data.

Our findings have important implications for public health surveillance on excessive alcohol consumption and related harms, and for the evaluation of population-

based programs to prevent excessive drinking. First, they affirm that both per capita sales and survey data are useful for assessing trends in alcohol consumption and that each provides a somewhat different perspective on alcohol consumption at both the national and state levels. Secondly, despite clear differences in sales- and survey-based estimates of per capita alcohol consumption, these two measures correlate quite well at the state level and can provide a useful basis for planning and evaluating prevention programs in states.

Finally, our findings show that alcohol consumption is even more substantially under-reported than reported elsewhere, thus current BRFSS estimates of key patterns of alcohol consumption such as binge drinking are probably only capturing a third or less of the actual amount of alcohol consumed by US adults. This emphasizes the need to continue monitoring both per capita sales and survey-based measures of alcohol consumption [1,50].

Declarations of interest

None.

Background. Genome-wide association studies (GWAS) may yield insights into longevity.

Methods. We performed a meta-analysis of GWAS in Caucasians from four prospective cohort studies: the Age, Gene/Environment Susceptibility-Reykjavik Study, the Cardiovascular Health Study, the Framingham Heart Study, and the Rotterdam Study participating in the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium. Longevity was defined as survival to age 90 years or older (n = 1,836); the comparison group comprised cohort members who died between the ages of 55 and 80 years (n = 1,955). In a second discovery stage, additional genotyping was conducted in the Leiden Longevity Study cohort and the Danish 1905 cohort.

Results. There were 273 single-nucleotide polymorphism (SNP) associations with $p < .0001$, but none reached the prespecified significance level of 5×10^{-8}. Of the most significant SNPs, 24 were independent signals, and 16 of these SNPs were successfully genotyped in the second discovery stage, with one association for rs9664222, reaching 6.77×10^{-7} for the combined meta-analysis of CHARGE and the stage 2 cohorts. The SNP lies in a region near *MINPP1* (chromosome 10), a well-conserved gene involved in regulation of cellular proliferation. The minor allele was associated with lower odds of survival past age 90 (odds ratio = 0.82). Associations of interest in a homologue of the longevity assurance gene (*LASS3*) and *PAPPA2* were not strengthened in the second stage.

Conclusion. Survival studies of larger size or more extreme or specific phenotypes may support or refine these initial findings.

Key Words: Longevity—Genome-wide association study—Meta-analysis.

Received September 22, 2009; Accepted February 15, 2010

Decision Editor: Luigi Ferrucci, MD, PhD

INCREASES in longevity of the general population worldwide are an unprecedented phenomenon with significant health and social impact. Although environmental factors have led to an increase in life span, there is ample evidence that genetic factors are involved in extreme longevity both in humans (1–7) and in other organisms (8). The protective genetic factors that lead to longevity are likely to involve fundamental processes of aging that may be different from those associated with early mortality or premature onset of age-related diseases in younger individuals. The mechanisms of aging in humans are far from understood, but available evidence suggests that several pathways—inflammation, oxidative stress and stress responses, cellular senescence, DNA damage and repair, and the growth hormone or insulin-like growth factor and insulin (GH, IGF, INS) axis—may play key roles (9–12). Model organisms suggest that inhibiting the GH, IGF, or INS axis, which is involved in regulating cell proliferation, cell death, wound repair, and metabolism, may promote longevity by reducing oxidative stress and slowing the rate of cell replication and the accumulation of somatic-cell DNA mutations (13). There is also evidence for other important pathways such as the heat-shock proteins and heat-shock factors that are highly conserved across species and play a role in prolongevity transcription pathways. Clinical and epidemiological investigations, including candidate gene studies, have suggested that inflammation pathways may affect life span and risk of age-related conditions such as cardiovascular disease (CVD) and its risk factors (14–19). A combination of multiple genetic variants may be required for an individual to achieve exceptional longevity, which may account in part for its rarity.

Two previous studies have used whole-genome screening to identify genetic variants associated with longevity (20,21). In a linkage analysis, the earliest report (20) identified a locus on chromosome 4 that has not been replicated. A recent report from the Framingham Heart Study (FHS) (22) identified modest associations between longevity (or age at death) and single-nucleotide polymorphisms (SNPs) in or near important candidate genes, including *FOXO1A*, *GAPDH*, *KL*, *LEPR*, *PON1*, *PSEN1*, *SOD2*, and *WRN*, but none of the associations achieved conventional levels of statistical significance; the sample size was modest, and the genotyping platform did not cover the genome well by current standards. The advent of genome-wide association studies (GWAS) has successfully led to the discovery of novel genetic variants that have strong evidence for replication and that are outside of traditional candidate gene regions for several common diseases (23–29). The detection of novel genetic variants associated with longevity holds the promise to provide important insights to biologic pathways in the aging process and thus the potential to develop innovative strategies to promote a long and healthy life.

We conducted a meta-analysis of GWAS findings for longevity within an international consortium of four longitudinal community-based cohort studies that followed adults over many years. Longevity was defined as survival to age 90 years or older, and a comparison group was drawn from each cohort. Furthermore, we identified two independent cohorts of long-lived individuals, the Leiden Longevity Study cohort and the Danish 1905 cohort, to evaluate initial findings for the strongest allelic associations for longevity in a second discovery stage.

Methods

Cohorts for Heart and Aging Research in Genomic Epidemiology Consortium

The Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium was convened to promote the discovery of new genomic loci involved in multiple complex traits in population-based follow-up studies using genome-wide association analysis (30). This meta-analysis used data from the CHARGE Consortium, which includes the Age, Gene/Environment Susceptibility-Reykjavik Study (AGES-Reykjavik) (31), the Cardiovascular Health Study (CHS) (32), FHS (33–36), and the Rotterdam Study (RS) (37).

The AGES-Reykjavik was funded by the National Institute on Aging (NIA) and was designed to examine genetic susceptibility and environmental interactions as risk factors for disease and disability in old age. Detailed phenotyping of the cardiovascular, neurocognitive, musculoskeletal, and body composition and metabolism was conducted in 5,764 men and women enrolled in 2002–2006 who were sampled from the 11,549 survivors of the AGES-Reykjavik of 30,000 men and women sampled from the 1907–1935 birth cohort (31). The CHS is a National Heart Lung and Blood Institute (NHLBI) contract-funded cohort study designed to evaluate risk factors for coronary heart disease (CHD) and stroke in older adults (32). Participants (n = 5,201) were recruited in 1989–1990, with an additional 687 minorities recruited in 1992–1993. The FHS is an NHLBI contract-funded cohort study initiated in 1948 to study determinants of CVD and other major illnesses. The original cohort comprised 5,209 men and women aged 28–62 years at enrollment who have undergone routine biennial examinations (33,34). In 1971, 5,124 offspring of the original cohort participants and offspring spouses, aged 5–70 years, were enrolled into the Framingham Offspring Study. Offspring participants have been examined approximately every 4–8 years (35,36). In the 1990s, DNA was obtained for genetic studies from surviving original cohort and offspring participants. The RS was planned and designed in the early 1990s as a longitudinal study investigating the incidence and progression of diseases in the elderly participants. From 1991 to 1995, all inhabitants of Ommoord, a district of Rotterdam in the Netherlands, who were aged 55 years or older, were invited to participate in this study (38). Of 10,275 eligible individuals, 7,983 agreed to participate (78%). The participants in the CHARGE studies are Caucasian by self-report. In each CHARGE study, population structure was assessed using principal components analysis, and outliers were removed. Any remaining within-study structure was adjusted for using appropriate methods (39). The details of each participating cohort study's genotyping platform, imputation algorithm, and quality control procedures used by each study are summarized in Supplementary Table 1. Each study was approved by the respective Institutional Review Board, and all participants provided consent.

Longevity and Comparison Group Definitions

In the present study, achievement of longevity was defined as reaching age 90 years or older, regardless of whether the participants were still living or had since died. Genotyped participants from these studies who died between the ages of 55 and 80 years were used as the comparison group. The comparison group was limited to deceased participants to ensure that no one in the comparison group could subsequently achieve longevity. The minimum age at death was set to match the minimum age at enrollment in the RS to promote age comparability of the comparison group across the four cohorts. The maximal age at death in the comparison group was set arbitrarily at age 80 years to include the majority of deaths, to maximize the overlap between birth cohorts, and to exclude those persons who survived far beyond average life expectancy for their respective birth cohort, that is persons who nearly reached longevity. Because of the timing of recruitment, DNA collection, and death, there was only partial overlap of the birth cohorts included in the comparison groups and the group of persons achieving longevity. Only Caucasian participants were included. Across the four studies, there were 1,836 persons who achieved longevity (144 from AGES-Reykjavik, 557 from CHS, 362 from FHS, and 773 from the RS), and the comparison group had 1,955 participants (122, 544, 355, and 934 participants from the AGES-Reykjavik, CHS, FHS, and RS, respectively). To facilitate comparison of results across studies, we imputed to 2.5 million SNPs using the HapMap Centre d'Etude du Polymorphisme Humain European Ancestry–genotyped samples as a reference. The effective sample size for all but one of the top SNPs was more than 80% of the full sample size of 3,791, indicating that the SNPs that were not directly genotyped were imputed well in most studies.

Second Discovery Stage Genotyping

Among the top 24 independent regions with the strongest associations for longevity in the four-study meta-analysis ($p < 10^{-4}$), we selected the 22 SNPs that had been tested in all four CHARGE cohorts in two additional Caucasian cohorts: the Leiden Longevity Study cohort and the Danish 1905 cohort. We excluded the two SNPs that could not be genotyped or imputed in all four CHARGE cohorts. Of the 22 SNPs selected for genotyping, 2 could not be genotyped and 4 did not pass quality control procedures; thus, 16 SNPs were analyzed in the second stage.

In the "Leiden Longevity Study" (7,40), a total of 950 long-lived proband siblings (mean age 94 years, range 89–104 years), 1,750 offspring (mean age 61 years, range 39–81 years), and 758 partners of offspring (mean age 60 years, range 36–79 years) were included. The additional genotyping of selected SNPs was undertaken in all 950 long-lived probands, and these were compared with the 744 partners of their offspring and an additional 680 blood bank donors

(60% men, mean age 31 years, range 18–40 years). All long-lived individuals and the comparison groups were from the Leiden area in the Netherlands and of European ancestry.

Participants in the "Danish 1905 Cohort Survey" are from the Danish 1905 birth cohort ascertained in 1998 when they were aged 92–93 years (41). Of the 3,600 participants alive from that cohort, 2,262 participants enrolled in the study. Participants underwent a home-based interview on health and lifestyle parameters, physical and cognitive tests, and collection of biologic material. The current genetic study comprises a total of 1,644 participants from this survey, mean age 93 years (range 92–93 years), 28% men. A comparison group included 2,007 Caucasians who were twins (one twin per pair) collected from all over Denmark, with a mean age of 57 years (range 46–68 years), 45% men.

Second Discovery Stage Genotyping Methods

Genotyping of the selected SNPs was performed using an iPLEX genotyping assay developed for use with the MassARRAY platform (Sequenom, Inc., San Diego, CA) (42). The iPLEX genotyping assay is based on mass spectrometry and enables genotyping of 25–36 custom SNPs on a sample in a single reaction. For the purposes of quality control, the system first automatically calls the genotypes and then generates cluster plots for all SNPs that are inspected individually by experienced technicians who check whether the plots show clear separation of the genotype clusters. There were two SNPs that did not pass quality control and two SNPs where no heterozygotes could not be detected; thus, lack of Hardy–Weinberg equilibrium was the quality control. Negative controls were included in the genotyping procedure (8 per 384-well plate), and importantly, 4% of samples were genotyped twice to confirm reproducibility (reproducibility was ≥99.7%).

Statistical Analysis

Using logistic regression, each imputed and observed HapMap SNP was tested for association with the longevity outcome using an additive genetic model adjusting for sex. The mean dosage of one of the alleles (a value between 0 and 2) was the predictor for imputed SNPs. The CHS additionally adjusted for field study site in the regression model, and the FHS used generalized estimating equations to account for familial correlations. We used the ratio of observed to expected variance in the imputed SNP genotype counts as a quality control metric for imputed SNPs (43). This ratio, multiplied by the sample size, is an estimate of the effective sample size. In the imputation software MaCH, this ratio is called r^2 as it is an estimate of the allelic correlation between the imputed genotypes and the true genotypes for the SNP. A total of 2,287,520 SNPs that had average minor allele frequency greater than 0.01 and were genotyped or imputed in all studies with variance ratio greater than 0.1 were meta-analyzed. The study-specific inflation factors (λ_{GC}) were computed using the set of chi-square statistics used for the meta-analysis for each study. The inflation factor is computed as the median of all chi-square statistics divided by the expected median of the statistics (approximately 0.456) for a chi-square distribution with 1 *df*. We calculated a meta-analysis odds ratio (OR) for each SNP using a fixed-effects model that combined logistic regression parameters and standard errors across the studies using inverse variance weights. The meta-analysis OR represents the increase in log-odds of surviving to age 90 years or older versus dying between ages 55 and 80 years for each additional copy of the minor allele of the SNP. SNP associations were considered to be significant on a genome-wide level at $p < 5 \times 10^{-8}$. The 16 SNPs in the second discovery phase effort were analyzed in the two study samples using an additive model. The results were added to the previous meta-analysis using a fixed-effects model as described earlier. Finally, using the top 24 results, we conducted a pathway analysis with the Database for Annotation, Visualization and Integrated Discovery (http://david.abcc.ncifcrf.gov/).

Results

Table 1 provides the characteristics of the persons achieving longevity and the comparison group in each of the four CHARGE discovery cohorts at the time of DNA collection. In line with the design of the study, persons achieving longevity were 10–20 years older than participants in the comparison group at baseline and were more likely to be women. Between 45% and 83% of those achieving longevity were still alive at the time that longevity status was ascertained. Among those who had died, the distributions of causes of death differed between those achieving longevity and the comparison group. Whereas 6%–12% of those achieving longevity died of cancer, more than 30% of the comparison group had death attributed to cancer. The prevalence of diabetes and a history of ever smoking were higher in the comparison group than in persons achieving longevity. The baseline prevalence of other cardiovascular risk factor levels showed substantial overlap between the two groups.

The genomic control inflation factor lambda (λ_{GC}) for each cohort was less than 1.05 (45). After meta-analysis, overall inflation of the meta-analysis *p* values was minor ($\lambda_{GC} = 1.034$; Figure 1). None of the SNP–longevity associations achieved the prespecified level of genome-wide significance of $p < 5 \times 10^{-8}$ (Figures 1 and 2). There were 273 SNP associations with meta-analysis $p < 10^{-4}$, and of these, 7 SNP associations had $p < 10^{-5}$ (Supplementary Table 2). Under the null hypothesis that there are no associations in the genome, we would expect $0.0001 \times \sim 2.3$ million = ~230 hits. Table 2 shows the top 24 independent SNPs associated with longevity along with the number of supporting SNPs (additional SNPs with linkage disequilibrium $r^2 > .80$ and $p < 10^{-4}$). Thus, for example, there were

Notes: In the CHS, ever smoking was defined as having smoked more than 100 cigarettes or five packs during the participant's lifetime; hypertension was defined as a systolic blood pressure 140 mmHg or more or a diastolic blood pressure 90 mmHg or more or a history of hypertension and taking antihypertensive medication; diabetes was defined as fasting glucose more than 125 mg/dL or use of insulin or oral hypoglycemic medications. In Framingham Heart Study, ever smoking was defined as self-reported cigarette smoking of at least 1 cigarette/d for a year at any attended examination; total serum cholesterol was measured using an automated enzymatic procedure (44); hypertension was defined as blood pressure 140/90 mmHg or more or on antihypertensive medication; diabetes was defined as fasting blood glucose more than 125 mg/dL, a random blood glucose of more than 200 mg/dL, or use of insulin or oral hypoglycemic agents. In the Rotterdam Study, ever smoking was defined as self-reported ever smoking (cigarette, cigar, or pipe); hypertension was defined as systolic blood pressure 160 mmHg or more and/or diastolic blood pressure 100 mmHg or more and/or blood pressure–lowering medication with an indication for hypertension; total serum cholesterol was measured using an automated enzymatic procedure (40); diabetes was defined as self-reported diabetes at baseline. In the AGES-Reykjavik, ever smoking was defined as having smoked more than 100 cigarettes in one's lifetime; total serum cholesterol was measured using an automated enzymatic procedure (40); hypertension was defined as systolic blood pressure 140 mmHg or more, diastolic blood pressure 90 mmHg or more, use of antihypertensive medications, or self-report; diabetes was defined as fasting glucose more than 125 mg/dL, use of insulin or oral hypoglycemic medications, or self-report. AGES-Reykjavik = Age, Gene/Environment Susceptibility-Reykjavik Study; CHS = Cardiovascular Health Study; CVD = cardiovascular disease.

*As a proportion of all deaths for those in the survival to age 90 years or older group.

19 supporting SNPs on chromosome 15 in or near the longevity assurance homologue 3 (*LASS3*) gene, with the strongest association (OR = 0.79, $p = 1.2 \times 10^{-5}$) noted for rs8029244. The study-specific ORs for the 24 SNP associations shown in Table 2 were in the same direction and were of similar magnitude across the four cohorts (Figure 3; Supplementary Table 3).

Of the 24 strongest independent regions shown in Table 2, the 22 SNPs tested in all four CHARGE cohorts were selected for further evaluation, and 16 were successfully genotyped in the second stage cohorts. Only 1 of the 16 SNPs had a smaller *p* value after including the replication

Notes: *p* Values are for the inverse variance–weighted meta-analysis. Distances to genes are given in base pairs. Position is for NCBI Build 36. ORs are for each additional minor allele. Number of supporting SNPs: The number of SNPs within 500 kb of the top SNP that are in LD with the top SNP in the HapMap CEU release 22 ($r^2 \geq .10$) and have association $p < .05$. For imputed and direction, study-specific information is presented in the order: Age, Gene/Environment Susceptibility-Reykjavik Study, Rotterdam Study, FHS, CHS, Leiden, and Denmark. Direction: + = minor allele increases odds of survival more than 90; − = minor allele decreases odds of survival; ? = not tested. CEU = Centre d'Etude du Polymorphisme Humain European Ancestry; CHARGE = Cohorts for Heart and Aging Research in Genomic Epidemiology; CHS = Cardiovascular Health Study; FHS = Framingham Heart Study; LD = linkage disequilibrium; MAF = minor allele frequency; OR = odds ratio; SNPs = single-nucleotide polymorphisms.

*For information on all SNP associations with $p < 10^{-4}$, see Supplementary Table 2.

†Genotyping requested, not completed.

‡Genotyping not requested.

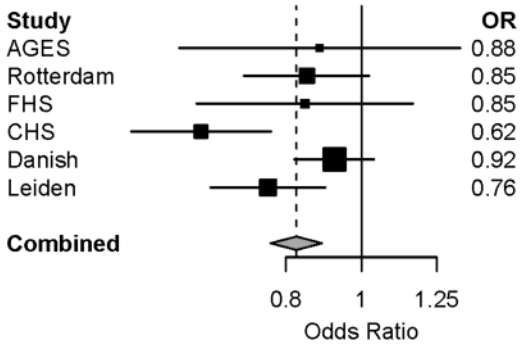

Figure 3. Study-specific odds ratios (ORs) and 95% confidence intervals for *MINPP1* (rs9664222) longevity association.

Note: AGES-Reykjavik = Age, Gene/Environment Susceptibility-Reykjavik Study; CHS = Cardiovascular Health Study; FHS = Framingham Heart Study.

studies in a joint meta-analysis, with the *p* value decreasing about 10-fold, from 1.61×10^{-5} to 6.77×10^{-7} and corresponding OR of 0.82. This SNP, rs9664222, is ~25 kb from the *MINPP1* gene (Figure 4). In the CHARGE analysis, the minor allele was associated with a lower odds of survival past age 90 (OR = 0.77). The Leiden study yielded a similar effect estimate (OR = 0.76, $p = .0014$), whereas the Danish study showed a nonsignificant trend in the same direction (OR = 0.92, $p = .19$). Findings for the other SNPs were inconsistent in direction of association such that the meta-analysis *p* values increased with inclusion of the second stage cohorts (Supplementary Table 3). Pathway analysis did not reveal significant findings in the top associations, though some groupings were biologically plausible.

Discussion

The CHARGE Consortium collaboration allowed us to conduct a meta-analysis of GWAS for longevity in a sample of long-lived individuals and a corresponding comparison group derived from the same longitudinal community-based cohort studies. Although none of the SNP associations for longevity in the first discovery phase achieved prespecified level of genome-wide significance, a polymorphism associated with the *MINPP1* genes was among the strongest associations observed in our sample, with effect sizes that were similar within the four cohorts. The finding related to the *MINPP1* gene was strengthened after including two additional cohorts in a second discovery phase but did not reach genome-wide significance. Among the top 10 associations in the initial meta-analysis, additional SNP associations of potential interest in longevity include SNPs in or near *LASS3*, *ACCN1*, *IL20RB*, and *PAPPA2*. These SNPs

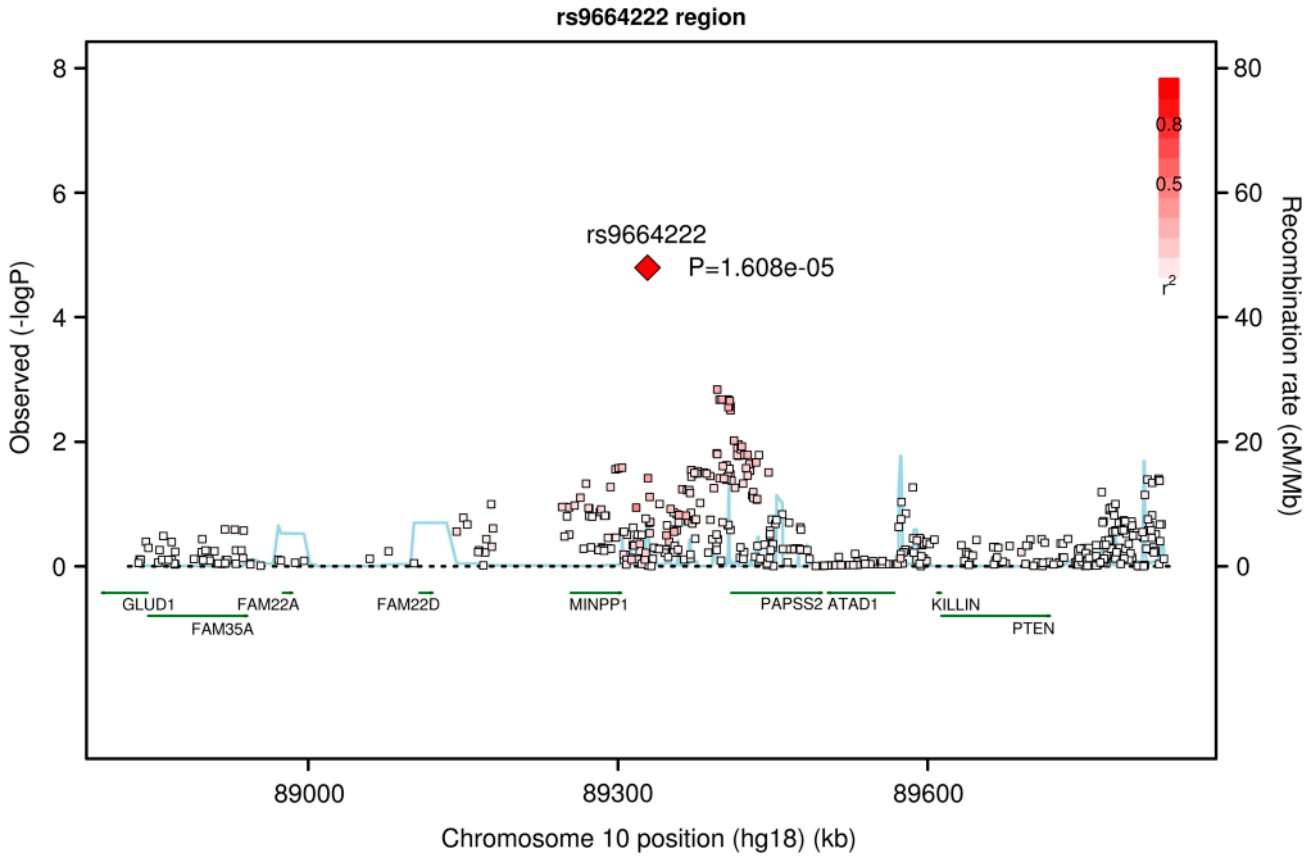

Figure 4. Regional plot for rs9664222 near *MINPP1*.

are near genes that have not previously been reported to be associated with longevity in human populations but are interesting because these genes are conserved in basic biologic pathways.

The *MINPP1* gene codes multiple inositol polyphosphate phosphatases, which are compartmentalized to the endoplasmic reticulum lumen. *MINPP1*-deficient mice have no obvious defects, though targeted deletion in vitro is associated with slowed cellular proliferation (46). There is no evidence that this SNP is functional; furthermore, its distance from the gene shows that it is not in strong linkage disequilibrium with SNPs in *MINPP1* (47). However, it is well known that important regulatory elements are found outside of genes. This SNP is within 50 kb of two copy number variants. The finding of an SNP near a gene regulating proliferation is intriguing because of the higher rate of cancer death in the comparison group.

The initial finding in the *LASS3* gene region was of interest because of the historical association of its homologue with longevity in yeast (46). The *LASS* gene family contains a group of highly conserved genes that are found in all eukaryotic species. *LASS* isoforms are mammalian homologues of the yeast longevity assurance gene 1, which encodes a protein that regulates life span (48). The strongest association was noted for rs8029244; this SNP is in the intronic enhancer region of the *LASS3* gene. *LASS3* is a member of the ceramide synthase family, which is important in sphingolipid metabolism, cell differentiation, cell cycling, and apoptosis (46). *LASS3* may be involved in sphingolipid synthesis or its regulation (49).

IL20RB, interleukin 20 receptor beta IL-20, plays a role in skin inflammation and the development of hematopoietic cells (50) and is of interest because of the strong associations of inflammation with the aging process (51). IL-20 is a pleiotropic cytokine with potent inflammatory, angiogenic, and chemoattractive characteristics and is involved in inflammatory diseases, such as psoriasis, atherosclerosis, and rheumatoid arthritis (50). The *ACCN1* gene encodes amiloride-sensitive sodium channels with two hydrophobic transmembrane regions and a large extracellular loop, which has many cysteine residues with conserved spacing (52,53). The member encoded by this gene may play a role in neurotransmission. *ACCN1* was found to be associated with multiple sclerosis (54). Pregnancy-associated plasma protein A2 (*PAPPA2*) is a metalloproteinase regulating local insulin-like growth factor pathway action (55). Genetic deletion extends life span in the mouse by 30%–40% (56) and is characterized by delay in thymic involution (57) and low rates of tumor incidence (56). Although the associations reported here did not reach the a priori specified level of significance, the findings are important to report so that they can be replicated in studies without whole-genome genotyping and compared with future studies, such as in centenarian studies and family studies of longevity. Effect size estimates noted here support the likelihood that longevity is a complex process, in that there were no variants with large effects, supporting the hypothesis that there may be many genes with small effects that contribute to longevity.

The strengths of this study include the community-based prospective design and the long-term follow-up of these cohorts. In all cases, vital status was confirmed using death certificates and hospital records. Another strength was our ability to use controls that were equally well characterized and were drawn from within the same cohorts. The number of long-lived individuals reported here is very large relative to other studies in the literature, allowing greater ability to identify SNPs with small effects. The cohorts were relatively homogeneous with respect to ancestry, limited to Caucasians of European decent. Our top associations were homogeneous across cohorts. Screening for latent population substructure also supported ethnic homogeneity. Thus, the findings reported are less likely to be due to population stratification.

There are important aspects of the study that need to be kept in mind when interpreting the results. The differences in causes of death in the longevous individuals versus the comparison groups are expected as death from cancer tends to occur earlier in life than death from heart disease or dementia. Many of the long-lived people are still alive and we do not yet know what their ultimate cause of death will be, but it is likely that cancer will be underrepresented among persons achieving longevity. Power remains a limitation. Thus, future GWAS aiming to identify variants for this phenotype will have to consider small effect sizes and target a sample size larger than our nearly 2,000 long-lived persons. DNA collection in cohort studies is a recent enough phenomenon that relatively few cohort members who had DNA collected have had the opportunity to survive to age 90 years. Continuous study of these and other similarly designed cohorts will allow us to extend this study to larger numbers and to older ages.

In our case comparison analysis, we attempted to account for birth cohort, but the overlap between birth year of the comparison group and of the long-lived participants was limited. Further follow-up of these cohorts is needed to increase our ability to examine potential birth cohort effects. The study design of the cohorts examined in the second stage was different from the initial four-study CHARGE meta-analysis in that the comparison groups were derived from younger participants, living and deceased, who were not from the same cohort as the individuals achieving longevity. Certainly, there are important environmental factors that would be necessary for the fulfillment of the genetic potential for longevity. Heterogeneity in environmental exposures and gene–environment interactions require further study. Finally, these results cannot be extended to populations of other ancestry.

In conclusion, this meta-analysis of GWAS data for longevity from four large cohorts and two additional

cohorts has implicated several genes involved in conserved basic mechanisms of cellular function. Analysis of more extreme survival phenotypes such as centenarians, additional follow-up to increase sample size in these cohorts for this phenotype, or evaluation of more specific phenotypes such as disease-free survival may support and refine these initial findings.

Funding

The CHS research reported in this article was supported by contract numbers N01-HC-85079 through N01-HC-85086, N01-HC-35129, N01 HC-15103, N01 HC-55222, N01-HC-75150, and N01-HC-45133 and grant numbers U01 HL080295 and R01 HL087652 from the NHLBI and R01 AG023629 from the NIA, with additional contribution from the National Institute of Neurological Disorders and Stroke. A full list of principal CHS investigators and institutions can be found at http://www.chs-nhlbi.org/pi.htm. DNA handling and genotyping was supported in part by National Center for Research Resources grant M01-RR00425 to the Cedars-Sinai General Clinical Research Center Genotyping core and National Institute of Diabetes and Digestive and Kidney Diseases grant DK063491 to the Southern California Diabetes Endocrinology Research Center. The FHS phenotype–genotype analyses were supported by the NIA grant numbers R01AG029451, R01AG028321, R01AG033193, and R01 AG031287. The FHS of the NHLBI of the National Institutes of Health (NIH) and Boston University School of Medicine were supported by the NHLBI's FHS contract number N01-HC-25195 and its contract with Affymetrix, Inc. for genotyping services (contract number N02-HL-6-4278). Analyses reflect intellectual input and resource development from the FHS investigators participating in the SNP Health Association Resource project. A portion of this research was conducted using the Linux Cluster for Genetic Analysis (LinGA-II) funded by the Robert Dawson Evans Endowment of the Department of Medicine at Boston University School of Medicine and Boston Medical Center. D.P.K.'s effort was supported by a grant from the National Institute of Arthritis, Musculoskeletal and Skin Diseases and the NIA (R01 AR/AG 41398). The RS is supported by the Erasmus Medical Center and Erasmus University Rotterdam; the Netherlands Organisation for Scientific Research (NWO); the Netherlands Organisation for Health Research and Development (ZonMw); the Research Institute for Diseases in the Elderly; the Ministry of Education, Culture and Science; the Ministry of Health, Welfare and Sports; and the European Commission (DG XII). The genetic analyses were supported by the Netherlands Organization for Scientific Research grant number 175.01.2005.011. This study was supported by the Netherlands Genomics Initiative-Sponsored Netherlands Consortium for Healthy Aging (nr 050-060-810). The work of S.W. was supported by Netspar. The AGES-Reykjavik is funded by NIH contract number N01-AG-12100, the NIA Intramural Research Program, Hjartavernd (the Icelandic Heart Association), and the Althingi (the Icelandic Parliament). Genotyping was conducted at the NIA Intramural Research Program Laboratory of Neurogenetics. The Leiden Longevity Study was supported by the Innovation Oriented research Program on Genomics, the Centre for Medical Systems Biology, and the Netherlands Consortium for Healthy Aging in the framework of the Netherlands Genomics Initiative, the Netherlands Organization for Scientific Research, the Netherlands Organization for Health Research and Development (ZonMw), the Danish National Programme for Research Infrastructure 2007 from the Danish Agency for Science Technology and Innovation, and Unilever PLC, UK. The Longevity Consortium, funded by the NIA, grant number U19 AG023122, provided administrative resources to CHARGE investigators for this phenotype as well as scientific opportunity funds to conduct follow-up genotyping. The Danish 1905 Cohort Survey was supported by grants from the Danish National Research Foundation and NIH/NIA grant P01 AG08761. The Danish Aging Research Center is supported by a grant from the Velux Foundation. The Atherosclerosis Risk in Communities Study is carried out as a collaborative study supported by NHLBI contract numbers N01-HC-55015, N01-HC-55016, N01-HC-55018, N01-HC-55019, N01-HC-55020, N01-HC-55021, N01-HC-55022, R01HL087641, R01HL59367, and R01HL086694; National Human Genome Research Institute contract number U01HG004402; and NIH contract number HHSN268200625226C. Infrastructure was partly supported by grant number UL1RR025005, a component of the NIH and NIH Roadmap for Medical Research.

Conflict of Interest

The content is solely the responsibility of the authors and does not necessarily represent the views of the NIA, NHLBI, the National Institute of Neurological Disorders and Stroke, or NIH.

Supplementary Material

Introduction

The Evolving Field of Health Literacy Research

MICHAEL K. PAASCHE-ORLOW

Section of General Internal Medicine, Department of Medicine, Boston University School of Medicine, Boston, Massachusetts, USA

ELIZABETH A. H. WILSON

LAUREN McCORMACK

Health Communication Program, RTI International, Research Triangle Park, North Carolina, USA

We are quite pleased to present the current special issue on Health Literacy of the *Journal of Health Communication*. We hope readers will see this issue as a marker of the Journal's long-term interest and commitment to health literacy research and as an exhibit of the rapidly evolving field of health literacy. This issue presents findings from the first Health Literacy Annual Research Conference (HARC) which took place in October 2009 at the National Academy of Sciences Building, Washington, DC. HARC is an interdisciplinary meeting for investigators dedicated to health literacy research. Our aim is to attract a full range of investigators engaged in health literacy research including those involved in a broad array of public health, health services, epidemiology, translational, and interventional research activities.

The Health Literacy Annual Research Conference (HARC) meeting was coordinated with the assistance of Rose Martinez on behalf of the Institute of Medicine Roundtable on Health Literacy and sponsored by a grant from the National Center on Minority Health and Health Disparities (NCMHD), Project Officer—Robert Netty, with additional significant support from the Agency for Healthcare Research and Quality (AHRQ), Project Officer—Cindy Brach. Additional coordination and support was provided by Helen Meissner, of the Office of Behavioral and Social Sciences Research (OBSSR) as well as the National Institute of Biomedical Imaging & Bioengineering (NIBIB), Project Officer—John Haller, and the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), Project Officer—Lynne Haverkos. Principal Investigator Michael Paasche-Orlow, 1 R13 MD003392. This Special Issue was supported by generous funding from RTI International, the Health Literacy and Learning Program, Division of General Internal Medicine, Feinberg School of Medicine at Northwestern University, the George Washington University Center for Global Health, and the Section of General Internal Medicine, Boston University School of Medicine.

Address correspondence to Michael K. Paasche-Orlow, 801 Massachusetts Avenue, 2nd Floor, Boston, MA 02118, USA. E-mail: mpo@bu.edu

Establishing an interdisciplinary research home for health literacy investigators can accelerate: (1) professional development, (2) advancement of the science of health literacy research, and (3) promotion of interdisciplinary research.

The HARC conference took place over 2 full days in October 2009 and highlighted areas of important research advancement as well as key lacunae in the field. A keynote address by David Baker, MD, MPH examined the role health literacy in patient education, and a keynote address by Anne Beal, MD, MPH, focused on the role of health literacy in health disparities. The conference also included four panels of invited speakers dealing with: (1) measurement; (2) health literacy and verbal interactions; (3) health information technology interventions; and (4) organizational assessment and change. Current gaps in the research were examined by invited speakers and in breakout sessions relating to public health approaches to health literacy, health disparities and health literacy, and health information technology. An additional 62 posters and 12 oral abstracts were presented, making this clearly the largest set of Health Literacy research presentations in any single meeting to date. The meeting was attended by an interdisciplinary array of investigators representing the strong majority of health literacy investigators in the United States.

HARC II will take place October 18–19, 2010, in Bethesda, Maryland (http://www.bumc.bu.edu/healthliteracyconference/).

While many important unanswered questions loom, the articles in this issue highlight the blossoming nature of health literacy research. In her commentary, Health Literacy: The Second Decade for Distinction, Parker chronicles the major landmarks of the last decade. A Pubmed exercise tells a similar story. Using the Health Literacy topic specific query under the Pubmed tools tab (see: http://www.nlm.nih.gov/services/health_literacy.html) reveals the tremendous growth of research in this field: in the 5 years between 1986 and 1990 there are 129 references in Pubmed; in the years 1991 to 1995 this search yields 306 references; between 1996 and 2000 there are 307 references; from 2001 to 2005 there are 602 references from this search; and in the current interval, between 2006 and 6/6/2010, there are already 1576 references returned by this search (see Figure 1). As striking as this may seem, it

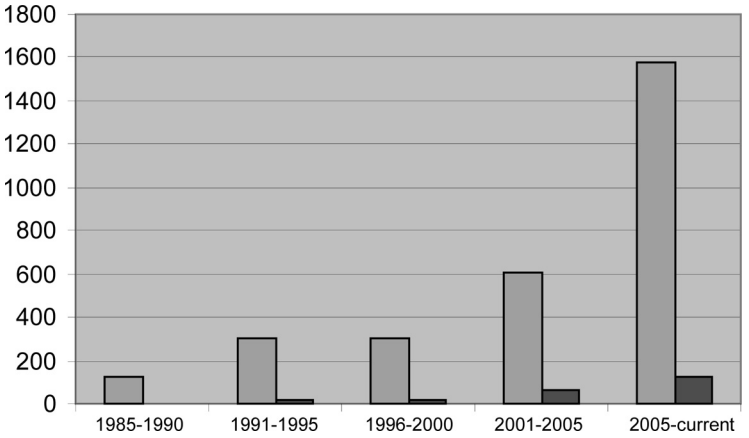

Figure 1. Health literacy citations in Pubmed. Lighter bars represent all citations identified by Health Literacy topic specific query. Darker bars represent the subset of these citations identified as trials, clinical trials, or randomized controlled trials.

is also important to note that this collection of references is dominated by observational research, indeed, fewer than 8% of these citations are tagged as trials.

An ongoing research area in the field relates to health literacy measurement. McCormack et al. presents pilot data from a new skills-based instrument, Yost and colleagues present data on the acceptability of a talking touchscreen assessment tool, and Gazmararian et al. describes a tool developed to assess the health literacy environment of health plans (McCormack et al.; Yost et al.; Gazmararian et al.). All such efforts inherently reflect underlying definitional issues, which are also the focus of a Commentary by Berkman et al.

This special issue also provides evidence about health literacy in an array of contexts including advanced care planning (Sudore et al.), informed consent for research among Spanish speakers (Cortés et al.), two articles about cancer screening (Wilson et al. and Mazor et al.), and the relationship between health literacy and the quality of communication in health care organizations (Wynia et al.). Self-efficacy is shown to link literacy and numeracy in glycemic control (Osborn et al.) and a new instrument of patient self-efficacy regarding communication with clinical encounters (Clayman et al.). Despite evidence of a large 'digital divide' by level of health literacy in accessing and using a patient-portal (Sarkar et al.), it appears that such barriers are surmountable, as Bickmore et al. present evidence from two trials of an 'embodied conversational agent' technology interface that is usable by people with limited literacy (Bickmore et al.).

We have also included a Commentary on the role of health literacy research for the elimination of health disparities (Paasche-Orlow & Wolf) and a Commentary that situates the field of health literacy within a public health paradigm (Baur). In addition, we have included an international policy paper that summarizes the health literacy objectives of the United Nations Millennium Development Goals (UN Economic and Social Council [ECOSOC]).

Taken together, the special issue reflects the important role that health literacy plays in many aspects of health communication. The Department of Health and Human Services recently outlined a National Action Plan to Improve Health Literacy (http://www.health.gov/communication/HLActionPlan/). Clearly, improving health literacy is a widespread goal. However, it is a means to end. Ultimately, improved health literacy can lead to clearer communication, better informed decisions, and the delivery of quality health care services. To achieve these objectives, we need to continue to study how to measure health literacy, which interventions can improve health literacy levels, and the relationships between health literacy and health outcomes.

Promoting Health Literacy Research to Reduce Health Disparities

MICHAEL K. PAASCHE-ORLOW

Section of General Medicine, Department of Medicine, Boston University School of Medicine, Boston, Massachusetts, USA

MICHAEL S. WOLF

Northwestern University School of Medicine, Chicago, Illinois, USA

Limited health literacy has been linked to worse health outcomes for a range of medical conditions. In addition, limited health literacy is more prevalent among specific racial and ethnic minorities. Although these findings have been widely acknowledged, little systematic research has been conducted to elucidate the role of health literacy in the creation of health disparities or to evaluate the possibility that interventions relating to health literacy may help eliminate health disparities. This paper presents recommendations for a research agenda that is focused on advancing the science for how health literacy research can promote the effort to eliminate health disparities.

In the United States, racial/ethnic and socioeconomic disparities within the educational system have long been reported. As a result, two thirds of African American adults and 74% of Hispanic adults have limited functional literacy skills, compared to 32% of whites (Kutner, Greenberg, Jin, Boyle, Hsu, & Dunleavy, 2007). The consequences of early failures in education have more recently been linked to problems in healthcare. Research has begun to emerge showing how a health literacy skill set is linked to a range of health outcomes, and evidence has also emerged demonstrating how deficits in these skills possibly explain certain disparities (Bennett, 2009; Osborn, Cavanaugh, Wallston, White, & Rothman, 2009; Osborn, Paasche-Orlow, Davis, & Wolf, 2007; Sentell, 2006; Waldrop-Valverde, 2010; Wolf, 2006).

According to the most widely cited definition, health literacy is the "degree to which individuals have the capacity to obtain, process and understand basic health information and services needed to make appropriate health decisions" (Nielsen-Bohlman, 2004). As such, health literacy must be framed in the context of the specific tasks that need to be accomplished. In its seminal 2004 health literacy report *A Prescription to End Confusion*, the IOM recognized that patients' health-related knowledge, skills, and behaviors are heavily influenced by: (1) cultural

Address correspondence to Michael K. Paasche-Orlow, 801 Massachusetts Avenue, 2nd Floor, Boston, MA 02118, USA. E-mail: mpo@bu.edu

background, (2) health system demands, and (3) prior learning opportunities (Nielsen-Bohlman, 2004). The report frames limited health literacy not as a patient problem, but as a challenge to healthcare providers and health systems to reach out and more effectively communicate with patients. Specifically, the construct incorporates not only the individual cognitive and functional skills one uses when making health-related decisions, but it takes into account the contextual demands placed on the individual by (a) their specific clinical condition and associated health care decisions, (b) the communication characteristics of the dominant medical culture, (c) the structure and function of clinical services that assume adequate health literacy proficiency and require self-advocacy and vigilance, and (d) the emphasis that society places on individual, rather than ecological, determinants of health.

As one of the primary public health goals in the United States and other industrialized countries is to better understand and respond to health disparities, a health literacy perspective provides an important new direction for seeking perhaps more potentially modifiable strategies for reducing inequities in the short-term, with a multitude of targets. Health literacy researchers are now recognizing the need for comprehensive strategies that go beyond considering only a patient's functional literacy abilities. Rather, health literacy interventions should examine the complexity of the tasks required of patients and families within healthcare settings, the accessibility of providers for the target populations, the preparedness of health and public health professionals to engage productively with patients, and the features of the health care system, working environments, and communities in which care-giving and self-management support take place.

Perhaps the most significant attribute of health literacy research is that it calls attention to the many ways in which unnecessarily complex healthcare exacerbates the impact of underlying educational and income disparities. The implications of this extensive body of literature should be understood as a direct challenge to health systems that have been organized for the most highly educated and affluent members of a society. While seminal reports about the problem of limited health literacy have been issued by the Institute of Medicine (Nielsen-Bohlman, 2004), Agency for Healthcare Research and Quality (Berkman, 2004), American Medical Association (1999) and Joint Commission among others (Murphy-Knoll, 2007), none have addressed how health literacy research may help eliminate disparities.

Herein, we have sought to present recommendations for a research agenda that is focused on advancing the science for how health literacy research can promote the effort to eliminate health disparities and thereby promote health care equity. As this field is currently insufficiently developed, and there are many things that are not yet known about eliminating health disparities, the agenda presented here should be viewed as a work in progress.

1. Integrate Health Literacy Assessment in Disparities Research

The first step in most circumstances is to measure health literacy. Without measurement, it is not possible to know when and how health literacy may be relevant, and it would be very easy to design interventions that fail to attend to relevant factors. For example, in an adjusted analysis that excluded health literacy, African Americans were 2.4 times more likely to be non-adherent to their HIV medication regimen than whites (95% confidence interval [CI] = 1.14–5.08). When health literacy was included in the final model adjusting for relevant covariates, the effect estimates of race

diminished to non-significance and health literacy remained a significant independent predictor of non-adherence (adjusted odds ratio [AOR] = 2.12, 95% CI = 1.93–2.32) (Osborn, Paasche-Orlow, Davis, & Wolf, 2007). In another study, patients were asked their preferences regarding end-of-life care if they would develop advanced dementia. The African American subjects were found to prefer more aggressive care than the white subjects. When health literacy was included in the final model, health literacy—but not race—significantly predicted of preferences for care (low literacy OR 7.1, 95% CI 2.1–24.2) (Volandes et al., 2008). Health literacy clearly mediated the influence of race on end-of-life preferences. In both of these investigations, completely different conclusions would have been made without concurrent evaluation of race and health literacy.

2. Improve Patient Education

Limited health knowledge has been the most widely identified outcome in health literacy research, followed by certain health behaviors (Berkman, 2004). Given the strong associations between race, educational attainment, and health literacy, improving the timely access to information for specific health conditions or recommended actions among vulnerable populations is a logical step for promoting health equity (Ayotte, Allaire, & Bosworth, 2009; Bailey et al., 2009). Decades of research have produced an innumerable supply of publicly and commercially available patient education tools, available in an array of print, video, and web-based formats. Very few of these materials have incorporated a range of patient perspectives in their development, and even fewer have been formally tested to confirm their utility among culturally diverse and lower literate populations. While learning styles vary, efforts should be made to direct health providers and systems to the best available educational tools. This will likely require established criteria for evaluating their adequacy. To do this will be particularly challenging, as many tools that have already been developed specifically for lower literate audiences have not been entirely successful. Gerber et al. demonstrated a lack of significant knowledge gains for educating patients on diabetes self-care concepts using state-of-the-art multimedia (Gerber, 2005), and early efforts by Davis and colleagues found plain language print health information to produce only minimal improvement compared to existing brochures for polio vaccination (Davis, 1998). While guidance is available throughout various sources as to how best to create and field test plain language health information materials for diverse patient groups, there remains a need to consolidate recommendations, systematically assess the efficacy of newly available materials, and offer streamlined means to disseminate them at low or no cost to health care providers and systems. Equally important, finding ways to fund and produce language concordant versions of patient education tools for use among practices serving patients with limited English proficiency should be viewed as a public health priority.

3. Simplification of the Health Care System: Access and Utilization

Unneeded and complex barriers to access and utilize health services exacerbate the impact of underlying educational disparities. There is great potential for health insurance reform to improve the lives of millions of Americans. However, health insurance and other health benefit systems need to be designed to succeed.

Complex application forms, terms and conditions, and documentation requirements are significant barriers that disproportionately burden vulnerable populations (Davidoff, 2010; Ettner, 2010). A health literacy lens should be taken to all public programs: How will a person with limited literacy get and use this program? Answering such questions will help economically progressive programs fulfill their mission of reducing socioeconomic class disparities.

4. Simplification of the Health Care System: Education and Training of Health Professionals

Health professionals contribute to the unneeded complexity of the healthcare system with poor communication and limited dedication to patient education. Clinicians frequently use jargon (Castro, 2007) and rarely confirm if their patients understand what is being discussed (Schillinger, 2003). Consequently, patients frequently misunderstand a broad array of critical information (Fang, 2009). The Centers for Disease Control hosts a Web-based training program on health literacy that is geared toward public health (http://www.cdc.gov/healthmarketing/healthliteracy/training/) and the Health Resources Services Administration hosts a unified health communication course (http://www.hrsa.gov/healthliteracy/) to address Health Literacy, Cultural Competency, and Limited English Proficiency. These are free, on-line training programs to improve patient-provider communication. Integration of health literacy curricula into professional education, however, is in a nascent state. To date, there is a dearth of research on the impact of educational initiatives to promote the knowledge and skills of health professionals regarding health literacy. Curricular initiatives to address health disparities are further advanced. There is a National Consortium for Multicultural Education for Health Professionals including educators from 18 U.S. medical schools, which collect lessons learned from curriculum implementation to guide similar educational endeavors across the consortium (Carter-Pokras, 2010). Indeed, several states have laws and or regulations that mandate training health professions in cultural competence (https://www.thinkculturalhealth.org/cc_legislation.asp). Inclusion of health literacy in such policy initiatives can help promulgate health literacy curricula, but research will be needed to identify programs that work, can be replicated, and help eliminate health disparities.

5. Simplification of the Health Care System: Self-Care

Renewed interest in case management services, including care coordination, patient navigation, and certain proposed definitions of a medical home offer possible means for having lay workers or allied health professionals support patients in self care endeavors. Many longstanding, controversial health care practices that have previously been implicated as examples of poor health system design are now being confronted. For instance, solutions are being tested to manage the longstanding problem of variable and poor quality clinician prescribing practices that have been at the root of patient misunderstanding and prescription misuse. In fact, laws have now been set that lay out standards for both prescribing and labeling medicines to ensure patient-centered and evidence-based practices are in place to promote comprehension and adherence. In California and New York City, these regulations include providing language concordant spoken and text medication information (Bailey, Pandit, Curtis, & Wolf, 2009; "California State Board of Pharmacy,

Title 16-1707.5 Patient-Centered Labels on Medication Containers"). Indeed, there is a broad range of self-care tasks that could benefit from simplification. For example, ways to improve the FDA's Nutritional Facts label have been proposed, as Rothman and colleagues had previously reported more than half of adults can successfully navigate the current label and compute necessary information to support appropriate and safe decision making on food products (Lokker, 2009). There are many excellent targets for simplification and standardization as methods to improve self care and there remain great research opportunities in designing self-care systems that are effective for people with low health literacy. Moreover, very little is understood about the role of health literacy and its influence on health disparities for all the self-care tasks that occur outside of any relationship with a health provider. The public health arena has really been under explored.

6. Health Information Technology

There are increasing opportunities to leverage various health technologies to deliver health literacy-related interventions for a variety of purposes. Information technologies may range from automated telephone calls, to integrated electronic health record systems with patient portals and computerized agents. The value is clear; as health systems become automated, these tools allow for greater outreach, accountability, and standardization in the way health and healthcare is communicated to patients and families. Sarkar and colleagues compared the effectiveness of a diabetes self-management intervention using automated telephone calls with a nurse follow-up versus group medical visits and usual care (Sarkar, 2008). Those receiving the automated calls reported better perceived diabetes care, communication, and both intervention arms documented improved self-care behaviors, fewer bed days, and less interference with daily activities. In a small pilot of an animated, computerized agent to standardize communication for an informed consent process, Bickmore et al. (2009) found patients to be more accepting of the technology even compared to human interactions, although no differences in knowledge acquisition were noted. In the current issue Bickmore and colleagues extend this work to show that people with no prior computer experience and limited health literacy can readily use such a system. These studies highlight the potential value of health technologies for engaging patients, particularly those with limited health literacy; yet more research is needed to better document the link between these interventions and health outcomes. Greater attention to human-computer interaction considerations must also be made as Czaja (2008) aptly described the health literacy challenge to older adults in attempting to navigate and access information on the Medicare website.

7. Target the Educational System

For decades, studies have repeatedly highlighted the strong association between lower educational attainment and poor health outcomes, including mortality. These relationships have remained significant even after adjusting for relevant socioeconomic indicators. It would follow that as the quality of primary and secondary education improves and disparities in academic performance are reduced, so might health inequities. However, high school graduation rates have remained relatively stagnant in the United States for decades. Much remains to be learned about the pathways from education to health. Elucidating how general literacy, which can

influence among other things factors like employment options, financial stability, and access to health care, operates in similar or different ways in people's lives as health literacy could help direct efforts in designing education programs that improve health and decrease health disparities. Disparities in basic literacy skills may have a very different—and even bigger—role in promoting health disparities in the United States than disparities in health literacy skills. Improving the high school graduation rate and improving the quality of primary and secondary education should be seen as long-term public health measures. Another long-term goal should be to develop successful initiatives that advance the health literacy of future generations by increasing patient skills and public health skills across the lifespan, throughout all levels of the education system. School curricula should include common and pertinent medical terminology, practical healthcare navigation skills, and age-related health issues such as physical activity and nutrition. This can lead to more accurate expectations of current and future roles and responsibilities regarding self-care and prevention, as well as instilling the type of self-efficacy that may be needed to engage health problems as they arise.

Conclusion

The fact that low health literacy is associated with worse health outcomes and with specific racial and ethnic groups makes this field of inquiry particularly appealing as a source of ideas, methods, and interventions to help eliminate disparities. And yet, to date, the fields of health literacy research and health disparities research have remained largely separate. We have presented seven high priority areas for what we hope may amount to the beginning of an active shared health literacy and health disparities research agenda. The agenda we present needs to be interpreted contextually and may need to be recast to meet the needs of various public health and international settings.

METHODS ARTICLE

Patient Navigation: Development of a Protocol for Describing What Navigators Do

Victoria A. Parker, Jack A. Clark, Jenniffer Leyson, Elizabeth Calhoun, Jennifer K. Carroll, Karen M. Freund, and Tracy A. Battaglia

Objective. To develop a structured protocol for observing patient navigators at work, describing and characterizing specific activities related to their goals.
Data Sources/Setting. Fourteen extended observations of navigators at three programs within a national trial of patient navigation.
Study Design. Preliminary observations were guided by a conceptual model derived from the literature and expert consensus, then coded to develop and refine observation categories. These findings were then used to develop the protocol.
Methods. Observation fieldnotes were coded, using both a priori codes and new codes based on emergent themes. Using these codes, the team refined the model and constructed an observation tool that enables consistent categorization of the observed range of navigator actions.
Findings. Navigator actions across a wide variety of settings can be categorized in a matrix with two dimensions. One dimension categorizes the individuals and organizational entities with whom the navigator interacts; the other characterizes the types of tasks carried out by the navigators in support of their patients.
Conclusions. Use of this protocol will enable researchers to systematically characterize and compare navigator activities within and across programs.

Key Words. Continuity of patient care, social support, health services needs and demands, case management, patient navigation

Challenges arise when people contemplate cancer screening. They multiply when tests suggest a threatening disease and indicate the need for follow-up investigations. And the challenges expand dramatically when such investigations reveal cancer, as people become "patients" in the complex realm of referrals, consultants, examinations, decisions, and often arduous treatment regimens.

Individuals who are socially and economically disadvantaged may find cancer care all the more problematic (Baquet et al. 2005). These people are at substantial risk of receiving inadequate care at each step of the cancer care continuum: screening, diagnostic follow-up of suspicious results, treatment when cancer is diagnosed, and survivorship surveillance. Moreover, the systems of care available to them, such as "safety net" institutions, are often beset with inefficiencies.

Patient navigation has emerged in the past decade in response to these widely recognized disparities in cancer care. Health care advocates, policy makers, and innovative health care organizations have called for the adoption of patient navigation to assist patients and remedy inefficiencies in the provision of timely care (Freeman 2006; Jandorf et al. 2006). As a result, patient navigation services have proliferated rapidly in recent years.

Research to date supports the promise of patient navigation for reducing cancer disparities (Gabram et al. 2008). Currently, a large, multisite cooperative study of patient navigation is being conducted. The National Cancer Institute's Patient Navigation Research Program (PNRP) is designed to evaluate the effectiveness of navigation in improving timeliness of care (i.e., time to follow-up of abnormal screening results and to completion of treatment when cancer is diagnosed) and patient satisfaction (Freund et al. 2008). The nine cooperating studies of the PNRP provide a laboratory for characterizing the actual work of patient navigators and linking variation in their activities to patient outcomes. The first step in such an effort is to design

procedures for systematically observing navigators' activities. This paper reports on the development of a protocol for observing what navigators actually do.

BACKGROUND

Despite continued advances across the spectrum of cancer care (Brenner, Gondos, and Arndt 2007), the distribution of these advances remains uneven. They are less likely to be enjoyed by those segments of our society defined by minority racial and ethnic status, low income, and limited health insurance (Weir et al. 2003; Shavers, Fagan, and McDonald 2007). Disparities in cancer care are persistent and may in some instances actually be widening (Ries et al. 2007). Inequitable outcomes may result from, among other factors, well-documented delays in accessing diagnostic and treatment services by the most at-risk populations (Chang et al. 1996; Peterson, Han, and Freund 2003; Battaglia et al. 2007).

Several seminal reports (Smedley et al. 2003; Weir et al. 2003) have highlighted the barriers to cancer care inherent to socioeconomic disadvantage. Patient navigation is a community-based approach to reducing these barriers (Dohan and Schrag 2005; Battaglia et al. 2007; Ell et al. 2007; Ferrante, Chen, and Kim 2008). Guided both by principles of disease management and by cultural sensitivity, navigators are responsible for identifying individuals most at risk for delays in cancer care and mitigating barriers to their receipt of that care (Vargas et al. 2008). Navigation programs also seek to remedy systemic barriers to care within organizations delivering care. Patient navigation services address barriers by assigning trained supportive staff who track patients and assist them in completing their diagnostic and treatment care, while also advocating for solutions to systemic causes of those barriers.

Navigation programs are usually funded through local resources or foundation support because insurers do not reimburse this care. Local innovation results in tremendous variability in program structures and activities. Trailing behind these developments is a small, but growing body of research documenting the efficacy of navigation (Battaglia et al. 2007; Ell et al. 2007; Ferrante, Chen, and Kim 2008; Gabram et al. 2008). While these studies provide evidence that navigation is effective, the key components of a successful navigation program are not well understood.

Conceptual Definition

Problems often arise in the evaluation of complex innovations such as patient navigation because the interventions have not been fully defined and developed (Campbell et al. 2000). Early evaluations of innovative programs often simply assume either that the intervention is in place as planned or that some variation is acceptable (Eccles et al. 2003). However, such assumptions lead evaluators to overlook the effects of variation. And in the case of patient navigation, a lack of information about variation in definition, style, and scope could lead to inaccurate conclusions about its effectiveness.

There is no generally accepted definition of patient navigation. Reviewing 56 articles published before early 2004, Dohan and Schrag (2005) identify two types of definitions: "service focused" and "barrier focused." Service-focused definitions attend to activities such as connecting individuals to resources and assisting patients in completing courses of care. Dohan and Schrag (2005) criticize these definitions as nonspecific: such activities could be, and often were, performed by other providers as part of their duties. Barrier-focused definitions, they argue, attend to activities that identify and remove impediments preventing patients from moving through screening, diagnostic follow-up, and treatment. Furthermore, these responsibilities were distinguishable from those usually assigned to social workers, case managers, community outreach workers, and health advocates. The latter roles, they argue, were typically proactive, providing education and counseling services, while navigation was essentially reactive to emergent impediments to care.

However, defining patient navigation in terms of resolving barriers for individual patients may be too constricting. While service-oriented definitions could blur distinctions between navigators and other service providers, focusing only on what navigators do in relation to barriers facing individual patients may obscure a variety of related activities they perform. They may tweak organizational practices to expedite patient care, develop local resources for multiple patients, and build cooperative relationships with and among clinic staff that facilitate more efficient movement of patients through systems. Thus, while staff other than navigators may facilitate patient access to services, to define patient navigation work solely in terms of barrier reduction risks artificially excluding other patient navigation functions.

We sought to avoid such exclusions. Informed by research to date, we noted that navigators work with health care organizations—sometimes within, sometimes externally—to facilitate patients' receipt of care from providers. This framing gives attention to the fact that navigators often must involve

others in their work, which, in turn, suggests that navigators' networks of relationships with these "others" might be essential to achieving their objectives. Drawing on research in various care settings, we then defined navigation in terms of tasks and networks: *navigators do things for patients by working with patients and other actors in both the social network of the organization itself and the community in which the organization resides.*

Social networks have been described as "patterns of relations joining actors" (Marsden 1990). Keating et al. (2007) use the social network approach to understand patterns of advice-giving and -following within a primary care practice. Earlier navigation research emphasized the pivotal role of the navigator in helping patients access necessary services, which suggests that part of navigation is knowing to whom to go for specific support. Thus, to understand what navigators do, we must understand their patterns of relations with others who provide services that facilitate screening, diagnosis, and/or treatment. Underscoring the importance of understanding these networks is a recent analysis of early patient navigation programs that defines patient navigation as a system, rather than a person (Vargas et al. 2008). The network framework is useful in bridging the service-focused/barrier-focused dichotomy: it usefully attends to the question of *how* navigators achieve their efforts on behalf of patients. Whether obtaining services proactively or in response to a specific barrier, navigators engage others in their networks to find, arrange, and seek reimbursement for those services.

The social network concept illuminates part, but not all, of the scope of patient navigation. We need also to describe the activities of navigators. Task analysis, with its emphasis on interaction of persons and environment, offers a useful complement. Task analysis is concerned with identifying the goal of a task, the criteria for reaching that goal, and the relevant resources and constraints. It also emphasizes that task-directed actions are determined by both the person carrying them out and the relevant environment (which presumably includes the person's social network), and that people develop personal expertise in how to accomplish their tasks (Norros and Nuutinen 2002). Navigators need to build a working knowledge of the tasks they must perform and a network of contacts to support their actions.

METHODS

Development of the observation protocol was grounded in a qualitative study of PNRP navigators at work. We began by surveying the nine PNRP sites to

characterize structural attributes of each program that would define the contexts in which navigators worked. Attributes included each program's physical site (facilities, geographic location, and populations served), its size, and the spectrum of navigation services offered. Based on these findings, we selected a convenience sample of three pilot programs that represented the diversity of settings and approaches to navigation implemented at the nine independent sites.

We also developed a preliminary guide for observing navigators at work. This guide was designed to enable the collection of comparable field observations of what navigators do (tasks) and the people and entities with whom they interact (networks) in accomplishing those tasks. The resulting data were analyzed to develop a comprehensive, yet simple observation protocol for observation of navigators across all PNRP sites and elsewhere.

Sample

The nine programs in the PNRP were selected through a competitive national process and designed according to general program criteria set by the NCI (Freund et al. 2008). The NCI sought to maximize diversity within this group to assess the usefulness of patient navigation across a range of settings. Thus, the programs differed in many respects, but they met common requirements regarding navigator training, patient population, patient criteria for inclusion, and collection of data. The programs address different combinations of four cancers—breast, cervical, prostate, and colorectal—where navigation would likely have a detectable effect in facilitating follow-up of suspicious screening results and completion of treatment (Freund et al. 2008). Each of these cancers is associated with a distinct patient population and pattern of care.

The locations where navigators work and interact with patients, medical providers, and others vary: hospital evaluation clinics, inpatient wards, and treatment units; primary care clinics; and community health centers. The scope of navigator involvement relative to the cancer care continuum also varies; some navigate in all phases, while others navigate only from diagnosis through treatment. At some sites, navigators focus on case finding, while at others, the focus is on supporting patients through treatment. The number of navigators employed varies, as does navigators' involvement in competing clinical or administrative responsibilities. Some navigators were hired and are supervised directly by the research program; others were hired by the clinical care sites themselves as a subcontract to the research program. Finally, the programs vary with respect to the professional background and training of

navigators: some use navigators with clinical training and credentials, while others use "lay" navigators selected for congruence with the target patient population.

In selecting the pilot sites, we excluded one program due to restrictive local access requirements. Site 2 was selected because it is the research team's home site and had a small, longstanding navigation program that predates the PNRP. Sites 4 and 7 were selected to provide informative, qualitative contrasts along the dimensions outlined above. Information about all eight programs is presented in Table 1.

Preliminary Data Collection

We enlisted other PNRP investigators to collaborate at their respective sites. Multisite, multi-investigator qualitative research required developing a common protocol. We designed a semistructured observation guide to support collection of comparable data across all sites. During a 1-day training, observers from each site were directed to describe specific actions of navigators and note the following: (1) the approximate duration of actions; (2) the parties with whom navigators interacted; (3) whether interactions were in person or via phone/email; (4) the relevance of the action to navigation.

Observers also were directed to query navigators about their actions at moments that would not interrupt observed activities. Navigators were asked to explain the relevance of observed activities to particular navigation issues and challenges, including (1) actions navigators took to develop a relationship with the patient and others relevant to the patient's case; (2) the role of others who were consulted for advice, direction, or assistance; (3) the initiation and extent of an interaction with a person; (4) the nature of the problems being addressed. Thus, while we focused on directly observable behaviors, we also explored navigators' reflections on the scope of and rationale for their actions.

Each navigator at each site was observed at least twice. Observations were scheduled in consultation with navigators to best capture the variation in their workflow, so the lengths of the sessions were defined by the ways navigators scheduled their own activities. For example, if a navigator worked with a specific provider seeing patients for screening follow-up, the observation ran the length of the provider's clinic. Most observations lasted about 4 hours.

At the end of each observation, navigators were asked further questions to characterize the representativeness of the actions just observed:

- How did you decide what to spend time on today?

Table 1: Characteristics of Patient Navigation Research Program (PNRP) (Protocol Development Sites Are Highlighted)

Program Location	*Cancer Targets*	*Number of Sites Where Navigation Is Offered*	*Type of Site(s) Where Navigator Is Based*	*Number of Navigators*	*Minimum Navigator Education Requirement (Set at Site)*	*Navigators Have Other Clinical/Administrative Responsibilities*
1	Breast	6	Hospital-based patients, hospital outpatient clinics, community health centers (CHCs)	8	None	Yes
2	Cervical, breast	6	CHCs	6	High school diploma	Yes
3	Breast, colorectal	10–12	CHCs	3	High school diploma	No
4	Cervical, breast, prostate, colorectal	5	CHCs, VA outpatient clinic	5	High school diploma	Yes
5	Breast, cervical	2	Hospital outpatient clinics, CHCs	4	BS/BA or LPN	No
6	Breast, colorectal, prostate	2	Specialty clinics at hospital	5	High school diploma, 2 years of work experience in medical setting	No
7	Breast, colorectal	11	CHCs, hospital outpatient oncology clinics and treatment units, primary care clinics	3	Completion of local Family Development Credential Program and in-house training	No
8	Breast, cervical, colorectal	6	Hospital outpatient clinic, CHCs	3	BA/BS and relevant work experience	No
9	Breast, cervical, prostate, colorectal	4	CHCs	4	PNRP and local training	Yes

- How did this action relate to prior activities for a particular patient or patients in general?
- Does this action reflect any specific strategies for assessing/obtaining what the patient needs?
- What will you do next?
- Did the problematic situation/barrier get resolved?
- How typical a day was this for you?

The observation guide was refined in a 1-day meeting of the observers, followed by regular conference calls. Issues of reliability were addressed by comparing observations within and between the three sites. Apparent discrepancies in the quality of observations were discussed and resolved by developing a consensus among all observers.

Analysis

Using the observation guide, investigators conducted a total of 18 comparable observations of nine navigators working in three program sites of the PNRP. The analysis focused on refining the observation protocol. Data from all three sites were compiled by the project PIs. Fieldnotes from each observation were imported into software supporting text-based analysis, HyperRESEARCH (ResearchWare Inc. 2008).

The analysis was informed by the general approach of grounded theory methodology (Glaser and Strauss 1967). The first three authors each reviewed separately one set of fieldnotes from each of the three sites, identifying themes that characterized the activities reported. The team then met to compare descriptive codes and reach consensus on code definitions before coding the rest of the fieldnotes. The primary aim of this analysis was to define a comprehensive, yet parsimonious set of categories that would enable other observers to reliably categorize navigator behavior.

Once these categories were developed, we also drafted observation instructions to guide subsequent field observations of the work of navigators. Drafts of the analytic categories were developed by the Site 2 researchers and shared with the Sites 4 and 7 observers for substantive critique and revision in a day-long research team meeting, which yielded the final protocol reported herein.

RESULTS

The three sites provided a wide array of contexts for observing navigation. They differed with respect to the scope of the navigation program, the phases of cancer care addressed (i.e., screening, diagnosis, or treatment), the history/longevity of the program, the emphasis placed on various navigator responsibilities, and the background (e.g., clinical, survivor, cultural/ethnic) of the navigators, as well as their physical and organizational location (e.g., community health centers, large medical centers, outpatient primary care, or treatment clinics). These contextual differences appeared to influence, to an undetermined extent, what navigators do. Thus, we sought an observation protocol that would reliably capture activities in these diverse settings.

Domains of Navigator Behavior

Guided by the concepts of *task* and *network*, we defined five categories each of navigator tasks and social networks. The task categories include navigating with a patient, facilitating for a patient, maintaining systems for all patients, documenting/reviewing actions, and other tasks. The five network categories include patient(s), clinical provider(s), nonclinical staff, formal and informal support, and medical record systems. Each of these categories is defined, described, and illustrated below.

Task Categories. Navigating tasks consist of identifying and mitigating barriers *with* patients. They include telling (explaining when and where biopsy will be done, describing what it will be like); inquiring (asking about barriers to attending the appointment, exploring the patient's concerns); supporting (listening to fears about treatment); and coaching (discussing questions that need to be asked at next appointment and how to ask them).

Facilitating tasks are performed *for* a specific patient. They include finding (locating current patients and ensuring that they will come to appointments); coordinating team communication (ensuring the entire care team is aware of the next steps); integrating information (ensuring that different types of patient data are documented and shared as needed); and seeking collaboration (enlisting other providers in addressing the patient's fears).

Maintaining systems tasks support *all* patients. They include identifying potential patients (reviewing lab results to note patients who need follow-up); building networks and referral routines (meeting with clinicians to explain

navigator role and discuss referral criteria); and reviewing cases (checking on ticklers and open issues).

Documenting activities and *reviewing* information constitute another major navigator task. They include recording navigator actions (recording steps taken with or on behalf of the patient in the patient's medical record or a separate navigation file); handling test results (retrieving and entering patient data from labs, radiology, or other sources); and processing other necessary information (recording information or activities relevant to navigator role).

Other activities are those apparently unrelated to navigation. It was important to capture all network interactions, even when their relevance to navigation was not apparent. For example, many navigators have other distinct roles unrelated to navigation; documenting these other activities will help in understanding how the navigator role fits in with other roles, both formally and informally. This category includes research-related activities, such as consenting patients, providing clinical back-up, activities unrelated to navigation (interpreting for nonnavigated patients), and socializing (having informal conversation with co-workers).

Network Categories. Navigators may interact with a specific *patient*, such as when phoning the patient with information about an upcoming diagnostic procedure.

Navigators may also interact with *providers*, both within and outside their immediate location. For example, s/he might speak with the physician to confirm the meaning of a test result before discussing it with the patient.

Nonclinical staff, such as receptionists or administrators coordinating insurance, represent another group with whom the navigator may interact.

People who provide *supportive services*, either formally (social workers, translators, transportation staff) or informally (friends, family) within or outside the facility are another group with whom navigators interact.

The final category—*paper or electronic medical record systems*—could be perceived as merely a means to communicate with members of the other four network categories, and it does function in that way. However, our preliminary observations indicated that, in the eyes of the navigator, the medical record itself takes on some of the qualities of a person, in that it needs to be informed and/or consulted before other actions are taken. This observation is consistent with those of many studies of human–computer interaction (Turkle 2003).

Observation Protocol Refinement

The current observation protocol incorporates solutions to problems encountered in the field using the preliminary observation guide. Initially, observers were required to take continuous notes, recording the duration and mode of the navigator's activity, the person with whom s/he spoke, the activity, and the patient on whose behalf the activity was taken, plus descriptive narrative. This recording burden proved too onerous in the field: recording all observed activities not only interfered with the primary goal of noting tasks and social networks used by the navigators, but it did not produce more useful data.

Based on this early finding, two important changes were made to the observation protocol: activities were observed in 15-minute intervals, and coding focused on the primary activity of each interval. This time sampling methodology facilitates detailed reporting of navigator activities without attempting to capture everything that occurs during an observation. Observers start a new form every 15 minutes, focusing notes and coding on the navigator's primary activity during that period. Thus, each hour of observation time yields four distinct chunks of description and activity coding. This sampling interval provides some sense of the relative proportion of a navigator's time spent on different activities, while allowing observers to record more detailed notes about the main activity. This approach necessarily involves some observer judgment: sometimes a navigator tackles multiple short tasks during a single 15-minute interval. In such instances, observers were instructed to either group-like tasks into a single entry (making appointment reminder calls to a list of patients could be meaningfully described as one task) or focus on the first activity during the time period.

Through discussion, a five-by-five matrix emerged, with tasks on the vertical axis and social networks on the horizontal axis. The observation form itself was redesigned to incorporate on a single page both this simple matrix and an open area for handwritten fieldnotes (see Figure 1).[1]

After field testing, several additional refinements were made. Certain combinations of tasks and networks cannot occur. For example, the task of navigating can be performed only with a patient, while reviewing a patient's file can be done only with the medical record. To further simplify the form, matrix cells representing combinations that cannot occur are blacked out.

Also, observers at some sites reported that a significant amount of navigation is carried out by telephone, leaving and returning voicemail messages. Therefore, for each observation of a navigator action that involves contact with a patient, the observer also notes whether the interaction is *synchronous*

Figure 1: Protocol Data Collection Form

*** Begin a new form every 15 minutes ***

Fieldnotes:

For each task observed, mark the appropriate empty cell. (Darkened cells are not in use.)

		1	2	3	4	5
	Tasks/Network	**Patient (S or A)**	**Provider**	**Non-clinical staff**	**Supportive services**	**Med rec / EMR**
A	Navigate with specific patient (tell, inquire, support, coach)					
B	Facilitate for specific patient (bring pt in, coordinate comm, seek advice)					
C	Maintain system for all patients (ID potential pts, build int/ext networks)					
D	Document/Review (record info, actions, results)					
E	Other (do research, provide clinic back-up, do non-nav tasks, socialize)					

If you cannot decide what box to mark, check here: _____

(happening in real time) or *asynchronous* (delayed, as when leaving a voicemail) by recording either "S" or "A" in the appropriate cell. For all other cells in the matrix, a checkmark is used.

Finally, because some observed activities may involve more than one person or task, observers are encouraged to mark more than one cell if that

best reflects what they are seeing. For example, if the navigator accompanies a patient to a physician visit, the observer puts an "S" in the cell representing "navigate/patient" and a checkmark in the box representing "facilitate/provider."

The matrix supports coding of real-time activities as they occur, but we realized the need for simultaneous, structured, narrative fieldnotes, as well. Hence, we developed observation guidelines directing the observer to note relevant contextual factors, such as the location of navigation activity, the language used in navigation, the racial/ethnic backgrounds of both patient and navigator if known, and the navigator's other roles (if any) in the organization.

This matrix facilitates rapid categorization of tasks and networks, allowing the observer to concentrate on writing narrative description that will document important information about context and content that cannot be fully captured by the matrix. The observer is encouraged to ask the navigator questions to develop a better understanding of what the navigator is doing and why.[2] Observers also are asked to record their impressions about interactions, clearly identifying these notes as their perceptions. For example, the observer might write "navigator and patient embraced warmly and seem to know each other well." While these impressions are particular to specific observers, they nevertheless add richness to the description.

DISCUSSION

Patient navigation represents an emerging innovation in care adapted to a variety of specific local contexts. Capturing local adaptations is crucial to meaningfully assess the efficacy of navigation across different sites. The protocol we have developed reflects a plausible, generic definition of navigation that has been found thus far to be applicable in multiple contexts. We expect the protocol to be useful in capturing the existing variation in navigation programs, and we will use it for this purpose as our research program goes forward. This type of data is essential to inform both research and practice.

While this protocol represents an important step, it certainly does not capture every detail of navigators' actions. For example, while interactions with other providers are categorized and noted, the protocol does not note how extensive or collaborative they might appear to be. Data from narrative fieldnotes will compensate for this limitation, while also providing the potential for further revisions to the protocol based on emerging patterns in these data.

This protocol is grounded in a qualitative study of navigation in three sites of the PNRP. As such, it has a measure of validity, yet its validity requires further examination through application. The current definitions of the task/network categories may reflect the particular realities of the sites we have observed in developing the protocol; they may evolve as new sites are studied. Likewise, variation in organizational, political, and community contexts in which operational navigation programs are developed may require modifications to this protocol. Moreover, while this protocol enables the systematic observation of what navigators do, it is only part of a comprehensive method for evaluating the processes and outcomes of patient navigation. The mix of patients served, their resources and ability to access care; the types of health problems for which access is needed; and the specific array of health services and providers for which navigation is needed must be taken into account in evaluating the effectiveness of what navigators do, as captured by this, or any protocol.

To further investigate the protocol's validity, we are implementing it on a wider scale. It is being used at eight sites to produce a dataset of approximately 130 observations (four half-day observations of each navigator at each site). As of this writing, 89 observations have been completed, and none has presented activities that fall outside the task/network categories described above. Quantitative and qualitative analyses of the data collected will enable the research team to characterize variation, both within and across sites, in navigator tasks, networks, and emphasis.

Protocol development thus far has illuminated important dimensions along which navigation programs may vary. By accurately characterizing this variation, researchers should be better able to interpret variation in patient outcomes associated with different navigation programs. While this protocol does not provide information on program effectiveness, it provides important process information that may help explain the connections between navigation context and outcomes. Of course, outcomes also may be affected by the actions of other health care providers and advocates, which may overlap with the actions of navigators. It is important not to over-attribute outcomes to the actions of specific navigators, but rather to keep analysis at the programmatic level. In other words, while patient navigator actions may often be directed at specific patients, navigation is properly conceptualized as a systemic intervention that changes how care is delivered. Thus, any change in outcomes observed may be the result of the actions of multiple individuals, including the navigator, whose actions have been influenced by the presence of the navigation program. The information obtained from further use of this protocol

to study the work of navigators may also inform the processes of selecting, training, supervising, and supporting navigators, as it will illuminate different practices that might optimize desired navigation program outcomes.

ACKNOWLEDGMENTS

Joint Acknowledgment/Disclosure Statement: The research reported in this paper was supported by a grant from the Avon Foundation to Boston Medical Center (BMC), which subcontracted with the research teams at University of Chicago (Chicago) and University of Rochester Medical Center (Rochester). Battaglia is principal investigator of the project. Parker is co-principal investigator; Clark, co-investigator; Freund, clinical consultant; and Leyson, research assistant. All authors except Parker are also principal investigators, co-principal investigators, or research staff at their respective participating sites in the National Cancer Institute's Patient Navigation Research Project (PNRP).

Approximate models for aggregate data when individual-level data sets are very large or unavailable

Erol A. Peköz,[a*†] Michael Shwartz,[a,b] Cindy L. Christiansen[c] and Dan Berlowitz[d]

In this article, we study a Bayesian hierarchical model for profiling health-care facilities using approximately sufficient statistics for aggregate facility-level data when the patient-level data sets are very large or unavailable. Starting with a desired patient-level model, we give several approximate models and the corresponding summary statistics necessary to implement the approximations. The key idea is to use sufficient statistics from an approximate model fitted by matching up derivatives of the models' log-likelihood functions. This derivative matching approach leads to an approximation that performs better than the commonly used approximation given in the literature. The performance of several approximation approaches is compared using data on 5 quality indicators from 32 Veterans Administration nursing homes. Copyright © 2010 John Wiley & Sons, Ltd.

Keywords: approximate Bayesian models; confidential data; Poisson binomial

1. Introduction

The field of approximate Bayesian computation (ABC) has developed in reaction to the computational demands of the growing size of data sets used in biology [1]. It is often necessary to summarize a huge amount of data by a few well-chosen summary statistics in situations where there are no exact sufficient statistics available. The recent article by Joyce and Marjoram [2] develops a framework for assessing whether an approximately sufficient statistics is useful; Le Cam [3] also addresses the concept of approximate sufficiency.

In this article, we look at a common statistical model often used to profile health-care facilities and develop customized approximately sufficient statistics. The setting of the problem is that there is a large amount of patient-level data located at many different facilities. A research group has developed risk-adjustment models to compute from the individual-level patient data a predicted probability that each patient experiences each of the different adverse events of interest and has developed a software that allows individual providers to calculate expected rates of adverse events; providers can compare these expected rates to observed rates as a way of monitoring their performance over time. In addition, a policy group would like to profile facilities. However, due to the volume of data and possible concerns about patient confidentiality, it is not feasible to transmit patient-level data to the policy group.

A realistic context for this problem arises out of software developed by the Agency for Healthcare Research and Quality (AHRQ) that hospitals can download in order to calculate risk-adjusted rates of patient safety indicators and of inpatient quality indicators from their own administrative data. As other measures of quality become acceptable (e.g. hospital re-admission rates), AHRQ is likely to continue to develop the software for calculation of relevant risk-adjusted rates. This software makes it easy for hospitals to use the quality indicators as part of their quality improvement programs. A useful service that AHRQ, other federal or state agencies, or private organizations could provide is to profile hospitals

based on the data generated from the software. Such an organization would encourage hospitals to submit results from use of the risk-adjustment software (much as AHRQ encourages hospitals to submit the results from use of its Hospital Survey on Patient Safety Culture, from which it then prepares comparative reports). To encourage flexibility in profiling, it would be most desirable for each hospital to submit, for each eligible patient for each adverse event of interest, the predicted probability of the outcome and whether or not the adverse event occurred. However, this would involve the transfer of large volumes of information. In addition, because patient-level information is being transferred, a variety of IRB considerations are likely to arise.

The goal of the research we present here is to identify useful summary statistics on quality indicators at each facility that can be conveniently transmitted to the profiling organization so that estimation approaches involving 'shrinkage' across facilities can be done. It is natural to consider sufficient statistics for this purpose, but there are none in our setting. We evaluate several alternate approaches to deal with the lack of sufficient statistics and identify one that performs well and does not introduce any computational complexity.

The organization of this article is as follows: In Section 2, we describe the statistical model and discuss the fact that sufficient statistics are not available. In Section 3, we describe the data to which we will apply our approach. In Section 4, we discuss two approaches for fitting approximate models for the data. In Section 5, we discuss the approximate models, in Section 6 we illustrate our approach using the data, in Section 7 we give a summary of the results, and Section 8 is an appendix containing the proofs.

2. The model

Let X_{ij} be a binary data variable that equals 1 if a particular adverse event happens to patient i, $1 \leqslant i \leqslant N_j$, in health-care facility j, $1 \leqslant j \leqslant M$, and it equals zero otherwise. We are interested in the following hierarchical model, which we subsequently refer to as the 'exact' model, where X_{ij} are the data values, p_{ij} are known constants, f is a given (known) link function and θ_j, μ, σ are unknown parameters that we would like to estimate:

$$X_{ij}|\theta_j, p_{ij} \sim \text{Bernoulli}(f(\theta_j, p_{ij})) \quad \text{and} \quad \theta_j|\mu, \sigma \sim \text{Normal}(\mu, \sigma^2). \tag{1}$$

In this model, p_{ij} is a risk-adjusted probability that has been previously calculated by taking into account various patient-specific characteristics, and it represents the chance patient i at facility j would have an adverse event if they were at an average facility. The parameter θ_j is a facility-specific factor, representing the quality at facility j, that increases or decreases the probability of an adverse event for the facility's patients. Note that this is a random effect model and therefore there should be shrinkage across facilities when estimating the model parameters. Our goal is to estimate the parameters θ_j for a function f such as

$$f(\theta, p) = \text{logit}^{-1}(\theta + \text{logit}(p)) = (1 + (1-p)e^{-\theta}/p)^{-1},$$

which we refer to as the logit link function, or

$$f(\theta, p) = \min(1, pe^{\theta}),$$

which we refer to as the log link function. These functions are both sensible to use, as they both equal p when $\theta = 0$ and they are increasing in θ. This means $\theta = 0$ corresponds approximately to an average facility and higher values of θ represent worse facilities. Typically, the function f will be increasing in θ and will have $f(0, p) = p$.

The standard Bayesian hierarchical modeling approach is to put prior distributions on the unspecified parameters and estimate the means of all the parameters conditional on the data. The difficulty in this situation is that the values of X_{ij} and p_{ij} are both confidential and are too numerous to conveniently transmit from each of the facilities to the main organization that performs the profiling. We need a method for summarizing these sets of numbers so that each facility only needs to report a small number of summary statistics. The usual approach is to use sufficient statistics, but, as we discuss in Section 4 below, there are no sufficient statistics we can use because the p_{ij} parameters are different across the N_j patients—if they were identical, we could use the total number of adverse events as a sufficient statistic which, conditional on the parameters, would have a binomial distribution. When they are not identical, the sum has what is called a Poisson-binomial distribution: the sum of independent Bernoulli trials with different success probabilities.

To implement the model in (1), it may seem as though each facility could simply transmit the maximum likelihood estimate of θ_j, but once these are gathered together there would be no obvious way to accurately allow for 'shrinkage' of the estimators across facilities. In fact, we test the approach of having each facility transmit the posterior mean and standard deviation of θ_j using separate (fixed-effect) models and then 'shrinking' them at the central organization using the assumption that they have a normal distribution. This approach does not work well on the data to which we applied it;

we call this the 'two-stage normal' approximation and illustrate it in Table III below. What is really necessary is for each facility to transmit enough information so that the central organization can, as best as possible, re-create the entire likelihood function for the data from each facility as a function of θ.

As there are no sufficient statistics available, the key idea we propose in this article is to use sufficient statistics from an approximate model fitted by matching moments or derivatives of the models' log-likelihood functions. In our recommended approach, described in Proposition 2 below, we use a binomial distribution to approximate the sum of non-identically distributed Bernoulli random variables where the two parameters of this distribution (the number of trials and the probability of success) are fitted using the first two moments of the probabilities from each facility. As a result, each health-care facility will simply need to report the total number of adverse events, as well as the first two moments of the predicted probabilities. For a different approach to approximating a similar model, see [4].

3. About the data

The data for this study were originally collected in 1998 from 35 Department of Veterans Affairs (VA) nursing homes that were selected to represent a balanced sample of different sizes, locations, and quality of care [5]. Complete data were available from 32 of the 35 nursing homes on five binary quality indicators (QIs) that reflect changes in patients' status over time. These 32 facilities are the ones included in our study. All the QIs have been used previously as measures of nursing home quality: pressure ulcer development [6–9]; functional decline [7–9]; behavioral decline [7, 10]; mortality [7, 11]; and preventable hospitalizations [12].

Data used in calculating QIs were from semi-annual patient assessments performed for case-mix-based reimbursements. Pressure ulcer development was recorded if a patient who was ulcer free at one assessment had a stage 2 or deeper pressure ulcer at the subsequent assessment. Functional decline was measured by a change between assessments in a score measuring limitations in eating, toileting, and transferring. Behavioral decline was measured by a change in a score measuring extent of verbal disruption, physical aggression, and socially inappropriate behavior. Mortality was recorded if there is a death within 6 months of an assessment regardless of location. Preventative hospitalizations occurred if the patient was admitted to an acute medical unit within 6 months of an assessment for one of 13 conditions identified as a potentially preventable hospitalization [13]. Risk-adjustment models have been developed for these QIs: pressure ulcer development [6], functional decline [14], behavioral decline and mortality [15], and preventable hospitalizations [16].

For each patient, the risk-adjustment models give a predicted probability of the adverse event in a six-month period based on the risk factors at the time of initial assessment. Thus, for each patient, we know whether each adverse event occurred (indicated by a 0 or 1) and the predicted probability of the adverse event from the relevant risk-adjustment model. Table I shows percentiles of the distribution of the predicted probabilities for each of the QIs. For 4 of the 5 QIs, individual predictions range from close to 0 to around 0.50 to 0.60; for mortality, there is a longer right tail, with predictions ranging almost to 1.

Table II shows percentiles of the distribution of the number of eligible cases (the total number of people who could potentially have the given adverse event) at each facility for the pressure ulcer and mortality QIs. The number of eligible cases ranges from 32 to over 400 for pressure ulcers (and for functional decline and behavioral decline, not shown in the table); and from slightly over 80 to almost 1200 for mortality (and preventable hospitalizations, also not shown). The second part of Table II shows percentiles of the distribution of the ratio of the observed number of adverse events at each facility to the predicted number for each of the QIs. The distribution is quite wide for 3 of the QIs, ranging from zero to over 2; it is tightest for mortality, ranging from 0.65 to 1.29.

Table I. Percentiles of the distribution of predicted probabilities by type of adverse event (pu—pressure ulcer development; fd—functional decline; bd—behavioral decline; mort—mortality; ph—preventable hospitalization).

Percentile	pu	fd	bd	mort	ph
Maximum	0.469	0.512	0.545	0.978	0.573
95th	0.107	0.348	0.320	0.759	0.197

Maximum	408	1193	2.07	2.26	2.78	1.29	1.59

4. Two approaches for finding an approximate model

The log-likelihood function for the data at facility j under the model in (1) is

$$LL_j(\theta)=\sum_i X_{ij}\log f(\theta, p_{ij})+(1-X_{ij})\log(1-f(\theta, p_{ij})). \tag{2}$$

In general, there are no sufficient statistics for the individual-level data X_{ij} under this model. For example, with $M=1$ facility having $N_1=2$ patients with probabilities $p_1=\frac{1}{3}$, $p_2=\frac{1}{4}$ (omitting the subscript j) and $f(\theta, p)=\theta p$, we simplify (2) to get

$$LL(\theta)=X_1\log\frac{\theta}{3-\theta}+X_2\log\frac{\theta}{4-\theta}+\log\frac{\theta}{3-\theta}+\log\frac{\theta}{4-\theta}.$$

Since this log-likelihood is of the form aX_1+bX_2+a+b, it can be seen that this cannot be expressed in terms of two quantities where one depends on a, b but not X_1, X_2 and the other depends on X_1, X_2 but not a, b.

In the absence of a sufficient statistic, we therefore propose several alternative approximate models for the data for which the sum of the data values

$$X_j=\sum_i X_{ij}$$

is a sufficient statistic for a facility. Notice, we omit the subscript i to indicate that the binary variables have been summed over i for a given facility.

We say that an approximate model for the data is a k moment approximation if, when $\theta=0$, the first k moments of X_j conditional on all other parameters under the exact model coincide with the corresponding conditional moments under the approximate model. We also say that an approximate model for the data is a k derivative approximation for the exact model if the first k derivatives of its log-likelihood function with respect to θ evaluated at $\theta=0$ match the first k derivatives for the exact model $LL_j(\theta)$.

These definitions can be formalized by saying that an approximate model for the data X_j given θ_j along with some set of parameters S is a k moment approximation if, with the above definitions

$$E[(X_j)^m|\theta_j=0, p_{1j}, p_{2j}, \ldots]=E^a[(X_j)^m|\theta_j=0, S]$$

for $m=1, 2, \ldots, k$. We use the superscript a to denote expectations with respect to the approximate model. An approximate model with log-likelihood function $LL_j^a(\theta)$ for the data X_j is a k derivative approximation with respect to θ if

$$\frac{\partial^m}{\partial\theta^m}LL_j^a(\theta)|_{\theta=0}=\frac{\partial^m}{\partial\theta^m}LL_j(\theta)|_{\theta=0} \quad \text{for } m=1, 2, \ldots, k. \tag{3}$$

We say that an approximate model with multiple parameters is a k derivative approximation with respect to a given set of parameters if (3) holds with respect to each parameter separately.

Both these approaches seem sensible. The moment approximation is simpler in the sense that it does not depend on the link function f, whereas the derivative approximation does depend on f. As we show empirically later, when they are different, the derivative approximation performs better. For some choices of f the two approximations will coincide, whereas for others they will be different.

The intuition for why the derivative approximation performs better is the following: To estimate the distribution of X_j conditional on the parameters, it seems best to match moments to directly approximate the distribution. To approximate

the posterior distribution of θ conditional on the data requires the likelihood function and so it seems natural that the best performance is obtained when the likelihood function is directly approximated using an approach such as the derivative approach.

In order to find a good approximation for this model, it is important for practical reasons that it be easy to implement in standard Bayesian software packages like WINBUGS. Thus, it would be best to use only common distributions such as the binomial, Poisson or normal. In the article by Peköz *et al.* [17], several different approximations to the distribution of the sum of independent Bernoulli random variables are considered and evaluated. A Poisson approximation performs well if the Bernoulli probabilities are all very small. The normal approximation performs well if the probabilities are mostly near $\frac{1}{2}$. The binomial distribution performs well if the probabilities are either very small or very large overall—or very similar to each other. In practical applications, the probabilities will be quite diverse: some facilities will have very low numbers while others have probabilities spread more evenly between zero and one. It is therefore important to have an approximation that can flexibly adapt across all the situations. With a standard binomial approximation, it makes sense to pick the probability parameter to match the mean of the distribution to be approximated. One way of improving the binomial approximation is to let both the probability and the number of trials be two free parameters that can be fitted. This means in principle it may be possible to match the first two moments. Another idea for improving the Poisson approximation is to consider a translated Poisson approximation where a constant is added to a Poisson random variable. The constant and the Poisson rate are then two free parameters that can be adjusted to approximately match the first two moments.

A good combination of these ideas is to try a translated binomial approximation, where a constant is added to a binomial random variable. This then allows three parameters to be adjusted and, in most cases, three moments or three derivatives could be matched. The article by Peköz *et al.* [17] evaluates all the approximations discussed here (and derives error bounds) over a range of different settings and finds that a translated binomial approximation performs the best. As we show later, our analysis demonstrates that a binomial approximation with two fitted parameters performs much better than the usual binomial approximation with one fitted parameter, and the three parameter binomial approximation does not perform much better than the two parameter binomial approximation—though it requires additional computations and data to be transmitted and stored. We will therefore recommend the two-parameter binomial approximation, though we will illustrate all three approximations below. Once an approximation is fit to the data, the unknown parameters can be computed using either a Bayesian approach in WINBUGS, maximum likelihood estimation or other transform methods [18].

5. The approximate models

The first approximation we propose is one that is commonly used and is both a one-moment approximation and one-derivative approximation. It assumes that X_j, conditional on the parameters, has a binomial distribution, where the number of trials is the number of eligible cases and the binomial probability is chosen to be the average Bernoulli probability at that facility. To implement this approximation, each facility must simply transmit the total number of adverse events X_j along with the total number of eligible cases N_j and the average probability $p_j = \sum_i p_{ij}/N_j$ at that facility. This first approximation is summarized next.

Proposition 1
The one moment, one-derivative approximation. With the above definitions and the model in (1) with

$$f(\theta, p) = \text{logit}^{-1}(\theta + \text{logit}(p)),$$

and $p_j = \sum_i p_{ij}/N_j$, the model

$$X_j|\theta_j, p_j \sim \text{Binomial}(N_j, f(\theta_j, p_j))$$

is both a one-moment approximation and a one-derivative approximation with respect to θ_j, $j = 1, \ldots, M$ for the exact model (1).

Proof
See Appendix.

The second approximation we propose is both a two-moment approximation and a two-derivative approximation for the exact model. It assumes that X_j, conditional on the parameters has a binomial distribution, where the number of trials and the probability of success are both chosen to match the first two moments. This means that the number of trials in the binomial distribution n_j will not necessarily equal the number of eligible cases N_j in the facility. To implement this

approximation, each facility must simply transmit the total number of adverse events X_j along with the first two moments of the probabilities $\sum_i p_{ij}^2$ and $\sum_i p_{ij}$. We will recommend this approximation based on the numerical illustrations below.

Proposition 2
The two-moment, two-derivative approximation. With the above definitions and the model in (1) with

$$f(\theta, p) = \text{logit}^{-1}(\theta + \text{logit}(p)),$$

and $p_j = \sum_i p_{ij}^2 / \sum_i p_{ij}$, $n_j = \sum_i p_{ij} / p_j$, the model

$$X_j | \theta_j, n_j, p_j \sim \text{Binomial}(n_j, f(\theta_j, p_j))$$

is both a two-moment approximation and a two-derivative approximation with respect to θ_j, $j = 1, \ldots, M$ for the exact model (1).

Proof
See Appendix.

Remark 1
With the above definition, n_j may not necessarily be an integer, though the number of trials in a binomial distribution must be an integer. In principle, we could round off the number of trials to the nearest integer. In practice, we are using the likelihood as a function of θ and so the use of non-integer values in some sense represents an interpolation of the likelihood functions at the two adjacent integer numbers of trials. Standard software packages such as WINBUGS allow non-integer values for the number of trials in a binomial distribution and so a non-integer n_j is not a limitation of the approach. So that the propositions make sense, we can assume that n_j happens to be an integer—though the approximations can be improved using non-integer values.

Our third approximation is both a three-moment approximation and a three-derivative approximation. It assumes that X_j, conditional on the parameters, has a translated binomial distribution. A translated binomial distribution is simply a binomial distribution plus a constant. The three parameters, which consist of the number of trials, the probability of success and the amount translated, are chosen to match the first three moments. To implement this approximation, each facility must transmit the total number of adverse events X_j as well as the first three moments of the probabilities p_{ij}.

Proposition 3
The three-moment, three-derivative approximation. With the above definitions and the model in (1) with

$$f(\theta, p) = \text{logit}^{-1}(\theta + \text{logit}(p)),$$

and $\lambda_{kj} = \sum_i (p_{ij})^k$ along with

$$p_j = \frac{\lambda_{2j} - \lambda_{3j}}{\lambda_{1j} - \lambda_{2j}},$$

$$n_j = \frac{\lambda_{1j} - \lambda_{2j}}{p_j(1 - p_j)},$$

$$s_j = \lambda_{1j} - n_j p_j,$$

the model

$$(X_j - s_j | \theta_j, s_j, n_j, p_j) \sim \text{Binomial}(n_j, f(\theta_j, p_j))$$

is both a three-moment approximation and a three-derivative approximation with respect to θ_j, $j = 1, \ldots, M$ for the exact model (1).

Proof
See Appendix.

Remark 2
It may be that the quantity s_j is not an integer. However, as discussed in Remark 1 above, this is not a limitation.

Our next result is that for the log link function $f(\theta, p) = \min(1, pe^{\theta})$, the k moment approximations above do not coincide with the k derivative approximations. We can derive a different k derivative approximation. Empirical evidence shows that this performs much better than the k moment approximation.

Proposition 4
The two-derivative approximation differs from the two-moment approximation with the log link function. With the above definitions and the exact model in (1) with

$$f(\theta, p) = \min(1, pe^{\theta}),$$

and $p_j = \sum_i p_{ij}^2 / \sum_i p_{ij}$, $n_j = \sum_i p_{ij} / p_j$, the model

$$X_j | \theta_j, n_j, p_j \sim \text{Binomial}(n_j, f(\theta_j, p_j))$$

is a two-moment approximation but is not a two-derivative approximation with respect to θ_j, $j = 1, \ldots, M$ for the exact model (1).

Proof
See Appendix.

We next present the two-derivative model for the log link function.

Proposition 5
With the above definitions and the exact model in (1) with

$$f(\theta, p) = \min(1, pe^{\theta}),$$

and

$$\alpha_j = \sum_i \frac{p_{ij}}{1 - p_{ij}} (1 - X_{ij}),$$

$$\beta_j = \sum_i \frac{p_{ij}}{(1 - p_{ij})^2} (1 - X_{ij}),$$

and letting

$$p_j = 1 - \alpha_j / \beta_j,$$

and

$$n_j = \frac{\alpha_j^2}{\beta_j - \alpha_j} + X_j$$

the model

$$X_j | \theta_j, n_j, p_j \sim \text{Binomial}(n_j, f(\theta_j, p_j))$$

is a two-derivative approximation with respect to θ_j, $j = 1, \ldots, M$ for the exact model (1).

Proof
See Appendix.

The final result in this section is a straightforward extension to multiple types of adverse events. Note in this model that θ_j is an underlying latent measure of quality at facility j that is reflected in the data for each of the quality indicators.

Proposition 6
A model for multiple adverse events. Suppose there are m different types of adverse events. Let X_{ijk} equal 1 if person number i in facility number j has an adverse event of type k, $1 \leqslant k \leqslant m$, and let it equals zero otherwise. Let p_{ijk} be the given probability associated with this variable. For the kth type of adverse event, we define

$$f_k(\theta, p) = \text{logit}^{-1}(d_k + c_k \theta + \text{logit}(p)).$$

Suppose that

$$X_{ijk} | \theta_j, p_{ijk} \sim \text{Bernoulli}(f_k(\theta_j, p_{ijk})) \quad \text{and} \quad \theta_j | \mu, \sigma \sim \text{Normal}(0, 1) \tag{4}$$

is the exact model for some unknown parameters c_k, d_k that are to be estimated. With $X_{jk} = \sum_i X_{ijk}$ along with $p_{jk} = \sum_i (p_{ijk})^2 / \sum_i p_{ijk}$, $n_{jk} = \sum_i p_{ijk} / p_{jk}$, the model

$$(X_{jk} | \theta_j, n_{jk}, p_{jk}) \sim \text{Binomial}(n_{jk}, f_k(\theta_j, p_{jk}))$$

Table III. The approximate models.

Proposition	Approximation (link function)	Summary statistics necessary
1	1-moment, 1-derivative (logit)	$N_j, \sum_i p_{ij}, \sum_i X_{ij}, \forall j$
2	2-moment, 2-derivative (logit)	$\sum_i p_{ij}^2, \sum_i p_{ij}, \sum_i X_{ij}, \forall j$
3	3-moment, 3-derivative (logit)	$\sum_i p_{ij}^3, \sum_i p_{ij}^2, \sum_i p_{ij}, \sum_i X_{ij}, \forall j$
4	2-moment (log)	$\sum_i p_{ij}^2, \sum_i p_{ij}, \sum_i X_{ij}, \forall j$
5	2-derivative (log)	$\sum_i \frac{p_{ij}}{1-p_{ij}}(1-X_{ij}), \sum_i \frac{p_{ij}}{(1-p_{ij})^2}(1-X_{ij}), \sum_i X_{ij}, \forall j$
6	2-moment, multiple QIs (logit)	$\sum_i p_{ijk}^2, \sum_i p_{ijk}, \sum_i X_{ijk}, \forall j,k$

is both a two-moment approximation and a two-derivative approximation with respect to θ_j, $j=1,\ldots,M$ for the exact model in (4) when $c_k=1$, $d_k=0$ for $1\leqslant k\leqslant m$.

Proof
See Appendix.

We summarize all the approximations, along with the necessary summary statistics, in Table III.

6. Numerical results and comparison of the approaches

In this section, we illustrate the different approximations. We will see that the two-derivative approximations (for both link functions we consider) seem to perform much better than the one-derivative approximations, and (for the logit link function) the three-derivative approximation performs quite similarly to the two-derivative approximation—though all the approximations are fairly reasonable. We will illustrate the approximations using two different approaches. In the first approach, we test the approximations on data from the Veterans Health Administration—see Section 3 for a description of the data.

To do the computations, we put flat priors on the top level unknown parameters and then estimate the posterior means of the facility effects conditional on the data under the exact model and various approximate models. We use the notation $\bar{\theta}_j$ to denote our numerical estimate (computed by averaging together samples from the posterior distribution using the software package WINBUGS) of the posterior mean $E[\theta_j|X_{ij},\forall i,j]$ under the exact model and we use the notation $\bar{\theta}_j^a$ to denote our numerical estimate of the posterior mean $E^a[\theta_j|X_j,\forall j]$ under some given approximate model. For the illustrations below, we measure the accuracy of an approximation using the average of the absolute value of the difference between our estimate of the facility-effect parameters under the approximate and exact models. We compute this using

$$\text{Error}=\frac{1}{M}\sum_{j=1}^{M}|\bar{\theta}_j-\bar{\theta}_j^a| \tag{5}$$

except for the multiple quality indicators in Proposition 6, where we instead use

$$\text{Error}=\frac{1}{m}\sum_{k=1}^{m}\frac{1}{M}\sum_{j=1}^{M}|\bar{\theta}_{j,k}-\bar{\theta}_{j,k}^a|, \tag{6}$$

where $\theta_{j,k}=d_k+c_k\theta_j$ and $\theta_{j,k}^a=d_k^a+c_k^a\theta_j^a$.

First, we illustrate the approximations given in Propositions 1, 2, 3. The top half of Table IV gives the errors for models using the logit link function $f(\theta,p)=\text{logit}^{-1}(\theta+\text{logit}(p))$. The standard deviation of the effect sizes in Table V, when compared with the first row of Table IV, shows that the error from the one-moment approximation is not bad; in many cases, it is of a smaller order of magnitude than the estimated standard deviation (of the effect size θ in Table V). The second line shows that the two-moment approximation is always much better than the one-moment approximation. In several cases, the error is an order of magnitude improvement on the one-moment approximation in the prior line. The third line of the table shows that the three-moment approximation does not perform consistently better than the two-moment approximation with the logit link function. The rightmost column (labeled as '3QIs') shows that when multiple quality indicators are included in the model (using the approach of Proposition 6 above, where only the two-moment case is illustrated—the one- and three-moment versions are analogous to those in Propositions 1 and 3) the

two-moment approximation performs much better than the one-moment, and the three-moment approximation performs quite similarly to the two-moment approximation.

The fourth line of the table, labeled 'two-stage normal,' illustrates an approximation approach where each facility separately computes its best estimate of θ_j, which is then transmitted to the organization and 'shrunk' using a hierarchical model. Specifically, first the posterior mean and standard deviation for θ_j is computed separately for each facility using a fixed-effects model with a flat prior for θ_j. Then, these facility estimates are combined in a model where we assume the θ_j values are the sum of two draws from a normal distribution: one is a distribution with an unknown mean and standard deviation that is common to all facilities, and the other is an error term that is normally distributed with mean zero and standard deviation which is specific to each facility. The fourth line shows that this approximation approach performs better than the one-moment approximation in most cases—though in cases where there are facilities with zero observed adverse events (for pu and bd), it performs much worse. Some adjustments to the model would need to be made to account for zero values. But, the approximation is not nearly as good as the two-moment approach in most cases.

The last two rows of the table show, using the log link function $f(\theta, p)=\min(1, pe^{\theta})$, that the two-derivative approximation in Proposition 5 performs much better than the two-moment approximation. This is evidence for the theory that the derivative approach works better than the moment approach when they differ.

In the second approach, we use to illustrate the accuracy of the approximations, we generate simulated data and compare the maximum likelihood estimates of the unknown parameters across the different models. In particular, we create a single health-care facility with 100 patients having predetermined risk-adjusted probabilities. In the first simulation, we create these probabilities according to equally spaced percentiles of a beta distribution with a coefficient of variation equal to 1; in the second simulation, the coefficient of variation is equal to 0.4. We also vary the means of these distributions from 0 to 0.2. These ranges are chosen in order to mimic the summary statistics we saw in the actual data for the risk-adjusted probabilities. We also use different values of the unknown parameter θ ranging from 0 through 4. Given specific values of the parameters, we use the logit link function to generate simulated data and then compute the maximum likelihood estimate of θ under the exact model and then under the various approximations. Our simulations show that when θ is in the range from 0 to 2, the two-moment approximation generally performs better than the one-moment approximation. As the value of the θ parameter becomes very large (this corresponds to the case where there is a large amount of variation in the risk-adjusted probabilities across facilities and implies large differences in underlying quality), we see that a two-moment approximation performs worse than the one-moment approximation. As there is rarely such large variation in underlying quality across facilities, it is not a surprise that the two-moment approximation performs well when tested on real data.

7. Conclusion

In conclusion, we see that the two- and three-derivative approximations performed the best. The three-derivative approximation requires more data and performs similarly to the two-derivative approximation, and so we recommend the two-derivative approximation. For the logit link function, the two-derivative and two-moment approximations are identical though, for the log link function, the two-derivative approximation seems to perform better. To implement the

two-derivative approximation, each health-care facility needs to report three summary statistics to the central profiling organization: the first two moments of the predicted risk-adjusted probabilities, as well as the total number of adverse events occurring. Then, the two-parameter binomial distributional approximation described in Proposition 2 can be fitted and used to estimate the likelihood function.

The approach we recommend is nice because the approximation is quite simple and easy to implement. The standard (one-moment) binomial approximation is commonly used and this two-parameter binomial approximation is an improvement with essentially no additional computational costs or model complexity other than computing and transmitting one additional summary statistic.

Appendix

In this section, we prove the propositions above. We drop the facility subscript j in each proof.

Proof of Proposition 1
As the first moment of a binomial distribution equals np, the fact that this model is a one-moment estimator follows immediately. To see that it is also a one-derivative estimator, let

$$f(\theta, p)=\frac{1}{1+\dfrac{1-p}{p}e^{-\theta}},$$

and recall that the exact log-likelihood function is

$$LL(\theta)=\sum_i X_i \ln(f(\theta, p_i))+(1-X_i)\ln(1-f(\theta, p_i)).$$

The log-likelihood function for this approximation is

$$LL^a(\theta)=X\ln(f(\theta, p))+(N-X)\ln(1-f(\theta, p))+c,$$

where we write $X=\sum_i X_i$ and $c=\ln(N!/(X!(N-X)!)$. It then follows that

$$\frac{\partial}{\partial\theta}LL(\theta)=\sum_i(p_i e^{-\theta}-e^{-\theta}-p_i)^{-1}(p_i-X_i p_i-X_i e^{-\theta}+X_i p_i e^{-\theta})$$

along with

$$\frac{\partial}{\partial\theta}LL^a(\theta)=(pe^{-\theta}-e^{-\theta}-p)^{-1}(Np-Xp-Xe^{-\theta}+Xpe^{-\theta}),$$

and we obtain

$$\frac{\partial}{\partial\theta}LL(\theta)|_{\theta=0}=\sum_i(X_i-p_i),$$

and

$$\frac{\partial}{\partial\theta}LL^a(\theta)|_{\theta=0}=(X-Np).$$

Solving the equation

$$\frac{\partial}{\partial\theta}LL(\theta)|_{\theta=0}=\frac{\partial}{\partial\theta}LL^a(\theta)|_{\theta=0}$$

for p yields the result of the proposition. □

Proof of Proposition 2
As the mean and variance of a binomial distribution equals np and $np(1-p)$ respectively, the fact that this model is a two-moment estimator follows immediately. To see that it is also a two-derivative estimator, we again let

$$f(\theta, p)=\frac{1}{1+\dfrac{1-p}{p}e^{-\theta}},$$

and recall that the exact log-likelihood function is

$$LL(\theta)=\sum_i X_i \ln(f(\theta, p_i))+(1-X_i)\ln(1-f(\theta, p_i)).$$

The log-likelihood function for this approximation is

$$LL^a(\theta)=X\ln(f(\theta, p))+(n-X)\ln(1-f(\theta, p))+c,$$

where we write $X=\sum_i X_i$ and $c=\ln(N!/(X!(N-X)!)$ and now the parameters n, p are both to be solved for. It then follows, using the results from the previous proposition, that

$$\frac{\partial^2}{\partial\theta^2}LL(\theta)=\sum_i(p_i e^{-\theta}-e^{-\theta}-p_i)^{-2}(p_i-1)(e^{-\theta})p_i,$$

and

$$\frac{\partial^2}{\partial\theta^2}LL^a(\theta)=(pe^{-\theta}-e^{-\theta}-p)^{-2}(p-1)(e^{-\theta})np,$$

and we obtain

$$\frac{\partial^2}{\partial\theta^2}LL(\theta)|_{\theta=0}=\sum_i(p_i^2-p_i),$$

and

$$\frac{\partial^2}{\partial\theta^2}LL^a(\theta)|_{\theta=0}=(np^2-np).$$

Using the results from the previous proposition, we can then solve the system of equations

$$\frac{\partial}{\partial\theta}LL(\theta)|_{\theta=0}=\frac{\partial}{\partial\theta}LL^a(\theta)|_{\theta=0},$$

and

$$\frac{\partial^2}{\partial\theta^2}LL(\theta)|_{\theta=0}=\frac{\partial^2}{\partial\theta^2}LL^a(\theta)|_{\theta=0}$$

for both n and p to obtain the result of the proposition. □

Proof of Proposition 3

The mean, variance, and third-central moment of a binomial distribution equals np, $np(1-p)$ and $np(1-p)(1-2p)$, respectively, and for a Poisson-binomial distribution W with probabilities $p_1, p_2, \ldots$ and $\lambda_j=\sum_i(p_i)^j$, we have $E[W]=\lambda_1$, $\mathrm{Var}(W)=\lambda_1-\lambda_2$ and $E[(W-E[W])^3]=\lambda_1-3\lambda_2+2\lambda_3$. The fact that this model is a three-moment estimator follows from these facts. To see that it is also a three-derivative estimator, we again let

$$f(\theta, p)=\frac{1}{1+\dfrac{1-p}{p}e^{-\theta}},$$

and recall that the exact log-likelihood function is

$$LL(\theta)=\sum_i X_i \ln(f(\theta, p_i))+(1-X_i)\ln(1-f(\theta, p_i)).$$

The log-likelihood function for this approximation is

$$LL^a(\theta)=(X-s)\ln(f(\theta, p))+(n-X-s)\ln(1-f(\theta, p))+c,$$

where we write $X=\sum_i X_i$ and $c=\ln(N!/(X!(N-X)!)$ and now the parameters s, n, p are all to be solved for. It then follows, using the results from the previous proposition, that

$$\frac{\partial^3}{\partial\theta^3}LL(\theta)=\sum_i(p_i e^{-\theta}-e^{-\theta}-p_i)^{-3}(p_i-e^{-\theta}+p_i e^{-\theta})(p_i-1)(e^{-\theta})p_i,$$

and

$$\frac{\partial^3}{\partial\theta^3}LL^a(\theta)=(pe^{-\theta}-e^{-\theta}-p)^{-3}(p-e^{-\theta}+pe^{-\theta})(p-1)(e^{-\theta})np,$$

and we obtain

$$\frac{\partial^3}{\partial\theta^3}LL(\theta)|_{\theta=0}=\sum_i(3p_i^2-p_i-2p_i^3),$$

and

$$\frac{\partial^3}{\partial\theta^3}LL^a(\theta)|_{\theta=0}=(3np^2-np-2np^3).$$

Using the results from the previous proposition, we can then solve the system of equations

$$\frac{\partial}{\partial\theta}LL(\theta)|_{\theta=0}=\frac{\partial}{\partial\theta}LL^a(\theta)|_{\theta=0},$$

$$\frac{\partial^2}{\partial\theta^2}LL(\theta)|_{\theta=0}=\frac{\partial^2}{\partial\theta^2}LL^a(\theta)|_{\theta=0},$$

and

$$\frac{\partial^3}{\partial\theta^3}LL(\theta)|_{\theta=0}=\frac{\partial^3}{\partial\theta^3}LL^a(\theta)|_{\theta=0}$$

for s, n and p to obtain the result of the proposition. □

Proof of Propositions 4 and 5

The fact that this approximation is a two-moment approximation follows from the argument in the proof of Proposition 2 above. Let

$$f(\theta,p)=pe^{\theta}$$

and recall that the exact log-likelihood function is

$$LL(\theta)=\sum_i X_i\ln(f(\theta,p_i))+(1-X_i)\ln(1-f(\theta,p_i)).$$

The log-likelihood function for this approximation is

$$LL^a(\theta)=X\ln(f(\theta,p))+(n-X)\ln(1-f(\theta,p))+c,$$

where we write $X=\sum_i X_i$ and $c=\ln(N!/(X!(N-X)!)$ and now the parameters n, p are both to be solved for. It then follows that

$$\frac{\partial}{\partial\theta}LL(\theta)=\sum_i X_i-e^{\theta}p_i\frac{1-X_i}{1-e^{\theta}p_i},$$

$$\frac{\partial^2}{\partial\theta^2}LL(\theta)=\sum_i -e^{\theta}p_i\frac{1-X_i}{1-e^{\theta}p_i}-e^{2\theta}p_i^2\frac{1-X_i}{(1-e^{\theta}p_i)^2}$$

along with

$$\frac{\partial}{\partial\theta}LL^a(\theta)=X-pe^{\theta}\frac{n-X}{1-pe^{\theta}},$$

and

$$\frac{\partial^2}{\partial\theta^2}LL^a(\theta)=-pe^{\theta}\frac{n-X}{1-pe^{\theta}}-p^2e^{2\theta}\frac{n-X}{(1-pe^{\theta})^2},$$

and we obtain

$$\frac{\partial}{\partial\theta}LL(\theta)|_{\theta=0}=\sum_i -p_i\frac{1-X_i}{1-p_i}-p_i^2\frac{1-X_i}{(1-p_i)^2},$$

and

$$\frac{\partial}{\partial\theta}LL^a(\theta)|_{\theta=0}=X-p\frac{n-X}{1-p},$$

and

$$\frac{\partial^2}{\partial\theta^2}LL^a(\theta)|_{\theta=0}=-p\frac{n-X}{1-p}-p^2\frac{n-X}{(1-p)^2}.$$

We can then solve the system of equations

$$\frac{\partial}{\partial\theta}LL(\theta)|_{\theta=0}=\frac{\partial}{\partial\theta}LL^a(\theta)|_{\theta=0}$$

along with

$$\frac{\partial^2}{\partial\theta^2}LL(\theta)|_{\theta=0}=\frac{\partial^2}{\partial\theta^2}LL^a(\theta)|_{\theta=0}$$

for both n and p to obtain the result of the proposition. □

Proof of Proposition 6
This proposition follows immediately from the same argument used to prove Proposition 2. □

Abstract

Exercise is known to facilitate physical and emotional adjustment among women treated for breast cancer, and exercise exerts a profound effect on clinical depression. However, the effect of exercise on reducing clinical depression among breast cancer patients has not been demonstrated, especially among ethnic minority women who have a higher incidence of depression and higher mortality following breast cancer. First, literature is presented to assess exercise effects on depression among women with breast cancer. Second, we present the results of a randomized controlled trial assessing the effect of a structured exercise intervention on depression and exercise behavior in a multiethnic sample of women with early stage breast cancer enrolled prior to the start of adjuvant treatment. Results suggest that, in comparison to population norms, the rate of depression was higher in breast cancer patients. Analyses further showed that the intervention significantly increased self-reported exercise and reduced depression. These data suggest that the beneficial effects of exercise may extend to breast cancer patients with depression and may be initiated prior to and during cancer treatment.

Key words: Exercise, breast cancer, depression

Corresponding author: Frank M. Perna, National Cancer Institute, Division of Cancer Control & Population Sciences, 6130 Executive Blvd., EPN 4074, Bethesda, MD 20892-7236. E-mail: pernafm@mail.nih.gov

Breast cancer is the second leading cause of cancer death for women in the United States, and the incidence rate of breast cancer has risen 24% in the last 10 years (Bigby & Holmes, 2005). It is estimated that clinical depression affects approximately 10-30% of women with early stage breast cancer, and patients diagnosed with cancer are more than three times as likely to experience depression in the following year (Deshields, Tibbs, Fan, & Taylor, 2006; Honda & Goodwin, 2004). Although this rate is higher than typically reported for women in the general population (20%), depression fortunately subsides over the course of breast cancer treatment and thereafter (Deshields et al., 2006). For example, Deshields and colleagues (2006) examined patterns of clinical depression among early stage breast cancer patients and noted that depression subsided in many women (recovery pattern) and did not occur in the majority of patients (resilience pattern), which is consistent with reports of positive emotional trajectories in most women in the year following surgery (Helgeson, Snyder, & Seltman, 2004).

Unfortunately, a significant number (12-29%) of women with breast cancer remain chronically depressed or become depressed during treatment and thereafter (Deshields et al., 2006). If left untreated, depression can become chronic and can increase the risk of chronic conditions such as cardiovascular disease (CVD), obesity, and diabetes (Chapman, Perry, & Strine, 2005). These data are particularly salient since many women—particularly black women—who are successfully treated for early stage breast cancer still experience untimely deaths attributable to CVD-related diseases (i.e., hypertension, diabetes; Bigby & Holmes, 2005).

Exercise and Clinical Depression

In the general population, exercise is consistently associated with a large reduction in clinical depression with effect sizes (ESs) ranging from 0.72 to 1.4 (Craft & Landers, 1998; Lawlor & Hopker, 2001). These ESs correspond to a 67-79% improvement in depression; only a 50% reduction in symptoms is considered clinically significant (Craft & Perna, 2004). Further, meta-analytic findings show the following regarding exercise: (a) it is effective for a variety of patient subgroups, (b) it is not significantly different from psychotherapy and pharmacological treatment, (c) it appears to equally benefit individuals with mild and severe depression (Craft & Landers, 1998).

Exercise and Breast Cancer

Randomized controlled trials have consistently demonstrated the psychosocial benefits of exercise among women with breast cancer; the added benefits of relieving or inhibiting cancer treatment-associated side effects (e.g., nausea and fatigue); and the improvement of cardiorespiratory fitness, body composition, and insulin sensitivity (Courneya, 2003; Galvao & Newton, 2005; Schmitz et al., 2005). Several of these physical health benefits have been proposed as mechanisms that may decrease the risk of recurrence and mortality following breast cancer treatment (Courneya et al., 2003; Demark-Wahnefried et al., 2001). Indeed, survival and morbidity following breast cancer was inversely related

to exercise frequency (Holmes, Chen, Feskanich, Kroenke, & Colditz, 2005). Moreover, the effect on mortality was demonstrated for relatively modest levels of exercise intensity and frequency, as demonstrated in walking programs. For these reasons, exercise has been advocated as a particularly important complimentary treatment for cancer patients (Courneya, 2003).

Breast Cancer and Depression Among Minority Women

The favorable effects of exercise notwithstanding, questions remain regarding the effectiveness of interventions for subsets of women with breast cancer. For example, although 5-year survival rates for breast cancer have improved significantly in the last decade, economically disadvantaged populations —Black women in particular—have relatively lower quality of life and 5-year survival rates for breast cancer, despite having a lower incidence rate (Bigby & Holmes, 2005; Bui, Ostir, Kuo, Freeman, & Goodwin, 2005). Research also suggests that despite similar depression rates between minority and Caucasian women, minority women are less likely to receive adequate treatment, to take antidepressants, or to receive specialty care (Dwight-Johnson, Sherbourne, Liao, & Wells, 2000; Miranda & Cooper, 2004). Further, minority women with breast cancer, who also have untreated depression, have more anxiety and pain, report poorer quality of life, and may die sooner (Ell et al., 2005; Goodwin, Zhang, & Ostir, 2004).

Exercise and Multiethnic Samples in Breast Cancer

Existing data suggest that interventions aimed at increasing the adoption of exercise are warranted, particularly for Black women with breast cancer who are at relatively greater mortality risk (Bigby & Holmes, 2005). However, a paucity of exercise trials exists. Those that have been conducted had participants who were mostly Caucasian (e.g., 80% or more) and resided in suburbia (Demark-Wahnefried et al., 2001; Mock et al., 1997; Mock et al., 2005; Pickett et al., 2002). Similarly, although small, uncontrolled, pilot exercise studies with Black women are promising (Wilson, Porter, Parker, & Kilpatrick, 2005) and the ES of exercise on depression across studies utilizing White samples is strong, there is a primary gap in the knowledge that centers on how well these findings generalize to depressed women of diverse racial and ethnic backgrounds. These data are especially important considering epidemiological findings that indicate the association of physical activity with reduced mortality is not moderated by race (Holmes et al., 2005; Schmitz et al., 2005).

The purpose of the present study was to assess the effect of a structured exercise intervention (SEI) in combination with cognitive behavioral exercise adherence counseling on depression and exercise behavior among a multiethnic sample of women with early stage breast cancer who were enrolled prior to the start of adjuvant treatment. This study extends the current literature by utilizing a prospective design, by examining depression prior to and during adjuvant treatment, and by recruiting a multiethnic and previously sedentary sample of women in an urban setting.

Method

Setting and Participants

The trial was conducted at the Boston University School of Medicine (BUSM) General Clinical Research Center and the Boston Medical Center (BMC). A joint BUSM and BMC institutional review board approved the study, and informed consent was obtained from all participants for all procedures. Eligibility criteria include (a) English speaking, (b) between 21 and 75 years of age, (c) sedentary lifestyle (i.e., exercise less than 3 times/week for greater than 30 min/session in last 6 months), (d) average or below average fitness as determined by a graded exercise test (GXT), and (e) recent diagnosis of breast cancer (Stage 0, I, II, or IIIa). Exclusion criteria include (a) non-cancer related contraindications to aerobic walking exercise (e.g., symptomatic coronary artery disease, psychotic spectrum mental illness, orthopedic problems), (b) pre-existing metabolic disease (e.g., diabetes, uncontrolled hypertension), and (c) a contraindication to exercise discovered on the exercise stress test (Winningham, 1991).

Experimental Design and Participant Recruitment

We present self-reported exercise and depression data on the 3-month follow-up of a larger study funded by the National Cancer Institute (CA R01-78801). The study employed a Group (structured intervention, information control) × Time (baseline, 3-month) prospective, randomized, and controlled clinical trial. Between April of 2001 and July of 2005, women who had completed breast cancer surgery but had not started radiation therapy, chemotherapy, or anti-hormone therapy were identified in weekly breast cancer case conferences. Post-doctoral fellows provided eligible breast cancer survivors with a study brochure and a consent form, and they discussed any questions. Baseline assessments consisted of a psychosocial survey, self-reported exercise, and physician-monitored GXT treadmill testing. Women in both intervention and control groups were given a $25 and $35 stipend for completing baseline and 3-month assessments, respectively.

Participants were stratified by cancer stage and randomly assigned to either a SEI or to an information control (IC) condition by use of a random number sequence table. Participant assignment to groups at enrollment was concealed from the project director, and the physicians monitoring GXTs were blinded to participant group assignment. Similarly, a physical therapist or an exercise physiologist, blinded to participant assignment, performed strength assessments.

Structured Exercise Intervention

Women assigned to the exercise group were given an individualized walking and resistance training program based on their GXT data, strength assessment, and established exercise recommendations for cancer patients (Winningham, 1991). Exercise training proceeded in two phases with a hospital-based portion followed by a transition to home-based exercise.

Hospital-based exercise. Participants were asked to come to exercise sessions three times a week for 4 weeks. For the aerobic component, participants began with 15-20 min of continuous treadmill walking 3 times per week at 50-70% of GXT-derived maximal heart rate (MHR). In subsequent weeks, duration was gradually increased by 5 min for a maximum of 40 min and a minimum of 30 min; intensity was increased to be within 70-85% of MHR according to participant comfort. Heart rate monitoring, rating of perceived exertion (RPE), and exercise enjoyment were used to assess participant comfort and to ensure participants were exercising in the appropriate training zone.

A resistance program consisted of upper body (i.e., bicep curl, triceps extension, chest fly, military press, upright row, and shoulder shrug) and lower body (i.e., leg squats and lunges) exercises. The upper-body resistance program was initiated with one set of 12 repetitions at the lightest weight, and as tolerated, repetitions were increased to 15 after the first week. After a participant could perform 15 repetitions of an exercise, another set was added. Upper-body exercises were performed with a padded weight belt with 1.0 lb bars that were used to adjust the total weight as necessary (range 0.5-20 lbs.). The participant's body weight was the only resistance used for lower body exercises. A physical therapist, kinesiologist, or exercise physiologist provided instruction on proper exercise technique. Participants were also provided with a manual, developed for this study, that used a woman model of the participants' approximate age and that depicted use of the adjustable weight belt, proper exercise technique, and key points for each exercise.

Home-based exercise. Participants were instructed to walk at least 3 times per week and were encouraged to walk most days of the week for 30 min or more. They were also provided with the adjustable weight belt and instructed to continue their resistance exercise 3 times a week. Participants were provided with monthly calendars to record their exercise activity and were contacted weekly by telephone or electronic mail according to patient preference.

Exercise adherence counseling and protocol delivery. Lastly, participants in the SEI condition received two 30-min exercise adherence counseling sessions during the hospital-based phase to enhance exercise maintenance for the transition to the home-based exercise. Participants were taught exertion cues and behavioral strategies (e.g. talk-test) to identify appropriate training zones and how to manage barriers encountered with a walking program (Winningham, 1991). The counseling also incorporated the use of behavioral contracting, contingency planning, goal setting, and self-monitoring techniques to promote exercise adherence (Prochaska & Marcus, 1994). Thereafter, SEI participants received weekly contact by telephone or electronic mail according to participant preference. To ensure uniformity of counseling, we developed a study-specific exercise adherence counseling manual for breast cancer and materials for staff training. The manual provided a detailed explanation of each counseling session that included the rationale, relevant behavior change, and micro-skills counseling principals; instructions to employ specific techniques (i.e., self-monitoring and goal setting); session handouts; and a checklist. For example, research assistant counselors specifically inquired regarding frequency and duration of exercise, instructed participants in the use of self-monitoring

calendars, provided verbal reinforcement and encouragement for exercise, and helped participants set goals. Lastly, as was appropriate, research staff aided participants in identifying solutions to existing or newly encountered exercise barriers and discussed ways to enlist social support for exercise. Clinical psychology and exercise psychology post-doctoral fellows delivered sessions and were supervised by a licensed psychologist with expertise in exercise and sport psychology.

Information Control

Women assigned to the IC condition received a 45-min information session consisting of individualized feedback of their physical assessment results and an informational brochure describing the potential physical and psychological benefits of exercise and their relevance to breast cancer. The brochure and information form describing the fitness component (e.g., oxygen consumption), the effect of exercise on the component, and the relevance for breast cancer were used to ensure uniform information delivery. However, the session specifically excluded the provision of an exercise prescription and discussion of strategies to address common exercise barriers. Participants who asked about an exercise prescription were told "do the best you can." To facilitate participant retention, control group participants were contacted once and then again 10 days prior to follow-up assessment.

Outcomes

The Center for Epidemiologic Studies Depression scale (CES-D) is a widely used and reliable (Cronbach Alpha $r = .85$) 20-item measure of depression that has been validated in breast cancer patients (Deshields et al., 2006). CES-D items indicative of depressive symptoms (e.g., "felt that I could not shake off the sad feelings even with help from my family or friends) are scored on a 0 (*Rarely or none of the time*) to 3 (*Most or all the time*) Likert scale. CES-D scores range from 0 to 60 and a cut-off score (≥ 16) to identify clinically significant depression has been established in both general and breast cancer samples.

Godin Leisure Time Exercise Questionnaire (LTEQ). The LTEQ self-report instrument surveys frequency of mild, moderate, and vigorous leisure-time physical activity over the past 7 days (Godin & Shephard, 1985). Metabolic equivalent values (3, 5, and 9 METS, respectively) are assigned to each exercise category and multiplied by frequency of occurrence to yield a total leisure score index. The LTEQ has been specifically validated in breast cancer studies, tested with ethnic minority populations, and has shown to be relatively free of social desirability (Courneya & Friedeneich, 1997; Courneya et al., 2003; Motl, McAuley, & DiStefano, 2005). The total leisure score is appropriately reliable (2-week test-retest reliability $r = .74$) and has been correlated with objective measures of fitness (accelerometer $r = .32$; VO_{2max} $r = .24$; Godin & Shepard, 1985; Motl et al., 2005). In our laboratory, we have validated LTEQ scores of breast cancer patients with VO_{2max} ($r = .28$, $p < .05$) and pedometer step counts ($r = .31$, $p < .05$).

Power Calculation and Data Analyses

Exercise intervention with breast cancer patients have large standardized effects (i.e., $d \geq .80$) on fitness and psychosocial outcomes (Courneya, 2003; Schmitz et al., 2005). An a priori power analysis, assuming a large effect ($d = .80$) and a .05 two-tailed alpha level, determined that 25 participants per group were needed to achieve .80 power. Fifty-seven participants were scheduled for baseline testing, and 7 participants were not enrolled due to undocumented hypertension, an orthopedic limitation, or abnormal blood pressure response to exercise testing. One participant was subsequently enrolled following a hypertension medication adjustment.

Analyses were conducted on all randomly assigned participants completing baseline assessments ($N = 51$). Because some participants missed follow-up assessments, and since intent-to-treat analyses are the recommended approach, we used several methods to impute missing values and then compared the concordance among results derived from each method (Tabachnick & Fidell, 2001). In all cases, these methods yielded the same result regarding interpretation of statistical significance. Because regression modeling is more widely applicable than carrying forward values, and since it is better than mean replacement, we used regression modeling to impute missing values to conduct our analyses.

Results

Participant Recruitment and Baseline Characteristics

As a first step, we used address and census data to compare eligible-enrolled to eligible-unenrolled participants and found they were not significantly different with respect to income, distance from BMC, and age ($p > .23$ for all calculations). We also had a high retention rate, with 80.4% randomly assigned participants completing follow-up assessments at 3 months; attrition was not significantly different between treatment and control groups at follow-up, $\chi^2(1, N = 51) = 1.45$, $p = .228$. Overall, participants completing follow-up assessments were not significantly different from follow-up noncompleters with respect to medical (i.e., cancer stage, surgery type, adjuvant treatment), demographic (i.e., age, race, marital status, employment, family income, or education), or exercise-related (i.e., BMI, VO_{2peak}, or arm and leg strength) characteristics.

We next compared intervention and control groups and found no significant differences with respect to demographic, cancer stage, treatment, and exercise characteristics. Participants ranged in age from 29-75 years ($M = 50.8$, $SD = 11.8$). Approximately one third (35%) worked full time and 37.3% were married or partnered. The majority (52.9%) of women had Stage I breast cancer and received lumpectomy surgery (74.1%). Many (44.1%) women received both radiation and chemotherapy, 26.5% received radiation only, 8.8% received chemotherapy only, and 20.6% received no adjuvant therapy. Women were generally obese (BMI: $M = 28.8$, $SD = 6.1$) and all had an average or below average fitness ($M = 21.8$, $SD = 6.3$ VO_{2peak} ml/kg/min). A large percentage of women were Black (44.1%), total ethnic minority group membership was high (45.1%), and about a third reported family incomes under $20,000.

Exercise Adherence and Protocol Delivery

Women assigned to the structured intervention completed an average of 83% of their scheduled hospital-based exercise sessions, (*M* = 9.9, *SD* = 3.3 sessions) and 76.9% completed all 12 sessions. These data are consistent with exercise adherence rates commonly reported in breast cancer literature (Courneya, 2003).

Depression

At baseline, 23.5% of women had CESD depression scores above the clinical cut-off, but depression rate did not differ between ethnic minority (26.1%) and non-minority women (21.4%) or between intervention (25.9%) and control (20.8%) groups, $\chi^2(1, N = 51) = .15$ and .18, $p = .699$ and .668, respectively. However, 33.3% of women were depressed at some point over the 3-month period, which was significantly higher than the general base rate of depression (e.g., approximately 20%) lifetime incidence in women, $\chi^2(1, N = 51) = 6.10$, $p = .014$.

Examination of intervention effect at 3-month follow-up revealed a significantly higher depression rate in the control group (37.5%) than in the intervention group (11.1%), $\chi^2(1, N = 51) = 4.917$, $p = .027$, $\varphi = -.311$. Analyzing the specific pattern of depression change indicated that 80% (4 of 5) of depressed participants remained depressed in the control group at 3-month follow-up, whereas only 42.9% (3 of 7) remained depressed in the intervention group. The rate of newly depressed patients (i.e., not depressed at baseline but depressed at follow-up) was 21% (4 of 19) in the control group, whereas it was 0% in the intervention group.

Exercise Behavior

At baseline, an ANOVA, with ethnic minority group and intervention group as independent factors and LTEQ score as a dependent factor, indicated that ethnic minority women were marginally less likely to exercise, $F(1, 47) = 3.63$, $p = .063$; however, control and intervention groups were not significantly different, $F(1, 47) = .19$, $p = .667$, and the interaction was nonsignificant, $F(1, 47) = .63$, $p = .43$. However at 3-month follow-up, a two-way ANCOVA, controlling for LTEQ score at baseline, revealed significantly higher LTEQ scores in the intervention group than in controls, $F(1, 47) = 9.99$, $p = .003$, $\eta^2 = .178$, but effects of ethnicity and the interaction between ethnicity and exercise-group membership were not significant, Fs (1, 47) = .11 and 1.67, ps = .739 and .203, respectively. These data suggest that the intervention was similarly effective in increasing self-reported exercise among ethnic minority and non-minority women. Specifically, LTEQ scores increased from baseline by 157% ($M = 9.7$, $SD = 8.1$ to $M = 25.0$, $SD = 13.1$) in the intervention group and by 32.7% among the control group ($M = 10.7$, $SD = 12.8$ to M=14.2, $SD = 11.8$).

Correlation Between Exercise and Depression

Finally, we sought to determine the relationship between exercise and depression level for those participants meeting criteria for clinical depression at any point during the study. We correlated LTEQ change with CESD change (from baseline to 3-month follow-up) and found a moderate but nonsignificant correlation of $r(17) = .38$, $p = .13$, (equivalent ES, $d = .69$).

Discussion

This is the first prospective, randomized controlled trial examining the exercise-depression relationship using intent-to-treat analyses in a multiethnic sample of breast cancer survivors. We found a similar depression rate between ethnic minority and non-minority women with breast cancer, but the overall depression rate (33.3%) was significantly higher than the lifetime population rate for women. These data are consistent with previous research with cancer patients (Deshields et al., 2006; Ell et al., 2005). Our results further demonstrated that SEI significantly improved physical activity and depression rate, and the intervention was similarly effective for ethnic minority and non-minority women. The amount of exercise had only a moderate, non-significant, correlation with exercise depression level.

These findings suggest that a structured intervention that transitions women from hospital- to home-based exercise may be an effective complimentary treatment to improve mental and physical health in breast cancer patients with depression. Moreover, the intervention ES (i.e., $d = -.69$) on depression we observed was comparable to the overall ES reported for depression among nonmedical population (i.e., $d = -.72$; Craft & Perna, 2004). These results are particularly important for minority women who are less likely to receive care for depression (Cooper et al., 2003), more likely than their Caucasian peers to be physically inactive (Crespo, Smit, Andersen, Carter-Pokras, & Ainsworth, 2000), have poorer breast cancer outcomes, and are at increased risk for CVD (Bigby & Holmes, 2005).

Assessment of the relationship between changes in physical activity and changes in depression revealed a moderate, but statistically nonsignificant, correlation. This may be attributed to several factors and study limitations.

One such limitation is the depression variable. Our study was not designed to specifically recruit depressed breast cancer patients, and thus, the subgroup correlation analysis' lack of statistical power may have contributed to non-significant findings. Similarly, although the CESD has established cut scores for depression, we did not verify depression by other means. However, a higher-than-expected rate of depression was observed in the sample that could not be attributed to other factors, such as support group attendance or antidepressant medication use.

Second, although not a study limitation per se, the lack of a significant inverse correlation between amount of exercise and depression may be questioned. It is possible that even a modest level of exercise is sufficient to promote positive changes in mental health among breast cancer patients and, once a threshold amount of exercise is met, no

further mental health benefit accrues from additional activity. This position is consistent with meta-analytic findings and with the magnitude of the correlation between exercise and depression we observed (Craft & Landers, 1998). These views are also consistent with prospective data from breast cancer patients indicating that improved mortality was achieved with only a minimal amount of exercise, whereas higher exercise level was not associated with improved mortality (Holmes et al., 2005). Given that many women with breast cancer may exercise with a lower frequency, and that this may still produce some physiological and psychological benefits, future research should manipulate exercise frequency and compare the effect of low-frequency exercise (e.g., 1-2 times per week) with more frequent exercise.

Third, we used a multifaceted intervention including a number of cognitive behavioral therapy characteristics. As such, we could not determine exactly which intervention component may have had the greatest effect. It is possible that intervention aspects, other than exercise, led to reductions in depression. For example, women in the SEI group engaged in self-monitoring and goal setting activities and may have derived a sense of self-efficacy and enhanced self-worth from meeting exercise goals. Similarly, women in the SEI group were contacted frequently to obtain data and were provided with brief supportive contact for their exercise attempts, and they may have perceived this support as therapeutic. Therefore, the exact mechanisms underpinning the intervention effect on depression are unclear; it is likely that various program components acted synergistically to increase exercise behavior and lessen depression among these women.

Finally, criteria for empirically validated therapies distinguish efficacious from specifically efficacious treatments (Chambless & Hollon, 1998). Treatment efficacy requires a finding that an intervention is superior to a control condition, whereas evidence that an intervention is superior to another treatment or an attention control is a criterion for treatment specificity. In the present study, research staff exposure time was not equivalent between conditions, but the design ensured that control and experimental groups received similar informational content, which was viewed as helpful, and the control condition represented an improvement over the standard no-treatment, control condition. As such, we have demonstrated the efficacy of an intervention to improve time spent in physical activity and to reduce the prevalence of depression among women with early stage breast cancer. Future research is needed to elucidate the mechanisms underlying this relationship.

We wish to acknowledge the valuable contributions of our physicians to the project including Rita Blanchard, Michele, David, Elizabeth Dupuis, Maureen Kavanah, Renee McKinney, Jane Mendez, and Carol Rosenberg by Noreen O'Shea and the nursing staff of the General Clinical Research Center, by Lara Johnson, and most importantly, by our participant breast cancer survivors.

Author Note

This work was funded by the National Cancer Institute (CAR0178801), and by the National Institutes of Health, General Clinical Research Grant, (M01RR00533). This work was completed while Dr. Perna was at Boston University School of Medicine in the Women's Health Unit, Section of General Internal Medicine.

were boys who had disease durations range from 4 months to 2 years. Associated atopic conditions were found in four out of five patients.

Vision was impaired in all patients. Indeed, visual testing was difficult due to symptomatic itching and photophobia. Those with corneal complications did worse (20/100 in patients 1, 3 and 5, who had corneal disease). Patient 1 had an established shield ulcer which failed to respond to hourly topical steroid, autologous serum and regular debridement. Patient 5 had advanced glaucomatous field losses with cup–disc ratios of 0.9 bilaterally, bilateral pseudophakia and glaucoma-drainage-devices. She had an old corneal scar and a baseline vision of 20/100. To control symptomatic itching and superior giant papillae, she had been using topical cyclosporine 0.05% twice daily with only moderate relief.

Topical tacrolimus 0.03% ointment twice daily was introduced at various time points. It was used for the shield ulcer that failed to respond (patient 1) after 3 weeks of treatment. For patient 2, it was used in place for steroid and mast-cell-targeted treatment, which added up to 16 administrations per day. For patients 3 and 4, it was added in substitution for topical steroid therapy when corneal epithelial breakdown was first noted. In patient 5, it was used instead of topical cyclosporine, owing to its lack of efficacy.

All patients responded. The only side effect was burning sensation that did not require cessation of treatment. There was significant reduction in symptoms and signs. Giant papillae regressed as early as 1 week post-treatment. The large shield ulcer seen in patient 1 healed within 3 weeks. For the two cases with early epithelial disease, the defects healed within 1 week with scarring (figure 1). Total treatment duration ranged from 1 to 5 months. Symptoms redeveloped in two patients after 2 months, which was controlled with mast-cell-targeted treatments alone.

In summary, topical tacrolimus 0.03% was found to be safe and effective for VKC. We would suggest its early use as a steroid-sparing agent to prevent blinding complications.

Ocular manifestations of torture: solar retinopathy as a result of forced solar gazing

Solar retinopathy as a result of sun gazing has been well documented and occurs as a result of thermal and photochemical processes after solar exposure.[1] Although solar exposure is usually a result of deliberate sun gazing, forced sun gazing can also be used as a torture method.

Torture is prevalent worldwide. In 2007, the Amnesty International documented cases of "torture and other cruel, inhuman or degrading treatment" in 81 countries.[2]

It is important for clinicians to be aware of the physical manifestations of torture because they are not always obvious. Torture methods are often devised to leave minimal long-term physical indications but often have tremendous psychological impact.[3] Survivors will often not disclose the experience of their torture with their physician, and the diagnosis may be missed.[4]

CASE

A 58-year-old West African man was referred to an ophthalmology clinic by his primary care physician with a chief complaint of difficulty reading and discomfort and blur on more than momentary reading. His medical history included torture in Cameroon 3 years earlier. On two consecutive days, he was taken from his cell and at gunpoint forced to stare at the sun for a duration that he believes was about an hour each day. He possessed no means for measuring time. He was threatened with death if he looked away or closed his eyes, and did observe the execution of another prisoner for failure to comply. He described great pain and blurred vision afterwards, but he felt that he recovered and was able to see well at close range and distance until recently when he developed difficulty reading.

On examination, the distance visual acuity was 20/20 in both eyes on the Snellen test without correction. Uncorrected near acuity was J7 in either eye. With appropriate presbyopic correction, his near vision improved to J0 in both eyes. Fundus examination of the left eye showed an atrophic area with pigment migration, shaped like two overlapping circles, approximately 1 mm in diameter. On retinal photographs, the lesion was exactly the same distance temporal to the fovea as the disc was nasal to the foveal umbo (see figure 1). The right fundus was normal. The visual fields were normal.

Diagnostic impressions were presbyopia *in both eyes* and solar burn in left eye secondary to torture by forced sun gazing. The appearance of the lesion is classic for the late lesion of solar gazing after the initial oedema of the neurosensory retina has faded. The patient was certain that he had looked directly at the sun, but the location of the unilateral burn suggested that he had instead instinctively arranged his gaze to place the image on the optic nerve head oculus dexter and temporal to the fovea *oculus sinister* to minimise pain. Because there was no optic atrophy, the lighter colour of the optic nerve presumably converted less light energy to heat than the darker fundus, including the retinal pigment epithelium and the choroidal pigment, and optic nerve tissue was not lost. In addition, the size of the extrafoveal lesion is comparable with the foveal lesions of patients seen with solar injury to the fovea.[5]

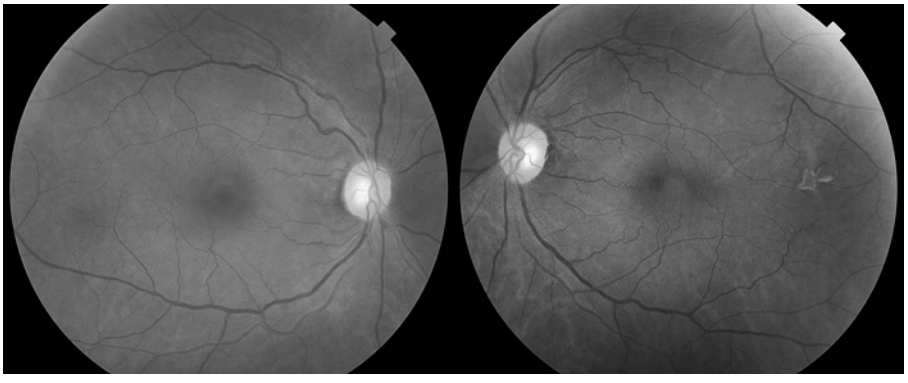

Figure 1 Fundi of patient showing scar temporal to the fovea in left eye secondary to solar burn.

Treatment with presbyopic correction eliminated his presenting symptoms.

DISCUSSION

In this report, we document that forced sun gazing can also be used as a physical torture method, which can result in solar retinopathy. Psychological sequelae may also be present in torture survivors, such as symptoms of post-traumatic stress disorder and major depression. If a physician identifies a patient as being a survivor of torture, it is important for them to be aware of programmes that specialise in the care of torture survivors such as the International Rehabilitation Council for Torture Victims.[6]

In summary, this is a unique report of forced sun gazing used as a torture method and resulting in solar retinopathy. Unlike with deliberate sun gazing, where solar burns are usually located foveal or perifoveal, torture victims may shift their eyes, causing solar burns offset from the retina. In the case presented in this report, an affidavit and testimony were given in court documenting the ophthalmic findings, which contributed to the patient being granted political asylum.

Decreased susceptibility to quinolones in methicillin-resistant *Staphylococcus aureus* isolated from ocular infections at a tertiary eye care centre

Methicillin-resistant *Staphylococcus aureus* (MRSA) is a serious cause of morbidity and mortality worldwide because of its multiple-drug resistance.[1] In the past, MRSA infections were considered as hospital acquired; however, in the 1990s, serious MRSA infections were reported in patients with no previous contact with the healthcare system.[2] Aggressive infections due to MRSA were observed in the eye and orbit in patients with no hospital exposure.[3] There are very few reports on ocular MRSA infections, and to the best of our knowledge, there are no reports on MRSA in ocular infections from India. The present study was carried out to study the changing trends of methicillin susceptibility in *S aureus* isolated from different ocular infections and to analyse the susceptibility of MRSA to quinolones and vancomycin.

We performed a retrospective review of microbiology records from January 2006 through December 2008 to determine the susceptibility pattern of *S aureus* isolated from corneal scrapings, vitreous, conjunctival swabs and lacrymal sac and adnexa to oxacillin (methicillin). *Staphylococcus* was identified to species level by conventional biochemical tests and by using Mini API (bioMérieux, France). Antibiotic susceptibility of the isolates was determined by using the Kirby Bauer disk diffusion method on cation-adjusted Mueller Hinton agar to oxacillin, ciprofloxacin, ofloxacin, moxifloxacin gatifloxacin and vancomycin. Plates were incubated at 35°C for 16–18 h in non–carbon dioxide incubator. The results were interpreted as per the Clinical Laboratory Standards Institute guideline.

STATISTICAL ANALYSIS

Changing the trends of oxacillin susceptibility in *S aureus* isolates was analysed by using χ^2 test, and the susceptibility evaluation of MRSA to different antibiotics was done by correlation analysis.

A total of 199 *S aureus* isolates were isolated during the study period. Of these, 74 were isolated from the corneal scrapings; 43, from the conjunctival swabs; 11, from the vitreous and 71 from the lacrimal sac and adnexa. Of 199 isolates, 68 (34.1%) were resistant to methicillin. Of 68 MRSA isolates, 22 (32.3%) were isolated from the conjunctiva, 23 (33.8%) were isolated from the lacrimal sac and adnexa, 20 (29.4%) were isolated from the corneal scrapings and 3 (4.4%) were isolated from the vitreous. All the 199 (100%) *S aureus* isolates were sensitive to vancomycin.

Yearwise distribution of *S aureus* isolates and their susceptibility to methicillin are shown in table 1.

The susceptibility rates of methicillin-resistant and methicillin-susceptible *S aureus* (MSSA) to quinolones are shown in table 2.

Methicillin-resistant *S aureus* causes severe ocular infections,[3 4] and prevalence of ocular MRSA infections varies from 3% to 30%.[1 5] In this laboratory-based investigation, the proportion of MRSA ocular infections increased from 26% in 2006 to 38% in 2008. An annual increase in MRSA incidence was observed in our study.

Hospital-acquired MRSA strains are usually multidrug resistant.[6] Community-acquired MRSA, though resistant to methicillin and other β lactam antibiotics (penicillin, cephalosporins and carbapenems), often remain sensitive to many other

CAREERS

Race, Disadvantage and Faculty Experiences in Academic Medicine

Linda Pololi, MBBS, MRCP[1], Lisa A. Cooper, MD, MPH[2], and Phyllis Carr, MD[3]

[1]Women's Studies Research Center, National Initiative on Gender, Culture and Leadership in Medicine: C - Change, Brandeis University, Waltham, MA, USA; [2]Johns Hopkins Medical Institutions, Baltimore, MD, USA; [3]Boston University School of Medicine, Boston, MA, USA.

BACKGROUND: Despite compelling reasons to draw on the contributions of under-represented minority (URM) faculty members, US medical schools lack these faculty, particularly in leadership and senior roles.

OBJECTIVE: The study's purpose was to document URM faculty perceptions and experience of the culture of academic medicine in the US and to raise awareness of obstacles to achieving the goal of having people of color in positions of leadership in academic medicine.

DESIGN: The authors conducted a qualitative interview study in 2006–2007 of faculty in five US medical schools chosen for their diverse regional and organizational attributes.

PARTICIPANTS: Using purposeful sampling of medical faculty, 96 faculty were interviewed from four different career stages (early, plateaued, leaders and left academic medicine) and diverse specialties with an oversampling of URM faculty.

APPROACH: We identified patterns and themes emergent in the coded data. Analysis was inductive and data driven.

RESULTS: Predominant themes underscored during analyses regarding the experience of URM faculty were: difficulty of cross-cultural relationships; isolation and feeling invisible; lack of mentoring, role models and social capital; disrespect, overt and covert bias/discrimination; different performance expectations related to race/ethnicity; devaluing of research on community health care and health disparities; the unfair burden of being identified with affirmative action and responsibility for diversity efforts; leadership's role in diversity goals; and financial hardship.

CONCLUSIONS: Achieving an inclusive culture for diverse medical school faculty would help meet the mission of academic medicine to train a physician and research workforce that meets the disparate needs of our multicultural society. Medical school leaders need to value the inclusion of URM faculty. Failure to fully engage the skills and insights of URM faculty impairs our ability to provide the best science, education or medical care.

INTRODUCTION

Medical schools hold a social mission to educate physicians who will care for the entire population.[1,2] Diversity among faculty enhances the ability of academic medicine to fulfill its educational, research and patient-care missions.[3] Inclusion of under-represented minority faculty members (URM) in medical schools promotes more effective health care delivery to a diverse population; improves the quality of medical education,[4] and may stimulate research attentive to the needs and concerns of minority groups.[5]

Despite these compelling reasons to draw on the perspectives and contributions of URM faculty members, there is an alarming dearth of these faculty in US medical schools and a serious paucity in leadership or senior roles[6–8] (Table 1).

Studies have shown that URM faculty are less satisfied and more likely to leave academic medicine, advance more slowly and are less likely to be in the basic sciences.[9–12,17,18] Additionally, minority faculty report experiences of ethnic harassment, biased treatment and racial "fatigue."[11,13–16] They spend more time in patient care and less in research than their non-minority colleagues. Efforts have increased the enrollment of URM medical students,[19–22] but the environment or culture for URM faculty has received much less attention.

Out of concern regarding the failure of academic medicine to adequately recruit, retain and advance diverse faculty, we formed a national collaborative, the National Initiative on Gender, Culture and Leadership in Medicine ("C - Change")[23] to engage five US medical schools in action research to facilitate culture change in academic medicine. In this partnership, we conducted an in-depth interview study of faculty to deepen our understanding of factors underlying the lack of URM faculty in the nation's medical schools.

METHODS

As part of the larger C - Change initiative, we selected five schools representing organizational characteristics of all US medical schools, [i.e., public (two)/private (three), NIH research intensive (two), primary care orientation/community orienta-

Table 1. Representation of Faculty Members of African-American/Hispanic/Latino and Native American Groups is Far Below the Demographics of These Groups In the US Population and US Medical Students.[6–8]

	US population 2000[6]	Medical students 2007[7]	All medical faculty 2007[7]	Medical faculty instructors/ assistant professors 2007[8]	Medical faculty associate/ full professors 2007[8]
African American	12.3%	6.4%	3.0%	8.0%	3.8%
Hispanic/Latino	12.5%	7.2%	4.2%	3.0%	2.2%
Native American	0.9%	0.3%	<0.1%		

tion (one)]. The sample represented all designated Association of American Medical Colleges (AAMC) regions. Sex and URM faculty demographics in these five schools were almost identical to national statistics.

Participant Criteria

Using purposeful and chain referral sampling,[24] we interviewed equal numbers of faculty from each school stratified by sex, race/ethnicity, department/discipline and career stage. Participants were research scientists, medical and surgical subspecialists, and generalist faculty holding doctoral degrees (84% MD/MBBS, 16% PhD) and represented 26 disciplines. The 96 faculty members interviewed in 2006–2007 represented (almost equally) four career stages: (1) early career (initial faculty appointment for 2 to 5 years), (2) "plateaued," (faculty for ≥10 years and who had not advanced as expected), (3) faculty in leadership roles such as deans, department chairs and center directors, and (4) former faculty who had left academic medicine. We oversampled women (55%) and URM. The 17% African American/Black, 4% Hispanic/Latino respondents represented 11 specialties/disciplines.

Data Collection and Analysis

A multidisciplinary research team (2 MDs, 2 PhDs) conducted in-depth, semistructured interviews—15% in person and 85% by telephone for convenience. Interviews (typically 1 h) were audio-recorded and transcribed verbatim. The interview guide (developed from pilot interviews) consisted of open-ended questions on aspirations of faculty, energizing aspects of their careers, barriers to advancement, collaboration, leadership, power, values alignment and work-family integration (Table 2). We concluded interviewing when we no longer obtained new information.

After deletion of all identifying information, transcribed data were coded and organized using Atlas.ti software. Inductive analysis [25,26] identified patterns and themes as they emerged from the coded data. The secondary analysis reported here utilized all coded data related to URM faculty and discrimination, and the entire interviews of URM faculty. We verified our findings using a consensus process. Brandeis Institutional Review Board approved the project. The example quotations illustrate themes stated repeatedly.

RESULTS

Male and female URM faculty experienced: difficulty in cross-cultural communication; feeling isolated and invisible; lack of mentoring, role models and social capital; disrespect, overt and covert bias and racism; devaluing of professional interests; being identified with affirmative action programs and diversity responsibilities; and financial hardship.

Cross-Cultural Communication

Many URM faculty described problems with conversation and relationship formation with Caucasian colleagues, e.g., *"Maybe they don't know how to talk to me because I'm an African American person."* They ascribed this to having different professional and social frames of reference. URM faculty didn't feel included and perceived that they caused Caucasians to be uncomfortable in conversing with them. This lack of connection created a barrier to collaborating with other faculty.

> It makes me feel like they're so uncomfortable. We don't have the same frames of reference. And it doesn't feel comfortable on either side of the conversation. I feel like I'm making people think about things they don't want to think about and so why bother? (URM female, plateaued)

Some described academic medicine as feeling like a foreign culture.

> So academic medicine is a foreign culture that isn't friendly to American Indians and Latinos. You're not going to attract Latinos, American Indians who have a community bent, who want to change social systems, who have a sense of family and community. It's very hard for us to fit in academic institutions, where that's about the individual. (URM male, early career)

Table 2. Interview Guide Questions

What is it about your work that energizes you?
When have you felt most successful in your work?
What's been your sense of being a part of your institution?
What has been difficult or frustrating in your work?
Can you talk about some experiences you've had related to the advancement of your own career in academic medicine?
What do you see as valued at your institution?
What does it take to get into a position of power or leadership in your school?
Is leadership something you've wanted or want for yourself?
How has power affected you/your career in academic medicine?
How do your personal values align or conflict with what you experience in academic medicine?
Why do you think there are so few women in the upper reaches of academic medicine?
What about underrepresented ethnic groups or people of color?
Tell me about the relationship between your work and family or personal life.
How are your aspirations for yourself in academic medicine being fulfilled?

Isolation

Isolation due to the scarcity of colleagues of color was cited frequently. This was especially prominent for female faculty.

> Early on, there were just no women and certainly, no faculty of color, and so you're just there by yourself. (URM female, leader)

Some URM faculty remarked that people of color need other supportive relationships from family, church or community outside medicine to survive the professional isolation.

Feeling Invisible

The sense of isolation was compounded by feeling invisible in the institution and at national professional meetings.

> What I struggled with for a long time here was my being an African-American woman, in a male, white male-dominated institution and the feeling that I was invisible. My opinion didn't matter, what I was feeling didn't matter. There were people who I passed every single day, who were chairmen of departments, and I mean, good God, after 5 years you've got to see a person… I would really hate to go to national meetings. Because I wouldn't see very many people who looked like me and even though I had met people the year before or 2 years before, they always acted as if they'd never seen me before. (URM female, plateaued)

Lack of Mentoring, Role Models and Social Capital

Many commented on the lack of support and mentoring and the paucity of URM role models in academic medicine. This was especially significant as many African American and Hispanic faculty came from backgrounds where they had little exposure to academia or the systems of higher education.

> When you're the first person in your family to reach this point, you are clueless. I was not receiving any counseling at all about what the next move was… A lot of people of color don't know that. (URM female, leader)

Programs for URM students and resident were available, but faculty believed it "*pretty well peters out at the faculty level*." Many faculty of color acknowledged that they lacked role models for themselves, but still felt responsible for serving in leadership roles and being role models for other URM faculty.

> The other reason that leadership is important for me is because you want your family, other people of color to say, "Okay, I can do this too, I can do it." Academics is not an area that people think about. (URM female, leader)

> I'm at a point in my career where I have to decide whether to stay or go, and if I go, where's the role model for the ones coming behind me? Then they have a similar experience like I did. (URM female, plateaued)

Disrespect, Prejudice, Bias and Racism

We heard numerous accounts of experiencing racist remarks and bias. Minority faculty described being stereotyped; sometimes being viewed as similar to uneducated minority patients or other people of color in service roles.

> If the majority of the patients that you're treating are African American and very poor and uneducated, and I'm African American, well, people are sometimes not able to make the distinction between some of those patients and you. (URM female, early career)

> So I showed up at the meeting last year, and one of the Division Directors asked me to take his luggage to his room…I was just puzzled. And he said, "You are at this meeting aren't you?" And then it became clear to me that he thought I was one of the organizers of the meeting. I said, "Well, yes I am at the meeting." And then he very sharply said, "Well then can you take care of this?" And I said: "Sir, I believe I'm at the meeting for the same reason you are." (URM female, leader)

Another minority physician remembered an incident as an intern.

> I was on call and one of the nurses interrupted me and said, "Oh go to room such and such, the sheets need to be changed." …making the assumption that if I am African-American, I'm here to clean the beds. (URM female, left academic medicine)

A pervasive example of stereotyping was that colleagues and supervisors often had low or mediocre expectations of what URM faculty (or students) could accomplish.

> I have heard it from African-American students that were very interested in science, and they had teachers that said, "I don't think you really can get a PhD." (URM female early-career)

Individually, URM faculty consistently believed that they had to perform at a higher level than others in similar situations to be perceived as accomplished.

> I think you always feel like you're expected to do a mediocre job. Always. And so, you strive to be super woman. To combat the expectation that you're only going to be mediocre. (URM female, plateaued)

Others recounted instances of racism.

> I sent my resume for something and when I showed up someone said to me, "Your resume didn't look black." Can you imagine someone saying that? (URM female, senior)

> There was a night shift that I worked, the resident came down and asked me if we could hold a patient in the emergency department because it had been a busy night for the resident, and he didn't want to admit the patient. And I said "No," because the patient was an older woman on a stretcher down here in the ED, I

> wanted her to go upstairs. He walked away and mumbled, "You black bitch." My boss happened to come down first thing in the morning, and I recounted the episode to him, and told him I was so angry I could have punched this guy and he says to me, "Well, you know, we don't live in the jungle." That was his response. I will never forget that. (URM female, plateaued)

Discrimination in recruitment emerged as a sub-theme. One respondent recounted her experience of discrimination by other faculty members. She pointed out the burden of dealing with discrimination for many years.

> So he asked the chair to bring me on as a faculty member. And one faculty went to the Dean, and said: "Let's not bring her on. Let's wait 'till next year because we want (name), because we believe that a white, Jewish male will fit the environment better." So, sometimes you look back and wonder why you stayed. (URM female, leader)

Another Caucasian faculty explained discrimination on the basis of class. He believed that prejudice exists against non-white speech patterns.

> I think that even though people may not be prejudiced against skin color, they may be prejudiced against—and I know I'm prejudiced—language patterns. It's the way I'm prejudiced against people who put their Rs in the wrong place. It's a sign of class. (Non-minority male, plateaued)

Devaluing of Professional Interests

In the departments where there was focus on research on underserved populations or community-based health care, URM faculty perceived a more favorable microenvironment for themselves. Such departments were better able to recruit URM faculty. Conversely, respondents commented on how research in communities and giving back to their communities, as well as research on minority health disparities (MHD) was less rewarded, and perceived as less weighty.

> I think from all the other departments' perspective they'd say, "What's going on with them? They're doing soft research out in the community and they're not real scientists." (URM male, left academic medicine)

Minority faculty felt a sense of responsibility to their communities that often conflicted with the demands of an academic career.

> It's important that we're out in the community actually caring for patients, giving back to our community. I know that my closest colleagues who are African-American definitely feel that way. They felt that they couldn't do that within the confines of academic medicine. (Non-minority male, left academic medicine)

Additionally, issues of tokenism and "window dressing" were voiced. Some faculty suggested that URM faculty are "*just a pawn to be used by the institution*" to show that the institution is attending to URM recruitment or doing something about MHD.

> The minorities see academia as an environment that they can potentially thrive in and they get played. They become the representative in that it shows that the institution is doing something about health disparities and they get used, and they also don't wind up in the decision-making circles. (Non-minority male, plateaued)

Burden of Affirmative Action Programs and Representing One's Own Race

Compounding tokenism, faculty spoke of the stigmata of having participated in affirmative action programs or programs specifically targeting MHD, thus being simultaneously benefited and disadvantaged. URM perceived that others thought they had *"got there because they were Black."*

> You almost feel that you have to do better than anybody else to prove that you are where you are because you deserve it. I was very lucky and I got my R01 very quickly and I got a very, very good score. I was really proud of that. I worked very hard on that grant. And a colleague of mine, he looked at me and said, "I'm convinced that these things are decided based on ethnicity." (URM female, leader)

Often URM faculty were asked to provide service and committee work to promote diversity. They felt conflicted in the realization that this service on behalf of URM detracted from personal scholarship and an individual need to advance in the system.

> They told me the only reason I got the job was because I was Black. And when I came into the Dean's office, there was talk of: "We don't have an Office of Minority Affairs (OMA) here." Every time they start talking about an OMA they start looking at me. And I said, "If I'm good enough to be the Dean of Minority Students, I'm good enough to be the Dean of all the students." (URM female, plateaued)

A dilemma for many faculty was how to manage concurrent efforts to take care of other people of color, as well as to advance professionally to be accomplished role models.

Responsibilities of Leadership

Many faculty commented on the pivotal role of leaders with respect to diversity and the scarcity of people of color in leadership roles in medical schools. Leaders were perceived as not valuing diversity and needing to make a firm commitment to diversity goals if to acheive real change. Leaders tolerated unacceptable behavior or even racism (e.g., see Racism section). Interviewees believed that leaders rarely selected people of color for leadership positions as doing so would detract from their sense of comfort interacting with people like themselves.

> It has to be something that leaders prioritize. When everything else is equal, you have to step up to the plate

and choose the person who does bring diversity. So you need leaders who are willing to stand for it. (URM male, senior)

Some commented that having more URM faculty in positions of leadership would dispel stereotypic myths and create greater exposure to minority excellence on an individual basis.

An intern on my teaching service said to me "I really enjoyed working with you. I truly respect the way that you take care of patients and I want to try to mimic the way I take care of patients after you." He was a non-minority young man and I thought that was incredibly important for me to be in a position to have somebody like him say that. But you have to have the commitment from schools, from hospitals, from administrators to find the people to be in those [leadership] positions and I think it has a huge calming effect on society in general. (URM male, early career)

URM faculty reported that they usually have to be the one to notice and comment on inequity and that this responsibility is not assumed by majority leaders. Some commented that when URM faculty assume administrative leadership, it's at the expense of advancing their own scholarship. On the other hand, having an URM in a leadership role gives the clear message about commitment to achieving diversity.

Some drew a contrast between African-American, and Asian or Middle Eastern faculty. perceiving that the latter groups often came from educated and privileged families who were more familiar with academic pursuits and hierarchies:

I think Asian and Middle Eastern men have been accepted much more than African-American men, and that reflects who's going to medical school. Second and third generation people from Pakistani, Indian and Iranian families. They're well trained and they're very hard workers, and excellent clinicians and teachers—so no issues there. But I think that gives the institution the feeling that they're ethnically diverse, but with all due respect, these are "WASPs" with brown skin. They're more similar in their behavior to the white Anglo-Saxon Protestant model than a Brooklyn Jew, for instance, who's noisy and loud. (Non-minority female, leader)

This white woman shows a nascent understanding of a certain way one has to act in order to be accepted, i.e., similarly to a white male. Asian and Middle-Eastern faculty with more privileged backgrounds may more easily adapt to expected behavior patterns and consequently advance more frequently than URM faculty.

Financial Hardship

A persistent interview theme was the financial sacrifice perceived by choosing a career in academic medicine.

So they are seen as not just the breadwinners for their household, but for the greater family at large. There's a sense of responsibility not only to give back to the community, but also to earn a higher wage to help out the extended family. (Non-minority male, left academic medicine)

Slowness of Change

The history of segregation and slavery in the US is still a part of many people's consciousness. Several faculty highlighted the slowness of realizing the full positive outcomes of legislation resulting from the civil rights movement. *"I'm just disappointed with the progress of our country."*

I mean it's your normal change process, establishing the value of the differing person or persons and eventually change occurs. It's the same process that we went through with integration. That wasn't overnight either. And we're still struggling with it in academic medicine. (Non-minority male, senior)

DISCUSSION

URM faculty bring knowledge and experience of different backgrounds and world views to medical schools. Our findings suggest that these valuable attributes and abilities, instead of being perceived and received as beneficial, are often responded to as untoward contributions and become barriers to acceptance in the systems of academic medicine.

Isolation and feeling like an outsider resulted from a combination of barriers to communication and relationship formation with majority faculty; scarcity of faculty of color; and lack of role models. Lack of family instrumental support and social capital combined with education-related debt added to the burden of trying to advance professionally. Faculty experienced disrespect, discrimination, racism and a devaluing of their professional interests in community service and MHD. Women faculty commented on the double disadvantage of gender and minority status.

URM faculty experience social as well as professional discrimination and may feel justifiably angry. The "tokenism" and "window dressing" they describe pertains to at least three concepts: a lack of authenticity among institutional leaders in efforts to include minorities; the burden of having to represent one's entire race; and being on the receiving end of special programs and assumptions that the achievements of people of color are due to special favors rather than merit. Faculty ascribe a pivotal role to leadership in combating discrimination and achieving diverse faculties. Many leaders lack the experience of having different types of people in leadership roles, and it may seem risky to put power in the hands of less experienced people. Most URM faculty come from non-affluent families (in contrast to many white majority students) and incur substantial debt during training. URM physicians supported their households and often their extended families. The combination of this and dedication to their communities contributed to URM leaving academic medicine.

While published research on diversity in medical school faculty report on a single school,[18] on URM physicians in practice[15] and some national recommendations,[27] this paper's contribution is in-depth data on the experience of URM medical faculty from diverse subspecialties, collected from five disparate schools in different US regions. While we have

focused on URM faculty, other faculty of color may contend with many of the same disadvantages. The findings on relational barriers align with our study results in non-minority faculty.[28] Limitations of the study are those inherent in qualitative studies with relatively small numbers of participants: selection or sampling bias, potential for response bias and the subjective nature of analytic strategy. Even so, qualitative studies singularly allow voicing of perceptions of individuals who voluntarily share such information. We found the themes to be consistent and highly congruent for faculty of varying rank, discipline and sex across the five schools.

McIntosh observed that people who benefit most (in the short term) from privilege systems are mostly unaware of and blind to the existence of privilege systems. This preserves the myths of moral and managerial meritocracy.[29] This likely occurs because the exposure of bias is often painful and disturbing, particularly among individuals who explicitly hold egalitarian and humanitarian views. Having inherited unconscious biases that are manifested unintentionally in interpersonal interactions, these individuals may feel guilty about their own advantage (acquired typically without effort or consent on their part) and its role in keeping others disadvantaged. Through elucidation of URM faculty experiences, we hope to raise awareness among health professionals, educators, administrators and policy-makers of obstacles to achieving the goal of having URM faculty as leaders in academic medicine.

Medical schools and their policies need to reward service and research on community-based health care and MHD, similarly to other accomplishments and research if this work is to be shouldered by a broader set of faculty. Health disparities in the US are among the highest in the developed world, and reducing them is a major health priority.[30–32] Successful strategies to reduce disparities must address the physician workforce.[27,33] We propose that having more URM faculty in senior and leadership roles in medical schools will support training a more diverse physician population and increase the cultural awareness and skills of all physicians-in-training and biomedical scientists. These factors will contribute to a greater capacity to care for underserved groups and to better elucidate the causes of and solutions to health disparities. Failure to fully engage the skills and insights of URM faculty means that we don't have the best science and the best medical care that we could have. We agree that medical schools and their leadership should be evaluated on the extent to which their graduates meet the health needs of the nation.[33–35] Achieving a diverse medical school faculty would help meet the institutional mission of academic medicine to train a physician and research workforce that meets the needs of our multicultural society.

Choice of Initial Antiepileptic Drug for Older Veterans: Possible Pharmacokinetic Drug Interactions with Existing Medications

Mary Jo V. Pugh, PhD,[ab] Anne C. VanCott, MD,[cd] Michael A. Steinman, MD,[ef] Eric M. Mortensen, MD,[ag] Megan E. Amuan, MPH,[h] Chen-Pin Wang, PhD,[ab] Janice E. Knoefel, MD,[ijf] and Dan R. Berlowitz, MD, MPH[hl]

OBJECTIVES: To identify clinically meaningful potential drug–drug interactions (PDIs) with antiepileptic drugs (AEDs), the AEDs and co-administered drugs commonly associated with AED-PDIs, and characteristics of patients with high likelihood of AED-PDI exposure.

DESIGN: Five-year retrospective cohort study of veterans with new-onset epilepsy.

SETTING: National Veterans Affairs and Medicare databases.

PARTICIPANTS: Veterans aged 66 and older with a new diagnosis of epilepsy between October 1, 1999, and September 30, 2004 (N = 9,682).

MEASUREMENTS: AED-PDI was restricted to clinically meaningful PDIs identified using prior literature review. AED-PDIs were identified using participants' date of initial AED prescription and overlapping concomitant medications. Logistic regression analysis identified factors associated with AED-PDI, including demographic characteristics, chronic disease states, and diagnostic setting.

RESULTS: AED-PDI exposure was found in 45.5% (4,406/9,682); phenytoin, a drug with many PDIs, was the most commonly prescribed AED. Cardiovascular drugs, lipid-lowering medications, and psychotropic agents were the most commonly co-administered AED-PDI medications. Individuals with AED-PDI exposure were more likely to have hypertension (odds ratio (OR) = 1.46, 99% confidence interval (CI) = 1.24–1.82) and hypercholesterolemia (OR = 1.40, 99% CI = 1.24–1.57) than those without and to be diagnosed in an emergency or primary care setting than a neurology setting (emergency: OR = 1.30, 99% CI = 1.08–1.58; primary care: OR = 1.29 99% CI = 1.12–1.49).

CONCLUSION: Exposure to AED-PDI was substantial but less common in patients with epilepsy diagnosed in a neurology setting. Because potential outcomes associated with AED-PDI include stroke and myocardial infarction in a population already at high risk, clinicians should closely monitor blood pressure, coagulation, and lipid measures to minimize adverse effects of AED-PDIs. Interventions to reduce AED-PDIs may improve patient outcomes. **J Am Geriatr Soc 58:465–471, 2010.**

Key words: drug–drug interaction; epilepsy; geriatrics; antiepileptic drugs

Although many consider epilepsy to be a disease of childhood, the incidence of epilepsy is highest in older adults, with prevalence estimates between 1.8% and 2%.[1] Management of epilepsy in older patients is clinically challenging. In addition to concerns about ensuring that seizures be controlled with minimal side effects, older patients tend to have a number of comorbid conditions which require medications,[2] many of which have the potential to interact with commonly used antiepileptic drugs (AEDs).

A number of published reviews of treatment of older patients with epilepsy highlight, but fail to quantify, the risk of potential pharmacokinetic drug–drug interactions (PDIs) in individuals receiving older AEDs that are hepatically metabolized (e.g., phenytoin, carbamazepine, phenobarbital).[3–5] These drug–drug interactions may cause AED toxicity or reduce the efficacy of the interacting drug.[6,7] Because many of the drugs with potential interactions with

AEDs are used to treat hypertension, hyperlipidemia, and coagulation disorders, prolonged exposure to AEDs and potentially interacting drugs (PDIs) may be associated with adverse outcomes such as falls and fractures, stroke, myocardial infarction, and mortality.[8–10]

Recently, it was found that the majority of patients in all age groups received AEDs with the potential for pharmacokinetic drug–drug interactions and that many also received medications that may interact with those AEDs,[11] although it is unclear the extent to which AEDs with the potential for these drug interactions were prescribed concomitantly with potentially interacting drugs. Thus, little is known about the extent to which AED-PDIs occur or whether clinicians were cognizant of, and avoided, potential interactions.[11]

This study used national databases from the Veterans Health Administration, Department of Veterans Affairs (VA), to identify the extent to which older veterans with new-onset epilepsy had AED-PDI exposure. Although pharmacodynamic drug–drug interactions are also possible, this article focuses exclusively on pharmacokinetic drug–drug interactions. The duration of AED-PDI exposure, older patients at greatest risk of AED-PDI exposure, and those most likely to have the potentially interacting drug continued after starting AEDs were further identified.

METHODS

Data

After approval was received from institutional review boards at the University of Texas Health Science Center at San Antonio and the Bedford and Hines VA Hospitals, national VA inpatient, outpatient, pharmacy and Medicare data October 1, 1999, to September 30, 2004 (FY00-FY04), linked with an encrypted identifier to identify older veterans ($\geq$66) with new-onset epilepsy within the VA medical system were gathered. These data also allowed identification of the initial AED regimen received, concomitant medications received at the time of the first VA AED prescription, comorbid conditions, and demographic variables.

Population and Setting

A previously validated algorithm[12,13] was used to identify elderly individuals with new-onset epilepsy. Using an algorithm described previously,[13] older veterans with new-onset epilepsy were identified using the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM), code for epilepsy (345.XX) or convulsion (780.39) in VA inpatient, outpatient, and Medicare databases, and who also received an AED from the VA outpatient pharmacy within 1 year of the initial epilepsy diagnosis. Prior research found that, of those identified with epilepsy using this algorithm, 98% had documented epilepsy in the electronic medical record.[13]

Measures

Dependent Variable: PDIs

PDIs were identified based on "clinically important drug interactions" based on pharmacokinetic properties described previously.[6] Clinically important drug interactions include PDIs that may affect the clinical management of the patient or that might have severe adverse outcomes for patients.[7] The assessment was further restricted to drugs for chronic conditions such as hypertension, hypercholesterolemia, and mental health conditions rather than acute conditions such as infection. Although there is a potential for interactions between AEDs, only a small number individuals received potentially interacting AEDs, and they also had AED-PDIs. Thus, the focus was exclusively on the matter of AED-PDI in this study. As such, these AED-PDIs do not completely reflect the VA drug–drug interaction screening criteria, which are more broadly defined and include drug interactions defined as mild[14] and drug interactions that are not relevant to older patients (e.g., oral contraceptives). Table 1 provides a list of the most common PDIs that are particularly relevant for older individuals and the potential effect of each AED-PDI. Most AED-PDIs are associated with older AEDs that are cytochrome P450 inducers (phenytoin, carbamazepine, phenobarbital). Moreover, Micromedex defines many of these AED-PDIs as moderate.[14]

The initial AED regimens prescribed within the VA were first identified. All AEDs prescribed the day of the initial VA prescription were considered in the assessment of PDI. Next all unique medications in the current drug regimen the day of the AED prescription were identified. These drugs were determined using an algorithm that identified the initial fill date plus the day supply of that fill and all subsequent fills plus 30 days, because most patients are not entirely adherent with medications and have some medications left over at the end of the fill period. For the initial approach, those receiving drugs for chronic conditions identified as having clinically meaningful drug interactions with the initial AED were classified as having AED-PDIs.[6] Because whether interacting drug prescriptions were discontinued could not be accurately determined, the final measure of AED-PDI was restricted to those who received a subsequent prescription of potentially interacting drugs after the initial AED prescription, which accounts for changes physicians made to drug regimens that may address the PDI. To further assess PDI exposure, the median duration of each AED-PDI for the year after the initial AED prescription was also determined. The day supply of medications during the year was calculated as long as the patient received both the AED and the potentially interacting drug.

Independent Variables

Demographic Characteristics

Using VA and Medicare data sources, the age, sex, and race of each patient were identified. VA data were also used to identify marital status (married vs not married). Although information on race is frequently missing from VA data, Medicare data were supplemented when VA data were missing for race, leaving less than 1% missing race data.

Diagnosis-Related Issues

Because prescribing patterns changed over the years of the study, with greater use of newer AEDs over time, the fiscal year of first AED prescription (FY00, FY01, FY02, FY03, FY04) was included in logistic regression analyses.[13] Furthermore, because individuals in this cohort are generally eligible to receive health care through Medicare, whether

Table 1. Clinically Meaningful Drug Interactions

Drug Class or Drug	Anticonvulsant	Interaction or Potential Outcomes
Cardiovascular drugs		
Disopyramide, mexiletine, and quinidine	CBZ, PHT, PB	Decreased antiarrhythmic concentrations
Propranolol, metoprolol	CBZ, PHT, PB	May require increase dosage of beta-blocker
Nifedipine, felodipine, and nimodipine	CBZ, PHT, PB	May nullify effects of the calcium channel blocker
Diltiazem	CBZ, PHT	Increase AED plasma concentration
Nimodipine	VPA	Increase plasma concentrations of nimodipine
Verapamil	CBZ	CBZ toxicity
Atorvastatin, fluvastatin, lovastatin, and simvastatin	CBZ, PHT, PB	May reduce statin efficacy
Ticlopidine	PHT, CBZ	CNS toxicity by elevated AED plasma concentration
Hematological agents		
Warfarin	CBZ, PHT	Decreased anticoagulant effect
Central nervous system agents		
Amitriptyline	CBZ, VPA	Increases metabolism of and reduces plasma concentration of amitriptyline
Bupropion, paroxetine	PHT, PB	Reduced plasma concentrations of the antidepressant
Nefazodone	CBZ	Contraindicated; CBZ toxicity and reduced effectiveness of nefazodone
Nortriptyline, clomipramine, and amitriptyline	PHT	Concurrent use can result in PHT toxicity
Nortriptyline, clomipramine	VPA	May inhibit metabolism of antidepressant causing elevated plasma concentrations
Chlorpromazine, clozapine, haloperidol, ziprasidone, olanzapine, quetipine, mesoridazine, risperidone	CBZ, PHT	Decreased antipsychotic plasma concentrations can result in therapeutic failure
Gastrointestinal agents		
Cimetidine	CBZ, PHT	AED toxicity
Sucralfate	PHT	Decreased phenytoin effectiveness
Omeprazole	CBZ, PHT	AED toxicity
Systemic anti-infective agents		
Erythromycin	CBZ, VPA	AED toxicity
Doxycycline	CBZ, PHT, PB	May reduce doxycycline effectiveness

Source: Patsalos and Perucca (2003).
AED = antiepileptic drug; CBZ = carbamazepine; PB = phenobarbital; PHT = phenytoin; VPA = valproic acid.

the epilepsy diagnosis was first documented in VA or Medicare data was also determined because treatment may have been initiated outside of the VA setting.

Comorbid Conditions

Validated ICD-9-CM code algorithms were used to identify comorbid conditions the patient experienced before the date of the initial epilepsy diagnosis.[15–18] Comorbidities identified included those that are commonly treated with drugs that interact with commonly used AEDs (e.g., hypertension, cardiovascular disease, diabetes mellitus, hypercholesterolemia, psychological disorders (any vs no psychological disorders)) and those comorbidities that have been associated with epilepsy in epidemiological studies (e.g., stroke, dementia, brain tumors, head injury).[19–22]

Medication Burden

The number of unique medications for each individual the year before inclusion in the cohort was tracked and considered to be a proxy for overall medication burden.[23] Initially, medication burden was classified according to quartiles to ease interpretation of data. Because odds ratios were the same for those in the second through fourth quartiles, those groups were combined to create a dichotomous measure: low medication burden (1–5 medications) versus high medication burden ($\geq$6 medications).

Analysis

Frequencies of demographic and clinical characteristics were calculated for the cohort, and the rate and duration of AED-PDI was identified overall and according to AED. Multivariable logistic regression analysis was then conducted to identify factors that were associated with AED-PDI and to identify characteristics of those for whom the offending drug was not renewed after initiation of the AED. Because of the large cohort size, $P < .01$ was used as the level of significance. Interactions were included in the initial models; because none were statistically significant, they were not included in the final model.

RESULTS

Demographic Characteristics

The cohort consisted of 9,682 older veterans who met the criteria for new-onset epilepsy. The cohort were mostly male (98.0%) and white (78.5%); representation of blacks (15.8%) and Hispanics (4.9%; 0.8% other (Native American, Pacific Islander, Asian)) was similar to that of the overall elderly population.[24] Only 4.6% were aged 85 and older; 48.1% were aged 75 to 84, and 47.3% were aged 66 to 74. The majority of the cohort (64.7%) was married.

Context of Epilepsy Diagnosis

Table 2 shows that the incidence of epilepsy was relatively consistent over the study period and that 61.0% (n = 5,913) of patients had their initial epilepsy diagnosis documented first in Medicare data. The initial seizure diagnosis was identified in a VA neurology clinic or by a Medicare neurology provider for approximately 27% of patients.

Clinical Characteristics

Table 3 shows comorbid conditions and the unique number of drugs received the year before epilepsy diagnosis. Consistent with a new diagnosis of epilepsy, substantial numbers had prior diagnoses of stroke, dementia, and brain

Table 2. Context of Initial Seizure Diagnosis

Variable	n (%)
Year of diagnosis	
2000	1,843 (19.0)
2001	1,978 (20.4)
2002	1,947 (20.1)
2003	2,153 (22.2)
2004	1,761 (18.2)
Source of initial diagnosis	
Neurology	2,646 (27.3)
Primary care	2,870 (29.6)

≥2	1,506 (15.6)
Unique drugs, quintile (number of drugs)	
Q-1 (0–5)	2,848 (29.4)
Q-2 (6–8)	2,533 (26.3)
Q-3 (9–11)	1,883 (19.5)
Q-4 (≥12)	2,418 (25.0)
Potential drug interaction	4,406 (45.5)

* Congestive heart failure, myocardial infarction, or angina pectoris.
Study cohort N = 9,682.

tumor. Moreover, this population had significant disease burden, evidenced by high prevalence of cardiovascular disease (myocardial infarction, angina pectoris, and congestive heart failure), cardiac arrhythmias, chronic obstructive pulmonary disease, and diseases associated with metabolic syndrome such as hypertension, diabetes mellitus, and hypercholesterolemia. The population had a high prevalence of psychiatric comorbidity diagnosed before epilepsy diagnosis, with approximately half having at least one psychiatric diagnosis recorded in administrative data. The median number of unique drugs received the year before epilepsy diagnosis was eight.

Overall, 60.1% (n = 5,822) of study subjects received a drug with potential for clinically significant interactions with the initial AED. Of those with AED-PDI exposure on the day of AED prescription, 24.0% (n = 1,416) did not receive a subsequent refill of the potentially interacting drug, leaving 4,406 (45.5%) individuals with AED-PDIs.

Table 4 shows that rates of AED-PDI were highest for phenytoin, with 57.8% of new prescriptions associated with PDI. More than half of individuals prescribed phenobarbital (51.6%) or carbamazepine (55.5%) also received a potentially interacting drug. Four groups of medications accounted for approximately 94% of those with a persistent AED-PDI: cardiovascular drugs (e.g., metoprolol, felodipine), lipid-lowering drugs (e.g., simvastatin, lovastatin), psychotropic drugs (e.g., olanzapine, trazodone), and anticoagulants (e.g., warfarin, dicoumarol). Of the cohort, 26.4% had cardiovascular drug AED-PDIs (n = 2,552), 20.7% had lipid-lowering drug AED-PDIs (n = 2,007), 14.9% had psychotropic drug AED-PDIs (n = 1,444), and 6.2% had anticoagulant

Table 4. Potential Drug Interactions(PDIs) According to Antiepileptic Drug (AED)

AED	n (%)	Initial Approach, n (%)*	Conservative Approach, n (%)†	Median Day Supply for All PDIs the Year After AED Prescription	Most Common Interacting Drugs
Phenytoin	6,477 (66.9)	4,965 (76.7)	3,721 (57.5)	239	Metoprolol, digoxin, felodipine, sertraline
Phenobarbital	246 (2.5)	167 (67.9)	127 (51.6)	265	Simvastatin, metoprolol, warfarin
Carbamazepine	824 (8.5)	565 (68.6)	457 (55.5)	216	Simvastatin, metoprolol, warfarin
Valproate	545 (5.6)	119 (21.8)	97 (17.0)	232	Sertraline, paroxetine, amitriptyline,
Totals	9,682 (100)	5,822 (60.1)	4,406 (45.5)		

AEDs with fewer than 11 potential drug interactions are not presented because of Department of Veterans Affairs data security requirements.
* All individuals who received an AED with a clinically meaningful drug interaction with ongoing medication on the day of the initial AED prescription.
† Only individuals with a subsequent prescription of interacting medications.

AED-PDIs (n = 601). Of those with a persistent AED-PDI, 48.0% had two or more concomitant AED-PDIs.

The duration of exposure was often long. Table 4 shows the median number of days of PDI prescription for the first year of epilepsy treatment. The day supply for AED-PDI was more than 200 days, with medians ranging from 216 to 265 days.

Odds ratios (ORs) and 99% confidence intervals (CIs) from the multivariable logistic regression analysis predicting AED-PDI exposure are presented in Table 5. The strongest predictors of PDI were having hypertension or hypercholesterolemia and receiving six or more medications the year before epilepsy diagnosis. Moreover, individuals initially diagnosed with epilepsy in an emergency department or primary care settings were significantly more likely to have AED-PDI exposure than were those initially diagnosed in a neurology setting. Individuals with a lower likelihood for AED-PDI exposure included those who were older and those with a diagnosis of liver disease.

Logistic regression analysis predicting renewal of interacting drug after initiation of AED (full data not shown) found that age, several chronic disease states, and year of initial AED prescription were significant predictors. Those who were aged 66 to 74 were less likely to have an interacting drug renewed after the prescription of the initial AED than those who were aged 75 to 84 (OR = 0.82, 99% CI = 0.70–0.98, $P = .004$). Individuals with dementia (OR = 0.80, 99% CI = 0.66–0.97, $P = .002$), metastatic cancer (OR = 0.64, 99% CI = 0.47–0.86, $P < .001$), and chronic obstructive lung disease (OR = 0.72, 99% CI = 0.60–0.85, $P < .001$) were less likely to have interacting drugs renewed. Finally, those receiving their AED in FY04 were less likely to have the interacting drug renewed after the prescription of the initial AED than were individuals who received their AED in FY00 (OR = 0.68, 99% CI = 0.52–0.88, $P < .001$).

Table 5. Logistic Regression: Predictors of Potential Antiepileptic Drug–Drug Interaction

Variable	Odds Ratio (99% Confidence Interval)	*P*-Value
Demographic characteristic		
Age (vs 66–74)		
75–84	0.86 (0.77–0.96)	<.001
≥85	0.69 (0.53–0.91)	<.001

DISCUSSION

Despite the availability of AEDs with low potential for AED-PDI, the majority of older patients with epilepsy in the United States are treated with AEDs with high AED-PDI potential (phenytoin, carbamazepine, and phenobarbital).[11,13] The problem of AED-PDI has been identified as a consideration in selecting AEDs for older patients in numerous review articles.[3–6] To the authors' knowledge, this is the first study that has systematically examined the scope of the AED-PDI problem in a geriatric population and further identified the patient characteristics (diagnostic setting, age, comorbidities) associated with risk of AED-PDI. Nearly half of all older patients in the current study received an AED that interacted with existing, chronic medications. Of those with AED-PDI exposure, nearly half had multiple AED-PDIs, and AED-PDI exposure was long, suggesting that healthcare providers need to increase their awareness of AED-PDIs in caring for older adults.

Of the four classes of concomitant medications that accounted for 94% of AED-PDIs, the most common were drugs used in the treatment of vascular disease. This is not surprising, because stroke is the most common etiology associated with new-onset epilepsy in older adults, and 80% of older adults have been diagnosed with hypertension and hyperlipidemia.[2,13] These potential interactions are of great clinical relevance, because they may affect health outcomes. Potential interactions identified by this study may significantly reduce the efficacy of antihypertensive medications, including beta-blockers, calcium agonists, and angiotensin-receptor blockers, in some case without altering serum drug concentrations.[25–28] In addition, previous research has found that co-administration of carbamazepine with orally

administered simvastatin, a 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor used in the treatment of dyslipidemia, led to an 80% reduction in bioavailability of simvastatin.[29] This effect would require increasing the dose of simvastatin by a factor of four to achieve therapeutic blood concentrations. Lastly, warfarin-related AED-PDIs may result in altered anticoagulation properties of this drug, leading to a prolongation of the prothrombin time. All of these AED-PDIs could potentially increase the risk for stroke and heart attack and hemorrhage, leading to significant patient morbidity and mortality.

These data highlight the complexity of adding medications to the regimens of older patients with multiple medical conditions. Healthcare providers caring for older patients must be vigilant in the selection of an AED, especially in those with vascular disease, and closely monitor the treatment of hypertension, dyslipidemia, and anticoagulation therapy. Although the data did not allow this clinical behavior to be examined, future research should consider the extent to which such monitoring is conducted.

The examination of risk factors for AED-PDIs and the likelihood of having an interacting drug renewed suggest that clinicians in neurology clinics may have a greater awareness of AED-PDIs than providers in primary care or the emergency department. The data also suggested more caution on the practioner's part with regard to medication problems in patients who might be considered frail. The oldest-old (85) and individuals with dementia and liver disease were less likely to have AED-PDI exposure than their younger counterparts and those without such disease. The finding regarding age is consistent with previous findings from studies of suboptimal prescribing in older adults.[30–32] The consistency of these findings to more general studies of suboptimal prescribing in older adults suggest that providers are generally more cautious when making changes to medication regimens in these more-vulnerable patients. Regarding liver disease, it is possible that providers preferentially prescribed gabapentin—a drug that is primarily renally cleared and has no significant drug interactions—for those with impaired liver function.[33]

The findings of the current study must be interpreted in light of several unique features of the study. First, it examined only AED-PDIs in those with new-onset epilepsy. This "incident case" approach allowed the extent to which providers are aware of, and consider, AED-PDIs in their initial AED prescribing decision and early on in treatment to be better understood, because AEDs are rarely changed once seizures are successfully controlled unless the patient experiences adverse drug events. Although individuals who did not have interacting medications continued after the initial AED prescription were excluded from the analysis, the method did not examine changes made to prescriptions that were continued. It is possible that clinicians altered dosage or increased monitoring in response to the AED-PDI. Future research should examine this possibility.

A second feature is that this study was based in a single integrated healthcare system (the VA healthcare system) in which most of the cohort had a copayment waiver because of poverty or severe disability. Thus, the generalizability of the findings to other settings is unclear. Other systems with a fee-for-service model or multitiered formulary may have had higher rates of AED-PDIs during the study period because AEDs with fewer PDIs tended to be more expensive than phenytoin or carbamazepine. Because prescribing patterns for AEDs appear to be similar to those presented previously[11] and this cohort included those whose first diagnosis (and possibly AED prescription) occurred in the context of a non-VA Medicare provider, it is likely that this bias is minimized, although it is possible that AED-PDI patterns are different in women because studies have found different patterns of suboptimal prescribing in women,[34] so further exploration of AED-PDIs in older women is needed.

Moreover, the analysis included only medications dispensed by the VA, but during the time of this study, most older veterans who receive prescription drugs through VA received few prescription drugs from outside sources;[35] thus this potential bias is limited.

Finally, these data reflect prescribing patterns several years ago. Increasing use of automatic, computerized medication alerts at the time of prescribing within the VA have occurred since this time and may be reflected in the significant reduction of AED-PDIs between October 1, 1999, and September 30, 2004, and the finding that individuals with AED-PDIs were more likely to have the interacting drug dropped in FY04 than in FY00. Examination of more-contemporaneous data is needed to examine changes in AED patterns and concomitant changes in AED-PDIs.

These data suggest that exposure to AED-PDI is highly prevalent in older patients newly diagnosed with epilepsy, primarily because of the high rates of use of phenytoin and to a lesser extent carbamazepine. Despite evidence of slowly growing awareness of this patient safety problem, there is substantial room for improvement. Because pharmacological data suggest that AED-PDIs may reduce the efficacy of the interacting drug or cause AED toxicity, prolonged AED-PDI exposure has the potential to result in adverse outcomes such as falls and fractures, stroke, myocardial infarction, excessive anticoagulation, or even death.[6,7] Thus, it is time to consider implementing interventions to reduce AED-PDIs in older patients with epilepsy. Data from prior studies suggest that integrating neurology[36] and clinical pharmacy consultation,[37] combined with electronic medical records systems that alert clinicians to PDIs,[38] may improve care quality and outcomes in this vulnerable population.

ACKNOWLEDGMENTS

A Pilot Study Assessing Knowledge of Clinical Signs and Physical Examination Skills in Incoming Medicine Residents

Subha Ramani, MBBS, MMEd, MPH
Brandi N. Ring, MA
Robert Lowe, MD
David Hunter, MBBS, MSc, PhD

Abstract

Background Physical exam skills of medical trainees are declining, but most residencies do not offer systematic clinical skills teaching or assessment.

Objective To assess knowledge of clinical signs and physical exam performance among incoming internal medicine residents.

Method For this study, 45 incoming residents completed a multiple choice question test to assess knowledge of clinical signs. A random selection of 20 underwent a faculty-observed objective structured clinical examination (OSCE) using patients with abnormal physical findings. Mean percentage scores were computed for the multiple choice question test, overall OSCE, and the 5 individual OSCE systems.

Results The mean scores were 58.4% (14.6 of 25; SD 11. 5) for the multiple choice question test and 54.7% (31.7 of 58; SD 11.0) for the overall OSCE. Mean OSCE scores by system were cardiovascular 30.0%, pulmonary 69.2%, abdominal 61.6%, neurologic 67.0%, and musculoskeletal 41.7%. Analysis of variance showed a difference in OSCE system scores ($P < .001$) with cardiovascular and musculoskeletal scores significantly lower than other systems.

Conclusion Overall, physical exam knowledge and performance of new residents were unsatisfactory. There appears to be a pressing need for additional clinical skills training during medical school and residency training and we are planning a new clinical skills curriculum to address this deficiency.

Editor's Note: The online version of this article includes the sample questions for the multiple choice test and the faculty scoring sheet for the OSCE for the cardiac exam station.

Background

Physical examination skills traditionally have been viewed among the most valuable skills taught during medical education,[1–4] contributing to more cost-effective use of diagnostic services, while rewarding physicians with the excitement and satisfaction of making a diagnosis using their knowledge and skills.[1,2] These skills also increase direct contact with patients, and the therapeutic value of the human touch is impossible to quantify.[2]

Several investigators have reported an overall decline in clinical skills of medical students and residents,[5–10] with residents less well prepared for taking an adequate medical history, performing a reliable physical examination, and effectively communicating with patients,[11] while relying on ordering tests without always knowing how to interpret them.[1,11] In an era of increasing health care costs we need to reconsider the importance of physical examination skills.[1,2]

Despite documented deficiencies in clinical skills, medical school and residency curricula do not emphasize clinical skills teaching or assessment.[3,7,12] Reported barriers to teaching clinical exam skills include a scarcity of good teaching patients, lack of time for teaching at the bedside, an over-reliance on technology, and a shortage of skilled faculty to impart this knowledge.[11,13]

Before developing a new clinical skills curriculum for our internal medicine residency program, we wished to explore the physical exam skills of our incoming residents as needs assessment.

Our study objectives were

1. To investigate the knowledge of clinical signs as well as the physical exam skills of new postgraduate year 1 (PGY-1) residents using volunteer patients during an objective structured clinical examination (OSCE)
2. To explore system-specific strengths and weaknesses in their physical exam skills

Methods

Setting and Participants

Incoming internal medicine PGY-1 residents at Boston University School of Medicine completed a written multiple choice question (MCQ) test on clinical signs and a randomly selected subsample completed a physical exam assessment during their residency orientation in June 2006. These tests were designed as a pretest prior to implementation of a new clinical skills curriculum. The protocol for this study was approved by the Institutional Review Board at Boston University School of Medicine.

A planning committee consisting of generalist and subspecialist faculty from the Department of Medicine discussed and finalized the MCQ test questions and the OSCE scoring sheets after review of questions from the Membership of the Royal College of Physicians and other examinations as well as detailed discussions of essential elements of system-specific physical examination. This core group of faculty consistently taught residents bedside clinical skills, had a reputation of being skilled clinical diagnosticians, and served as preceptors for the OSCE.

The written test consisted of 25 MCQs designed to evaluate the ability of the residents to interpret and diagnose physical exam findings. The 5 major systems, cardiovascular, neurologic, pulmonary, gastrointestinal, and musculoskeletal, were represented.

The OSCE used volunteer patients with abnormal physical findings recruited from the medical wards and clinics. The 5 stations included cardiac, pulmonary, abdominal, neurologic, and musculoskeletal systems. At each station a faculty examiner instructed the residents to perform a focused physical exam, completed a scoring sheet, and provided feedback in 10 minutes. All faculty preceptors underwent an orientation to the procedures of observation and feedback during the OSCE as well as the scoring. A sample score sheet is included in Appendix B. Each item on the scoring sheet was graded on a 3-point rating scale from 0 to 2 points. Two points were awarded if the element was performed correctly, 1 point if the element was performed with room for improvement, and no points awarded if the exam was omitted. The OSCE encompassed 5 to 6 elements on exam technique and 1 to 2 elements on interpretation and diagnosis, for a maximum score of 58 points.

Statistical Analysis

Descriptive analysis was performed on the data collected for the PGY-1 cohort, and we calculated mean percentage scores for the MCQ test and the OSCE. The OSCE scores were then analyzed by individual organ system. We wished to examine whether there were differences in physical exam performance for different systems. Scores for each individual system were ranked and then compared using analysis of variance. If a difference was detected, we explored further where the differences lay by pair-wise comparison using Tukey minimum significant differences. All analysis was run at $\alpha = .05$ level using SAS version 9.0 (SAS Inc, Cary, NC) and Excel XP (Microsoft, Redmond, WA).

Results

A total of 45 internal medicine PGY-1 residents at Boston University School of Medicine completed the MCQ test and 20 completed the 5-station physical exam OSCE. Most were US medical graduates from several different medical schools; 2 were international medical graduates.

The overall mean score for the written test was 58.4% with a standard deviation of 11.5 and range 36.0 to 80.0 ($n = 45$). There was no statistical difference between the scores of those residents chosen to undergo the OSCE and those not selected ($P = .261$).

The mean overall OSCE score was 54.7% with a standard deviation of 11.0 and range 39.7 to 84.5 ($n = 20$). Analysis of variance showed significant differences in the OSCE scores for individual systems ($P < .05$) with the cardiovascular and musculoskeletal examination scores being significantly lower than the pulmonary, neurology, and abdominal examinations scores. The overall MCQ, OSCE, and individual system scores are shown in the TABLE.

Examples of errors observed in residents' physical exam include

1. Faulty exam technique
   a. Not using bell and diaphragm of stethoscope
   b. Not eliciting shifting dullness correctly
2. Lack of systematic exam
   a. Skipping inspection or palpation completely
   b. Not following a stepwise exam such as motor strength, tone, reflexes, gait, and so forth
3. Failure to identify findings
   a. Identification of diastolic murmur
   b. Identification of bronchial breath sounds
4. Failure to interpret findings and make a diagnosis
   a. Differentiating between upper and lower motor neuron signs

TABLE **Mean Percent Scores**

Test	N	Mean	Median	SD	Score Range
MCQ (all PGY-1)	45	58.4	56.0	11.5	36.0–80.0
MCQ (PGY-1 w/OSCE)	20	61.0	60.0	11.9	36.0–80.0
OSCE total	20	54.7	61.3	11.0	39.7–84.5
Cardiology	20	30.0	30.0	21.3	0–100
Pulmonary	20	69.2	66.6	18.2	41.7–100
Abdominal	20	61.6	58.3	16.6	33.3–91.7
Neurologic	20	67.0	66.6	14.8	33.3–100
Musculoskeletal	20	41.7	37.5	17.1	25–100

Abbreviations: MCQ, multiple choice question; OSCE, objective structured clinical examination; PGY-1, postgraduate year 1.

5. Difficulty formulating differential diagnosis for a given finding
   a. Causes of ascites
   b. Causes of knee effusions

Discussion

The newly graduated medical students entering internal medicine residency in our study scored less than 60% on average in a knowledge test of clinical signs as well as a physical exam OSCE. Errors were noted in physical exam technique as well as diagnosis. Many studies have reported less than satisfactory physical exam skills among trainees. Dupras and Li[14] found mean scores of 50 ± 11 in physical examination and diagnosis stations of an OSCE assessing postgraduate year 2 internal medicine residents.[14] Vukanovic-Criley and colleagues[9] reported that cardiac exam skills improved between years 1 and 2 of medical school and reached a plateau thereafter.

The variability of exam performance between systems may be a result of different exposures during medical school clinical rotations and a measure of interest in the given field. However, based on the substantial difference from other systems we surmise that there are deficiencies in both cardiovascular and musculoskeletal teaching.

The strengths of this study are the use of trained faculty members to observe and assess the OSCE allowing for more consistent scoring. The study used real patients with abnormal physical examination findings rather than standardized patients with scripted history and answers to questions. This is a more accurate representation of the kind of encounters that medical trainees will be exposed to in clinical practice. The OSCE also served as a learning tool as participants were provided with immediate feedback from faculty on their physical examinations skills.

Limitations

Our study has some limitations. We tried to limit variability in scoring by faculty orientation and use of objective and easily observable physical exam behaviors, but different faculty observers may exhibit variable leniency in scoring. There also may have been variability in the degree of difficulty between patients at different stations. We present cross-sectional data that may reflect many different factors including prior medical school training and interest. We hope to ascertain in subsequent studies the trajectory of knowledge and skills following implementation of a clinical skills curriculum. We did not set out to test the psychometric properties of our assessment instrument but tried to address content validity to ensure that the instrument is appropriate to measure what we intended to measure, but future studies need to test the validity of instruments that can assess physical diagnosis skills with precision while being reliable.

Conclusions

There is a strong indication that additional clinical skills training and assessment are needed during medical school as well as residency training. Standardized patient examinations should supplement, but not replace, direct observation of trainees as only real patient interactions can help educators document longitudinal growth of trainees' clinical skills.[14] Faculty development is also crucial as many clinical faculty do not feel confident of their own clinical skills.[13] Questions have been raised about the validity of standardized patient encounters alone in assessing higher-level trainees as they cannot assess diagnostic skills.[15–17]

Although many educators espouse the value of clinical skills,[1–3,18] some skeptics have questioned whether these skills are anachronistic.[19] Future studies will need to investigate whether a formal curriculum will improve and sustain the clinical skills of residents. The predictive values of many physical examination techniques and findings have

been evaluated,[2,18] and the *JAMA* Rational Clinical Examination series is the foremost example of evidence-based physical diagnosis.[20] It is vital that clinical educators continue to study the clinical utility of physical findings and discard signs or maneuvers of little value; modern technology can be very helpful in achieving these goals.

Our pilot study examined the status of physical exam skills in a sample of newly graduated medical students. It is one step in a comprehensive attempt to assess the details of physical examination deficiencies among our residents to advance our understanding of the underlying concepts of such deficiencies. Ideally, before the findings are used in the design of a clinical skills curriculum, a larger group of residents needs to be studied using precurriculum and postcurriculum intervention assessment, and the reliability and validity of instruments to assess physical diagnosis skills need to be tested, to assess whether previously validated OSCE assessments would be useful. To reinforce and maintain the improvement in clinical skills that could be achieved through a systematic curriculum, educators also need to reinforce these skills in the clinical setting, role-model their use, and demonstrate their value in quality patient care. Finally, research is needed to assess whether improvement in clinical skills is essential for patient care in modern-day medicine, namely, whether improved clinical skills lead to more timely diagnosis, reductions in inappropriate use of resources, and improvements in patient satisfaction.

Cohort study

High blood pressure while taking antithrombotic medication is associated with an increased risk of developing intracranial haemorrhage

Commentary on: **Toyoda K**, Yasaka M, Uchiyama S, *et al.*; Bleeding with Antithrombotic Therapy (BAT) Study Group. Blood pressure levels and bleeding events during antithrombotic therapy: the Bleeding with Antithrombotic Therapy (BAT) Study. *Stroke* 2010;**41**:1440–4.

Context

Major haemorrhage, particularly intracranial haemorrhage (ICH), is a dreaded consequence of antithrombotic therapy. Strategies to mitigate this risk are needed as indications for antithrombotic therapy increasingly extend to older, high-risk patients. A previous large-scale randomised controlled trial demonstrated the benefits of lowering blood pressure (BP) in preventing recurrent stroke.[1] In addition, a posthoc analysis of pooled data from the SPORTIF trials suggested a threshold BP of <140/80 mm Hg to decrease risk of stroke. In that study, extrapolation to haemorrhagic stroke was limited by the small number of ICH events (n=17).[2] The current study sought to validate these findings in a non-trial setting and to better define the temporal relationship between BP and recurrent stroke.

Methods

The study focused on a prospective, observational cohort of 4009 patients from 19 stroke and cardiovascular centres in Japan. All patients were receiving antiplatelet agents and/or warfarin for cardiovascular prevention; most (57%) had a prior ischemic or haemorrhagic stroke. Patients were observed for 2–30 months; BP was measured at 1-month intervals. The outcome of interest, assessed by questionnaire at each monthly visit, was major haemorrhage. For this study, patients were divided into three groups: ICH, ECH (extracranial haemorrhage requiring transfusion or entailing a risk of disability) and no haemorrhage. The relationship between BP (both systolic (SBP) and diastolic (DBP)) and outcomes was analysed using entry BP, mean overall BP and most recent BP. Covariates (known or suspected risk factors for haemorrhage) included age, sex, prior stroke, heart disease, cancer, cirrhosis, hypertension, diabetes, hyperlipidemia, current or previous smoking and alcohol consumption of two or more drinks per day.

Findings

BP at study entry was not a significant predictor of outcomes after adjustment. However, after adjustment, average SBP between 1 and 6 months of follow-up (HR 1.45 per 10 mm/Hg increase), average SBP between 7 and 12 months (HR 1.47) and average DBP between 7 and 12 months (HR 2.05) were significantly associated with ICH (but not ECH). The relationship between the most recent BP and the risk of ICH was even stronger and more monotonic: BP preceding ICH (142/81 mm/Hg) was significantly higher than BP preceding no haemorrhage (132/75 mm/Hg). Using receiver operating characteristic curves, the optimal BP level to reduce the risk of ICH was determined to be 130/81 mm/Hg or lower.

Commentary

This study affirms the relationship between BP and risk of ICH in a non-trial, high-risk population receiving antithrombotic therapy. As older age, prior stroke and antithrombotic therapy all increase the risk of ICH, the importance of BP control in this patient population cannot be overemphasised. It is of note that in this study, BP worsened over time, unlike the improved control seen in most trials. This would have strengthened the association between the most recent BP and ICH. More intensive management of BP can improve control,[3] and it is likely that the patients in this study would have benefited from more intensive BP management. As acknowledged by the investigators, the relatively small number of ICH events (n=31) precluded exploration of BP thresholds among the highest-risk subsets, for example, older individuals on dual therapy. In addition, almost half of the patients were taking warfarin; it would have been ideal to account for the contribution of INR (international normalized ratio) control as a predictor of major haemorrhage[4] when examining the impact of BP.

This study also showed that while uncontrolled BP increases the risk of ICH, it does not seem to increase the risk of ECH. It is likely that extracranial vascular beds are less subject to the changes in flow and sheer stress and subsequent vascular remodelling wrought by uncontrolled hypertension. The authors properly suggest that though scrupulous BP control may help reduce the risk of ICH, reducing the risk of ECH may require other approaches.

Overall, this study demonstrates that real clinical benefit can be expected from efforts to improve BP

control in high-risk patients. The next step would be an implementation study of a programme to improve BP control in patients receiving antiplatelet and/or anticoagulant therapy. Such a study should be designed to demonstrate not only that the intervention helped patients but also how it can practicably be replicated in diverse settings.

Summary. *Background:* In patients receiving oral anticoagulation, improved control can reduce adverse outcomes such as stroke and major hemorrhage. However, little is known about patient-level predictors of anticoagulation control. *Objectives:* To identify patient-level predictors of oral anticoagulation control in the outpatient setting. *Patients/Methods:* We studied 124 619 patients who received oral anticoagulation from the Veterans Health Administration from October 2006 to September 2008. The outcome was anticoagulation control, summarized using percentage of time in therapeutic International Normalized Ratio range (TTR). Data were divided into inception (first 6 months of therapy; 39 447 patients) and experienced (any time thereafter; 104 505 patients). Patient-level predictors of TTR were examined by multivariable regression. *Results:* Mean TTRs were 48% for inception management and 61% for experienced management. During inception, important predictors of TTR included hospitalizations (the expected TTR was 7.3% lower for those with two or more hospitalizations than for the non-hospitalized), receipt of more medications (16 or more medications predicted a 4.3% lower than for patients with 0–7 medications), alcohol abuse (− 4.6%), cancer (− 3.1%), and bipolar disorder (− 2.9%). During the experienced period, important predictors of TTR included hospitalizations (four or more hospitalizations predicted 9.4% lower TTR), more medications (16 or more medications predicted 5.1% lower TTR), alcohol abuse (− 5.4%), female sex (− 2.9%), cancer (− 2.7%), dementia (− 2.6%), non-alcohol substance abuse (− 2.4%), and chronic liver disease (− 2.3%). *Conclusions:* Some patients receiving oral anticoagulation therapy are more challenging to maintain within the therapeutic range than others. Our findings can be used to identify patients who require closer attention or innovative management strategies to maximize benefit and minimize harm from oral anticoagulation therapy.

Keywords: ambulatory care, anticoagulants, chronic disease, quality of health care, warfarin.

Background

Warfarin is received by millions of patients in the USA for the treatment and prevention of thromboembolic diseases [1]. Although it is highly effective, warfarin has a narrow therapeutic window, and undergoes numerous interactions with drugs, diet, and comorbid conditions [1]. The potential consequences of deviating from the therapeutic range are serious: insufficiently anticoagulated patients remain at risk for thromboembolic events [2], and over-anticoagulated patients are at risk for major hemorrhage, particularly intracranial hemorrhage [3].

Despite the importance of good control for patients receiving warfarin, little is known about patient-level predictors of percentage time in therapeutic International Normalized Ratio (INR) range (TTR) [4], a measure of anticoagulation control over time. White *et al*. [5] identified several patient-level factors that predicted poor control (TTR < 60%): non-white race, paroxysmal as opposed to continuous atrial fibrillation, and being new to warfarin ('inception'). Our group [6] found additional factors that predict poor control: non-standard target INR range (i.e. other than 2.0–3.0), and female sex. These studies examined a relatively narrow range of patient-level factors, and lacked the power to examine uncommon predictors or factors with real, but modest, effects on TTR.

Here, we used data from almost 125 000 patients receiving oral anticoagulation from the Veterans Health Administration

[Veterans AffaiRs Study to Improve Anticoagulation (VARIA)], to explore a more comprehensive range of patient characteristics as potential predictors of anticoagulation control. Our findings could help clinicians and healthcare systems to identify patients who require extra attention or innovative management strategies to achieve acceptable levels of anticoagulation control.

Methods

Data

The VARIA database included all patients deemed to be receiving oral anticoagulation therapy (OAT) from the Veterans Health Administration (VA) between 1 October 2006 and 30 September 2008. The VA, the largest integrated health system in the USA, delivered care to 5.6 million patients in 2009, representing 1.8% of the US population [7]. Patients become eligible to receive VA care by serving in the military for two or more years; eligibility is for life. Many patients receive all of their care in the VA system, although some also visit non-VA healthcare facilities for a portion of their care. The VA collects comprehensive data regarding the care delivered within the VA system, including demographics, dates of service, pharmacy, and laboratory data. Laboratory data, including INR values, are first entered into local clinical databases (uploaded from the laboratory analyzer), and then these local databases are periodically uploaded to the national VA Corporate Data Warehouse, the source for our data. The study was approved by the Institutional Review Board of the Bedford VA Medical Center.

Each VA site consists of a central hospital along with its on-site outpatient clinics and several outlying satellite clinics. By policy, all VA anticoagulation care is delivered in dedicated anticoagulation clinics (ACCs) [8]. However, VA ACCs differ in organization, management, and performance. We address these between-site differences in a separate article.

We included INR tests within the VA when patients were 'on warfarin': that is, when a patient was either (i) 'in possession' of warfarin or (ii) having INR tests every 42 days. A similar approach was used to define time 'on warfarin' in a previous study [9]. We defined the period of warfarin possession as the duration of the most recent VA prescription for warfarin, plus 30 days. Because patients may be instructed to take half-doses of warfarin, we recognize that going more than 30 days beyond the end of a prescription does not necessarily indicate that warfarin therapy has stopped. We therefore also allowed a consistent pattern of INR measurements (i.e. every 42 days or less) to indicate that a patient was still being managed. Patients with chronic liver disease only qualified though receipt of warfarin; frequent INR tests for such a patient might have been performed to monitor liver function. We excluded INR tests performed while the patient was hospitalized within the VA system. Patients who are hospitalized may receive temporary parenteral anticoagulation (e.g. with heparin) or no anticoagulation, so low INR values are likely to be intentional.

Dependent variable: TTR

We calculated TTR (between 0% and 100%) using Rosendaal's method [4], which uses linear interpolation to assign an INR value to each day between two successive observed INR values. Gaps of 56 days or more between INR values are not interpolated. After interpolation, the percentage of time during which the interpolated INR values lie between 2 and 3 is calculated [4]. Previous studies have linked TTR and clinical outcomes such as stroke, venous thromboembolism (VTE), and major hemorrhage [5,10], thus validating this intermediate outcome measure for use as a surrogate endpoint for OAT [11].

Independent variable: primary indication for OAT

Patients receiving OAT for different indications may vary in duration of therapy, INR target range, health status, and other factors. We developed an algorithm to assign a primary indication for therapy to patients with more than one of these conditions. A list of the ICD-9 codes used to define these conditions is given in Appendix S1. When present, valvular heart disease (VHD) was considered to be the primary indication; if VHD was absent, VTE was the primary indication; if both VHD and VTE were absent, atrial fibrillation (AF) was the primary indication. If VHD, VTE and AF were absent, a group called 'other indications' (including cardiomyopathy, left ventricular thrombus, and left ventricular aneurysm) encompassed all other therapeutic indications [1].

Independent variables: demographics

We collected patient demographics, including sex, age, race/ethnicity, and zip code of residence. Race/ethnicity was classified as non-Hispanic White, non-Hispanic Black, Hispanic, Asian, Native American, and Missing (11%). We did not attempt to impute race, because of concern that it was not missing by chance [12]. The patient's zip code of residence was linked to US Census data [13] to obtain the percentage of people living below the federal poverty line in each geographic area, which was used as a proxy measure for socio-economic status [14]. We also used the patient's zip code of residence to obtain the straight-line driving distance between the centroid representation of the zip code and the nearest VA healthcare facility.

Independent variable: warfarin experience

We have previously observed that anticoagulation control differs markedly between the first 6 months of therapy ('inception') and the period thereafter ('experienced') [6]. We therefore examined predictors of TTR separately for each period. We defined each patient's date of warfarin initiation, looking back as far as 1 October 2001. Initiation was defined as the first INR value greater than 1.2 or the first outpatient warfarin fill, whichever came first. It would be extremely unusual for a patient to record an INR value above 1.2 unless

he or she had taken warfarin. We then stratified the sample into inception time (the first 6 months of warfarin therapy for each patient) and experienced time (any time thereafter). A single patient might contribute only to the inception dataset (if he or she had less than 6 months of therapy), only to the experienced dataset (if he or she began warfarin more than 6 months prior to the inception of our study), or to both. Having controlled for inception data through stratification, we also considered duration of warfarin experience as a potential indicator within the experienced dataset.

Independent variables: clinical variables

We used ICD-9 codes to define comorbid conditions as detailed in Appendix S2. Previous studies have demonstrated that ICD-9 codes can be used successfully to identify comorbid conditions within VA databases [15,16]. Conditions were examined because they were expected to affect anticoagulation control. Examples include conditions already shown to worsen anticoagulation control (e.g. cancer) [17], conditions treated with medications that interact with warfarin (e.g. epilepsy and bipolar disorder), conditions associated with chaotic lifestyle or poor adherence (e.g. dementia and substance abuse), and conditions that directly interfere with hepatic function (e.g. alcohol abuse and chronic liver disease). To further characterize each patient's illness burden, we also counted the number of times each patient was hospitalized within the VA system during the inception period (zero, one, or two or more) and during the experienced period (zero, one, two, three, or four or more), as well as the total number of distinct classes of non-warfarin medications received chronically (for at least 30 days) during the study period (0–7, 8–11, 12–15, and ≥ 16).

Assembling the final database

Figure 1 describes our database construction. First, we required at least two interpolable between-test intervals of 56 days or fewer for study entry, to ensure that our population consisted of 'VA users', or patients who use the VA for most or all of their care. We excluded patients whose primary indication for warfarin was VHD, since their target INR range might be 2.5–3.5 rather than 2–3. We also excluded patients who only recorded INR values 1.2 and lower, reasoning that their INR tests were unlikely to be related to warfarin management. Finally, we required at least two interpolable between-test intervals of 56 days or fewer for study entry, to ensure that our population consisted of 'VA users', or patients who use the VA for most or all of their care.

There are 128 sites of care in the VA system. We excluded 28 of these sites from our study and also excluded several months of data from an additional 14 sites, because our data-checking procedures revealed possible problems with data completeness at those sites. The problem with data completeness relates to the laboratory data only. Whereas accurate data are collected about which laboratory tests are performed (because something akin to a billing code is generated), the data regarding laboratory results must be checked carefully. Specifically, the name given to each laboratory test by the local facility is not uniform throughout the system, and these names may change unexpectedly. After this happens, there may be a period of

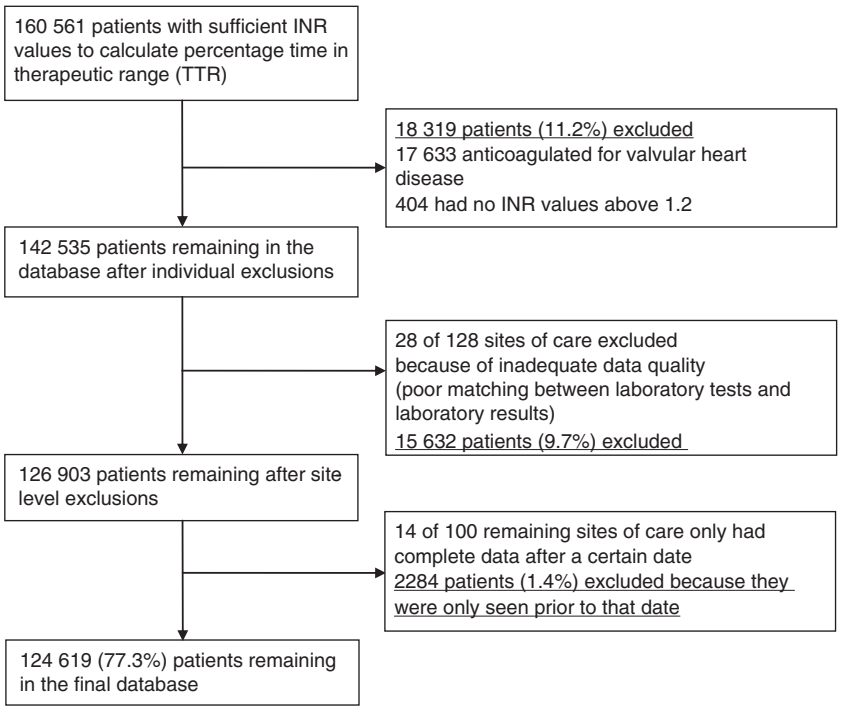

Fig. 1. Enrollment flowchart. INR, International Normalized Ratio.

several months when the local laboratory results are not captured by the national database, until the name change is noted. We identified which sites had this issue by dividing the data into 3-month periods; problematic sites had few or no INR results in certain periods, whereas the number of INR tests performed remained constant over time. In contrast, there were 86 sites that had complete data for the entire 2-year study period, and 14 sites that began to have complete data during the period and continued to have it through to the end. Thus, 28 sites were excluded because of incomplete data, and 14 sites were partially included.

Statistical analyses

We calculated TTR for each patient; for patients with both inception and experienced data, we calculated TTR separately for each period. We also analyzed the inception and experienced data separately, in each case first examining the effect of each variable upon TTR individually and then in a fully adjusted multivariable model. We used linear regression for our adjusted models, employing a mixed model (SAS PROC MIXED) with exchangeable correlation structure to account for the correlation of patient outcomes by site of care. We performed all analyses with SAS version 9.1 (SAS Corporation, Cary, NC, USA).

Creation of a clinical prediction tool

When considering the initiation of warfarin therapy, clinicians may find it useful to know which patients could be difficult to control in the future. We therefore developed a clinical prediction tool to help predict a patient's future TTR at the time of initiation of therapy. The predicted TTR during the experienced period may be especially helpful, so the prediction tool provides separate estimates for the first 6 months of therapy (inception) and the 18 months after that (experienced). The models underlying the tool were generally based on our main results, but we re-derived the models using only data that would be available to clinicians at the time of initiation.

To enable our model to predict TTR during the inception period, we located all patients in our database who were new to warfarin and remained on it for a full 6 months thereafter (n = 25 788). To enable our model to predict TTR during the experienced period, we located all patients who were managed in the experienced period for at least 18 months (n = 86 731). We assessed all the predictor variables at baseline, that is, during the year prior to the patient's first INR value in our model. We divided each of these datasets into a larger (60%) derivation set and a smaller (40%) validation set. We derived and validated a somewhat simplified model to predict the mean TTR over the first 6 months (inception) and the succeeding 18 months (experienced). The model was simplified as follows: race was removed (because of our concern that keeping race in the model might perpetuate racial disparities in care), poverty and distance were removed (their effects were small, and clinicians might not be able to assess them easily), and the list of comorbid conditions was abbreviated to those that had statistically significant effects in at least one time period. In addition, only hospitalizations that occurred during the year prior to warfarin initiation were considered as a predictor of TTR. On the basis of the parameters of this simplified model, we then created a clinical prediction tool in the form of a spreadsheet.

Results

Enrollment and baseline characteristics

After exclusion of individual patients and sites of care with missing data, there were 124 619 patients who received anticoagulation from 100 sites of care. There were 163 144 total patient-years of observation in the database. TTR could not be calculated during 34 963 of these 163 144 patient-years (21.4% of all patient-time), because of hospitalizations or gaps in therapy.

Details of the study sample are given in Table 1 (inception) and Table 2 (experienced management). The following results are for patient characteristics during the inception period; experienced period results were similar. The sample was overwhelmingly male. The age distribution reflects the fact that the indications for anticoagulation are most common in the elderly. A considerable number of minority patients were enrolled (e.g. 11.3% non-Hispanic Black). Most patients were anticoagulated for AF (55%), with the remainder being anticoagulated for VTE (35%) or other indications (10%). Patients had a considerable burden of comorbid illness. For example, 80% had hypertension, 37% had diabetes, 26% had heart failure, and 10% received a new diagnosis of cancer during the study. Mental health and substance abuse conditions were also common: 24% had major depression, 14% abused alcohol, and 7% abused some other substance. Medication and hospitalization data also reflect high levels of comorbid illness: 61% received at least eight non-warfarin chronic medications, and 22% were hospitalized at least once during the 6-month inception period.

Predictors of TTR: inception period

We observed inception (first 6 months of therapy) for 39 447 patients (Table 1). Mean TTR during inception was 48%. In the adjusted analysis, younger age predicted worse control; patients under age 55 years had TTR 3.9% lower than the reference category (age ≥ 75 years). Most racial minorities had lower TTR during inception, although these relationships were attenuated after multivariable adjustment. Poverty in the zip code of residence predicted worse control, with residents of the poorest areas having TTR 2.7% lower than the wealthiest. Driving distance to the nearest VA had a small negative influence upon inception-period TTR, but only when the distance was 20 miles or greater (− 1.3%). Most comorbid conditions reduced inception-period TTR. Among the physical illnesses that had the strongest adverse effects during inception

†Patients whose main indication for anticoagulation was valvular heart disease or prosthetic heart valve were excluded from this study.

were cancer (− 3.1%), diabetes (− 1.3%), and chronic kidney disease (− 0.9%). In general, mental illnesses exerted a stronger effect than physical illnesses, especially alcohol abuse (− 4.6%), bipolar disorder (− 2.9%), substance abuse (− 2.4%), and dementia (− 1.6%). There were several conditions that had paradoxical effects (associated with improved control), most notably hyperlipidemia (+ 2.5%). The number of chronic non-warfarin medications was inversely related to inception TTR: those receiving the most medications had TTR 4.3% lower than those receiving the least. Although inpatient INR values were excluded from calculations of TTR, hospitalizations were still associated with lower TTR, with those hospitalized two or more times having TTR 7.3% lower than those not hospitalized.

Predictors of TTR: experienced period

We observed post-inception ('experienced period') therapy for 104 505 patients (Table 2). Mean TTR during the experienced period was 61%. In the adjusted analysis, women had lower TTR (− 2.9%), an effect not seen during inception. Similar to what was found for the inception period, age less than 55 years predicted lower TTR (− 4.7%), and Black patients had lower TTR (− 2.6%) than Whites. Area poverty predicted lower TTR, but the effect size in the experienced period (1.5% lower in the poorest areas) was smaller than it had been during inception. In contrast to what was found for the inception period, driving distance was unrelated to TTR. Even during the experienced period, further experience with warfarin was associated with improved control: TTR was highest among patients who began warfarin at least 6 months before the study began.

As in the inception period, most comorbid conditions predicted lower TTR. Medical conditions with the strongest adverse effects included cancer (− 2.7%), chronic liver disease (− 2.3%), epilepsy (− 1.6%), chronic kidney disease (− 1.6%), diabetes (− 1.0%), and heart failure (− 1.0%). Mental health conditions had stronger effects, particularly alcohol abuse (− 5.4%), dementia (− 2.6%), substance abuse (− 2.4%), major depression (− 2.0%), and bipolar disorder (− 1.8%). As was seen during inception, several conditions were somewhat surprisingly associated with improved control, especially hyperlipidemia (+ 2.0%). Medications and hospitalizations were powerful predictors of control, even after adjustment for comorbid conditions. For example, patients hospitalized four or more times had TTR 9.4% lower than those not hospitalized.

Clinical prediction tool

We developed a tool to help clinicians to predict inception and experienced TTR for each patient on the basis of patient-level characteristics available at the time of initiation of therapy (Appendix S3). The tool is available as an online-only supplement to this article, and may be downloaded and used to predict TTR on the basis of patient characteristics known at the time of inception. The model parameters were generally quite similar to those presented in Tables 1 and 2. R^2 for inception TTR was 3.4% in the derivation set and 3.2% in the validation set. R^2 for experienced TTR was 6.5% in the derivation set and 6.8% in the validation set.

Discussion

Using data from the VA, we examined patient-level factors related to anticoagulation control with warfarin, measured asTTR. Our study demonstrates that some patients are more difficult to keep within the target INR range than others. We estimated the effects of multiple patient-level characteristics on TTR, clarifying the contributions of illness burden and clinical complexity to poorer anticoagulation control. Alcohol abuse, substance abuse, cancer and dementia were particularly strong predictors of poor control. The persistence of hospitalizations as a strong predictor of TTR, even after controlling for a broad range of comorbid conditions, bears mention. Because we did not consider inpatient INR values, this finding suggests that the period after a hospitalization is also characterized by poorly controlled anticoagulation. A hospitalization event entails numerous changes in diet, lifestyle, and health status, which can perturb the management of warfarin, as has been noted in earlier studies [18]. Patients who have been hospitalized require prompt and

vigilant follow-up after discharge to prevent such derangements, which have now been seen in multiple studies spanning multiple settings.

Several conditions were associated with improved TTR, most notably hyperlipidemia. To explore this, we compared patients receiving HMG-CoA reductase inhibitors (statins) for hyperlipidemia to those receiving fibrates, hypothesizing that statins themselves may improve TTR; however, the groups did not differ. Another possibility is that the presence of a code for hyperlipidemia (an asymptomatic risk factor) is a proxy for a proactive patient–clinician health maintenance partnership. This is supported by the similar positive effect for hypertension.

We found that achieving good control with warfarin is harder during the inception period than during the experienced period (mean TTR 48% vs. 61%), and that predictors of TTR differ between the two periods. Our study also suggests that, even within the VA, a system that provides comprehensive coverage and access, disparities in anticoagulation control still exist, with poorer, more distant, female and minority patients all experiencing poorer control in one or both of our study cohorts. In a previous non-VA study, our group also found that women have lower TTR than men [6]. The reason for this finding is unclear, but it is apparently not limited to the VA, and should be investigated further. In addition, younger patients experienced worse TTR. Although we cannot be certain, it is possible that the demands of a full-time job may be difficult to reconcile with the frequent follow-up expected of anticoagulation patients. On the basis of this finding, the VA may wish to consider improving access to care for working patients receiving anticoagulation.

Previous studies have explored only a few possible predictors of TTR, including inception status, race, and sex [5,6]. Other studies have examined the effect of a single predictor in detail, including cancer [17], non-white race [19–21], health literacy [22], and the patient's understanding of the reason why warfarin was prescribed [23]. Although our study echoes some of these earlier findings, we examined a much more comprehensive set of predictors and adjusted for confounding, strengths not found in previous studies. In addition, the size and scope of our database allowed us to examine relatively uncommon predictors such as chronic liver disease and epilepsy.

The primary purpose of the models presented here is risk adjustment. Risk adjustment allows fair comparisons of outcomes between sites of care, despite the fact that some sites will have more challenging patient populations than others [24]. Thus, these models may be used to compare sites of care on risk-adjusted TTR, which could spur quality improvement and improve patient outcomes [11]. The results reported here will underpin a planned effort to improve anticoagulation control for VA patients receiving warfarin.

Our findings can also be used to identify patients who may require greater attention or innovative management strategies to achieve acceptable levels of anticoagulation control. The effect of each individual variable upon TTR in our study was relatively small, and no single risk factor that we studied establishes a patient as being too high-risk for anticoagulation therapy to be contemplated. In combination, however, the variables that we studied would indeed be useful for risk-stratifying patients receiving oral anticoagulation. To facilitate the use of this information to guide clinical practice, we have offered, with this article, a simplified version of our models in the form of a clinical prediction tool. This tool can help clinicians to predict a patient's eventual level of anticoagulation control before starting therapy. Such information could be helpful in determining which patients might require aggressive interventions to help them achieve an acceptable level of control, and which patients have such poor predicted control that they might not be suitable candidates for warfarin. Although warfarin is a superior therapy, aspirin is available as a second-line agent, at least for patients with AF [25], and its safety and effectiveness are unlikely to be compromised by patient characteristics in the same way.

In addition, it seems likely that novel oral anticoagulants may soon be approved for use, particularly dabigatran [26,27]. On the basis of studies of dabigatran and previous studies of other similar drugs, novel anticoagulants are likely to offer similar safety and effectiveness to warfarin, at a much higher cost [28], but might be a superior choice for patients with poor control on warfarin (although this has not yet been proven). Models such as the ones presented here could possibly be used prospectively to identify some patients who are likely to do well with warfarin and others who are unlikely to do well and might be candidates for the novel agents. Restricting the use of these agents to patients who are poor candidates for warfarin could markedly improve their cost-effectiveness.

Although our study is unprecedented in the amount and richness of the data collected to study anticoagulation, we do acknowledge some important limitations. First, there are some caveats regarding the clinical prediction tool. This tool is intended to predict TTR at the time of initiation; after a patient has received warfarin for several months, his or her past control will clearly be the best predictor of future control. In addition, a clinical prediction tool should not only be validated in the source population ('internal validation'), as ours was, but should also be validated again in a separate population ('external validation'). It is even more useful if the investigators can demonstrate the impact of the tool on patient outcomes as compared with usual practice [29,30]. Our rule has not yet been externally validated, and nor has its impact on clinical care been demonstrated. Clinicians should access this tool if they find it useful, but should be aware that it has not yet achieved these benchmarks for the highest-quality clinical prediction tools. In future research, we hope to accomplish these tasks to help this tool gain wider acceptance and increase its impact on clinical management.

Second, VA patients are mostly male and have a high burden of physical and mental health conditions. It is unclear how our results might have differed in a population of patients with more women and a lesser degree of comorbidity. Third, we studied an intermediate outcome of care (TTR) rather than definitive outcomes such as stroke or major hemorrhage.

However, TTR has been convincingly linked to definitive outcomes [5,10], making higher TTR a good target for improving health outcomes [11]. Fourth, our administrative database did not contain information on some known determinants of anticoagulation control, such as adherence to therapy and dietary variation. Such data could only be collected through expensive procedures such as frequent questionnaires, which would greatly limit sample size. This would have precluded a study of such size and scope. In addition, the intended use of our models is to risk-adjust TTR, a task that must be accomplished with administrative data alone to be feasible. Fifth, our database did not contain information on care received outside the VA, and there is no comprehensive database of INR values obtained outside the VA system. This precluded a consideration of INR values obtained outside the VA. However, because we required at least two between-test intervals of 56 days or fewer for study entry, the great majority of the patients that we studied would have been 'VA users', who are likely to visit the VA for most, if not all, of their care.

Finally, although ICD-9 codes have been used in many previous studies to identify comorbid conditions, we acknowledge that this approach may lack sensitivity, particularly for some conditions that are stigmatized or difficult to recognize, such as alcohol abuse or dementia. We addressed this concern in part by requiring only one ICD-9 code for these conditions rather than two, a strategy that increased their frequency somewhat and thus presumably improved sensitivity (see Appendix S2 for details). Through this and other carefully considered decisions, we have tried to improve the performance of ICD-9 codes in identifying comorbid conditions as much as possible.

In conclusion, we have collected a database of patients receiving oral anticoagulation that is unprecedented in its size and scope. We used this database to identify the combined effect of multiple patient-level predictors of anticoagulation control. These data and models could enable the VA to measure and improve the quality of its oral anticoagulation care.

Summary

Little is known about patients who receive oral anticoagulation for valvular heart disease (VHD) in community-based practice. It was this study's objective to describe the characteristics, management, and outcomes of patients anticoagulated for VHD, compared to patients anticoagulated for atrial fibrillation (AF). We used a nationally-representative cohort of community-based anticoagulation care in the United States. Data collected included indications for therapy, demographics, selected comorbid conditions, international normalised ratio (INR) target ranges, INR control, and clinical outcomes. We identified 1,057 patients anticoagulated for VHD (15.6% of the overall cohort) and 3,396 patients anticoagulated for AF (50.2%). INR variability was similar between the two groups (0.64 vs. 0.69, p = 0.80). Among patients with aortic VHD, for whom a standard (2–3) target INR range is recommended, 461 (84%) had a high target range (2.5–3.5), while 95 (16%) had a standard target range. VHD patients had a higher rate of major haemorrhage compared to AF patients (3.57 vs. 1.78 events per 100 patient-years, incidence rate ratio 2.02, 95% CI 1.33 – 3.06). The rate of stroke/systemic embolus was similar between groups (0.67 vs. 0.97 events per 100 patient-years, incidence rate ratio 0.71, 95% CI 0.32 – 1.57). In our community-based study, approximately 15.6% of patients receiving warfarin were anticoagulated for VHD. VHD patients achieved similar anticoagulation control to patients with AF, as measured by INR variability. Nevertheless, the rate of major haemorrhage was elevated among VHD patients compared to AF patients; this finding requires further investigation.

Introduction

The three major indications for long-term anticoagulation with warfarin are atrial fibrillation (AF) (1–2), venous thromboembolism (3), and valvular heart disease (VHD)(4). Of these three categories, we know the least about patients who are anticoagulated for VHD, a heterogeneous category that includes bioprosthetic valve replacements, mechanical valve replacements, valve repairs, and various other kinds of VHD. There is evidence to support the efficacy of anticoagulation in preventing strokes in this population, and considerable information about the expected rate of thromboembolic events with and without anticoagulation (5–23). For example, among patients with heart valve prosthesis not receiving anticoagulation, the yearly rate of thromboembolic events is approximately 12% with an aortic prosthesis and 22% with a mitral prosthesis (23). Various studies have found that anticoagulation lowers this rate to approximately 1–2% per year (4). Given this large effect size, prosthetic heart valves and other VHD conveying a similar risk of thromboembolism are considered a near-absolute indication for long-term anticoagulation.

However, previous studies have not elucidated the characteristics of patients who receive anticoagulation for VHD in real-life clinical practice, including their demographics, comorbid conditions, precise indications for therapy, target international normalised ratio (INR) ranges, anticoagulation control, and outcomes. One large cohort, the ATRIA study, only included patients with AF (24). Another cohort, the ISCOAT study (25), enrolled 479 patients with VHD (17.5% of the cohort), but did not analyse them separately. Other important cohorts (26–27) did not explicitly report the proportion of patients anticoagulated for VHD.

Our objective, therefore, was to characterise the care of patients anticoagulated for VHD in community-based practice using a large, nationally-representative database of anticoagulation care in the United States. This study can provide important information regarding the proportion of patients who receive anticoagulation for VHD, the relative proportion of sub-categories of VHD, the demographics and comorbid illnesses of VHD patients, the target INR ranges chosen for patients with VHD, the anticoagulation control achieved by patients with VHD, use of low-molecular-weight heparin (LMWH) to "bridge" periods of low INR, and rates of thromboembolic and haemorrhagic events in routine clinical practice.

Materials and methods

Study enrolment

Data collection for the Anticoagulation Consortium to Improve Outcomes Nationally (ACTION) study has been described in detail elsewhere (28). The objective of ACTION was to collect a representative cohort of anticoagulation patients managed in community-based settings, in order to facilitate outcomes research and health services research on important anticoagulation-related topics. Physician practices that were registered users of CoumaCare® software (Bristol-Myers Squibb, Princeton, NJ, USA) were invited to participate. In total, 174 practices registered online to participate and 101 sites had the technologic capability and the review board approval necessary to proceed. The 101 study sites were from diverse geographic regions, representing 34 states in the United States. All sites had at least one dedicated provider managing warfarin, usually within the setting of a community-based, physician group practice.

Patients were invited to participate by letter, clinic flyer, or in person (at the time of a routine appointment). To be eligible, patients had to be 18 years of age or older and provide written informed consent. Enrolment began in April 2000 and follow-up ended in March 2002. Encrypted data from the electronic patient anticoagulation record were downloaded to the data-coordinating centre weekly. Missing data fields and data entry errors were flagged and resolved directly with the sites by the data-coordinating centre before data were transferred to the study investigators. The study was approved by Western Institutional Review Board® (WIRB®) of Olympia, WA, USA and by local review boards where they existed.

Study variables

Data collected included patient demographics, the presence or absence of several important comorbid conditions (congestive heart failure, coronary artery disease, diabetes, hypertension, and prior stroke), INR target ranges, INR values, and patient management notes. We characterised INR control using the INR variability measure described by Fihn et al. (26, 29) This measure computes the mean INR value for each patient, and then uses the standard deviation (SD) around this mean as a measure of INR variability over time. We chose to use INR variability in this study because patients with VHD may have either standard (2 – 3) or high (2.5 – 3.5) INR target ranges, and the calculation of INR variability is independent of the INR target range. However, we also calculated percent time in therapeutic range (TTR), as originally described by Rosendaal (30). For this calculation of TTR, patients were assigned a target INR range of 2.0 – 3.0 ("standard") or 2.5 – 3.5 ("high") according to the target range indicated in the clinical record.

Indications for anticoagulation

Patients in the database had a recorded primary indication for therapy and in some cases a secondary indication as well. These were confirmed by review of the clinical notes. When a patient had VHD and another indication for therapy (e.g. AF), VHD was considered the primary indication. VHD patients were further subdivided by the anatomic location and nature of the valvular abnormality. When patients had both aortic and mitral valve disease, the mitral valve abnormality was considered the primary indication for therapy. In some cases, the anatomic location of the VHD (i.e. aortic vs. mitral position) could not be determined. We also compared these patients with VHD to the 3,396 patients in the ACTION study anticoagulated for AF, who have been described in a previous report (28). Patients with AF form a useful comparison group, since the management and outcomes of anticoagulation for AF has been studied extensively and is comparatively well-understood.

Low INR values and bridging with LMWH

We identified all INR values 1.5 or lower among patients anticoagulated for VHD, and used linear interpolation (30) to identify periods of time when the INR was ≤1.5. For each low INR value, we reviewed the clinical notes to determine whether clinicians employed "bridging" with heparin or LMWH as part of the management of the low INR value, and to characterise the circumstances surrounding such episodes.

Adverse events

Ischaemic stroke, systemic arterial embolism, and major haemorrhage were the adverse outcomes of interest. All events were confirmed by manual review of the clinical notes in the database. Major haemorrhage was defined according to the International Society on Thrombosis and Haemostasis (ISTH) definition (31): a

fatal event, an event requiring hospitalisation with transfusion of at least two units of packed red blood cells, or bleeding involving a critical anatomical site such as the cranium or the retroperitoneum. All patient progress notes were individually reviewed for evidence of adverse events; events were validated directly with the sites by the data coordinating centre.

Statistical analyses

We compared the VHD and AF groups with regard to demographics, comorbid conditions, frequency of INR testing, frequency of intentional interruptions of warfarin therapy, INR variability, and percent time in the therapeutic INR range (TTR). Within the VHD group, we investigated patient-level factors associated with assignment to the standard or the high target INR range, using bivariate analyses. To account for intra-class correlation within clinical site, p-values for continuous variables were calculated using Generalized Estimating Equations (GEE), while p-values for nominal variables were calculated using 10,000 Monte Carlo simulations. We compared rates of bridging per 100 low INR values between the VHD and AF groups. We computed the rate of stroke/systemic embolus among VHD patients and estimated the proportion of these events attributable to periods of low INR. We computed the rate of major haemorrhage among VHD patients, and estimated the proportion of these events attributable to the use of bridging. When comparing rates of bridging or clinical events between the VHD and AF groups, we computed incidence rate ratios with 95% confidence intervals (CI) via bootstrapping with 10,000 iterations.

We compared the rates of these adverse events among our VHD cohort to the rates we previously described among a cohort of AF

Table 1: Comparison of patients anticoagulated for valvular heart disease (VHD) and for atrial fibrillation (AF).

	Valvular heart disease (n = 1057)	Atrial fibrillation (n = 3396)	P-value
Mean age (SD)	67.2 (12.2)	74.1 (9.4)	< 0.001
Female gender	460 (44%)	1433 (42%)	0.44
Race			
White	959 (91%)	3182 (94%)	0.04
Black	23 (2%)	47 (1%)	
Other	75 (7%)	167 (5%)	
Comorbid conditions			
Congestive heart failure	216 (20%)	642 (19%)	0.37
Coronary artery disease	247 (23%)	855 (25%)	0.80
Diabetes	139 (13%)	508 (15%)	0.14
Hypertension	395 (37%)	1530 (45%)	< 0.001
Prior stroke	104 (10.0%)	359 (11%)	0.52
Measures of warfarin management			
Mean days in database (SD)	358 (124)	328 (133)	< 0.001
Mean number of INR values (SD)	21 (11)	16 (8)	< 0.001
Mean INR values/month (SD)	1.79 (0.84)	1.65 (0.90)	< 0.001
Intentional interruptions of warfarin for procedures per patient-year (95% CI)	0.35 (0.29, 0.39)	0.43 (0.35, 0.44)	0.001
Anticoagulation control – INR variability			
Mean INR value	2.93	2.45	< 0.001
Variability around mean value	0.64	0.69	0.80
Anticoagulation control – time in range*			
Percent time below target range	21.5 (18.9)	20.1 (18.8)	0.02
Percent time in target range (TTR)	64.3 (19.6)	66.6 (19.7)	0.003
Percent time above target range	14.5 (15.5)	13.3 (13.5)	0.22

To account for intra-class correlation within clinical site, p-values for continuous variables were calculated using Generalized Estimating Equations (GEE), while p-values for nominal variables were calculated using 10,000 Monte Carlo simulations. *Time in Range is calculated using a target INR range of 2.0 – 3.0 for patients with a standard target range and 2.5 – 3.5 for patients with a high target range. Some patients with valvular heart disease had a high target INR range, but no patients with atrial fibrillation had a high target range.

patients drawn from the same database (28), computing separate rates as well for periods when the INR was above, below, or within the target range. Within the VHD group, time within the target range was calculated according to whether the patient had a high (2.5 – 3.5) or normal (2 – 3) target range. Calculation of incidence rates and their confidence intervals were accomplished by Poisson regression for count data, run via GEEs in order to account for the correlation of data by site of care. Analyses were performed using the R statistical package, version 2.8 (R Foundation, 2009).

Results

Study cohort

There were 1,116 patients anticoagulated for VHD in the ACTION database. Of these, 28 patients had bioprosthetic heart valves; such patients ordinarily require only a brief period of anticoagulation following surgery, unless there is another risk factor for stroke such as AF (4). Because these patients were so few, and were not representative of most patients with VHD, they were excluded from our study. In addition, we excluded 31 patients with two or fewer INR values in the database, too few to characterise their care. After these exclusions, our final VHD cohort included 1,057 patients (15.6% of the entire cohort of 6,761 patients, and 94.7% of the original 1,116 VHD patients). By comparison, there were 3,396 patients anticoagulated for AF in the ACTION cohort (50.2%).

Among VHD patients, 556 (53%) had a disorder of the aortic valve, while 417 (39%) had a disorder of the mitral valve (with or without a concomitant aortic valve disorder). For 84 (8%), the anatomic location of the valvular heart condition was unclear from the clinical record. As to the valve pathology necessitating the anticoagulation, 952 (90%) had heart valve prostheses, while 105 (10%) had other VHD.

VHD patients compared to AF patients

VHD patients were compared to AF patients, a group which has been well-characterised in previous studies (▶Table 1). VHD patients were considerably younger than AF patients (mean age 67.2 vs. 74.1, $p < 0.001$). The prevalence of several important comorbid conditions (congestive heart failure, coronary artery disease, diabetes, and prior stroke) was similar between the two groups. However, hypertension was somewhat more common in the AF group (45% vs. 37%, $p < 0.001$).

Patients with VHD had their INR tested somewhat more often (1.79 vs. 1.65 tests/month, $p < 0.001$), and had fewer intentional interruptions of warfarin therapy for procedures per patient-year (0.35 vs. 0.43, $p = 0.001$). The mean INR value was higher in the VHD group than the AF group (2.93 vs. 2.45, $p < 0.001$), reflecting the many VHD patients with a high target range. Patients with AF achieved a slightly higher percentage of time in therapeutic range (66.6% vs. 64.3%), a difference which was statistically significant due to the large sample size. However, the two groups had similar INR variability (0.64 vs. 0.69, $p = 0.80$), suggesting that the two groups experienced similar INR control.

Standard vs. high target INR range among VHD patients

Most VHD patients (84%) had a high target INR range (i.e. 2.5 – 3.5), as opposed to a standard target range (i.e. 2.0 – 3.0). We compared VHD patients with a standard target range to those with a high target range (▶Table 2). The mean INR values achieved in the two groups (2.51 vs. 3.00, $p < 0.001$) suggest that the target ranges stated in the record were actually pursued in practice. Patients with a standard target range were older, a difference of marginal statistical significance (mean age 69.6 vs. 66.7, $p = 0.053$), but the two groups were similar in terms of gender, race, and comorbid conditions. Patients had a similar likelihood of assignment to a high target range regardless of whether their VHD was in the aortic or the mitral anatomic position (83% vs. 86%, $p = 0.28$).

Low INR values and bridging in patients with VHD

Bridging was more commonly employed among patients anticoagulated for VHD than for AF, although most episodes of low INR did not trigger bridging even in the VHD group. VHD patients had 8.1 episodes of bridging per 100 low INR values (95% CI 6.0 – 10.5), while AF patients had a rate of 1.1 (95% CI 0.8 – 1.5, $p < 0.001$ for a between-group difference). Of the 39 episodes of bridging that occurred among the VHD cohort, the great majority (34 episodes) were in response to intentional interruptions of therapy for a procedure ("holds"), while only five were in response to routinely encountered (unplanned) low INR values.

Sites differed widely in their practice regarding bridging. For example, with regard to VHD patients, of 79 sites that had at least one episode of low INR, there were 60 sites (76%) with no episodes of bridging. The rate among the 19 sites that did employ bridging was 15.0 episodes per 100 low INR values (95% CI 11.2 – 19.5).

Rates of adverse events

In the VHD cohort, there were seven ischaemic strokes (and no systemic emboli) in 1038.2 patient-years of follow-up, an incidence rate of 0.67 events per 100 patient-years (95% CI 0.32 – 1.43). The overall rate of stroke/systemic emboli in the VHD cohort was similar to the rate of such events among AF patients in this database (0.97 events per 100 patient-years). The incidence rate ratio between the two groups (comparing VHD to AF) was 0.71 (95% CI 0.32 – 1.57).

Among the VHD cohort, there were 37 major haemorrhagic events in 1038.2 patient-years of follow up (3.57 events per 100 patient-years, 95% CI 2.59 – 4.92). Three of these events (an intraperitoneal haemorrhage, a gastrointestinal haemorrhage, and a retroperitoneal haemorrhage) occurred during episodes of bridging. Among our AF cohort, the rate of major haemorrhage was 1.78 events per 100 patient-years. The incidence rate ratio (comparing VHD to AF) was 2.02 (95% CI 1.33 – 3.06), a difference that was statistically significant at the 0.05 level.

Rates of adverse events, stratified by indication for therapy and INR value at the time of the event, are given in ▶Table 3. The rate of major haemorrhage was higher among VHD patients than among AF patients only while the INR was below or within the target range, but not above. However, this finding should be considered in light of the fact that most patients in the VHD group had a high target range (2.5 – 3.5). Of the 13 major haemorrhagic events that occurred in the VHD cohort during time below the target range, 10 occurred while the INR was between 2 – 2.5. Similarly, of

Incidence rates are expressed as events per 100 patient-years. *Time in range is calculated using a target INR range of 2.0 – 3.0 for patients with a standard target range and 2.5 – 3.5 for patients with a high target range. Some patients with valvular heart disease had a high target INR range, but no patients with atrial fibrillation had a high target range.

Table 3: Adverse events and relationship to anticoagulation control among patients anticoagulated for valvular heart disease (VHD) and atrial fibrillation (AF).

the 19 major haemorrhagic events that occurred in the VHD cohort during time within the target range, seven occurred while the INR was between 3 – 3.5.

Discussion

To our knowledge, this is the first study to describe the patient population receiving long-term oral anticoagulation for VHD in community-based practice. VHD patients composed 15.6% of our community-based anticoagulation cohort, a similar proportion to that seen in a previous Italian anticoagulation cohort (25). We describe the different types of VHD represented in our VHD cohort. Most patients (90%) were anticoagulated because of a prosthetic valve, while only 10% of patients had other VHD. Compared to patients with AF, VHD patients were considerably younger, but otherwise similar in terms of demographics and most comorbid conditions. This younger age among VHD patients is probably due to the fact that older patients requiring valve replacement would have received bioprosthetic valves, which require only a brief period of anticoagulation after surgery (4). Despite the fact that most (84%) VHD patients had a high target INR range, their INR variability was similar to that of the AF group, suggesting that their INR was similarly well-controlled.

Despite similar anticoagulation control in both groups, VHD patients experienced a higher rate of major haemorrhage than AF patients. Stratification of these events into those that occurred within different INR ranges (▶Table 3) suggests that the use of a high target INR range for many of the VHD patients may have played a role in this between-group difference. Another possible reason for this finding is that clinical guidelines, both now (4) and at the time of the study (32–33), recommend adding low-dose aspirin to warfarin for many patients with prosthetic heart valves. This recommendation was based on several well-conducted trials and meta-analyses, which suggested that the addition of low-dose aspirin for patients already receiving warfarin could improve outcomes like mortality with only a minimal increase in the rate of major haemorrhage (34–36). The guidelines caution, however, that patients at elevated risk for haemorrhage probably should not receive aspirin in addition to warfarin (4, 32–33), because the risk may outweigh the benefit. We searched the anticoagulation record of all VHD patients that experienced major haemorrhage for a mention of aspirin therapy. Four patients were clearly receiving aspirin at the time of a major haemorrhage, and a fifth patient was receiving clopridogrel at the time of her two major haemorrhagic events. The other charts contained no evidence of concomitant antiplatelet therapy. This is a limitation of our study, because the absence of documentation is not conclusive.

Regarding target INR ranges, the overwhelming majority of VHD patients in our sample (84%) had a high INR target range, whether their valve pathology was in the mitral or the aortic position. This is surprising, because clinical guidelines both now (4) and at the time of the study (33, 37–39) would have recommended a standard target range for patients with aortic prosthetic valves, except for the three subgroups: those with concomitant AF, those with prior stroke despite adequate anticoagulation, and those with caged-ball prosthetic valves. Caged-ball valves, which were first implanted in the 1960s, were quickly supplanted after the introduction of newer, less thrombogenic valves in the early 1970s (40). Since our study began in 2000, it is doubtful that many of our patients had these older caged-ball valves.

However, it is possible that the other two subgroups accounted for some of our findings. Therefore, we identified all of the patients with aortic valve prostheses who had prior stroke/systemic embolus and/or AF. For the purpose of this sensitivity analysis, we assumed that all prior strokes had occurred while the patient was receiving warfarin and was within the therapeutic range. Of the 556 patients with aortic valve prostheses, 130 had one or both of these possible reasons for a high target range. Of these 130 high-risk patients, 82% had a high target range, compared to 84% of the patients without these additional risk factors ($p = 0.60$ for comparison). This non-differential management suggests that clinicians in our study were unaware of or did not agree with clinical guideline recommendations regarding the recommended target INR range for patients with a prosthetic aortic valve (41). As discussed above, it is possible that this guideline-discordant use of a high target range contributed to the higher rate of major haemorrhage observed in the VHD group in our study. The selection of target INR ranges for VHD patients might be improved through education and outreach.

Regarding the management of low INR values, our study suggests that "bridging" is employed much more often for VHD patients than AF patients, almost always in response to a planned interruption of therapy. In a previous analysis of the ACTION database, we characterised the use of bridging for intentional interruptions of therapy, as well as the risks of haemorrhage and thromboembolism with and without bridging (42). However, this previous study did not examine patients with VHD, who may have the highest risk of thromboembolism with therapy interruptions, and thus the strongest rationale for bridging. Another study, performed using a different database, examined the risk of thromboembolism during the 90 days after a low INR value among patients with diverse indications for anticoagulation, although there were few VHD patients in that study (4%). That study suggested that the risk of thromboembolism attributable to a low INR value, compared to patients who did not have a low INR, is minimal (43).

In this study, we observed considerable variations in practice regarding bridging. Several sites in our sample used bridging relatively often for VHD patients, while most sites (78%) did not use it at all. This variation in practice reflects a lack of evidence and consensus regarding this difficult clinical decision (44), which requires clinicians to balance considerable risks and benefits in the absence of empiric evidence (1–2, 4, 45). An ongoing randomised trial of bridging is expected to help clarify the risks and benefits of bridging (46). However, this trial will only enroll patients anticoagulated for AF who have intentional interruptions of therapy, so it will not directly inform decisions for patients with VHD or patients with incidentally noted low INR values.

This study has several important strengths. Our database was large and nationally-representative, drawn from 101 clinical sites in 38 states. It therefore provides a generalisable picture of VHD patients in community-based practice. Our database also contained a degree of clinical detail that would not be possible with automated data alone.

However, this study also had some limitations. First, most of the patients in the ACTION study were prevalent users of warfarin as opposed to an inception cohort. It is well-known that patients new to warfarin have poorer anticoagulation control and higher rates of complications than experienced users (28, 47). Therefore, the relatively good anticoagulation control and low rates of adverse events reported in this study may not be generalisable to patients new to warfarin. Second, we computed percent time in therapeutic range (TTR) for patients with different target INR ranges (2.0 – 3.0 and 2.5 – 3.5), although TTR has not explicitly been demonstrated to mean the same thing in patients with different target ranges. However, the group that invented the TTR measure has used it to measure anticoagulation control in patients with varying target INR ranges (30, 48), so this assumption may be justified. Third, while our results suggest that many patients with aortic VHD were inappropriately treated with a high target range, we cannot fully exclude the possibility that some patients had a valid reason for a high target range which was not recorded in the clinical notes.

What is known about this topic?

- Warfarin is indicated for the prevention of stroke in patients with valvular heart disease or prosthetic heart valves (VHD).
- The risk of stroke is higher with VHD than with atrial fibrillation (AF). Therefore, VHD is considered an almost absolute indication for anticoagulation, while the decision to anticoagulate patients with AF is based on a risk-benefit analysis.
- Previous studies of anticoagulation for VHD have been clinical trials conducted in academic medical centers. There have been no large cohort studies describing patients anticoagulated for VHD in community-based practice.

What does this paper add?

- This paper describes the care and outcomes of 1,057 patients anticoagulated for VHD at 101 community-based sites of care located in 31 states of the United States. Approximately 15.6% of patients receiving warfarin at these sites of care were anticoagulated for VHD.
- Despite similar levels of anticoagulation control between the two groups, patients anticoagulated for VHD had a higher rate of major haemorrhage than patients anticoagulated for AF (incidence rate ratio 2.02, 95% CI 1.33 – 3.06). Further studies are needed to investigate the cause of this between-group difference in outcomes.

Similarly, there were some patients in our study whose VHD was not completely characterised regarding anatomic position and/or type of prosthetic valve. Furthermore, our database lacked explicit detail regarding the causes of valvular heart disease (rheumatic, etc.), the exact type of prosthesis (St. Jude, Bjork-Shiley, etc.), the exact date of cardiac surgery, and the exact date of initiation of anticoagulation. Finally, as noted earlier, we found few references to concomitant antiplatelet therapy in the charts of VHD patients with major haemorrhagic events, but the absence of documentation is not conclusive. Complete data regarding antiplatelet therapy might have allowed further elucidation of the elevated risk of major haemorrhage that we observed for VHD patients.

In conclusion, 15.6% of patients taking warfarin in community-based practice receive anticoagulation for VHD. VHD patients are considerably younger than AF patients, but the two groups are otherwise similar in many respects, including comorbid conditions and degree of anticoagulation control. Community practice regarding LMWH for patients with VHD for episodes of low INR ("bridging") is highly variable, reflecting a lack of evidence and clinical consensus. Finally, patients with VHD experienced a greatly elevated risk of major haemorrhage in this study, compared to patients with AF. Further study will be necessary to confirm and explain this finding.

ARTICLE | Annals of Internal Medicine

The Spread of Alcohol Consumption Behavior in a Large Social Network

J. Niels Rosenquist, MD, PhD; Joanne Murabito, MD; James H. Fowler, PhD; and Nicholas A. Christakis, MD, PhD

Background: Alcohol consumption has important health-related consequences and numerous biological and social determinants.

Objective: To explore quantitatively whether alcohol consumption behavior spreads from person to person in a large social network of friends, coworkers, siblings, spouses, and neighbors, followed for 32 years.

Design: Longitudinal network cohort study.

Setting: The Framingham Heart Study.

Participants: 12 067 persons assessed at several time points between 1971 and 2003.

Measurements: Self-reported alcohol consumption (number of drinks per week on average over the past year and number of days drinking within the past week) and social network ties, measured at each time point.

Results: Clusters of drinkers and abstainers were present in the network at all time points, and the clusters extended to 3 degrees of separation. These clusters were not only due to selective formation of social ties among drinkers but also seem to reflect interpersonal influence. Changes in the alcohol consumption behavior of a person's social network had a statistically significant effect on that person's subsequent alcohol consumption behavior. The behaviors of immediate neighbors and coworkers were not significantly associated with a person's drinking behavior, but the behavior of relatives and friends was.

Limitations: A nonclinical measure of alcohol consumption was used. Also, it is unclear whether the effects on long-term health are positive or negative, because alcohol has been shown to be both harmful and protective. Finally, not all network ties were observed.

Conclusion: Network phenomena seem to influence alcohol consumption behavior. This has implications for clinical and public health interventions and further supports group-level interventions to reduce problematic drinking.

Primary Funding Source: National Institutes of Health and the Robert Wood Johnson Foundation. The Framingham Heart Study is supported by the National Heart, Lung, and Blood Institute.

Alcohol use is common in the United States. In 2002, 55% of adults reported having had at least 1 drink in the previous month, and the prevalence of past-month alcohol consumption was somewhat higher for men (62%) than for women (48%) (1). The lifetime prevalence of alcohol use disorders has been measured at 14.6% (1). Excessive alcohol use, either in the form of heavy drinking or binge drinking, increases the risk for numerous health and social problems (2, 3), and approximately 75 000 deaths in 2001 were attributable to excessive alcohol use, which makes it the third-leading lifestyle-related cause of death (3).

Alcohol consumption behavior has many determinants. Previous studies (3, 4) suggest that biological factors have a significant effect on the progression from experimentation to regular use and that social and cultural factors play a critical role in experimentation with alcohol and the development of drinking patterns over time. Given the social nature of this behavior, it is not surprising that previous work has identified interactions with friends and family members as key factors (4–8). Although this literature primarily focused on cross-sectional panels, some studies (6–8) have attempted to test whether social influences act over time. These studies, which focused on peer influence among college students, showed inconsistent results and tended to focus just on pairs of connected persons.

The study of social influences on behavior has expanded in recent years to the study of networks of linked individuals over time (9). Recent work in this area has shown that various health-related phenomena, ranging from sexually transmitted diseases to obesity, smoking, and even suicide, may travel along and within social networks (10–15).

Using a longitudinal, dynamic network of 12 067 persons, we analyzed the role of social networks in alcohol use, focusing on 1) whether clusters of heavy drinkers and abstainers existed within the network; 2) whether a person's alcohol consumption behavior was associated with that of his or her social contacts; 3) the extent to which such associations depended on the nature and direction of the social ties (for example, friends of different kinds, siblings, spouses, coworkers, or neighbors); and 4) whether gender affected the spread of alcohol consumption across social ties.

METHODS

Source Data

We used data from participants in the Framingham Heart Study (FHS). The FHS is a population-based, longitudinal, observational cohort study that was initiated in 1948 to prospectively investigate risk factors for cardiovascular disease. Four cohorts, who mostly represent different generations linked to an original cohort, are included in the entire FHS. Participant data, collected every 2 to 4 years, includes physical examinations, laboratory tests, noninvasive cardiac and vascular testing, battery testing (such as the Mini-Mental State Examination), questionnaire results, and basic demographic information. For our analyses, we aligned the examination waves for the original cohort with those of the second-generation offspring cohort, which allowed us to treat all participants as having been examined in 7 waves. The offspring cohort, initiated in 1971, is the source of our study's principals, or focal individuals in the network (16). However, we included other FHS participants whom the principals listed as social contacts and refer to them here as "contacts." Therefore, even though principals come only from the offspring cohort, contacts are drawn from the entire set of both the original and offspring cohorts.

To ascertain social network ties, we created a separate data set that linked individuals through self-described social ties, collected in each of the 7 waves of the study. We could then detect relationships between participants (for example, spouse, sibling, friend, coworker, or neighbor) and observe changes in these ties across time. Either party to a link between 2 people might identify his or her link to the other. This is most relevant to the "friend" link, which could exist if A nominated B or B nominated A as a friend. We also used complete records of participants' and their contacts' address in each wave since 1971 in our analyses, although we have no information about relationships that participants did not report. For each wave, we could determine who is whose neighbor and the geographic distance between persons (10, 17). **Table 1** provides descriptive statistics for the 5124 principals in our sample.

Measures

Alcohol consumption was self-reported in all studied waves, with participants reporting their average number of drinks per week over the past year as well as the number of days within the past week during which they consumed alcohol (beer, wine, and liquor). Self-reported data are generally considered a valid and reliable source when assessing alcohol consumption, although recall measures, such as those used in this study, can be subject to recall bias from participants (18).

We treated alcohol consumption as a continuous variable in some analyses (for example, number of drinks per day, calculated from participant responses) but conducted others with dichotomous cut-points, defining heavy drinkers as those who averaged more than 1 (for women) or 2 (for men) drinks per day; moderate drinkers as those whose alcohol consumption was less than the cutoff values for heavy drinkers; and abstainers as those who reported no alcohol consumption. We did not use self-reported number of days drinking in the past week as a measure in and of itself but rather as a means to calculate average number of drinks in a day. (These labels do not reflect clinical definitions of alcohol abuse or dependence.) **Table 2** shows averages for the study population across time, including age, alcohol consumption, and percentages of abstainers and drinkers. Although the differences in how we measured heavy drinking made it difficult to compare our results with those for other population samples, the other averages for the mean-age groups in each year of the given waves are roughly similar to national averages of alcohol consumption behavior (1, 19, 20).

Context

A person's alcohol use might mirror that of his or her social contacts.

Contribution

Using the same group of Framingham Heart Study participants who helped to define the associations between social networks and other health behaviors, the researchers found that alcohol use was similar among individuals in a social cluster. Furthermore, changes in a person's alcohol intake over time followed changes in the alcohol intake of their social contacts.

Caution

Alcohol use was self-reported, and the researchers did not have access to social contacts who were not participating in the study.

Implication

Changing alcohol use may require intervening with social groups as well as with individuals.

—The Editors

Statistical Analysis

Our first goal was to evaluate whether a person's alcohol consumption behavior was associated with that of his or her social network ties at various degrees of separation. To test this hypothesis, we took an observed clustering of persons (and their alcohol consumption behavior) within the whole network and compared them with 1000 simulated networks with the same topology and overall prevalence of drinking as the observed network, but with the incidence of drinking (for example, at least 1 drink per day) randomly distributed across the nodes ("random drinking networks"). If clustering occurs in drinking behavior, then the probability that a contact is a drinker given that a principal is a drinker should be higher in the observed network than in the random drinking networks (21). We used the Kamada–Kawai algorithm, which itera-

tively repositions nodes to reduce the number of ties that cross each other, to draw the networks (22).

Our second goal was to examine the possible determinants of any clustering in alcohol consumption behavior. We considered 3 explanations for nonrandom clustering of alcohol consumption behavior in the network: principals might choose to associate with like contacts (homophily) (23, 24); principals and contacts might share attributes or jointly experience unobserved contemporaneous events that cause their alcohol consumption behavior to covary (omitted variables or confounding); and contacts might exert social influence or peer effects on principals (induction). The availability of dynamic, longitudinal data on both network connections and drinking behavior allowed us to distinguish between interpersonal induction of drinking and homophily (25).

Our basic statistical approach involved specifying longitudinal logistic regression models in which a principal's drinking status at time $t + 1$ is a function of his or her various attributes, such as age, sex, and education; his or her drinking status at time t; and the drinking status of his or her contacts at times t and $t + 1$ (25). We used generalized estimating equation procedures to account for multiple observations of the same principal across both waves and principal–contact pairings (26). We assumed an independent working correlation structure for the clusters (27).

By using a time-lagged dependent variable (lagged to the previous examination) for alcohol consumption, we

eliminated serial correlation in the errors (28) (evaluated with a Lagrange multiplier test) and substantially controlled for the principal's genetic endowment and any intrinsic, stable predilection to drink. In addition, the lagged independent variable for a contact's drinking status substantially controlled for homophily (25, 29). The key variable of interest is a contact's alcohol consumption behavior at time $t + 1$. A significant coefficient on this variable would suggest either that a contact's drinking affects a principal's drinking or that a principal and a contact experience contemporaneous events that affect both of their alcohol consumption behaviors. We tested the possibility that omitted variables or unobserved events could explain the associations by examining how the type or direction of the social relationship between contacts affected the association between principal and contact drinking.

To calculate risk ratios and 95% CIs, we simulated the change in risk for principal drinking when contact contemporaneous drinking changes from 0 to 1 by using 1000 randomly drawn sets of estimates from the coefficient covariance matrix and assuming all other variables were held at their means (30). All of these tests are 2-tailed. For repeated tests that involved different types of social contacts, we applied a Bonferroni correction to the CIs.

We assessed the sensitivity of the results with multiple additional analyses (**Appendix**, available at www.annals.org). For example, we considered the possible effect of incomplete or biased network data. If people who drink heavily are more likely to name people outside the study, underestimation of the effect of one person's alcohol consumption behavior on another might occur. We found no significant correlation between number of drinks per day and number of ties to people outside the study ($\rho = 0.01$; $P = 0.15$), which suggests that the network data generation procedure did not bias the analyses.

Role of the Funding Source

The study was supported by the National Institutes of Health and the Robert Wood Johnson Foundation. The funding sources played no role in the design, conduct, or analysis of this study. Each researcher's institutional review board approved the study.

RESULTS

The **Appendix Figure**, available at www.annals.org, shows the largest connected subcomponent of the social network of friends, spouses, and siblings in the year 2000. Clusters of drinkers and abstainers can be seen in the network.

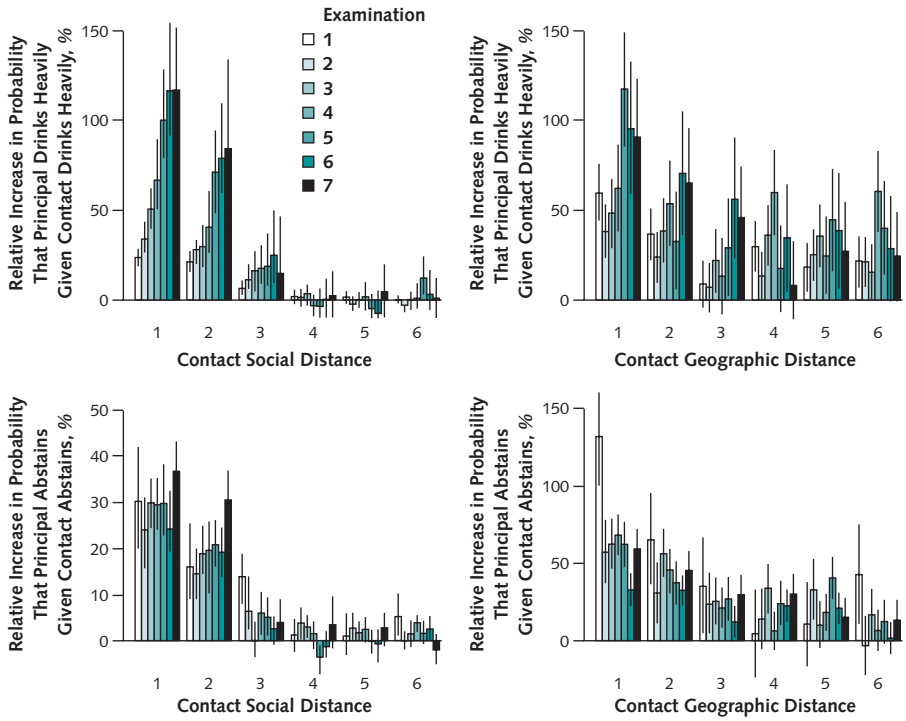
Figure 1 shows the correlation between principals and contacts with regard to their drinking behavior (the **Appendix**, available at www.annals.org, contains numerical results for this and the other figures). Our results indicate that principals are 50% (95% CI, 40% to 62%) more likely to drink heavily if a person they are directly connected to (1 degree of separation) drinks heavily. The size of the effect is 36% (CI, 25% to 48%) for people at 2 degrees of separation (such as the friend of a friend) and 15% (CI, 8% to 25%) for people at 3 degrees of separation (such as the friend of a friend of a friend). The effect disappears at 4 degrees of separation (4% [CI, −2% to 10%]), which is consistent with the "3 degrees of influence" rule of social network contagion that has been shown for obesity, smoking, happiness, depression, loneliness, word-of-mouth advertising, and the spread of ideas among inventors (10–14, 31). Analyses of the full network also show that persons are 29% (CI, 23% to 36%) more likely to abstain if someone they are directly connected to (1 degree of separation) abstains. The size of this effect is 21% (CI, 16% to 27%) at 2 degrees of separation and 5% (CI, 1% to 10%) at 3 degrees of separation, and it disappears at 4 degrees of separation (2% [CI, −1% to 6%]).

Of note, the decline in effect size with social distance in **Figure 2** contrasts with a lack of decline in effect size as people become more geographically distant from one another. We confirmed this by testing an interaction between distance and the effect size. Our results suggest that a friend or family member who lives hundreds of miles away is associated with as big an effect as one who lives next door.

The actual alcohol consumption behavior of social contacts affects a person's alcohol consumption behavior. **Figure 3** shows the smoothed bivariate relationship between the fraction of a principal's friends and family who drank heavily or abstained at one examination and the average number of drinks per day that principal reported at the next examination. Being surrounded by heavy drinkers increased the reported alcohol consumption by about 70% (CI, 35% to 142%) compared with those who were not connected to any heavy drinkers. Conversely, being surrounded by abstainers decreased reported alcohol consumption by half.

When we controlled for age, sex, education, and examination and regressed each principal's future alcohol consumption behavior on the basis of number of contacts who were heavy drinkers, moderate drinkers, or abstainers, we found that each additional heavy drinker increased the likelihood that a principal drank heavily by 18% (CI, 11% to 25%; $P < 0.001$) and decreased the likelihood that a principal abstained by 7% (CI, 2% to 12%; $P = 0.009$) but had no effect on moderate alcohol consumption behavior (CI, −8% to 1%; $P = 0.113$). Conversely, each additional abstainer significantly reduced the likelihood that a principal drank heavily by 10% (CI, 4% to 15%; $P = 0.001$), increased the likelihood that a principal abstained by 22% (CI, 17% to 28%), and decreased the likelihood that a principal drank moderately by 11% (CI, 8% to 14%). Finally, each additional moderate drinker had no significant effect on whether a principal drank heavily (CI, −2% to 7%; $P = 0.214$) but significantly decreased the probability that he or she abstained by 5% (CI, 2% to 9%) and increased the likelihood that he or she drank moderately by 6% (CI, 2% to 9%).

Figure 1. **Relationship of social and geographic distance to heavy drinking and abstaining in connected persons.**



We derived effects by comparing the conditional probability of drinking in the observed network with an identical network (with topology preserved) in which the same number of heavy drinkers or abstainers were randomly distributed. "Contact social distance" refers to the closest social distance (or degree of separation) between the contact and principal (for example, a direct friend = 1 and a friend's friend = 2). For geographic distance, we ranked all physical distances between the homes of directly connected principals and contacts (pairs at 1 degree of separation) and created 6 equally sized groups (1 = closest, 6 = farthest). The average distances for these groups are 0 miles (group 1), 0.26 mile (group 2), 1.5 miles (group 3), 3.4 miles (group 4), 9.3 miles (group 5), and 471 miles (group 6).

We next evaluated the extent of paired, interpersonal association in alcohol consumption behavior. As discussed, our models account for homophily by including a time-lagged measure of a contact's alcohol consumption behavior. We evaluated the possible role of unobserved contemporaneous events by separately analyzing models on subsets of the data that involved various principal–contact pairings. **Figure 3** summarizes the associations from the models (the **Appendix**, available at www.annals.org, contains numerical results). With respect to friends, we found significant sex differences in the spread of heavy alcohol consumption behavior. If a principal's female friend started drinking heavily, then the principal's chances of drinking heavily increased by 154% (CI, 30% to 354%). In contrast, a male friend's heavy alcohol consumption behavior seemed to have no significant effect on the principal. The type of friendship also seemed to be important: A woman did not seem to have a significant effect if she thought of the principal as a friend, but not vice versa (a contact-perceived friend), but the overlapping CIs indicate that the difference in the effect size is not significant. Sex also played a role among spouses. Heavy drinking by a wife increased the likelihood that the husband drank heavily by 196% (CI, 91% to 329%), whereas heavy drinking by a husband increased the likelihood that a wife drank heavily by 126% (CI, 67% to 202%). Among siblings, the effect was significantly smaller and did not differ whether the contact was a sister (37% [CI, 0% to 85%]) or a brother (34% [CI, 8% to 66%]). Immediate neighbors and coworkers had no significant effects on a principal's drinking behavior.

We repeated our analyses for abstention behavior and found broadly similar results. The effect of female friends abstaining was about the same size as that of male friends abstaining (42% [CI, 9% to 84%] vs. 44% [CI, −3% to 106%]), although the latter was barely insignificant. Wives who abstained seemed to have more influence than husbands (74% [CI, 40% to 115%] vs. 56% [CI, 32% to 82%]), but the effect of a sister was weaker than that of a brother (28% [CI, 13% to 45%] vs. 39% [CI, 19% to 60%]). Once again, immediate neighbors and coworkers had no effect on a principal's drinking behavior with respect to abstention.

DISCUSSION

Alcohol consumption behavior among persons and those in their social networks is highly correlated. Interpersonal effects with respect to alcohol behavior vary in size according to the type of relationship. Induction of these

effects may occur through social norms (10, 12, 32–35); unfortunately, the study data include no measures of attitudes toward alcohol consumption, and claims about the underlying mechanisms for the network effects remain speculative.

Our general findings correspond with previous literature on obesity, smoking, happiness, and depression (10–14), although certain patterns of spread seem to be specific to alcohol use. One unique pattern we found relates to the bimodal nature of the social network effects. Whereas network effects were found for smoking cessation (11) (a positive health outcome) and for gaining weight (10) (a negative health outcome), the effect seems to be bidirectional in alcohol consumption with respect to both heavy drinking and abstaining. This suggests that social network effects may have both positive and negative health consequences for alcohol consumption behavior, depending on the circumstances.

Another important finding relates to the role of sex in the spread of alcohol consumption behavior. Our findings suggest that female contacts are significantly more likely

Figure 2. **Effect of heavy drinking and abstaining contacts on principals in the Framingham Heart Study social network.**

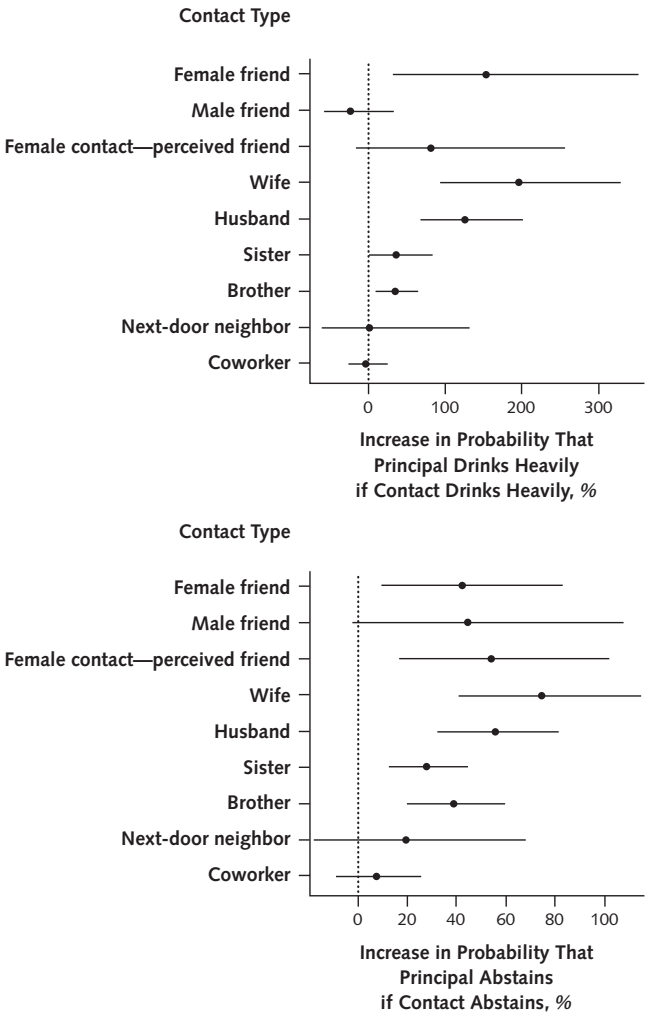
Figure 3. **Contact type and drinking in the Framingham Heart Study social network.**



Changes in principal alcohol consumption given contact alcohol consumption are shown. Estimates are based on generalized estimating equation logit models of drinking in several subsamples of the Framingham Heart Study social network. The dependent variable in each model is principal drinking status. Independent variables include lagged principal drinking status; contact drinking status; lagged contact drinking status; principal age, sex, and education; and fixed effects for each wave. The **Appendix** (available at www.annals.org) contains full models and equations. To calculate mean effect sizes and Bonferroni-corrected 95% CIs, we simulated first difference in contact contemporaneous drinking (changing from 0 to 1) by using 1000 randomly drawn sets of estimates from the coefficient covariance matrix and assuming all other variables to be held at their means. **Top.** Effects of heavy drinking. **Bottom.** Effects of abstention.

than male contacts to influence the spread of heavy alcohol consumption behavior. Although differences may have been expected in principals of different sex (men and women perceiving peer influences and social norms about alcohol differently [36, 37]), the effect of contact sex was unexpected. One possible explanation is that significant increases in drinking behavior among women are much less common and more often associated with dramatic shifts in roles and contexts in life, such as job changes and work stress, which would reflect the effect of confounding factors (38). A related possibility is that changes in perceived norms toward drinking among women are more powerfully transmitted along social networks, possibly because women are usually perceived as sharing norms for less alcohol consumption (37, 38) and a woman who changes her behavior would therefore be a stronger stimulus.

Although our results have several significant associations, it is important to revisit whether they represent the spread of alcohol consumption behavior (induction) or reflect selection effects (homophily) or shared environmental effects (confounding) (23, 39, 40). Although we cannot completely rule out these alternative explanations, several of our findings strongly suggest that induction plays an important role (41). First, the directionality of friendship ties is significant in predicting the spread of alcohol consumption behavior. This provides some evidence for the interpersonal induction of alcohol consumption behavior and suggests that covariance in drinking between friends is not the result of mutual unobserved contemporaneous exposures. If it were, the influence should be equally strong regardless of the directionality of friendship. Second, our results show that neither immediate neighbors nor geographic distance modifies alcohol consumption behavior. If shared exposure (such as proximity to liquor stores or local economic hardship) were key, the effects would decay with distance. Third, because our models control for a principal's previous drinking status, we can account for sources of confounding that are stable over time (such as childhood exposures or genetic endowment). Finally, we can control for a contact's previous drinking status, thus accounting for a possible tendency of drinkers to form ties among themselves. To further control for homophily and environmental exposures, we are currently pursuing follow-up studies that use econometric and experimental methods.

Our study has limitations. First, our outcome measure is not a clinical tool, so we cannot make any specific conclusions about the spread of alcohol-related disorders per se in our sample. Second, we cannot estimate the relative negative health effect of increasing alcohol use, because alcohol use has been reported to have both positive and negative health effects. For example, moderate alcohol use is consistently associated with a lower risk for myocardial infarction (relative to abstention) in prospective cohort studies (42). This beneficial effect of moderate alcohol intake has been found to hold even for men with relatively healthy lifestyles (43, 44). In addition to cardiovascular effects, some evidence suggests that mild to moderate alcohol intake may be related to better cognitive functioning in older adults (45). Therefore, network effects that increase or decrease alcohol consumption could both have health benefits. Third, our sample is ethnically (but not socioeconomically) homogenous. Finally, all network ties were observed in the data set, which means our estimates may be biased.

Our results support the basic idea that because persons are connected, their health is also connected. Network phenomena might be exploited to spread positive health behaviors, a suggestion supported by numerous studies in the domain of drinking. For example, drinking cessation programs that provide peer support—that modify the social network of the target—are more successful (46–48). Of note, the oldest peer social support network in the country, Alcoholics Anonymous, is specifically designed to help foster social network connections, to encourage abstinence among its members and establish ties between principals and principal-identified contacts known as "sponsors." Alcoholics Anonymous reflects the creation of a kind of deliberate social network. Both good and bad behaviors may spread across a range of social ties at some distance from their origin. Our findings also reinforce the idea that drinking is a public health and clinical problem that involves groups of interconnected people who evince shared behaviors, and targeting these behaviors would rightly involve addressing groups and not just individuals.

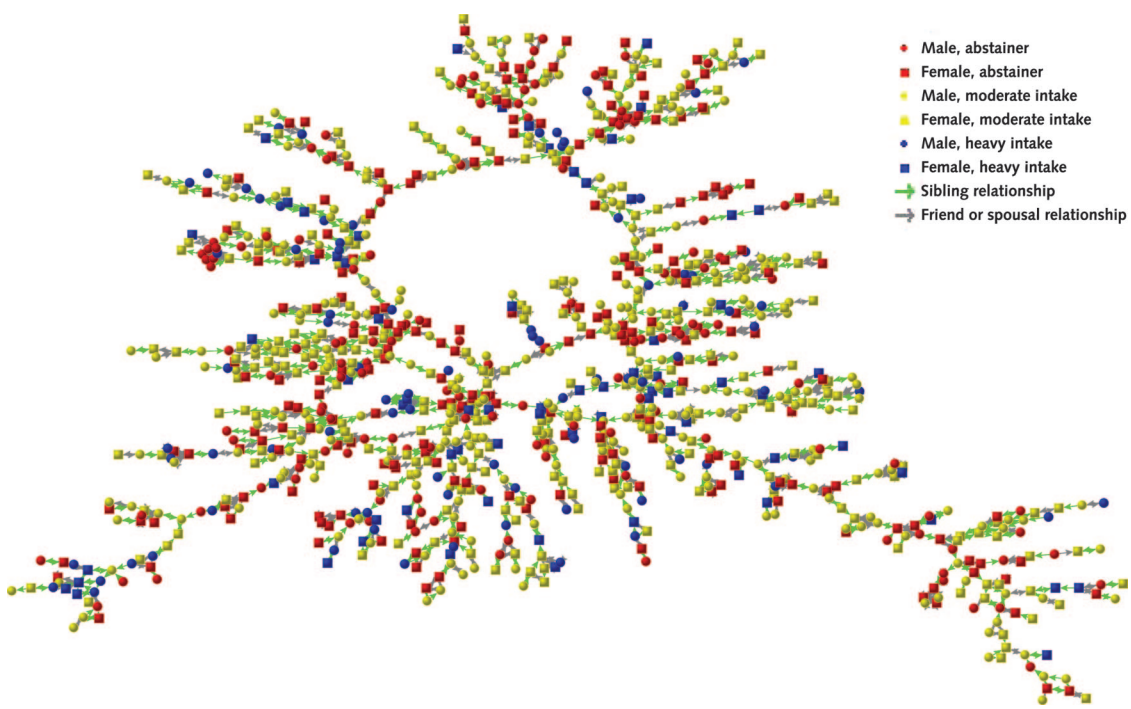
Appendix Figure. **Drinking in the Framingham Heart Study social network in 2000.**



A sample of the largest component of friends, spouses, and siblings at examination 7 (centered on the year 2000); 1073 individuals are shown. Each node represents 1 person. The graph suggests clustering in abstention and heavy alcohol consumption behavior, both of which are confirmed by statistical models.

Candidate Performance Measures for Screening for, Assessing, and Treating Unhealthy Substance Use in Hospitals: Advocacy or Evidence-Based Practice?

Richard Saitz, MD, MPH

The Joint Commission recently proposed candidate performance measures addressing unhealthy substance use in hospitalized patients. The proposed measures of screening and brief intervention (SBI) assume that interventions that work in one setting (primary care outpatient practice) would work in another (hospital); treatment would have the same benefits for persons identified by screening as for those with symptoms who seek help; treatments that work for persons less severely affected by substance use would also work for those with more severe illness; and an approach that works for nondependent, unhealthy alcohol use would work for drug use. However, these assumptions extrapolate evidence of the effectiveness of SBI for primary care outpatients with nondependent, unhealthy alcohol use to the inpatient setting, persons with dependence, and other substances. Although quality of care for unhealthy substance use in all medical settings needs to improve, the evidence base for SBI in the hospital is too limited for the implementation of performance measures assessing this care.

Ann Intern Med. 2010;153:40-43. www.annals.org
For author affiliation, see end of text.

Unhealthy substance use is the spectrum from risky alcohol and other drug use (for example, marijuana, stimulants, opioids) through dependence. A technical advisory panel for the Joint Commission recently proposed candidate performance measures for evaluating screening and brief intervention (SBI) for unhealthy substance use in hospitalized patients (**Table**) (1). The proposed measures raise questions about the balance between advocacy and evidence when considering policy.

Persons with unhealthy substance use in medical settings are often unrecognized and do not receive minimally acceptable management. Performance measurement makes sense as part of a strategy to improve care; however, performance measures must be evidence-based (2), and the proposed practices are not.

The proposed measures have some technical limitations that could be solved when final measures are developed. For example, measures should be separate for alcohol and drug use because SBI tools and practices differ and because specificity would provide information about which practices to improve. In addition, the measures should specify the frequency of screening. Reporting would not be possible without that specification, but the conceptual problem with the measures is of greater interest and is worth broader discussion.

Several assumptions have been made in the development of these measures: interventions that work in one setting (primary care) would work in another (hospital); treatment would have the same benefits for persons identified by screening as for those with symptoms who seek help; treatments that work for persons less severely affected would work for those with more severe illness; and an approach that works for one condition would work for another similar but distinct condition. Randomized trials do not support these assumptions.

On the basis of 12 randomized trials in primary care settings, the U.S. Preventive Services Task Force recommended SBI for nondependent, unhealthy alcohol (but not other drug) use in outpatient primary care settings (3, 4). These studies have shown modest decreases in alcohol consumption at 1 year (4). The proposed Joint Commission measures (1) cite this evidence as supporting alcohol and drug SBI in inpatients, yet these results may not translate there. The best evidence for SBI efficacy is in primary care (4), where screening is often done by a patient's clinician and in a context the patient knows and visits longitudinally for preventive and comprehensive care.

Screening and brief intervention for drugs and alcohol is a cornerstone of the Office of National Drug Control Policy's strategy (5). The Substance Abuse and Mental Health Services Administration has spent several hundred million dollars on SBI in diverse general health settings, including emergency departments, trauma and primary care centers, and hospitals. A pre–post, uncontrolled, retrospective evaluation of self-reported data collected to meet government administrative requirements reported dramatic decreases in drug use after brief intervention in those settings (6). Among patients identified as eligible for brief intervention, treatment, or referral at 6 sites, 10% were selected for follow-up, and 4% to 75% of the selected patients across those sites were lost. This evidence was cited to support the proposed hospital measures (1), but the effect sizes observed are not plausible when one considers the modest effects seen in meta-analysis of controlled trials of SBI for alcohol use in primary care (4). Secular trend and self-change are more likely explanations, with some smaller contribution made by regression to the mean.

Table. **The Joint Commission Candidate Performance Measures for Assessing and Treating Alcohol and Other Drug Use and Dependence***

Name of Measure	Proposed Numerator	Proposed Denominator
Alcohol and other drug use screening	The number of hospitalized inpatients 12 y or older who were screened for alcohol and drug use by using validated screening tools for unhealthy drinking and drug use	The number of hospitalized inpatients 12 y or older
Alcohol and other drug use and dependence—brief intervention or treatment	The number of hospitalized inpatients 12 y or older who were identified with unhealthy alcohol or drug use and received a brief intervention or, if found to have dependence, received substance use treatment as an inpatient or a referral for treatment	The number of hospitalized inpatients 12 y or older who were identified with unhealthy or dependent alcohol or drug use, including prescription drug misuse
Alcohol and other drug use and dependence—treatment management at discharge	The number of hospitalized inpatients 12 y or older who were identified as dependent on alcohol or drugs who 1) received/filled at discharge a prescription for medication for alcohol or opioid dependence with follow-up appointment(s) and 2) received a referral to an addictions treatment program, addiction treatment specialist, or mental health program or mental health specialist explicitly for follow-up for substance use or addiction treatment or 3) received a referral to a medical or health professional explicitly for follow-up for substance use or addiction	The number of hospitalized inpatients 12 y or older who were identified with alcohol or drug dependence or abuse disorders
Alcohol and other drug use and dependence—follow-up for unhealthy use and/or disorders	The number of discharged patients who were identified during a hospital stay with unhealthy alcohol or drug use or alcohol and/or drug use disorders who indicated they decreased or stopped using alcohol or drugs or have received follow-up addiction treatment from a specialty substance use treatment program, behavioral health specialist, or medical professional	The number of discharged patients 12 y or older who screened positive for unhealthy alcohol or drug use or dependence who received a follow-up call within 2 wk after hospital discharge

* Candidate measures were posted for public comment in September 2009 at www.jointcommission.org/NR/rdonlyres/05904E01-E5F7-49F1-8AD2-EC5058D91794/0/CandidateFinalMIFTADD8.doc. Tobacco measures were included in that posting but are not shown because they are not the subject of this article. A notice accompanying the candidate measures states, "All candidate measures are subject to change and may be eliminated from future consideration."

To my knowledge, only 2 randomized trials of drug SBI, in outpatient adults have been published. One reason for this is the paucity of brief drug-screening tools validated in general health settings (7). The relatively low prevalence of drug use is probably another reason. One small published study was in Brazil, and it deserves replication (8). The other was a large outpatient study (urgent care, homeless, and women's clinic) that showed modest benefits: Abstinence was greater by 9% for opioids and 5% for cocaine compared with control participants (9). The National Institute on Drug Abuse and the Substance Abuse and Mental Health Services Administration have funded trials of drug SBI in primary care, recognizing that the evidence is insufficient, as has the U.S. Preventive Services Task Force (2). To my knowledge, no randomized trials of SBI for the spectrum of other drug use in inpatients have been published.

Although cautious optimism may be warranted on the basis of the 2 outpatient studies, we have good reason for concern that brief intervention after drug screening will not be efficacious. One reason is that the target condition is heterogeneous. It is at least plausible that persons identified by screening with occasional marijuana use will have a different response to brief intervention than persons who inject heroin many times daily. Another reason for concern is that the proportion of persons identified by drug screening who have dependence is higher than that of those with unhealthy alcohol use identified by screening. Dependence is probably not as responsive to brief intervention as nondependent use.

We also have good reason for concern that alcohol or drug SBI will not be efficacious in the hospital. The prevalence of dependence is much higher among persons identified by screening in the hospital than in primary care settings. Brief intervention in persons identified by screening has proven efficacy only for those without dependence. Brief intervention could "work" for persons with dependence even if it did not reduce use or consequences if it led patients to enter addiction treatment. However, few studies have addressed this outcome (10). In 1 trial, brief intervention substantially increased linkage to alcohol treatment, but participants with dependence were largely excluded, even though most inpatients with unhealthy alcohol use have dependence (11). A second trial reported no increase in completed referrals for alcohol treatment (12).

A systematic review identified 11 alcohol SBI studies of 2441 patients who received medical, surgical, orthopedic, and trauma inpatient services (10). Results were inconclusive. Brief intervention reduced weekly alcohol consumption at 6 months in 3 studies with substantial heterogeneity. Brief intervention did not reduce weekly drinking at 1 year, laboratory markers, self-report of heavy drinking or driving offenses, or death. Exclusion of 1 of the studies that tested a not-so-brief 3-session intervention and had nonblinded outcome assessments made the 6-month weekly consumption results nonsignificant.

Of interest, alcohol screening is now a requirement for accreditation of trauma centers (13). This standard was largely based on 1 single-site study that had 54% follow-up for the self-report consumption outcome that improved with brief intervention. The study found a nonsignificant reduction in reinjury in administrative data for the whole sample (hazard ratio, 0.52 [95% CI, 0.21 to 1.29]) (14). Four other randomized trials inform the question of efficacy of alcohol SBI in hospitalized trauma patients. In a study of 126 patients, a brief intervention-associated decrease in driving while intoxicated was not significant (15). The decrease became significant in multivariable analyses despite the absence of baseline differences between groups. Another study of 120 trauma patients was not an alcohol SBI study per se; patients were not identified by alcohol screening, nor did they have to have unhealthy alcohol use (16). A collaborative care intervention that addressed posttraumatic stress disorder, depressive symptoms, and alcohol use prevented a 1-year increase in the proportion of patients with an alcohol use disorder; no differences at 6 months occurred, and drinking was not an outcome. Results from the 2 other studies were negative (17, 18). These 5 studies are not conclusive about the effect of universal alcohol SBI in trauma centers: 1 had limited follow-up and a nonsignificant main result; 1 was small, with positive results only in a secondary analysis; 1 showed benefits of a disease management intervention; and 2 had negative results.

The proposed measures go beyond SBI to address treatment and follow-up (**Table**). Treatment and follow-up for persons with recognized substance dependence make sense if patients are ready and willing, particularly for those who ask for help, but giving it to all persons identified by screening is of unknown effectiveness and may be counterproductive if patients perceive that they are being pushed into treatment. Behavior-change counseling can help (4), but effectiveness probably varies by context (10).

The Joint Commission should be commended for trying to address the poor quality of care that patients with unhealthy substance use receive in hospitals, but performance measures for universal alcohol and drug SBI in hospitals risk misdirecting efforts to ineffective practices and may divert attention from currently fixable problems.

Screening and brief intervention for inpatients seem to be simple, logical, and inexpensive. Hospitalization could be a teachable moment—and SBI dissemination could highlight the problem—and in theory improve care. These reasons could justify demonstration projects but not performance measures. Performance measures should assess evidence-based practices, and SBI in hospitals is not evidence-based. In addition, SBI is not simple, inexpensive, or obviously effective. Adding validated questionnaires to busy hospital routines is not simple, particularly because of the need to address positive results. Many institutions have hired staff to implement SBI (6). These complexities and costs and the potential harms of breaches of confidentiality, stigma, discrimination, and unpredictable effects on substance use could be justifiable, but only if hospital SBI has proven health benefits.

Patients with addictions who are in hospitals and seek help have great difficulty receiving addiction-specialty treatment. The first step toward improving quality of care should be taking care of these patients. Performance measures could address evidence-based care, such as pharmacotherapy for opioid and alcohol dependence and counseling. Hospitals should also have addiction treatment referral resources available for care after discharge. Routine practice should include asking about and documenting substance use, as clinicians do for medications. The purpose of identifying substance use is to consider it when making medical diagnoses and implementing treatments, such as prescriptions for addictive medications for treating pain. However, asking should not be confused with SBI, the use of a validated questionnaire, and counseling aimed at substance use.

In primary care, performance measures (19) and other strategies should be implemented to improve low rates of alcohol SBI. The Joint Commission measures could be developed for alcohol SBI in primary care settings that would be evidence-based. Research and demonstration projects should begin to address the growing problem of prescription drug abuse and the integration of behavioral health issues, including substance use and medical care. However, the evidence is insufficient to develop and implement performance measures for practices that may not improve outcomes. Unhealthy substance use is common and the cause of suffering for many. Although advocacy and policy play very important roles in getting good care to patients, this is not the time to allow them to trump the need for evidence to support best practices for patients.

Alcohol screening and brief intervention in primary care: Absence of evidence for efficacy in people with dependence or very heavy drinking

RICHARD SAITZ

Boston University Schools of Medicine and Public Health and Boston Medical Center, Boston, USA

Abstract

Issues. *Although screening and brief intervention (BI) in the primary-care setting reduces unhealthy alcohol use, its efficacy among patients with dependence has not been established. This systematic review sought to determine whether evidence exists for BI efficacy among patients with alcohol dependence identified by screening in primary-care settings.* ***Approach.*** *We included randomised controlled trials (RCTs) extracted from eight systematic reviews and electronic database searches published through September 2009. These RCTs compared outcomes among adults with unhealthy alcohol use identified by screening who received BI in a primary-care setting with those who received no intervention.* ***Key Findings.*** *Sixteen RCTs, including 6839 patients, met the inclusion criteria. Of these, 14 excluded some or all persons with very heavy alcohol use or dependence; one in which 35% of 175 patients had dependence found no difference in an alcohol severity score between groups; and one in which 58% of 24 female patients had dependence showed no efficacy.* ***Conclusion and Implications.*** *Alcohol screening and BI has efficacy in primary care for patients with unhealthy alcohol use, but there is no evidence for efficacy among those with very heavy use or dependence. As alcohol screening identifies both dependent and non-dependent unhealthy use, the absence of evidence for the efficacy of BI among primary-care patients with screening-identified alcohol dependence raises questions regarding the efficiency of screening and BI, particularly in settings where dependence is common. The finding also highlights the need to develop new approaches to help such patients, particularly if screening and BI are to be disseminated widely.* [Saitz R. Alcohol screening and brief intervention in primary care: Absence of evidence for efficacy in people with dependence or very heavy drinking. *Drug Alcohol Rev* 2010;29;631–640]

Key words: alcohol, alcohol dependence, primary care, brief intervention, systematic review.

Background

Alcohol brief intervention (BI) has proven efficacy in primary-care patients with non-dependent unhealthy alcohol use identified by screening [1–4]. Systematic reviews of controlled trials have found a reduction in alcohol consumption of 38 g per week [2] and a 12% reduction in the proportion of patients drinking risky amounts [1] among patients receiving BI compared with those receiving no intervention. However, screening identifies people with the range of unhealthy alcohol use, from risky use without consequences through dependence, and the efficacy of BI for patients with very heavy use or dependence, particularly those identified by screening, has not been established. This observation is important, as 20% of primary-care patients with unhealthy alcohol use identified by screening have dependence [5].

Furthermore, readiness to change and effectiveness of treatment should not be assumed to be the same for people seeking help versus those identified by screening. People with non-dependent unhealthy use may simply be unaware of the consumption amounts that risk health consequences or may have experienced few, if any, consequences related to drinking. As a result, they often are not seeking help or advice. In that circumstance, and without loss of control over their drinking, one would expect them to respond to brief advice from their physician, whom they see for preventive and primary care, when it is offered appropriately.

Received 24 December 2009; accepted for publication 2 June 2010.

On the other hand, people with dependence who seek help often *do* benefit from treatment, including BI [6]. In such cases, the patient has already taken the first steps towards change, unlike the patient identified by screening. Although patients with dependence often report high readiness to change [7], by definition (i.e. dependence criteria), they have great difficulty doing so. Those identified through screening are not actively seeking help and therefore are less likely to be amenable to change. Thus, the literature on efficacy of treatment for people with alcohol dependence may not apply to those identified by screening. The widespread and continued existence of (not brief) specialty care for alcoholism confirms that experts have not concluded that BI is sufficient treatment for dependence. Furthermore, some believe that severity of unhealthy use is an explanation for negative studies of alcohol BI [8].

In clinical practice, the severity of alcohol use is not known until after screening, and clinicians need something efficacious to offer all patients identified as having unhealthy use, including those with greater severity or with dependence. The solution has been to perform BI among patients with dependence with a goal of motivating change, including referral and treatment. Yet it remains unknown whether BI in such patients leads to a decrease in use or alcohol-related consequences or to linkage with treatment. This systematic review of randomised controlled trials (RCTs) sought to find evidence to determine whether BI among patients identified by screening in primary-care settings as having alcohol dependence decreases consumption or alcohol-related consequences or increases initiation of, or engagement in, further alcohol treatment.

Methods

Inclusion criteria

This analysis included RCTs published in English in the peer-reviewed literature through September 2009 that compared primary-care patients with unhealthy alcohol use identified by screening who received BI with patients who received no intervention. BIs were conducted in-person (not by telephone, mail or computer). Each could include up to four follow-up sessions. The goal of the BI could be to reduce drinking and/or alcohol consequences or to provide a referral to additional care.

Exclusion criteria

Studies conducted among hospital inpatients or in emergency departments, trauma centres or other settings not considered primary care per the US Institute of Medicine definition (i.e. integrated, accessible health care by clinicians who are accountable for addressing a large majority of personal health-care needs, who develop a sustained partnership with patients, and who practice in the context of family and community [9]) were excluded, as were studies including patients with comorbid conditions (e.g. gastrointestinal disease, hypertension or pregnancy). Studies that compared BI with another active treatment (vs. usual care or no intervention) were also excluded, as were studies among patients not identified by screening, as motivation for change and severity of use can be substantially different in such patients. Additional exclusions were duplicate reports of results from the same study and studies with methodological flaws as defined in Whitlock *et al.* [4]. They used internal-validity [10] and quality [11] criteria to exclude trials of poor quality. Major quality problems were non-random assignment, non-comparable baseline conditions, attrition greater than 30%, inadequate or unavailable consumption data, or lack of data on alcohol-related consequences or treatment linkage outcomes [4].

Search strategy

Studies were selected from two recent exhaustive, high-quality systematic reviews by Kaner *et al.* [3] and Whitlock *et al.* [4], which identified RCTs of alcohol BI among primary-care patients through 2006. References from six other systematic reviews of alcohol BI in primary care were examined to identify additional studies [1,2,12–15]. Other systematic reviews may exist but were not identified and therefore were not included in this review. Finally, an electronic literature search was conducted to identify RCTs published from 2006 through September 2009 using an inclusive search strategy that combined relevant keywords and medical subject headings (MeSH) across five relevant and comprehensive online databases (Appendix 1).

Study selection

Thirty-three studies were identified by Whitlock *et al.* [4] and Kaner *et al.* [3]. Of these, 19 were excluded from this analysis, the reasons for which are listed in Appendix 2. The remaining 14 studies [16–29] were included in this analysis. Examination of the six additional systematic reviews [1,2,12–15] identified one RCT [30] meeting inclusion criteria (found in Bertholet *et al.* [2]), which was also included in this analysis.

The electronic search of Medline and the Cochrane Database of Systematic Reviews identified 227 potential articles published between 2006 and September 2009, of which eight were studies of alcohol BI. Seven

of the eight studies did not meet inclusion criteria. The reasons for exclusion are listed in Appendix 2. Searches of four additional relevant databases yielded a number of potential additions, but no additional studies meeting inclusion criteria. Thus, one study [31] was included from this search. Combined with the RCTs identified in the previously published systematic reviews, a total of 16 studies (N = 6839 patients) were included in this analysis (Table 1).

Findings

Of the 16 RCTs meeting inclusion criteria, 14 excluded some or all subjects with very heavy alcohol use or dependence, the definitions of which were specific to each study (Table 2). Only two studies included patients with dependence or did not exclude people based on an upper limit of consumption (Table 3). In the study by Burge *et al.* [30], 10–15 min BI by resident family physicians was compared with six weekly 90 min educational sessions, receipt of both interventions or receipt of no intervention among 175 Mexican Americans (75% of whom were men, 35% of whom had dependence and 65% of whom had abuse). Follow up occurred over 18 months. No difference was found between groups on drinks per week or Addiction Severity Index (ASI) alcohol scores. An interaction between BI and ASI alcohol score was not significant, suggesting a similar lack of response to intervention across the range of severity. The ASI family scale score improved among all subjects at 12 months, but at 18 months, BI was associated with a loss of this initial improvement among women. All groups showed improvement in the ASI medical score at 12 months, but only those in either intervention group continued to improve at 18 months, while those who received both interventions or no intervention did not. There were no group outcome differences in employment, legal problem severity, psychiatric severity or laboratory test results (mean corpuscular volume, gamma-glutamyltransferase or alanine or aspartate aminotransferase levels). In the study by Chang *et al.* [17], including 24 women (58% of whom had dependence, 8% of whom had abuse and 21% of whom had a past alcohol use disorder), no difference in alcohol consumption was observed between groups, the BI was done by an experienced addiction psychiatrist, and duration was not specified. Both study samples were recruited from single clinic sites. Neither study addressed treatment linkage as a goal of BI, although in Chang *et al.* referral to treatment was the control condition. Despite this, no control patients followed through on the referral in that study, and linkage to treatment was not reported for the BI group.

Conclusions

Results of the two studies identified in this systematic review offer no evidence to support alcohol screening and BI efficacy among primary-care patients with very heavy drinking or dependence. Furthermore, the studies were of limited generalisability. Patient samples were small in both studies; one study included only women, and the other included only Mexican Americans; results were not specifically analysed by dependence; the range of outcome measures could have been greater; and, in one of the studies, the intervention was conducted by an expert.

Other evidence in the literature suggests that screening and BI has efficacy for those who drink too much but do not have dependence. It may turn out to have efficacy for those with more severe unhealthy use, but evidence to date is not available to support this. There is a difference between an absence of evidence and evidence for absence of effect: the circumstance here is the former. Regardless, it is clear that we cannot conclude, on the basis of high-quality evidence in the scientific literature, that BI among those identified by alcohol screening in primary care works for people with very heavy drinking or dependence.

This study had several limitations. Ideally, systematic reviews are conducted by at least two independent raters, and interrater reliability is reported. Such a process might have strengthened this paper. Second, the findings relied largely on prior systematic reviews, exclusion criteria in original articles were sometimes not clearly specified, and non-English language studies were not included. However, of the four non-English studies included in the prior systematic reviews, two excluded patients with dependence and patients who had received treatment for alcohol problems [32,33], one excluded patients who had received treatment [34], and one excluded people with heavy drinking (≥95 units per week) and failed to provide clear data on randomisation methods [35]. As such, these studies would have either been excluded from the current review based on criteria other than language or, if included, would have appeared among the studies that excluded patients with very heavy use or dependence (and thus would not have contributed information on efficacy of BI in such patients).

One might wonder whether the BI literature beyond primary care might inform the question asked in this review. However, the context of care appears to be quite important for BI. In the literature on BI in emergency departments, most studies found no impact of BI on drinking [36–38]. Severity may be an explanation for inconsistent results on BI efficacy in other settings, such as hospitals [39]. For example, one of the few BI studies in any setting that did not exclude people with

Table 1. *Summary of alcohol screening and BI trials included in the systematic review*

Author (year)	Setting	Participants (age)	Intervention
Anderson & Scott (1992) [16]	8 primary-care group practices in England	154 men (17–69 years)	10 min BI, including advice and feedback from usual physician provider
Burge *et al.* (1997) [30]	US family practice outpatient clinic	175 Mexican-American adult men and women (18+ years)	10–15 min BI from physician and 6 group psychoeducational sessions (90 min each)
Chang *et al.* (1997) [17]	US general internal medicine clinic	24 women (average age, 39 years)	BI with psychiatrist (duration not reported)
Curry *et al.* (2003) [18]	US urban primary-care clinic	307 men and women (mean, 47 years)	BI from usual physician provider plus and up to 3 telephone follow-up sessions and self-help booklet
Fleming *et al.* (1997) [19]	17 US primary-care practices	774 men and women (18–30 years)	2 15 min BI from usual physician provider 1 month apart plus follow-up phone call from nurse 2 weeks after each visit and self-help booklet
Fleming *et al.* (1999) [20]	24 US primary-care practices	158 men and women (65–75 years)	2 10–15 min BI from usual physician provider 1 month apart plus follow-up phone call from nurse 2 weeks after each visit and self-help booklet
Lock *et al.* (2006) [21]	40 UK primary-care practices	127 men and women (mean, 44 years)	5–10 min BI from nurse and self-help booklet
Maisto *et al.* (2001) [22]	12 US primary-care clinics	301 men and women (mean, 46 years)	Intervention 1: 30–45 min BI from staff with motivational enhancement plus 2 15–20 min follow-up sessions and self-help booklet; Intervention 2: 10–15 min BI from staff and self-help booklet
Nilssen (1991) [23]	University community-health centre in Norway	290 men and 48 women (12–62 years)	Intervention 1: single BI from physician and self-help booklet plus follow-up letter; Intervention 2: more extensive intervention from physician plus self-help booklet and offer of follow-up consultations
Ockene *et al.* (1999) [24]	4 primary-care academic medical centres in the USA	530 men and women (mean, 44 years)	5–10 min BI from trained interventionist and self-help booklet
Richmond *et al.* (1995) [25]	40 primary-care practices in Australia	378 men and women (mean, 38 years)	Intervention 1: 5 min session from physician and self-help booklet plus additional 15–20 min BI 1 week later, additional 5–25 min BI 1 month later and 2 additional 5 min follow-up sessions; Intervention 2: 5 min BI from physician and self-help booklet
Schaus *et al.* (2009) [31]	College student health centre	363 men and women (mean, 20 years)	2 20 min BI sessions from trained providers
Scott & Anderson (1991) [26]	8 primary-care practices in England	226 men and women (mean, 45 years)	10 min BI from physician and self-help booklet
Senft *et al.* (1997) [27]	3 primary-care group practices in the USA	516 men and women (mean, 42 years)	30 s advice from physician, physician's assistant or nurse immediately followed by 15 min BI from health counsellor plus self-help booklet
Wallace *et al.* (1988) [28]	47 primary-care group practices in the UK	909 men and women (17–69 years)	BI from physician plus 1–4 follow-up sessions and self-help booklet
WHO Brief Intervention Study Group (1996) [29]	10 primary-care settings in 8 countries	1260 men (average, 37 years) and 299 women (average, 36 years)	Intervention 1: 5 min BI Intervention 2: 15 min BI with behavioural techniques plus up to 3 follow-up visits

BI, brief intervention.

Table 2. *Alcohol screening and brief intervention trials included in the systematic review that excluded patients with very heavy alcohol use or dependence*

Author (year)	Exclusion criteria
Anderson & Scott (1992) [16]	Heavy use (>105 drinks per week) or advice to cut down in past year
Curry *et al.* (2003) [18]	AUDIT score >15
Fleming *et al.* (1997) [19]	Heavy use (>50 drinks per week), past year alcohol treatment or withdrawal, receipt of physician advice to reduce alcohol use
Fleming *et al.* (1999) [20]	Heavy use (>50 drinks per week), past year alcohol treatment or withdrawal, receipt of physician advice to reduce alcohol use
Lock *et al.* (2006) [21]	AUDIT score >15 for men or >13 for women, or severe dependence
Maisto *et al.* (2001) [22]	Acute dependence symptoms or recent substance abuse treatment
Nilssen (1991) [23]	Dependence
Ockene *et al.* (1999) [24]	In an alcohol treatment program
Richmond *et al.* (1995) [25]	Severe dependence, alcohol-related problems, any past alcohol treatment
Schaus *et al.* (2009) [31]	Consumption of >200 drinks in the last 30 days
Scott & Anderson (1991) [26]	Consumption of >71 drinks per week and/or past year advice to cut down or abstain
Senft *et al.* (1997) [27]	AUDIT score >21
Wallace *et al.* (1988) [28]	Recent health professional advice to reduce drinking and/or gamma-glutamyl-transferase level of 150 IU L^{-1}
WHO Brief Intervention Study Group (1996) [29]	Known or suspected dependence or very high daily consumption, liver damage, prior alcohol treatment, prior health professional warning to abstain

AUDIT, Alcohol Use Disorders Identification Test.

Table 3. *Alcohol screening and brief intervention trials included in the systematic review that did not exclude subjects with very heavy alcohol use or dependence*

Author (year)	Description
Burge *et al.* (1997) [30]	Sample: N = 175 Mexican-American men and women; 65% had abuse and 35% had dependence. Results: no difference in alcohol severity scores by intervention group
Chang *et al.* (1997) [17]	Sample: N = 24 women; 71% had lifetime dependence (58% with current dependence) and 8% had abuse (8% with current abuse); past alcohol treatment was an exclusion. Results: brief intervention not associated with reduced alcohol consumption

dependence found no efficacy for BI in hospitalised patients; 77% of patients in the sample had dependence, because that was the nature of the population found in the hospital [7,40]. A subgroup analysis from the same study found there may have been an impact of BI on drinking among those without dependence only [41]. Another hospital study that excluded patients with dependence or alcohol-related conditions found the effectiveness of BI for decreasing consumption was comparable to that achieved by providing a self-help booklet compared with controls who received no intervention [42]. An additional analysis of BI in the hospital setting by Freyer-Adam *et al.* [43] found no difference in consumption or alcohol-related consequences among the 45% of patients with dependence. Studies that compare BI with more extensive interventions could theoretically be informative, but they have generally not included people identified by screening [6]. In such studies, BI has similar efficacy to longer interventions among those seeking help. It is not known how such results would translate to BI among people with dependence who are not necessarily seeking help.

One might consider the use of categorisation of patients as having dependence a simplification of what is likely a spectrum of severity. Although it is probably true that severity of unhealthy use is on a spectrum rather than a dichotomous phenomenon, it also remains likely that, when patients are categorised as 'dependent', such categorisation includes patients with greater severity. Continuous measures of severity could be used in future studies to better identify those patients for whom BI does or does not have efficacy, but, generally speaking, studies to date have not done so.

This review has methodological strengths as well. Many systematic reviews of BI in primary care have preceded this one, making it likely that few, if any, studies have been missed. Experts in systematic review

methodology have recently encouraged the appropriate inclusion of prior systematic reviews in those that follow [44]. This review focused on the primary-care setting as defined by the US Institute of Medicine and used a wide range of electronic databases. It also excluded studies with substantial methodological limitations.

Based on this review, it is clear that most randomised trials of alcohol BI for screen-identified patients in primary-care settings published to date have excluded patients with very heavy alcohol use or dependence. In the two studies that did include patients with dependence, the efficacy of BI for such patients remains unknown.

Implications

In clinical practice, most do not advocate BI for patients with alcohol dependence, recognising it will likely be insufficient to address this more complex and severe condition. Yet such patients often receive no intervention, whether BI or more extensive treatment. Although BI is expected to lead to referral, treatment initiation, and reductions in alcohol consumption and related problems, these results and those of other studies in other settings suggest this is unlikely. In a study of hospitalised patients by Elvy *et al.* [45], BI decreased alcohol-related consequences and increased treatment enrolment (14% of patients in the BI group enrolled in treatment vs. 4% of patients who got no BI); however, most participants did not have dependence. In a study by Saitz *et al.* involving general hospital patients, no differences in treatment entry were seen, although hypothesis-generating subgroup analyses showed some promise for women and younger men with dependence [40].

Bischof *et al.* [46] compared computerised feedback and telephone-based care with no intervention among primary-care patients with unhealthy alcohol use, including dependence. They found a decrease in heavy drinking only among those with risky use or abuse, but no other outcome differences were observed, and no benefits were observed among patients with dependence. (Specifically, BI did not increase help seeking.) D'onofrio *et al.* [47] conducted a study among emergency department patients without dependence and found no difference in substance abuse or mental health treatment utilisation among those receiving BI versus those receiving no intervention. Finally, although success of drug and alcohol treatment varies depending on rapid availability of treatment, the nature of treatment (e.g. opioid agonist treatment for opioid dependence vs. naltrexone for alcohol dependence) and the availability of support services (e.g. transportation), US programs that provide alcohol screening, BI and referral to treatment (SBIRT) [48] report that most patients with dependence referred to treatment do not accept the referral and, thus, do not enter treatment (Alford D and Smith J, 2009, Personal Communication).

In sum, screening, even when the goal is BI for people with non-dependent unhealthy use, identifies patients with dependence, and the rationale for implementing BI universally among such patients is questionable considering the lack of evidence for its efficacy. We should not 'throw the baby out with the bathwater', however. Clearly, BI has efficacy for primary-care patients with less severe unhealthy alcohol use, and that should continue. The question is whether such screening should be universal if evidence for benefit in an important subgroup is lacking. Some might conclude that it should, because BI will eventually be proven to have efficacy among those with dependence. Others will disagree. Nonetheless, research is needed to determine what, if anything, may have efficacy for patients with alcohol dependence identified by screening in primary care as well as in other health-care settings. Such studies of BI should assess subjects with continuous measures of unhealthy alcohol use severity; be widely generalisable, with few exclusion criteria; and measure important clinical outcomes (e.g. consumption, consequences, cost, referral completion and other health-care utilisation).

The absence of evidence for the efficacy of BI among primary-care patients with screening-identified alcohol dependence raises questions regarding the efficiency of screening and BI, particularly in settings where dependence is common. The finding also highlights the need for developing new approaches to help such patients, particularly if screening and BI are to be disseminated widely.

Acknowledgements

Dr Saitz would like to thank Ms Donna Vaillancourt for editorial preparation of the manuscript for publication. His research is supported in part by support from the US National Institute on Alcohol Abuse and Alcoholism and the National Institute on Drug Abuse (grant numbers R01DA025068 and R01AA10019).

Appendix 2

Studies excluded from the systematic review and reasons for exclusion.

Author (year)	Reason for exclusion
Aalto *et al.* (2000) [49]	Quality: inadequate allocation concealment, >30% of patients lost to follow up, important baseline differences between groups, unclear blinding in outcome assessment
Aalto *et al.* (2001) [50]	Quality: inadequate allocation concealment, >30% of patients lost to follow up, important differences in baseline characteristics between groups, unclear blinding in outcome assessment
Altisent *et al.* (1997) [32]	Language: not published in English
Bischof *et al.* (2008) [46]	Setting: intervention conducted by telephone and via World Wide Web
Cordoba *et al.* (1998) [51]	Quality: 270 of 546 subjects (49%) excluded from analysis because they were lost to follow up or did not adhere to protocol; no intent-to-treat analysis; practice was unit of randomisation, patient was unit of analysis
Crawford *et al.* (2004) [52]	Setting: intervention conducted in an emergency department
Diez *et al.* (2002) [35]	Quality/language: not published in English; randomisation unclear
Fernandez San Martin *et al.* (1997) [34]	Language: not published in English
Fleming *et al.* (2004) [53]	Co-occurring condition: subjects had hypertension or diabetes
Gentilello *et al.* (1999) [54]	Setting: intervention conducted in a trauma centre
Guth *et al.* (2008) [55]	Quality: study lacked a control group
Heather *et al.* (1987) [56]	Quality: post-randomisation exclusions of which the numbers were not reported; less than half of subjects received the full intervention
Huas *et al.* (2002) [33]	Language: not published in English
Israel *et al.* (1996) [57]	Quality: 30% of subjects lost to follow up; baseline comparisons unclear
Kuchipudi *et al.* (1990) [58]	Co-occurring condition: subjects had gastrointestinal disease
Kunz *et al.* (2004) [59]	Setting: intervention conducted in the emergency department
Kypri *et al.* (2008) [60]	Setting: screening and intervention conducted via World Wide Web
Lee *et al.* (2009) [61]	Type: subgroup analysis of Oslin *et al.* (2006) [66]
Longabaugh *et al.* (2001) [62]	Quality/setting: intervention conducted in the emergency department; randomisation unclear; inadequate allocation concealment
Maheswaran *et al.* (1992) [63]	Co-occurring condition: subjects had hypertension
Manwell *et al.* (2000) [64]	Type: subgroup analysis of Fleming *et al.* (1997) [19]
McIntosh *et al.* (1997) [65]	Quality: unclear allocation concealment; baseline characteristic differences between groups; inadequate power
Oslin *et al.* (2006) [66]	Type: compared two interventions, with both groups in active treatment
Pal *et al.* (2007) [67]	Quality: lacked randomisation (alternate group assignment)
Persson & Magnusson (1989) [68]	Quality: consumption measures reported for intervention group but not controls; 31% attrition rate; blinding of participants and outcome assessors unclear
Reinhardt *et al.* (2008) [69]	Type: subgroup analysis by gender of Bischof *et al.* (2008) [46]
Rodriguez-Martos *et al.* (2005) [70]	Language/setting: not published in English; intervention conducted in the emergency department
Romelsjo *et al.* (1989) [71]	Quality: no statistical analysis of results; 151 of 258 patients excluded post randomisation; no intent-to-treat analysis; no adjustment for important differences between groups at baseline
Rose *et al.* (2008) [72]	Quality/co-occurring condition: practice-level intervention lacked randomisation; subjects had hypertension
Salaspuro (2003) [73]	Quality: not peer-reviewed; methodology not adequately reported
Seppä (1992) [74]	Quality/co-occurring condition: randomisation methods unclear; poor follow-up attendance; subjects had macrocytosis
Tomson *et al.* (1998) [75]	Quality: 50%–62% attrition rates; unequal randomisation results (100 in the intervention group, 122 controls); control group not assessed for consumption amounts at baseline; analyses not adjusted for baseline differences

Editorial

Evidence-based medicine: time for transition and translation (to practice)

Richard Saitz

rsaitz@bmjgroup.com

It is a time of change for evidence-based medicine (EBM, the field) and for *EBM* (the journal). With this issue of *EBM* I become its new Editor; I have assembled an editorial board consisting of primary care and internal medicine practitioners with expertise in both critical appraisal and clinical practice (general practice, family medicine, internal medicine, paediatrics and obstetrics and gynaecology). The main purpose of the journal remains the same: to briefly summarise and critically appraise articles that appear in the peer-reviewed health literature and are likely to be valid and relevant for clinical practice. The world of healthcare, however, has changed since EBM arrived on the scene.

The past 20 years have seen the birth of *EBM*[1] and its adolescence, during which grown-ups in medicine either seemed skeptical about the upstart movement or described it as nothing new. I witnessed this development and took on a role that included its teaching and practice. Journal club during my residency (postgraduate training) usually involved an article that was chosen for little apparent reason (not because of a question it was likely to address). The article was then shredded (at least figuratively) by a resident, and then specialist commentary based on clinical experience and expertise was sprinkled in. When the concept of EBM appeared in the literature, and I had attended a teaching-EBM workshop at McMaster University, my eyes were opened to how much more useful the medical literature could be. The need to handle the information explosion in an organised fashion was great. EBM served as a framework for selecting and evaluating articles. It became a useful tool for keeping up with the literature and a solid basis for practicing medicine.

That science is now mature, EBM firmly in middle age, with experts in searching and critical appraisal all around. And research methodology has advanced, perhaps even outstripping its clinical utility at times. But many challenges remain for EBM on using it to its fullest potential.[2] It is still difficult to keep up with the literature, and for many, critical appraisal is an elusive skill. *EBM* (the journal) helps with these issues. But the real challenges are how to translate evidence into policy and practice. Such translation involves values and preferences. Recent controversies about breast cancer screening and vaccines do not appear to have been as much about evidence as they were about values, preferences, beliefs and translation of evidence into practice and policy (including issues of cost and payment).[3 4] Decisions about what care to pay for vary based on data beyond efficacy, as I recently was reminded during a visit to meet with *British Medical Journal* Group editors in the UK where the news was about how varicella vaccine was not paid for by the National Health Service; in contrast, the vaccine is widely disseminated, considered to be the standard of care and covered by health insurance in the USA. Clinicians and patients (and policymakers) want good evidence, but they also want to know what to do with it. Critical appraisal of an article seems simple in comparison, and practice guidelines help only a little bit in the clinic with individuals.

A few more examples are in order. In this issue of EBM, the reader will find a commentary on the results of a randomised trial of dutasteride for preventing prostate cancer.[5] The study found efficacy for men 50–75 years of age who had had a recent negative prostate biopsy and prostate specific antigen (PSA) level of 2.5 (3.0 if age ≥60) to 10.0 ng/ml. The commentator concludes that the effects of the medication are clinically relevant and that drugs in this class should be considered for men at high risk (eg, like those in the trial). I come to different conclusions from the same evidence. I would emphasise that the effect of dutasteride was limited to low grade cancers, and that we don't know whether prevention of such cancers (often the focus of over-identification and overtreatment) will improve morbidity or reduce mortality. In that context the 5% absolute risk reduction seems of unclear clinical relevance (follow-up biopsies were part of the protocol, not based on symptoms or PSA level). An editorialist wrote that the drug did not prevent prostate cancers; rather it temporarily shrank tumours with low potential for being lethal.[6] He also pointed out that the suppressed PSA levels might delay diagnosis and treatment until the development of high-grade disease. The interpretation of such results depends on much beyond the evidence per se.

I hope international readers will forgive me for a parochial example. I use it because it illustrates the challenges for EBM well. Jacoby Ellsbury is a popular baseball player with the Boston Red Sox. In April this year, another player slammed into him knee first, and a plain radiograph was negative.[7] He was put on the 'disabled list' because of pain in his chest to return when better. Eleven days after the injury he had a CT scan, which he said was done at his request. The CT scan found non-displaced hairline rib fractures, leading a sportswriter to write that "it wasn't just a contusion, as the team discovered yesterday." The team physician pointed out that the test hadn't changed anything – the treatment was the same (rest) – and the player could return when the symptoms subsided. We know a CT scan can identify fractures not seen on plain films. But what is the value of that information? It was of no value to the team physician, but the player (and his fans) felt it was valuable in explaining the duration of symptoms. In fact they seemed surprised that a physician would withhold such testing. Ellsbury said "I'm glad I went about it and did it just to kind of get some closure in what's going on."

What will we do here at *EBM* to help readers keep up and to address the transition of EBM into middle age?

Here is my plan, and I hope to hear from you about it, and whether or not it is meeting your needs.

1. From among the numerous potentially valid peer-reviewed studies published, we will summarise and comment on those most likely to have clinical relevance for medicine practiced by general practitioners, family physicians and internists.
2. We will combine a summary of the original article along with commentary. Original article abstracts can be found online through the link provided. We will summarise the context, key methodological features and results in a structured commentary with subheadings that allow readers to go directly to the section they seek. Experts will provide their view on implications for practice. Our editorial board will peer-review these commentaries.
3. We will include occasional EBM-relevant editorials and perspectives either about articles summarised or about broader issues.
4. *EBM* intends to be a home for 'EBM-ers', those who teach, study and practice EBM. To that end we invite systematic reviews, EBM teaching and research methods articles, 'primer' articles focusing on EBM tools and concepts and an occasional review of what has appeared elsewhere in the literature relevant to EBM (an EBM Roundup).

In addition to this content, I also recognise that, while the paper journal is certainly endearing and has its many fans and users (it will continue), electronic publishing makes it even easier to keep up with the literature through *EBM*. We will make commentaries available online when they are ready, and readers will be able to receive alerts and read them in smaller boluses more frequently if that is their preference.

EBM is at a crossroads, a transition from searching, finding, appraising and keeping up, to translating evidence into policy and practice. It is time to enter the second 20 years during which we will no doubt see EBM fulfil even more of its promise. Hopefully *EBM* will continue to be a useful tool and home for all of you during this next phase. Our plans should help with that as should your comments and recommendations.

LETTER TO THE EDITOR

Most inpatients with unhealthy alcohol use have an alcohol use disorder

Richard Saitz

Published online: 10 June 2010

I read the paper by Bischof et al. (2010) with interest because it addresses an important question with implications for screening and brief intervention. They concluded that at-risk drinkers without alcohol use disorders are "the largest group of unhealthy alcohol consumers" in both hospitals and general practices. They state that our prior study that concluded most inpatients with unhealthy alcohol use had dependence was flawed. I believe they have not interpreted their data and this prior study correctly.

In our hospital study, 81% of those who screened positive had an alcohol disorder (Saitz et al. 2006). Bischof et al. (2010) question these results because (1) they are from one hospital, (2) from a subsample in an intervention study, (3) because of a change in entry criteria during the study, and (4) insurance differences in the US. These are unlikely to explain differences in our findings. In a study in Germany, over half of those who screened positive in the hospital had dependence (after excluding false positives) (Freyer-Adam et al. 2008). In another general hospital study, 66% of those who screened positive in a Barcelona hospital had dependence (Martinez et al. 2007). In our study (Saitz et al. 2006), we were able to screen 99% of 5,813 inpatients who agreed to be screened and 17% were positive. Although compared to those who did not enroll in the clinical trial, those who enrolled (and had diagnostic interviews) were more likely to have Alcohol Use Disorders Identification Test (AUDIT) scores 8 or greater (86 vs. 82%), differences were not statistically significant. Although we did change entry criteria during the study, only one-fifth of subjects were enrolled when the criterion was an AUDIT score of 8 that Bischof et al. (2010) state may have been responsible for discrepant results. In addition, before and after entry criteria changed, the prevalence of unhealthy alcohol use was similar, 19 and 17%, respectively. While lack of insurance was common during this study, our urban safety-net hospital provided care regardless of ability to pay and most admissions are through the emergency department, hospitalizations less sensitive to insurance.

Perhaps more important, the data presented by Bischof et al. (2010) are actually consistent with findings in the literature that suggest that the majority of those who screen positive in hospitals have dependence. In their hospital sample, 15% had unhealthy alcohol use [similar to our and prior studies (Saitz et al. 2006; Roche et al. 2006)], 5.5% had dependence, 2.8% abuse, and 6.2% drank risky amounts; thus, 57% of those with unhealthy use had an alcohol use disorder. This figure is substantially higher than the 33% reported in general practices in their study.

Bischof et al. (2010) are correct that the number of risky drinkers in hospitals is high, and there may be opportunity to intervene, although studies in these settings have been inconclusive, and severity may be part of the explanation, though efficacy has yet to be proven even among those without dependence (Freyer-Adam et al. 2008; McQueen et al. 2009). The literature to date is clear that the majority of patients identified by alcohol screening in hospitals have more severe unhealthy use (an alcohol disorder) than in general practice settings where alcohol brief intervention is known to have efficacy for those without dependence. At a minimum, if screening is implemented in hospitals, clinicians need to be prepared to address substantial numbers of patients they will find with dependence.

Screening and Brief Intervention for Unhealthy Drug Use in Primary Care Settings: Randomized Clinical Trials Are Needed

Richard Saitz, MD, MPH, Daniel P. Alford, MD, MPH, Judith Bernstein, PhD, ADN, MSN, Debbie M. Cheng, ScD, Jeffrey Samet, MD, MA, MPH, and Tibor Palfai, PhD

Abstract: The efficacy of screening and brief intervention (SBI) for drug use in primary care patients is largely unknown. Because of this lack of evidence, US professional organizations do not recommend it. Yet, a strong theoretical case can be made for drug SBI. Drug use is common and associated with numerous health consequences, patients usually do not seek help for drug abuse and dependence, and SBI has proven efficacy for unhealthy alcohol use. On the other hand, the diversity of drugs of abuse and the high prevalence of abuse and dependence among those who use them raise concerns that drug SBI may have limited or no efficacy. Federal efforts to disseminate SBI for drug use are underway, and reimbursement codes to compensate clinicians for these activities have been developed. However, the discrepancies between science and policy developments underscore the need for evidence-based research regarding the efficacy of SBI for drug use. This article discusses the rationale for drug SBI and existing research on its potential to improve drug-use outcomes and makes the argument that randomized controlled trials to determine its efficacy are urgently needed to bridge the gap between research, policy, and clinical practice.

Key Words: addiction, drug use, primary care, drug screening, brief intervention

(*J Addict Med* 2010;4: 123–130)

Unhealthy drug use is the spectrum from use that risks health consequences (also known as "at-risk use" or "risky use") through dependence. It could be argued that all illicit drug use is unhealthy, because any drug use risks some health or legal consequences. Unhealthy drug use is prevalent in the United States and is associated with numerous health consequences. About 20.4 million Americans (8.3%) aged 12 years and older report past-month illicit drug use, and 2% have a current clinical disorder (ie, abuse or dependence) (Compton et al., 2007; Substance Abuse and Mental Health Services Administration, 2007a). Drug use costs the United States $181 billion per year, primarily because of productivity loss, healthcare costs, and crime (Office of National Drug Control Policy, 2004).

Not all drug use is associated with substance dependence, the most severe disorder. However, for those who develop it, similar to other chronic illnesses, substance dependence is associated with long-term physiologic changes, a relapsing course, variable adherence to care, and the need for ongoing care (McLellan et al., 2000, 2002). In addition to social and legal consequences, co-occurring medical and psychiatric disorders such as depression are common and can trigger relapse (Regier et al., 1990; Kessler et al., 1994; Brindis et al., 1995; Brooner et al., 1997; Ziedonis and Brady, 1997; Friedmann et al., 1998; McLellan et al., 1999; Hasin et al., 2002). Patients with substance dependence are more likely than those without this diagnosis to have myriad conditions including injury, anxiety, psychosis, back pain, headache, arthritis, asthma, peptic disorders, chronic obstructive pulmonary disease, hepatitis C, hypertension, alcoholic gastritis, diseases of the pancreas, and cirrhosis (Mertens et al., 2003; Compton et al., 2007). In addition, the treatment of co-occurring medical and psychiatric conditions in patients with substance dependence is complicated by their risk of poor adherence to medication and other self-care (Golin et al., 2002).

Drug use that does not meet criteria for abuse or dependence can also put people at risk for health consequences. They can not only develop dependence but other medical complications (eg, pneumothorax, myocardial infarction, accidents, and trauma) can also result from such use. Unsafe sex practices and injection drug use are major routes of transmission for human immunodeficiency virus (HIV) (Hudgins et al., 1995; Raj et al., 2007). Mechanisms for increased risk include impaired judgment, increased sex drive, unsafe injection practices, and exchange of sex for drugs. Although risk-reduction interventions in addiction

treatment settings and sexually transmitted disease clinics have been effective in decreasing these behaviors (Kamb et al., 1998; Lubelczyk et al., 2002; Woody et al., 2003), many people at risk, including those in primary care settings, do not receive such interventions (Wenrich et al., 1997).

However, it is worth noting here that a number of studies have failed to demonstrate health risks associated with drug use in some circumstances. One study found no association between marijuana use and declines in pulmonary function (Tetrault et al., 2007), another found no association between cocaine use and a marker of coronary artery disease (Pletcher et al., 2005), and a third found little evidence of psychological harm associated with drug use among young adults (Macleod et al., 2004). In circumstances in which the risks associated with drug use are small or nonexistent, risk-reduction interventions have had no effect on outcomes.

Clearly, early detection and treatment of drug use that does risk harms could be important if efficacious, yet opportunities for early intervention are limited. To date, the primary focus of treatment has been on persons with more severe unhealthy use; ie, those who meet criteria for substance abuse or dependence. Furthermore, most people with dependence do not seek treatment (Olfson et al., 2000; Compton et al., 2007), and detection and treatment efforts in medical care settings are limited. Thus, reliable methods to screen and treat people who use drugs in the primary care setting have the potential to dramatically improve care and patient outcomes.

SCREENING AND BRIEF INTERVENTION

Screening and brief intervention (SBI) is a comprehensive, integrated, public-health approach to the delivery of early intervention and treatment services for people with the full spectrum of unhealthy substance use. Screening identifies people with unhealthy use and, when followed by an assessment of the severity of substance use, can identify the treatment goal (ie, cutting down or abstinence). Brief intervention (BI) generally involves 1 or 2 counseling sessions of 10 to 30 minutes each, although sessions may be as short as 5 minutes (generally referred to as brief advice) or as long as 1 hour for 4 sessions. Referral may be provided for those identified as needing more extensive specialized treatment.

Primary care centers, hospital emergency departments, and other community health settings see the broadest number and range of patients and thus provide ideal opportunities to screen for and address drug use before more severe consequences occur. Primary care settings provide the best context and opportunities for change over time, because patients have an expectation of preventive care and often have a longitudinal trusting relationship with a clinician.

Conceptual Framework

Although BI includes clear directive advice, focus is primarily on increasing patient insight and awareness regarding substance use and encouraging behavioral change through motivational interviewing (MI) and self-management approaches (Miller, 1983; Miller and Rollnick, 1991; Heather, 1995). MI is based on psychological theories of attitude and behavior change (Rogers, 1957; Becker, 1974; Bandura, 1977; Miller, 1983; Prochaska and DiClemente, 1986; Miller and Rollnick, 1991), addressing the fact that patients frequently neither recognize their health behaviors as hazardous nor acknowledge a desire to change (Rollnick et al., 1992). Factors that enhance willingness and ability for behavior change have roots in self-management (Mahoney, 1979), self-control (Carver and Scheier, 1982), and self-regulation (Kanfer, 1986) theories that describe how individuals plan, guide, and monitor behavior. A number of these factors have been used successfully in interventions for unhealthy alcohol use, such as altering norms and standards (Dimeff et al., 1999) specifying change plans (Sobell and Sobell, 1983), and increasing the probability of action by helping the patient take the first step, such as facilitating referral to treatment (Heather, 1995).

Elements of effective BIs include Feedback on personal risk, emphasis on Responsibility, clear Advice, a Menu of change options, clinician Empathy, and facilitation of patient Self-efficacy (FRAMES) (Bien et al., 1993). BI models tested in primary care have been delivered by physicians, nurses, health educators, advocates, computer, or pamphlet. Each involved feedback, advice, goal setting, and follow-up. Models may differ by how, by whom, and in what context they are delivered; therefore, different training, supervision, and quality monitoring are required (Miller et al., 2005). Although patient and interventionist characteristics are important, feasibility and cost are particularly relevant to effective implementation in (usually) busy general health settings with numerous other priorities.

SBI for Unhealthy Alcohol Use

SBI for unhealthy alcohol use has been described in the scientific literature for nearly 50 years. In 1961, Chafetz (1961) found that subjects with alcoholism in an emergency department were significantly more likely to follow-up in an alcohol clinic after brief advice from a psychiatrist than after no advice (42% vs 1%). Later studies (Edwards et al., 1977, 1983) found that BI was as efficacious as more intensive treatment (although this finding was likely attributable to studying treatment-seeking patients rather than those identified by screening—a critical distinction). Thirty years after Chafetz published his findings, Bien et al. (1993) reviewed 32 studies that showed BI effectively reduced unhealthy alcohol use, and meta-analyses have confirmed its efficacy for non-dependent unhealthy alcohol use in primary care settings leading to a universal screening practice guideline in the United States (Wilk et al., 1997; Moyer et al., 2002; Beich et al., 2003; Ballesteros et al., 2004; US Preventive Services Task Force, 2004; Bertholet et al., 2005; Kaner et al., 2009).

Such evidence-based guidelines, as is appropriate for universal preventive services, only appeared after randomized trials provided supportive evidence. These trials most often involved primary care clinicians delivering BIs, although in some cases, interventions were conducted by other healthcare professionals hired specifically to deliver them. Some of the most notable studies found that more than 1 contact improved efficacy (Fleming et al., 1997; Longabaugh et al., 2001; McKay et al., 2005; Brown et al., 2007).

Despite this relatively robust evidence, several studies show that BI was not effective in hospitalized patients (Em-

men et al., 2004; McQueen et al., 2009), in largely alcohol-dependent patients with prevalent use of other drugs (Saitz et al., 2007), in emergency departments (Daeppen et al., 2007; D'Onofrio et al., 2008; Havard et al., 2008; Nilsen et al., 2008), and in some general practice settings (Richmond et al., 1995; Beich et al., 2007). Factors such as sex, age, homelessness, and cognitive status influence effectiveness (Saitz et al., 2006), and SBI has not been effective in linking medical inpatients with treatment for alcohol dependence after discharge (Saitz et al., 2007). The best evidence for alcohol BI is for reductions in consumption (in contradistinction to consequences) among patients in the primary care setting who have unhealthy use that is not severe (Kaner et al., 2009).

SBI for Unhealthy Drug Use

Although randomized controlled trials have proven the efficacy of SBI for nondependent unhealthy alcohol use in primary care settings (US Preventive Services Task Force, 2004; Kaner et al., 2009), the evidence is much more limited regarding its effectiveness for other drug use. Although the prevalence of drug use in primary care is variable, it is much lower than that of unhealthy alcohol use. Estimates range from 3% of adults reporting past-year use in a Health Maintenance Organization setting (Mertens et al., 2005), to 5% reporting past 90-day use in practices in Wisconsin (Manwell et al., 1998), to 8% reporting past-year use in an urban practice (among whom only 22% received treatment) (Olfson et al., 2000). Marijuana use is especially common: in 1 study, 8% of young women used marijuana monthly (Rose et al., 2007); in another, 9% to 17% of adults report past 6-month use (Pasternak and Fleming, 1999).

Because most US adults (83%) report having an outpatient visit in the past year (Pleis and Lethbridge-Çejku, 2007), primary care settings provide a natural setting to pursue health behavior change, including unhealthy drug use. Because of this, US policymakers have sought to make SBI, referral, and treatment (Substance Abuse and Mental Health Services Administration, 2007b) an important part of addressing the nation's drug problems, and reimbursement codes for insurers to compensate clinicians for these activities have been approved by the American Medical Association (Anonymous, 2006). However, scarcity of evidence from controlled clinical trials in the primary care setting (or in any setting among those identified by screening in contradistinction to those seeking help) has prevented the inclusion of drug SBI in preventive service recommendations (US Preventive Services Task Force, 2008). No major professional organizations recommend universal drug SBI in primary care settings, and its dissemination has been limited mainly to externally funded programs that specifically support the activity. To date, few randomized trials have addressed the question of whether SBI reduces illicit drug use and its consequences when identifying patients who need treatment before they seek it. They have also not adequately explored whether the benefits of SBI outweigh potential harms such as increased use, consequences of breached confidentiality, or stigma.

Screening Tools for Unhealthy Drug Use

One reason for the scarcity of SBI research in primary care may be the lack (perhaps until recently) of brief and valid screening instruments for substances other than alcohol or tobacco. Screening tests have been used for unhealthy drug use, however, most have been alcohol tests modified for drug use, have focused on dependence, or have not been validated extensively. For example, the Drug Abuse Screening Test (DAST) detects drug use problems and has been widely used in federal SBI programs, but it was not validated in primary care until recently (Skinner, 1982; Smith et al., 2010).

In recent years, screening instruments for drug use have been developed and validated in primary care settings. The Alcohol Smoking and Substance Involvement Screening Test (ASSIST) (Humeniuk et al., 2008a) is used for tobacco, alcohol, cannabis, cocaine, stimulants, sedatives, hallucinogens, opioids, and several other drugs. Although it does not directly identify risky amounts of alcohol consumption (a substantial clinical limitation), it has excellent concurrent validity compared with the Addiction Severity Index-Lite version, the Severity of Dependence Scale, and the Alcohol Use Disorders Identification Test (Humeniuk et al., 2008b) as well as construct validity, test-retest reliability, discrimination of severity, and sensitivity and specificity for a drug use disorder and, in some cases, any drug use (cocaine, amphetamine, benzodiazepines, and opioids) (Newcombe et al., 2005; Humeniuk et al., 2008b). In a Brazilian study of the ASSIST that included 99 patients from mostly primary care settings and 48 patients in drug treatment, sensitivity and specificity were 84% and 98%, respectively, for a cocaine use disorder, and 87% and 95%, respectively, for a marijuana disorder (Henrique et al., 2004). However, an important drawback of the ASSIST is that it may be too lengthy to be feasible in busy primary care settings.

In addition to the ASSIST, Smith et al. (2010) evaluated a single-item screening tool—"How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?"—among 286 primary care patients in a large urban hospital-based setting. Thirty-five percent screened positive for any drug use, and 13% (more than one-third of those who screened positive) met criteria for a current drug use disorder. A response of "1 or more" was 100% sensitive and 74% specific for a drug use disorder, 94% sensitive and 91% specific for use with consequences, and 93% sensitive and 94% specific for any drug use. This single-item tool has promise, although it has been validated in only 1 primary care practice. Other brief tools with limited validation have generally focused on disorders and not the spectrum of unhealthy use (Brown and Rounds, 1995; Brown et al., 2001) and often combine both alcohol and drugs. The availability of brief validated screening tools is an important foundation for increased research on the effectiveness of SBI for drug use in primary care.

EFFICACY OF DRUG SBI: CURRENT EVIDENCE

Substantial evidence in nonprimary healthcare settings and under different circumstances (eg, among people actively seeking help) informs the question of whether drug SBI has

efficacy in primary care but does not establish definitive answers (Bashir et al., 1994; Cormack et al., 1994; Stephens et al., 2000; Copeland et al., 2001; Babor, 2004; McCambridge and Strang, 2004, 2005; Baker et al., 2005; Denis et al., 2006; Carroll et al., 2006; Voshaar et al., 2006; Ball et al., 2007). To our knowledge, no randomized controlled trials of drug SBI in adult primary care settings have been published in the peer-reviewed literature.

Madras et al. (2009) conducted a before/after retrospective uncontrolled study to evaluate the 6-state SBI referral and treatment initiative of the Center for Substance Abuse Treatment. Settings were diverse, including trauma centers, emergency departments, primary and specialty care sites, and hospitals. Of the 459,599 patients screened for the study, 23% tested positive for risky or problematic alcohol or drug use. Of these, 70% had screening results that suggested BI would be a reasonable course of action, 14% were recommended for brief treatment, and 16% had screening results that suggested they should be referred to specialty substance dependence treatment. How many patients actually received intervention or treatment is unknown. Ten percent of patients who screened positive were randomly selected for reassessment 6 months later, at which time self-reported rates of heavy alcohol use and illicit drug use had decreased by 39% and 68%, respectively. Self-reported rates of overall health, employment, housing status, and criminality among persons who were in categories in which they should have been offered brief treatment or referral had also improved significantly.

In a landmark randomized controlled study of BI in adult outpatients with cocaine or heroin use identified by screening, Bernstein et al. (2005) screened 23,660 patients from women's health, homeless, and urgent care clinics and randomized those who screened positive for risky cocaine or heroin use (N = 1175) to a brief negotiated interview (BNI) or to receipt of a referral list and written advice. Although a homeless clinic and women's health clinics could be considered primary care settings, urgent care settings are different from primary care, and subgroup analyses by site are not available. Ninety-five percent of eligible subjects were enrolled in the study, and 82% were available for follow-up. Post hoc, 19% of those followed up were excluded because baseline drug use was not confirmed biochemically. At 6 months, abstinence was documented among 40% of the intervention subjects and 31% of control subjects who used opiates at baseline, and 22% of the intervention subjects and 17% of the control subjects who used cocaine at baseline (statistically significant differences). No difference in receipt of help (90% of which was detoxification) was observed between groups.

In an uncontrolled study by Bernstein et al. (1997), patients who screened positive for substance problems in the emergency department were given a BNI. At 60 to 90 day follow-up (completed by 8% of those who screened positive for alcohol or drugs), patients who received the BNI had significant reductions in substance use, including a 45% reduction in drug-problem severity. The number of referrals and receipt of addiction treatment also quadrupled from 6% to 23% after a BNI.

The Health Evaluation and Linkage to Primary Care study linked 470 drug and alcohol abusers at a detoxification unit to primary medical care and assessed the effect during a 2-year period, during which 85% completed at least 1 follow-up assessment (Samet et al., 1996, 2003). Results showed that a brief multidisciplinary intervention could link people with primary medical care and that primary care exposure was associated with greater drug abstinence (Saitz et al., 2005). What component led to improvement, and whether BI was a factor, is not known.

Finally, a number of studies have suggested that BI may decrease substance use among teens. In a randomized trial of adolescents with recent drug use (N = 59) in a primary care setting in Brazil, BI decreased ecstasy and marijuana use and related drug problems (De Micheli et al., 2004). In the United States, Project CHAT examined the effect of a brief MI intervention on alcohol consumption and drug use for high-risk teens in a primary care clinic (D'Amico et al., 2008). Teens who screened positive for negative consequences related to substance use were randomized to receive either a brief MI intervention or to a control group (care as usual). Participants in the intervention group reported less marijuana use, lower perceived prevalence of marijuana use, fewer friends who used marijuana, and decreased intent to use marijuana in the next 6 months compared with controls.

In 2 randomized controlled trials by Tait et al. (2004, 2005), BI among adolescents in an emergency department increased drug-treatment attendance and reduced return visits for consequences related to substance use. In another study, a single MI-style feedback session decreased some drug use (but not alcohol or marijuana use) among homeless adolescents (Peterson et al., 2006), and additional studies have shown its efficacy for youth in mandated treatment and in high schools (White et al., 2006; Srisurapanont et al., 2007; Winters and Leitten, 2007). In a pediatric emergency department, BI for marijuana use resulted in greater levels of abstinence at 1 year compared with controls who received only written advice (Bernstein et al., 2009). A randomized trial in a hospital assessed effects of 2 counseling sessions on psychoactive prescription drug use and found that intervention was associated with decreased use. However, some of the subjects had regular use but not abuse, and it is not clear whether the decrease was beneficial because some patients were taking pain medication regularly for pain (Zahradnik et al., 2009).

Reasons for Caution

Although SBI has proven efficacy for nondependent unhealthy alcohol and drug use in some healthcare settings and populations, this benefit may not translate to drug users identified by screening in primary care (or elsewhere) due to a number of clinical concerns and challenges. In a general health setting, BI for drug use is likely to be more complicated than BI for alcohol use and is likely to involve a greater proportion of patients with dependence than is BI for screen-identified unhealthy alcohol use.

The many patients who use more than 1 drug or use alcohol and another drug make BI more complicated than it is for alcohol alone (Falk et al., 2006; McCabe et al., 2008). These drugs have variable forms, costs, risks, consequences, and ways for clinicians to identify use. For example, in our experience implementing drug SBI clinically, a BI for depen-

dent injection heroin use, with its attendant risks of overdose and HIV infection, is different from a BI for occasional users of marijuana who perceive their use to be without risk or even beneficial to their health. Most abused drugs are illegal or used illegally, which can complicate addressing their use in medical settings by raising patient and physician concerns about confidentiality and medical record documentation. Prescription drug abuse presents additional challenges as clinicians struggle to distinguish between appropriate and inappropriate use.

Another clinical concern is that a larger proportion of patients with drug use identified by screening will have dependence compared with those identified as having unhealthy alcohol use (Substance Abuse and Mental Health Services Administration, 2007b). BI, even with a goal of referral, has not been proven even for alcohol in such circumstances, and is not widely recommended as the sole intervention for dependence (Moyer et al., 2002; McQueen et al., 2009).

In addition to the aforementioned clinical concerns, the state of the evidence regarding screening is an additional reason for caution. Limited availability of feasible brief screening tools presents a significant barrier to implementation. Few validation studies have been conducted in general health settings on the screening tools discussed herein, and the DAST and ASSIST cannot be considered brief, having 10 to 80 or more items. Given the known challenges to implement SBI for alcohol with 1- to 3-item screening tests, the DAST and ASSIST are not likely to be disseminated widely, even if extensively validated. Although the single-item screening tool discussed earlier has the potential to minimize this barrier to implementing drug BI, further validation is needed.

With regard to BI, the lack of randomized trial evidence along with the inability to generalize results among treatment seekers compared with those identified by screening are additional concerns surrounding universal drug SBI. The assumption that drug-treatment efficacy among those seeking help will apply to people identified by screening and not necessarily seeking treatment is likely inaccurate. Assessing whether BI has efficacy among people identified by screening—the common situation in primary care—is important, because these patients present with varying levels of readiness to change and a range of drug-use severity. Unfortunately, this distinction is challenging to test empirically because randomizing these 2 patient populations to the same treatment and control groups and comparing the effects would prove difficult, and people with less severe unhealthy use are not likely to be well represented in treatment-seeking populations. For a condition such as drug use in which motivation plays an important role, it seems logical that BI (ie, counseling that addresses motivation to change) would have different outcomes among those seeking help versus those not seeking it.

Aside from the challenge of translating study results from patients seeking help to those identified by screening, the absence of randomized trial evidence for drug SBI among adults in the primary care setting is a major concern. Observational studies and uncontrolled trials have limited ability to establish causality and thus cannot provide sufficient evidence to support recommendations for universal implementation of drug SBI. Improvements in the range of 40% to 70% seen in such studies (Bernstein et al., 1997; Madras et al., 2009) may be the result of many factors besides BI, including regression to the mean, natural history of drug use after a patient-initiated voluntary healthcare contact, and confounding by prognostic factors that change across time. Effects seen in randomized trials are much more modest (about one-tenth of the magnitude).

In the only randomized controlled trial of SBI in a primary care setting (aside from the Brazilian study involving adolescents described earlier [De Micheli et al., 2004]), World Health Organization researchers who developed the ASSIST conducted a 5-country Phase III randomized trial of BI among 731 persons who screened positive on the ASSIST for risky cannabis, cocaine, amphetamine, or opioid use. The results appear in a technical report (Humeniuk et al., 2008a) not yet published in a peer-reviewed journal. Patients recruited from sexually transmitted disease clinics, walk-in clinics, a dental clinic, and community medical care sites (only some of which could be considered primary care) were randomly assigned to either BI or no counseling. Although BI reduced substance-use scores in a preliminary single-site subgroup in the study (Newcombe et al., 2005), results of the larger trial were less conclusive (Humeniuk et al., 2008a). Differences between the 2 groups were small and of unknown clinical importance (3 points on a scale with a maximum value of 336 points), effects were seen for cannabis and stimulants but not for opioids, and substance use was not significantly impacted at the US site. Although the authors speculate that the lack of efficacy in the US was due to informed-consent procedures having an intervention effect, numerous alcohol SBI studies in the United States that had informed-consent procedures have found SBI effects (Whitlock et al., 2004). In summary, intervention effects in this study were not convincingly significant, nor were most patients recruited from settings that could be considered primary care (ie, longitudinal, continuous, comprehensive care). As such, the study does not settle the question of whether SBI for drug use is of clinical benefit in primary care.

In addition, effects seen in trials that involve substantial training and effort to maintain intervention fidelity may not translate into real-world clinical practice. Effects in practice are likely to be smaller than those seen in research studies, which are small to begin with. BI for alcohol, a less complex clinical problem than drug use, among those identified by screening is associated with a 10% to 12% absolute decrease in risky use (Whitlock et al., 2004; Bertholet et al., 2005; Kaner et al., 2009). In the randomized trial by Bernstein et al. (2005) among outpatients who screened positive for cocaine or heroin use, BI was associated with a 5% to 9% increase in abstinence. These small effects could be wiped out in practice if training and fidelity maintenance are not as good as in controlled trials in which clinicians or other interventionists are trained by study personnel for study purposes. The issue of translating efficacious interventions into practice also raises feasibility concerns if the commitment of clinical staff to delivering BI is uneven or inadequate.

Conversely, results in controlled research settings could be smaller than those observed in clinical practice because of assessment effects (ie, the notion that research assessments alone may lead to behavioral change much as an intervention might) among control group patients. However, assessment effects are unlikely to explain the large improvements shown in some nonrandomized studies for such a recalcitrant clinical condition as a drug use disorder. In fact, no assessment effects were found in at least some BI studies that tested for them (Daeppen et al., 2007).

CONCLUSION

Although SBI can occur in many settings and can target alcohol, drugs, or both, determining its efficacy and feasibility in primary care requires rigorous testing of brief screening tools and of different models of SBI. This issue, at a key clinical and policy crossroads, is of great importance given the severity and cost of the drug problem in the United States. The discrepancy between policy developments (reimbursement codes for drug SBI and a large federal SBI grant-funded program that includes drugs) and the existing evidence base for drug SBI underscore the need for randomized clinical trials to determine its effectiveness in primary care. Taking into consideration the perspectives of national professional societies, quality measurement groups, and practice guideline developers (none of which has come out in support of drug SBI), current policy and practice—at least as part of federally funded SBI programs—have gone well beyond the evidence base. Existing studies are insufficient to justify changes in clinical practice, just as decades of alcohol SBI data did not move practice guidelines in the United States until the completion of 2 large randomized controlled trials (Fleming et al., 1997; Ockene et al., 1999; US Preventive Services Task Force, 2004). Validated screening tools exist and can be further tested, and most adults visit primary medical care settings in which drug problems can be identified and BI can be conducted.

Although randomized clinical trials are challenging to implement, particularly with drug-using persons and those of lower socioeconomic status, including homelessness, high follow-up rates can be achieved (Samet et al., 1996, 2003; Saitz et al., 2003, 2005; Bernstein et al., 2005). Findings from a pragmatic trial in primary care, enrolling people who use drugs and who are at risk for or have experienced related consequences, are necessary to determine whether BI should be widely disseminated to reduce the national burden of drug-related illness and other negative effects, including the spread of HIV. Efficacious BI models with favorable economic characteristics have the potential to significantly reduce the national burden of drug use and consequences. Conversely, lack of efficacy or excessive cost would force reconsideration of drug SBI as a broadly applicable strategy and would, appropriately, redirect efforts to address the problem.

Given that even proven strategies of SBI (eg, SBI for alcohol in primary care settings) have not been widely implemented in practice, efficacy studies should include elements that can inform real-world effectiveness and implementation. Features might include minimizing restrictive entry criteria, recruiting subjects from diverse populations, minimizing intensity of study procedures to improve retention, and testing strategies that can be reproduced and financed in clinical practice settings. It is time for US efficacy studies of drug SBI in primary care settings that test models feasible in the real world and consider costs, sustainability, and outcomes.

Adolescent Alcohol Use and Violence
Are Brief Interventions the Answer?

Richard Saitz, MD, MPH
Timothy S. Naimi, MD, MPH

VIOLENCE AND ALCOHOL USE ARE RISK FACTORS for the 3 leading causes of death among individuals aged 12 to 20 years: unintentional injuries, homicide, and suicide.[1] Thus, the devastating health effects of alcohol and violence on youth lead to an appropriately overwhelming desire to intervene in clinical practice.

Brief counseling could be an answer. In adults, such interventions reduce drinking among those with nondependent unhealthy alcohol use who are identified by screening in primary care settings.[2] These brief counseling interventions are among the most cost-effective but least performed preventive services; are recommended by professional groups, including those that require the highest levels of evidence; and are now reimbursable services.[2,3]

However, the effects of alcohol brief interventions in other settings (eg, emergency departments, hospitals), among adolescents, and on any outcomes besides consumption are less certain.[2,4,5] The US Preventive Services Task Force has found insufficient evidence to recommend for or against screening and counseling to prevent or reduce alcohol misuse by adolescents. Even less evidence is available to support screening and intervention for violence, and results in adults are not promising.[6]

Systematic reviews of studies of alcohol brief interventions for adults in emergency departments find substantial heterogeneity in designs and results, with only about half of studies finding beneficial effects on consumption or consequences.[4,5] Although level I trauma centers are required by accreditation standards to provide alcohol screening and brief intervention, the evidence for efficacy in that setting is limited. One randomized trial had substantial loss to follow-up and a nonsignificant effect on the primary outcome of reinjury. Of 3 subsequent randomized trials, 2 were negative and 1 was positive for reducing the incidence of any arrest for driving under the influence of alcohol in secondary adjusted analyses, but not in primary unadjusted analyses.[4,5,7]

Even less convincing evidence is available for the benefits of brief interventions for alcohol use or violence among youth. For alcohol, 3 randomized trials have tested brief intervention after screening in emergency departments among young people, and results have been inconsistent. One trial found a decrease in drinking but not alcohol consequences, while another found a decrease in consequences but not in drinking.[8,9] A third trial (http://www.clinicaltrials.gov; identifier: NCT00183157) has recently been completed, but the results have not yet been published. The prevention of youth violence has not been sufficiently studied in emergency settings,[10] and the results of the few available studies have been mixed. One trial reported a reduction in self-reported (but not trauma registry–documented) reinjury,[11] suggesting that self-reported outcomes for violence may be biased in this population.

Despite the lack of evidence for the effectiveness of interventions to reduce alcohol use and violence separately, it does seem logical to address these risky behaviors together, because they so often co-occur. This was the approach taken by Walton et al in this issue of *JAMA*.[12] Adolescents receiving emergency services for illness or injury who reported both alcohol use and physical aggression were randomized to receive a brochure, a 35-minute motivational intervention delivered by a therapist, or a self-administered animated computer intervention.

Overall, positive results were noted for few outcomes, effect sizes were small, and none of the observed 3-month benefits were sustained at 6 months. The 24

comparisons of binary outcomes (2 intervention groups compared with controls, 2 outcome time points, 3 alcohol and 3 violence outcomes) did not show statistically significant group differences in "alcohol misuse" (ie, unhealthy alcohol use) or "binge drinking" (ie, ≥5 drinks) at 3 or 6 months; however, both intervention groups had significantly larger (by 6%-8%) decreases in alcohol-related consequences vs the control group at 6 (but not 3) months. Computer-delivered interventions did not affect any of the violence-related outcomes except being the recipient of peer violence at 6 months. Therapist counseling had a modest effect (eg, 13% absolute reduction in peer aggression compared with controls) for all 3 violence-related outcomes at 3 months but not at 6 months. Of the additional 24 comparisons of frequency-based outcomes, only 1 was statistically significant: a lower number of violence consequences at 3 months in the therapist group.

In addition to the mixed results and modest effects, the study's trial registration suggests that additional primary outcomes were measured, such as drug use, injury, delinquency, and weapon carrying,[13] raising the concerns that type I error in the setting of multiple comparisons (7 of 48 reported comparisons were statistically significant at a 1-tailed $P < .05$) or a focus on more positive outcome domains might explain the results. If this study had measured more objective outcomes such as physician-documented injury events or school-based reports of violent incidents, rather than self-reported risk behaviors, the findings might have been more convincing. Although the authors used validated survey instruments, social desirability bias is of concern with self-reported outcomes, because study participants in the counseling groups might be less likely to report behaviors in follow-up that they were told were unsafe or undesirable. This might be a greater concern for study participants who received the therapist intervention than those who received the computer intervention or the brochure. Violence and alcohol consequences might be seen by adolescents as most embarrassing, and these accounted for the observed differences, whereas behaviors that were possibly perceived as less embarrassing, such as alcohol use, were not less reported in the intervention groups. Taken together, these concerns support the authors' recommendation that their study should be replicated in other settings.

Even a modest benefit of a relatively inexpensive intervention for common health problems might be worth pursuing on a large scale. However, there are barriers to the widespread implementation of screening and brief intervention programs in clinical settings. Although brief intervention for alcohol has been recommended for decades in primary care settings, levels of implementation have been dismal for a variety of reasons, such as inadequate training, lack of clinician time, and inadequate reimbursement.[3] Although computerized intervention seems more likely to be disseminated successfully than a 35-minute expert therapist–delivered session, the computer intervention used in the study by Walton et al[12] affected only 1 secondary violence outcome (a decrease in being a recipient of peer violence) at 1 time point. However, the computer intervention was associated with a decrease in alcohol consequences, which is a potentially promising use for this intervention.

The most proven and effective method to reduce youth drinking, and likely alcohol-related violence, is to implement population-based strategies such as raising alcohol excise taxes and enforcing minimum legal drinking age laws.[14] These strategies have been neglected. For example, the federal beer tax, which is based on a fixed amount per volume, has eroded by almost 40% in real terms since it was last adjusted in 1991. Until the findings of Walton et al[12] can be replicated (and hopefully improved), brief interventions for violence prevention in emergency departments do not seem promising. However, existing evidence supports the implementation of screening and brief intervention for unhealthy alcohol use in adult primary care settings, especially for young adults in whom the prevalence of this risky behavior is greatest.

For adolescents, alcohol screening is currently recommended by the American Academy of Pediatrics.[15] While specific screening strategies for underage youth have not been fully elucidated, the focus of screening should be on any use of alcohol (with appropriate assessment of those screening positive), irrespective of their experience with violence, because any use of alcohol by adolescents, not just binge drinking, is associated with a variety of adverse outcomes.[16] However, the ultimate benefit of such screening remains dependent on the development, testing, and implementation of effective clinical strategies to reduce youth alcohol consumption and violence and their adverse consequences.

Financial Disclosures: Dr Saitz reports having been a consultant for online alcohol-related screening and brief intervention education projects supported by National Institutes of Health (NIH) grants to Medical Directions and Inflexxion, and for NIH grants to Kaiser Permanente, the University of Massachusetts, and Brandeis University. He also has been compensated by Beth Israel Deaconess Hospital and the National Institute on Alcohol Abuse and Alcoholism for serving on data and safety monitoring boards. He is compensated for editorial work by the Massachusetts Medical Society, the British Medical Journal Group, and the American Society of Addiction Medicine. He has developed educational materials for Fusion medical education and consulted for Saatchi and Saatchi Healthcare on alcohol dependence treatment. He has or anticipates being compensated as a speaker on alcohol and drug topics by multiple government agencies, academic institutions, and professional societies. He has also provided expert opinion on legal cases involving identification and management of alcohol and drug-related problems. Dr Naimi reports currently receiving NIH grant support and was supported through his federal salary while employed by the US Public Health Service.

Intimate partner violence (IPV) is estimated to be the leading contributor to the global burden of mental health problems among women of reproductive age.[1] There is an increasing urgency for rigorous, good-quality evidence about what is effective in preventing or ameliorating such harm in community and health care settings.[2] A recent Cochrane review of partner violence advocacy trials found only 2 trials conducted in community settings and overall concluded that evidence of health benefit is scarce in any setting.[3]

In this issue of *JAMA*, Tiwari and colleagues[4] report a study in which Chinese women survivors of IPV attending a Hong Kong multipurpose community center were randomly assigned to receive a 12-week advocacy intervention to reduce depression and IPV compared with usual community services. The intervention consisted of a 30-minute empowerment session delivered by a registered social worker (trained to implement a social support and empowerment protocol) followed by weekly telephone social support from the same social worker. The empowerment session involved a focus on enhanced choice making and problem solving, combined with safety assessment and planning. Staff providing telephone support reminded women that help was available and aimed to respond flexibly to the expressed stressors and needs in women's lives at the time.

See also p 536.

The 200 women participating in this study were married, in their late 30s, and living in secure housing in a stable community in which they remained for the duration of the study. Their abuse status was assessed with the Chinese version of the Revised Conflict Tactics Scale (C-CTS2) and their depressive symptoms with the Chinese version of the Beck Depression Inventory II (C-BDI-II), with measurements obtained at baseline, at 3 months (when the intervention ended), and at 9 months.[4] Although mean scores for partner psychological aggression as measured by the C-CTS2 (eg, shouted at, stomped out of room) were elevated at baseline, mean scores for physical assault and sexual coercion were low and remained low throughout the study. With the exception of 2 women, none had disclosed any abuse previously or sought help from health or social services. Women in both study groups reported mean rates of severe depression at baseline, moderate depression at 3 months, and mild depression at 9 months. Women in both groups reported an initial increase in mean rates of partner psychological aggression and then low rates at study completion. The reported mean differences between the study groups on both measures were modest but did reach statistical significance. However, the difference of –2.7 units in depression scores did not reach the clinically meaningful level of 5 units that is recommended for the C-BDI-II.[5] In the follow-up telephone support calls, women's expressed needs focused on

Interventions Targeting HIV-Infected Risky Drinkers

Drops in the Bottle

Jeffrey H. Samet, M.D., M.A., M.P.H., and Alexander Y. Walley, M.D., M.Sc.

Alcohol use is common among people infected with HIV and may contribute to adverse consequences such as reduced adherence to treatment regimens and increased likelihood of risky sexual behaviors. Therefore, researchers and clinicians are looking for treatment approaches to reduce harmful alcohol consumption in this population. However, clinical trials of existing treatment models are scarce. A literature review identified only 11 studies that included HIV-infected patients with past or current risky alcohol use and which targeted alcohol use and other health behaviors. Four studies focusing on HIV-infected participants with alcohol problems found mixed effects on adherence and on alcohol use. Five clinical trials included at least 10 percent of HIV-infected subjects who use alcohol; of these, only one reported significant evidence of a favorable impact on alcohol consumption. Finally, two trials targeting alcohol users at high risk for HIV infection identified treatment effects that were not sustained. Taken together, these findings provide limited evidence of the benefit of behavioral interventions in this population. Nevertheless, these studies give some guidance for future interventions in HIV-infected patients with alcohol problems. *Key Words: Alcohol and other drug use; alcohol consumption; alcohol use disorder; human immunodeficiency virus; HIV-infected patients; sexually transmitted disease; unsafe sex; treatment method; treatment outcome; intervention; clinical trial; literature review*

In the United States, people infected with the human immunodeficiency virus (HIV) drink more alcohol than people in the general population. Specifically, a higher proportion drink risky amounts[1] or have an alcohol use disorder (i.e., abuse or dependence) (Conigliaro et al. 2003; Galvan et al. 2002; Lefevre et al. 1995; Samet et al. 2003*a,b*, 2004). Risky alcohol use in HIV-infected people has been associated with the following range of adverse effects:

- Reduced adherence to medication regimens for treatment of HIV infection (Chander et al. 2006; Conen et al. 2009; Cook et al. 2001; Golin et al. 2002; Halkitis et al. 2003; Samet et al. 2004);
- Lack of a health care provider for the HIV infection (Metsch et al. 2009);
- Delayed linkage to HIV medical care (Samet et al. 1998);
- Increase in risky sexual behaviors (Kalichman et al. 2002; Metsch et al. 2009);
- Increased transmission of sexually transmitted infections (Kalichman et al. 2000); and
- Progression of HIV disease (Conigliaro et al. 2003; Miguez et al. 2003; Samet et al. 2007).

Given the spectrum of problems associated with such alcohol use among HIV-infected patients, one important avenue to improving the health of this population is to develop interventions

[1] According to the National Institute on Alcohol Abuse and Alcoholism (2007), women who drink more than 3 drinks per day or more than 7 drinks per week and men who drink more than 4 drinks per day or more than 14 drinks per week are at increased risk for alcohol-related problems. Alcohol consumption levels above these limits are considered risky drinking.

Jeffrey H. Samet, M.D., M.A., M.P.H., *is a professor in the Clinical Addiction Research and Education (CARE) Unit, Section of General Internal Medicine, Department of Medicine, Boston University School of Medicine, and in the Department of Social and Behavioral Sciences, Boston University School of Public Health, both in Boston, Massachusetts.*

Alexander Y. Walley, M.D., M.Sc., *is an assistant professor in the CARE Unit, Section of General Internal Medicine, Department of Medicine, Boston University School of Medicine, Boston, Massachusetts.*

that target alcohol use and its associated consequences. Accordingly, interventions have been designed to both decrease alcohol consumption and address the specific adverse health consequences.

The concept that negative consequences of alcohol use can be reduced in patients with HIV infection is based on research demonstrating the impact of clinical interventions on alcohol consumption and associated negative consequences in patients without HIV infection (Institute of Medicine 1990; Kristenson et al. 1983). Alcohol research over the past three decades has demonstrated that behavioral interventions can be effective, with benefits varying based on setting, severity of alcohol problems, and patient characteristics. For example, meta-analyses of randomized controlled trials (RCTs)[2] of interventions to reduce risky alcohol use demonstrated decreased drinking for patients in primary care settings (Beich et al. 2003; Kaner et al. 2007). However, no such effects were found in meta-analyses of interventions delivered in hospital settings (Emmen et al. 2004), possibly because inpatients typically have greater severity of alcohol problems (i.e., most are alcohol dependent) (Saitz et al. 2007, 2008). Several high-quality RCTs of brief interventions delivered in emergency departments also detected no or limited benefit (D'Onofrio and Degutis 2002; Daeppen et al. 2007; Longabaugh et al. 2001; Monti et al. 1999). The influence of the patient's consumption levels also was demonstrated in several studies. For example, in two separate RCTs in the primary-care setting (Fleming et al. 1997; Ockene et al. 1999), where patients were seeking medical care but not necessarily for an alcohol problem, implementation of a 5- to 15-minute discussion reduced alcohol consumption in patients who met the criteria for risky drinking. Studies of such brief interventions among patients who met the criteria for alcohol dependence, however, have shown no benefit (Kaner et al. 2007; Whitlock et al. 2004; Wutzke et al. 2002).

For alcohol-dependent patients, more extensive behavioral interventions (e.g., cognitive–behavioral coping skills, motivational enhancement, 12-step facilitation) can be effective (*Project MATCH* Research Group 1997). In addition, several medications (i.e., disulfiram, naltrexone, and acamprosate) are approved for the treatment of alcohol dependence, and other medications (e.g., topiramate) are being further evaluated (Anton et al. 2006; Garbutt et al. 2005; Kranzler and Van Kirk 2001; Olmsted and Kockler 2008; Rubio et al. 2001).

Given the strong evidence that alcohol consumption is an important health issue for many people with HIV infection, efforts to potentially ameliorate these problems by addressing alcohol use are of great interest. The studies in non–HIV-infected people reviewed above suggest that interventions among HIV-infected people with alcohol problems could be beneficial. However, the wide range of results in these intervention studies based on setting and disease severity argues for the need to carefully assess efforts to mitigate alcohol's deleterious impact on health in HIV-infected patients. As an important step in this direction, this article summarizes the findings of a review of the clinical trial literature on interventions addressing alcohol consumption and its consequences among HIV-infected patients. After describing the design of the literature search and evaluation, the article reviews the findings of the studies identified and discusses the implications of those findings.

Design of the Literature Review

The literature review sought to identify clinical trials of interventions among HIV-infected people with past or current unhealthy alcohol use (i.e., the spectrum from risky drinking to alcohol dependence [Saitz 2005]) that reported effects on any of the following outcomes:

- HIV disease progression;
- Receipt of HIV treatment;
- HIV medication adherence;
- HIV risk behaviors;
- Acquisition of sexually transmitted infections; and
- Alcohol use.

To be included in the review, the studies had to report alcohol-specific outcomes. Beyond that, the studies were classified into three categories of specificity. The most specific category comprised clinical trials that included only HIV-infected people with past or current unhealthy alcohol use. The second category comprised clinical trials that included only HIV-infected people but in which not all of the participants exhibited unhealthy alcohol use. For a study to be included in this category, at least 10 percent of participants had to report current alcohol use. The third category of studies comprised trials that were aimed at preventing alcohol use and sexual behaviors that put people at risk of HIV infection among alcohol-using people. Although these studies did not include HIV-infected participants or did not report the HIV status of the participants, they were reviewed because they may inform future research on people at risk of HIV transmission in the setting of alcohol use.

Initially, the review intended to include only RCTs. However, very few studies were identified that met this criterion in the first two categories. Therefore, the search was expanded to include nonrandomized and non-controlled clinical intervention trials in categories 1 and 2.

To identify relevant studies, the literature database MEDLINE was searched through September 30, 2009, using the search terms "HIV, alcohol, hazardous drinking, risky drinking, problem drinking, counseling, brief intervention, 12 step, pharmacotherapy, naltrexone, acamprosate, disulfiram, topiramate, and clinical trial." For all articles identified using this approach, the reference lists also

[2] RCTs are clinical studies in which patients randomly are assigned to either one or more groups receiving the treatment under investigation or to a control group receiving no treatment or a treatment of known efficacy.

were scanned, as were related articles identified by the search engine for the MEDLINE data base to look for additional studies. Reference lists for articles that were closely related, but did not meet the criteria, also were reviewed. Finally, articles referenced in relevant review articles were examined. Titles of all articles were reviewed to determine if the articles met the selection criteria. If the nature of the study could not be discerned through the title, the abstract and/or full text of the article was retrieved and reviewed.

For all studies that met the criteria for one of the three categories, information on the setting, study design, methodological quality, type of intervention, outcomes reported, period of follow-up, and results was extracted. The following sections summarize the findings of these analyses. They are presented as a descriptive narrative synthesis because studies were too few and heterogeneous to perform a standard meta-analysis.

Results of the Literature Review

The search strategy described above identified 241 potentially relevant studies that were evaluated further. Of these, four studies including a total of 578 patients (Aharonovich et al. 2006; Parsons et al. 2007; Samet et al. 2005; Velasquez et al. 2009) met the selection criteria for the first category (see table 1). Another five clinical trials that included 1,311 patients (Gilbert et al. 2008; Naar-King et al. 2006, 2008; Rotheram-Borus et al. 2001, 2009; Sorensen et al. 2003) fell into the second category. In addition, two informative studies of interventions among people at high-risk for HIV reported outcomes specific to alcohol use (Kalichman et al. 2008; Morgenstern et al. 2007). All of these studies are reviewed below. Some other studies that involved alcohol-using, HIV-infected patients, but were excluded from this discussion because of serious design or methodological limitations, are listed in Table 2 because they may inform additional research. Interestingly, no controlled trials of the four medications recommended by NIAAA (2007) for the treatment of alcohol dependence (i.e., disulfiram, naltrexone, acamprosate, and topiramate) have been conducted in HIV-infected patients.

Clinical Trials Among HIV-Infected People With Past or Current Unhealthy Alcohol Use

Velasquez and Colleagues (2009) Study. These investigators conducted an RCT among 253 HIV-infected men who had had sex with men in the previous 3 months and who scored more than eight points on the AUDIT questionnaire (Babor et al. 2001). The intervention group received four manual-guided individual sessions and four manual-guided peer education and support group sessions that utilized motivational interviewing (MI) counseling strategies (Miller and Rollnick 2002) to guide participants through the stages of change of Prochaska and DiClemente's Trans-Theoretical Model[3] (Prochaska and DiClemente 1982). In contrast, the control group received educational materials on HIV and alcohol, referral information, and advice to stop or cut back on their alcohol use. At the 12-month follow-up, the investigators determined some benefits of the intervention on some of the measures evaluated. For example, the control group had 1.4 times the number of drinks per 30 days and 1.5 times the number of heavy-drinking days per 30 days compared with the intervention group. For other measures (e.g., having anal sex without a condom, number of drinking days, or number of days on which both drinking and sex occurred), however, no significant difference existed between the two groups. Only when the analysis of same-day drinking and sex was restricted to participants who had shown this behavior at baseline, did those in the control group have significantly (i.e., 2.19 times) more days on which drinking and sex occurred than the intervention group. The interpretation of these findings is limited by the fact that there was differential loss to follow-up—that is, the analyses included only 81 percent of participants randomized to the intervention group and 90 percent of subjects randomized to the control group. Thus, one cannot exclude the possibility that particularly in the intervention group, participants with worse outcomes were not included in the analysis.

Aharonovich and Colleagues (2006) Study. In this pilot study, 31 HIV-infected primary-care patients with heavy alcohol use received one session of MI from a trained counselor, followed by daily telephone-based interactive voice response (IVR) assessments of drinking amounts and graphic feedback of changes in drinking at 30 and 60 days. This intervention resulted in a decrease in the number of drinks per day at 30 and 60 days (from 3.2 drinks per day at baseline to 1.7 drinks at 30 days and 1.2 drinks at 60 days). The IVR system was utilized; 77 percent of all possible daily calls were completed at 30 days. However, these improvements can not be attributed to the intervention with confidence because there was no control group.

Parsons and Colleagues (2007) Study. These investigators conducted an RCT among 143 HIV-infected people with "hazardous drinking" (defined as more than 16 standard drinks per week for men or more than 12 standard drinks per week for women), assessing treatment effects on HIV medication adherence and alcohol outcomes. The intervention involved eight 1-hour individual sessions of MI and cognitive behavioral skills training over 3 months and was compared with a time- and content-equivalent control.[4] Over the

[3] The transtheoretical model (TTM) is a health behavior theory that assesses the individual's readiness to change a particular behavior in order to facilitate the desired behavior change. The stages of change are: precontemplation, contemplation, preparation, action, and maintenance.

[4] With a time- and content-equivalent control group, participants in that group spend the same amount of time with a health care provider/therapist as the intervention group, and they receive the same type of information. The only difference between the intervention and control groups is the method used to deliver the information, allowing researchers to determine whether one approach is more effective than the other.

follow-up period (3 and 6 months), both groups exhibited substantial improvement for both total alcohol drinks over 14 days or drinks per drinking day, although no significant differences existed between the intervention and the control group. However, compared with the control group, the intervention did improve medication adherence, number of virus particles detectable in the blood (i.e., viral load), and CD4 cell[5] counts at 3 months. These statistically significant improvements were not sustained at 6 months.

[5] CD4 cells are a type of white blood cell that is the main target of the HIV virus; accordingly, levels of these cells in the blood decline with progressing HIV infection and are a marker for disease progression.

Samet and Colleagues (2005) Study. This RCT included 151 HIV-infected patients on antiretroviral therapy (ART) who had a history of alcohol problems. The participants received either four nurse-delivered, 30- to 60-minute sessions focusing on HIV medication adherence and alcohol counseling, both in a clinic

Table 1 Studies Identified During a Literature Search on Interventions to Decrease Alcohol Use and Related Behaviors among HIV-Infected People and Alcohol Users at High Risk for Infection

Study	Population/Setting	Design	Outcomes/Results	Comments
Category 1: Clinical trials among HIV-infected people with past or current unhealthy alcohol use				
Velasquez et al. 2009	**Population**: 253 HIV-infected men who had sex with men (MSM) in the previous 3 months and an AUDIT score of more than 8. **Setting**: Recruited from HIV organizations, advertising, and social venues between 1999 and 2003.	**Intervention:** Randomized Controlled Trial (RCT) of four sessions of motivational interviewing (MI)-based individual counseling and four sessions of transtheoretical model–based peer-group education/support. **Control:** HIV and alcohol educational materials, resource referrals, and advice to stop or reduce drinking. **Assessment:** Baseline, 3, 6, 9, and 12 months.	**Alcohol use:** Control group had 1.38 times the number of drinks per 30 days and 1.50 times the number of heavy drinking days per 30 days compared with the intervention group. **Sex risk:** No significant effect was demonstrated for anal sex without a condom or number of days on which drinking and sex occurred.	**Alcohol measures**: AUDIT, 90-day timeline follow-back (TLFB) at follow-up assessments. Differential loss to follow-up at 12 months (34% in intervention group and 26% in control group). Only 95 of 118 (81%) of the intervention group and 121 of 135 (90%) of the control group were included in the analyses.
Aharonovich et al. 2006	**Population**: 31 HIV-infected men and women engaged in HIV primary care. **Alcohol use**: All had four or more drinks at least once in the past 30 days, 55% had five or more drinks in the last week. **Setting**: HIV primary care clinic.	**Intervention**: 30-minute MI session on reducing alcohol use by counselor trained in MI plus an automated daily telephone self-monitoring interactive voice response (IVR) system with graphical feedback at 30-day follow-up meetings. **Control**: No control group. **Assessment:** Baseline, 30, 60, and 90 days.	**Drinks per day**: Using 7-day recall, mean drinks per day was 3.2 at baseline, 1.7 at 30 days, and 1.2 at 60 days. Mean highest drinks per day was 8.4, 4.1, and 3.8, respectively. **Cocaine use:** Decreased significantly at 60 days.	**Alcohol measures**: Quantity and frequency in past week and past month. Qualitative assessment of the program demonstrated satisfaction with daily calling and the feedback graph. Not a randomized controlled trial.
Parsons et al. 2007	**Population**: 143 HIV-infected subjects on antiretroviral therapy (ART) with hazardous drinking (more than 16 drinks per week for men, more than 12 drinks per week for women) recruited through HIV clinics and advertising from 2002 to 2005. **Setting**: Behavioral research center.	**Intervention**: RCT of eight 60-minute MI plus cognitive behavioral skills training (CBST) session by Masters-level counselors. **Control**: Eight 60-minute time and content-equivalent education sessions by health educators. All sessions delivered individually in private office over 12 weeks. **Assessment**: Baseline, 3 and 6 months.	**Alcohol use**: No significant effects on total drinks over 14 days or drinks per drinking day. Decreases in both groups from baseline to 3 and 6 months for these two drinking outcomes. **Medication adherence**: Significant improvement in dose and day adherence at 3 months, but difference not retained at 6 months. **HIV viral load/CD4 cell count**: Significant improvement at 3 months but not at 6 months.	**Alcohol measure**: Self-report 14-day TLFB to calculate total drinks and drinks per drinking day. **Adherence measures**: Self-report dose adherence = number of doses taken/number of doses scheduled over 14 days. Self-report day adherence = number of days with perfect adherence/14 days.

and at home, or no intervention. The study found no significant differences between groups upon examination of the following outcomes: 3-day medication adherence, 30-day adherence, CD4 cell count, viral load, drinks per day, percent reporting drinking, or percent reporting hazardous drinking. Study limitations were that not all participants were non-adherent to their HIV medication at baseline and a substantial percentage were not in the risky-drinking range of unhealthy alcohol use, the group most amenable to brief interventions.

Clinical Trials Among HIV-Infected People of Whom at Least 10 Percent Currently Use Alcohol

Five studies identified in the literature review fell into this category, and only one of these (Rotheram-Borus et al. 2009) demonstrated significant treatment effects on alcohol use (see table 1). This study was a subanalysis of a parent RCT among 936 HIV-infected people who were sexually active without a condom with at least one HIV-negative partner or two HIV-infected partners (Wong et al. 2008). The participants received either 15 90-minute individual sessions of cognitive–behavioral therapy (CBT) delivered over 15 months or usual care. The subanalysis by Rotheram-Borus and colleagues (2009) was limited to 270 HIV-infected participants who were homeless or without stable housing. In this group, the intervention was found to reduce alcohol or marijuana use from 36 to 28 days in the prior 90 days, whereas in the control group the frequency of alcohol or marijuana use was unchanged at 35 of the last 90 days. However, this

Table 1 con't

Study	Population/Setting	Design	Outcomes/Results	Comments
Samet et al. 2005	**Population**: 151 HIV-infected patients on ART, with current or lifetime alcohol problems, determined by two or more positive responses on CAGE questionnaire or clinical diagnosis of alcohol disorder recruited from 1997 to 2000. **Setting**: Hospital (patients receiving HIV medical care).	**Intervention**: RCT of four 15- to 60-minute sessions over 3 months with MI-trained nurse who (1) addressed alcohol problems, (2) educated about ART efficacy, and (3) delivered tailored adherence advice including a reminder watch and a home visit. **Control:** Standard care **Assessment:** Baseline, 6, and 12 months.	**Alcohol use**: No significant effects on drinks per day, percent reporting any drinking, percent reporting hazardous drinking. **Medication adherence**: No significant effects on 3-day or 30-day adherence. **HIV viral load/ CD4 cell count**: No significant effects on mean CD4 cell count or mean log HIV RNA.	**Alcohol measures**: Self-report 30-day alcohol use from the Addiction Severity Index. **Adherence measures**: Self-reported AIDS Clinical Trial Group scale with 100% and 95% or more thresholds at 3-day and 30-day adherence, respectively.
Category 2: Clinical trials among HIV-infected people of whom at least 10% have current alcohol use				
Rotheram-Borus et al. 2009	**Population**: 270 HIV-infected people sexually active without a condom with at least one HIV-negative partner or two HIV-infected partners who were marginally housed and had four or more assessments; recruited from 2000 to 2002. **Alcohol use**: Mean number of days using alcohol or marijuana in the last 90 was 37. **Setting**: Recruited from community agencies, medical clinics, and advertisements.	**Intervention**: RCT of 15 90-minute individual counseling sessions, organized in three modules ("Coping" at 0–5 months, "Act Safe" at 5–10 months, and "Stay Healthy" at 10–15 months). **Control**: No intervention, only assessments **Assessment**: Baseline, 15, 20, and 25 months.	**Alcohol or marijuana use in the last 3 months**: At 25 months, the intervention group reduced its use from 36 to 28 days in the prior 90 days, whereas the control group was unchanged at 35 days of the last 90. Number of HIV negative partners and risky sexual acts also was reduced.	**Subanalysis of a clinical trial (Wong et al. 2008)**: 5% used alcohol/ marijuana in the parent study. Proportion of alcohol users at baseline not presented in this study. Parent study reported only transmission act outcomes and demonstrated an effect that was not maintained at 25 months. Imbalance in transmission risk acts at baseline resulted in ineffective randomization, thus propensity scores were used to adjust for imbalances.

Table 1 con't

Study	Population/Setting	Design	Outcomes/Results	Comments
Naar-King et al. 2006, 2008	**Population**: 65 HIV-infected patients, aged 16–25 regardless of alcohol use or risk behaviors. **Alcohol use**: 77% lifetime, 39% had used alcohol in last 30 days at study entry. **Setting**: Adolescent HIV care clinic within a tertiary care children's hospital.	**Intervention**: RCT of four 60-minute sessions of motivational enhancement. Therapy focused on two of three areas: substance use, sexual risk, or medication adherence over 10 weeks. **Control**: Wait list and standard care. **Assessment:** Baseline, 3, 6, and 9 months.	No significant effects at 9-month follow-up. **Alcohol use**: Borderline significant reduction in number of drinks in the week containing the maximum number of drinks (–9.65 vs. –1.3) at 3 months (n = 51). **Marijuana use**: Borderline significant reduction in number of times marijuana was used (n = 65). **Sexual risk**: Borderline significant reduction in total number of intercourse acts without a condom at 6 months (n = 65). **HIV viral load**: Significant reduction in log viral load at 6 months (n = 65).	**Alcohol and drug measures**: Timeline follow-back, though time window is not stated. **Sex risk measure**: Total number of unprotected intercourse acts without a condom. Note: 3-month outcomes on 51 subjects were published in 2006 and 6- and 9-month outcomes on 65 subjects published in 2008.
Gilbert et al. 2008	**Population**: 476 patients with alcohol risk (38%), defined as exceeding NIAAA safe drinking limits or drug risk (42%), or sex risk (60%), were recruited between 2003 and 2006. **Setting**: Outpatient HIV clinics.	**Intervention**: RCT of two sessions of tailored risk-reduction counseling at study entry and 3 months using a MI "Video Doctor" via laptop computer, printed educational worksheet, and delivery of a cueing sheet on reported risks to clinic care providers. **Control**: Standard care. **Assessment**: Baseline, 3, and 6 months.	**Alcohol use**: No significant effects on any risky drinking or number of drinks per week. **Drug use**: Significantly decreased 30-day illicit drug use at 3 and 6 months and fewer days of illicit drug use at 6 months. **Sex risk**: Significantly decreased 3-month unprotected sex at 3 and 6 months and fewer casual sex partners at 6 months. No effects on condom use.	**Alcohol measures**: Self-reported NIAAA risky drinking over 3 months. **Drug use measures**: Self-reported drug use over 30 days included any cocaine, methamphetamine, or heroin or 3 or more days of barbiturates, prescription opiates, hallucinogens, inhalants, or methylene-dioxymethamphetamine (MDMA).
Sorensen et al. 2003	**Population**: 190 HIV-infected patients with substance dependence; recruited from inpatient medical wards, detoxification clinic, and the emergency department from 1994 to 1996. **Alcohol use**: 61% in the last 30 days. **Setting**: Public general hospital.	**Intervention**: RCT of 12 months of case management by certified substance counselors in the community with caseload of 1:20 **Control**: Single brief contact with education about reducing HIV risk, information on HIV services, referrals to addiction treatment, social services. **Assessment**: Baseline, 6, 12, and 18 months.	No outcomes showed significant change between study groups at any time points, except decreased sex risk index. **Outcomes measured**: Addiction severity index composite scores, AIDS risk assessment scores, Beck depression inventory, health status questionnaire, and support evaluation list.	Summary/index score is shown without explanation of the raw measure.

Table 1 con't

Study	Population/Setting	Design	Outcomes/Results	Comments
Rotheram-Borus et al. 2001	**Population**: 310 HIV-infected patients (age 13–24) from nine adolescent clinics recruited from 1994 to 1996. **Alcohol use**: 67% nonabstinent at baseline. **Setting**: Adolescent clinics.	**Intervention**: 23 group sessions of two modules ("Stay Healthy" and "Act Safe"). **Control**: Standard care. Eligible for receiving the intervention at the conclusion of the study. **Assessment**: Baseline, 9, and 15 months.	**Alcohol/marijuana use:** 63% for attendees vs. 67% for control vs. 84% for nonattendees at 15 months.	Sequential assignment of 15 youths to intervention versus control groups (not randomized). The reported comparisons were attendees versus non-attendees versus control subjects. No intention-to-treat analysis was reported. Differential loss to follow-up. No alcohol-specific outcome was reported.
Category 3: Randomized controlled trials among alcohol users at high risk for HIV infection				
Morgenstern et al. 2007	**Population**: 198 MSM with current alcohol user disorder. **Alcohol use**: 88% with alcohol dependence. Mean drinks per drinking day was 10.4. **Setting**: Subjects recruited through advertisements in gay media, internet chat rooms, outreach to gay bars and clubs.	**Intervention**: 12 sessions of combined MI and coping skills training (MI+CBT) over 12 weeks (n = 47). **Control**: Four sessions of MI over 12 weeks (n = 42). Non–help-seeking (NHS) control group (n = 109). **Assessment**: Baseline, 12 weeks, and 12 months.	**Drinks per day**: At 12 weeks, the MI group had greater decreases in drinks per day than the MI+CBT group. This difference was not sustained at 12 months. Both intervention groups had greater decreases then the NHS group, but the NHS group also had substantial decreases in drinking.	**Alcohol measures**: CIDI at baseline. TLFB and short inventory of problems at followup. Potential subjects with drug use more severe than alcohol use disorder were excluded. Less than 10% HIV infected. Subjects lost to follow-up not included in the analysis.
Kalichman et al. 2008	**Population**: 342 men and women who drink in South African shebeens. **Setting**: Informal alcohol establishments (shebeens).	**Intervention**: 3-hour skills-based HIV–alcohol risk-reduction group session. **Control**: 1-hour HIV-alcohol information group session. **Assessment**: Baseline, 3, and 6 months.	The following behaviors were improved significantly at 3 months among the intervention group: • alcohol use before sex • unprotected intercourse • percent of sex with condoms • number of sex partners. Intervention effects were significantly stronger in those drinking less and dissipated at 6 months.	**Alcohol measures**: AUDIT, frequency of drinking before sex in previous month. Change in AUDIT scores not reported. 7% HIV infected in intervention group. 4% HIV infected in control group.

study had substantial methodological limitations, some of which pertain to the parent study. For example, in the parent study, random assignment of participants to the groups resulted in an imbalance between the groups with respect to baseline HIV risk behaviors or demographics. Moreover, the subanalysis was limited to participants who completed four follow-ups and were homeless or without stable housing. Finally, the outcome was alcohol or marijuana use in the last 3 months with no alcohol-specific results provided.

The four other studies in this category did not demonstrate any significant effects of the interventions tested on alcohol use:

- In a preliminary analysis of 3-month outcomes among 51 subjects randomized to four 1-hour motivational enhancement therapy sessions in an adolescent clinic, Naar-King and colleagues (2006) observed a trend, but no statistically significant reduction, in the number of drinks per week during the week with the

Table 2 Studies Identified but not Selected for the Literature Review

Citation	Population	Reason Excluded
Golin et al. 2003	140 HIV-infected patients. **Setting**: Hospital HIV clinic.	No data on the proportion of drinkers at baseline.
Goujard et al. 2003	326 HIV-infected patients. **Setting**: Hospital- and university-based centers.	No specific alcohol outcomes; alcohol group not analyzed independently.
Jones et al. 2003	174 women with AIDS from three U.S. cities recruited in 1997 from outpatient clinics, community health centers and agencies, and participant referrals. **Alcohol use**: 32% with history of alcohol. **Setting**: Primarily recruited from outpatient clinics, community health centers, and participant referrals.	No alcohol-specific outcomes reported.
Pradier et al. 2003	244 HAART-treated patients. **Setting**: Hospital	No specific alcohol outcomes; alcohol group not analyzed independently.
Samet et al. 2008	181 Russian men and women who reported any alcohol or drug dependence and who reported at least one incidence of unprotected sex in the past 6 months. **Setting**: Narcology hospitals	No alcohol-specific outcomes reported. Although both HIV-infected and alcohol-dependent patients were included in this study, the HIV-infected patients were not the alcohol-dependent patients.
Sampaio-Sa et al. 2008	107 HIV-infected, antiretroviral-naïve patients at an Brazilian HIV clinic for whom antiretrovirals were indicated were recruited from 2003 to 2004. 45% with alcohol use in the last 3 months.	Alcohol-specific outcomes not reported.
Simoni et al. 2007	136 HIV-infected men and women. **Setting:** Outpatient clinic	No information on current use; no specific alcohol outcomes.
Wong et al. 2008	936 HIV-infected from four U.S. cities recruited between 2000 and 2002. **Setting:** Community agencies, AIDS service organizations, and medical clinics	Alcohol-specific outcomes not reported; absolute numbers for outcome not presented.

maximum number of drinks. Moreover, in the final analysis of the study, which included 65 subjects, 39 percent of whom used alcohol, this difference was not sustained at 6 or 9 months (Naar-King et al. 2008).

- Gilbert and colleagues (2008) randomized 476 HIV-infected patients, 38 percent of whom reported risky drinking, to an MI-based "Video Doctor" intervention via laptop computer or a control group receiving usual care. The intervention resulted in decreased 30-day illicit drug use, lower mean number of drug use days, and a modest reduction of unprotected sex at 3 and 6 months. However, no differences in alcohol use existed between the intervention and control groups.

- Sorensen and colleagues (2003) randomly assigned HIV-infected patients with drug dependence, 61 percent of whom reported current alcohol use, to 1 year of continuous case management or to a brief contact (i.e., one HIV risk education session and printed information). No differences were noted in alcohol outcomes at 6, 12, or 18 months.

- A study among HIV-infected youths compared the effects of 23 2-hour group sessions and usual care on risk behaviors (Rotheram-Borus et al. 2001). The investigators found no changes from baseline on a measure reflecting alcohol and marijuana use and no difference between the intervention and control groups.

RCTs Among Alcohol Users at High-Risk for HIV Infection

Two informative RCTs have been conducted among alcohol drinkers at high risk for HIV infection. Morgenstern and colleagues (2007) performed a study with 198 high-risk, HIV-negative men who had sex with men and who were diagnosed with alcohol abuse or dependence but were seeking to moderate their alcohol use. The investigators compared the effects of 12 weekly MI sessions augmented with CBT with 4 sessions of MI alone. Unexpectedly, the investigators found that the nonaugmented MI group had less drinking and fewer alcohol-related drinking problems than the MI-plus-CBT group during the 12 weeks of the intervention and that there were no significant differences at 12-month follow-up. Thus, the addition of CBT to MI techniques provided no additional benefit regarding alcohol outcomes and potentially even diminished effects in this population. Subgroup analyses demonstrated that the detrimental effect of augmentation occurred particularly in participants with a concomitant drug use disorder.

Another RCT (Kalichman et al. 2008) compared a 3-hour, skills-based HIV and alcohol risk reduction group session with a 1-hour HIV/alcohol information group session among 342 South Africans frequenting drinking establishments. In this study, the extended session resulted in decreases in alcohol use before sex and unprotected intercourse at 3 month but not at 6 month follow-up. Moreover, intervention effects were stronger in participants drinking less at baseline.

Discussion

Given the high prevalence of unhealthy alcohol use among HIV-infected people and its associated adverse health consequences, development of clinical and public health interventions that seek to address alcohol use and improve health outcomes in this population is a priority. In recognition of this, NIAAA, as early as 1996, issued a request for applications entitled "Developing Alcohol-Related HIV Preventive Interventions (AA–97–03)." Since then, several studies have been published that describe clinical outcomes of interventions in this population. However, as this article has demonstrated, the literature on this important topic still is not extensive. A literature search revealed only four clinical intervention studies focusing exclusively on HIV-infected patients with current or past unhealthy alcohol use; five other clinical trials included and documented the alcohol use of some of their HIV-infected participants. Overall, the current state of research strongly suggests that although the problems related to alcohol in HIV-infected people are abundant, effective interventions are few and new ones are urgently needed. Hence, addressing alcohol problems remains an important issue in HIV research.

Not only are studies among alcohol-abusing, HIV-infected patients scarce, but the existing studies also yielded mixed results. Two of the four studies that specifically targeted HIV-infected people with alcohol problems showed improvement in drinking outcomes. Velasquez and colleagues (2009) demonstrated reduced drinking levels over 12 months after an intervention that included both MI and peer support. The intervention was particularly strong in reducing same-day drinking and sex, which compels further research on interventions targeting alcohol use at the time of HIV risk behaviors (Velasquez et al. 2009). Although the intervention types used in the study only were shown to be effective in a sample of men who have sex with men, they warrant study among other populations. In the other study, Aharanovich and colleagues (2006) demonstrated the feasibility of ongoing telephone-based interactive voice response and graphic feedback, which should inspire the inclusion of automated, tailored, ongoing intervention boosting as part of behavioral interventions. It is important to note, however, that both these studies had methodological limitations (e.g., substantial or differential loss to follow-up, incomplete assessments) and their findings therefore are not definitive. Nevertheless, they provide some guidance for future more rigorous clinical trials.

The other two clinical trials (Parsons et al. 2007; Samet et al. 2005) among alcohol-abusing HIV-infected people attempted to improve ART adherence. This is an appropriate target of alcohol

intervention studies in this population because medication adherence is of utmost importance for achieving good HIV disease outcomes, and alcohol-using patients have been documented to exhibit suboptimal ART adherence (Braithwaite et al. 2005; Chander et al. 2006; Conen et al. 2009; Samet et al. 2004). The results of both of these trials are discouraging, however, because although they explicitly addressed both alcohol use and medication adherence, one study (Samet et al. 2005) found no impact on adherence, alcohol consumption, or any HIV outcome, and the other (Parsons et al. 2007) only detected short-lived improvements (i.e., they were evident at 3 months, but not at 6 months). Thus, these two high-quality studies suggest that achieving clinically beneficial outcomes in HIV-infected people with alcohol problems is more difficult than has been the case with populations of HIV-infected without diagnosed unhealthy alcohol use (Amico et al. 2006; Simoni et al. 2006). Among the latter group, RCTs to improve adherence that used interventions with a range of intensities did reveal improvements in adherence which were sustained for up to 12 months, as well as in HIV viral load and CD4 counts (Tuldra et al. 2000). The difficulty of achieving positive benefits (e.g., improved ART adherence) through interventions among HIV-infected people who have alcohol problems also is evidenced by the study by Kalichman and colleagues (2008) among drinkers who were not infected with HIV. The findings of that study suggest that, as in brief intervention studies, intervention effectiveness varies by severity of alcohol use, with less improvement noted in dependent than in nondependent drinkers. Thus, levels of alcohol consumption, alcohol use disorder severity, and alcohol-related consequences are important covariates to be assessed and reported in HIV intervention studies.

A notable finding of this literature review was that as of 2009, no study of pharmacotherapy for alcohol dependence in HIV-infected patients had been published. This is surprising given that pharmacotherapy plays a major role in addressing the AIDS epidemic by improving outcomes of HIV-infected subjects. Moreover, some preclinical research has demonstrated that naltrexone, an effective medication for alcohol dependence, inhibits alcohol-mediated enhancement of HIV infection (Wang et al. 2006) and may potentiate the anti-HIV effects of antiretroviral medications (Gekker et al. 2001). Therefore, testing the effectiveness of naltrexone and other medications in alcohol-dependent HIV-infected patients is an important current research direction.

Two of the studies reviewed here that included HIV-infected patients among whom at least 10 percent currently used alcohol, targeted risky sexual behaviors rather than alcohol consumption. Assessing treatment effects on sex risk factors is appropriate for studies among HIV-infected drinkers because several studies have demonstrated an association between alcohol use and risky sex (Purcell et al. 2001; Stein et al. 2009). In both the study by Gilbert and colleagues (2008) and the study by Naar-King and colleagues (2006, 2008), sex risk behaviors were decreased in the group randomized to the intervention at 3 and 6 months, but there were no or only transient effects on alcohol use. These findings suggest that behavioral interventions which are not specifically tailored to address alcohol use are unlikely to impact alcohol problems in a sustained fashion.

The dearth of studies focusing on alcohol consumption among HIV-infected people is understandable. Although the spectrum of unhealthy alcohol use ranging from risky use to alcohol dependence occurs in this population, other pressing health concerns (e.g., ART adherence, risky sexual behaviors, or engagement in HIV care) appropriately become the main focus of clinical trials that also may address alcohol consumption in their intervention arms. Developing interventions that target a specific behavior (e.g., sex) at the time of alcohol use is a worthy pursuit, and understanding the importance of decreasing alcohol use in order to successfully achieve behavior change is crucial for developing future interventions.

One interesting development noted in the studies reviewed here was the use of new technology (e.g., interactive voice-response systems) in two of the studies (Aharonovich et al. 2006; Gilbert et al. 2008). These approaches to delivering a behavioral intervention merit further exploration because they have the potential for providing scalable, ongoing delivery of tailored automated messages that may boost a more intensive directly administered intervention.

When assessing the relevance of the studies reviewed here, particularly those conducted among HIV-infected patients with past or current unhealthy alcohol use, it is important to consider the methodological quality of the work (i.e., the potential for bias, design limitations, and outcome measures). The report by Velasquez and colleagues (2009) is the only controlled study demonstrating a sustained clinically significant treatment effect on an alcohol-specific outcome, making publication bias (i.e., the preferential publication of studies that find significant differences) unlikely.

Regarding their design, most, but not all, of these studies met important design criteria, such as random allocation of participants to treatment groups and intention-to-treat analyses[6] in the presentation of results. As with all behavioral intervention studies, keeping participants in the dark about which treatment they receive (i.e., blinding of participants to their treatment) is not possible. However, both Parsons and colleagues (2007) and Gilbert and colleagues (2008) utilized time- and content-equivalent controls to allow for the detection of effects

[6] An intention-to-treat analysis is based on the initial treatment intent, not on the treatment actually administered. Thus, every participant who begins the treatment is considered to be part of the trial, whether they finish it or not. This is done to avoid various misleading artifacts that can arise in a study. For example, if participants who have a more serious problem tend to drop out at a higher rate, even an ineffective treatment may appear to provide benefits if one only compares the condition before and after the treatment among participants who finish the treatment and ignores participants who were enrolled originally but did not finish the treatment.

specific to the counseling method studied.

The outcome measures reported were not consistent across studies and not always meaningful, limiting the comparability of study outcomes. For example, Naar-King and colleagues (2006) used an alcohol-specific measure—the number of drinks per week during the week with the maximum number of drinks at 3 months—that is not widely used and of questionable clinical meaning. Sorensen and colleagues (2003) only report a measure called the Addiction Severity Index Alcohol Composite Score, without any explanation or reporting of the individual components, complicating judgment of its clinical meaning. Finally, Samet and colleagues (2005) focused on ART adherence as an outcome, yet this study may underestimate the effectiveness of the intervention because the criteria for eligibility to participate in the study did not exclude patients with already good adherence. Thus, participants with good adherence at baseline provided little opportunity for an intervention to reveal a clinically meaningful impact.

In summary, as of 2009 the medical literature on clinical trials focused on people with HIV infection and unhealthy alcohol use is limited (i.e., "drops in a bottle"). Few of these studies were able to document improved outcomes, and any effects observed generally were modest and transitory. Based on these findings and current knowledge, the following questions need to be addressed:

- What are the characteristics of interventions that mitigate the health consequences of alcohol use in HIV-infected people?
- How does the treatment setting impact the effectiveness of behavioral interventions?
- How can technology best be used to extend and enhance intervention effects?
- What characteristics of HIV-infected drinkers suggest greater challenges when attempting to improve clinical outcomes?
- How can individual, network, or community interventions in people with multiple overlapping problems, including alcohol use, optimally reduce unhealthy behaviors?
- How might combined pharmacotherapy and behavioral therapy be utilized to address the spectrum of clinical consequences that accompany heavy alcohol consumption?

Obtaining answers to these questions is the key next step in the successful development of clinical and public health interventions to mitigate the adverse outcomes from alcohol use in HIV-infected patients. ■

Published online: 11 June 2010

Abstract Unprotected heterosexual transactional sex plays a central role in the spread of HIV in India. Given alcohol's association with risky sex in other populations and alcohol's role in HIV disease progression, we investigated patterns of alcohol use in HIV-infected female sex workers (FSWs) and HIV-infected male clients of FSWs in Mumbai. Analyses identified factors associated with heavy alcohol use and evaluated the relationship between alcohol use and risky sex. We surveyed 211 female and 205 male individuals; 80/211 FSWs (38%) and 127/205 male clients (62%) drank alcohol in the last 30 days. Among females, 32 and 11% drank heavily and were alcohol-dependent, respectively; among males the respective proportions were 44 and 29%. Men's heavy alcohol use was significantly associated with inconsistent condom use over the last year (AOR 2.40, 95% CI 1.21–4.77, $P = 0.01$); a comparable association was not seen in women. These findings suggest a need to address alcohol use both to avoid the medical complications of its heavy use in this population and to mitigate inconsistent condom use, the latter issue possibly requiring gender specific approaches. Such efforts to reduce drinking will be an important dimension to secondary HIV prevention in India.

Background

In India, unprotected heterosexual transactional sex is a major risk behavior fueling the HIV epidemic [1]. Among Indian female sex workers (FSWs), the prevalence of HIV infection is about 15 times that of the general population [2]. Identifying factors associated with on-going high-risk sexual behavior among HIV-infected persons involved in transactional sex, both FSWs and their clients, is therefore a crucial component of HIV prevention efforts.

Studies from other countries document associations between alcohol use and high-risk heterosexual behaviors among those with and without HIV infection [3–6]. In India, only a minority of the population drinks any alcohol (i.e., 2% of women and 32% of men), although it is becoming more common [7, 8]. A national survey, however, suggests that FSWs and their male clients are more

likely than other groups in India to drink [2]. Furthermore, men who drink alcohol when visiting Indian FSWs engage in riskier sexual behavior (e.g., unprotected anal sex) and are more likely to have HIV and other sexually transmitted infections (STIs) [9]. Heavy alcohol use among HIV-infected persons has also been associated with increased risk of HIV disease progression as measured by CD4 cell count decline and absence of viral suppression [10–12].

These data suggest that interventions to reduce alcohol use may be an important component of primary HIV prevention efforts in India, but it is not clear whether alcohol use is common among FSWs and clients who are *already* infected with HIV, or whether alcohol plays a role in high-risk behaviors in this group. Independent of any relationship with risky sex, the medical morbidity due to heavy alcohol use among HIV-infected persons is another aspect of potential concern related to this population. Hence in this study, we survey HIV-infected FSWs and HIV-infected male clients of FSWs in Mumbai, with an aim of characterizing alcohol consumption in these groups. Analyses identified factors associated with heavy drinking and evaluated the association between alcohol consumption and risky sexual practices.

Methods

Recruitment and Enrollment

The Transactional sex and Alcohol: Justification for a research initiative (TAJ) research team completed surveys on HIV-infected FSWs and HIV-infected male clients of FSWs in Mumbai, India ($n = 416$) from November 2008 to February 2009. Female participants ($n = 211$) were recruited from the ASHA Center, a community based organization in Mumbai, run by a group of FSWs who provide support and linkage to care for HIV-infected sex workers and HIV-infected clients. The ASHA Center is associated with the HIV Positive People's Network in Maharashtra (NMP+), an NGO committed to the treatment and care of HIV-infected people in India. Male participants ($n = 205$) were recruited from ASHA and two other sites affiliated with NMP+.

HIV-infected outreach workers at the respective agencies reviewed client lists and selected every fifth individual from the list to be contacted (by phone or in person) for study participation. A total of 326 women and 418 men were contacted for study recruitment, of which 246 (75%) women and 372 (89%) men came into their respective recruitment sites. Upon reaching the site, an outreach worker introduced the participant to gender-concordant research staff trained in HIV survey research. Two men and two women were excluded from screening due to intoxication. Of the 244 women and 370 men screened, 216 women and 210 men met eligibility criteria: 18 years or older; HIV-infected; and reporting sex trade involvement in the past year (selling sex for women, purchasing sex for men) and penile–vaginal or anal sex in the past 30 days. HIV infection was confirmed by medical records brought by the participants. Of those eligible for the study, 5 women and 5 men did not complete their interviews and were thus excluded from the analyses, providing the final sample size of 211 female and 205 male participants ($n = 416$).

Human Participants Protections

This study was conducted as a partnership among Boston Medical Center, Boston University, Population Council, and NMP+. Procedures for this study were reviewed and approved by the institutional review boards of Boston University Medical Campus, Network of Maharashtra by People Living with HIV/AIDS (NMP+) and the Indian Council of Medical Research.

Subject Assessment

Participants received a 45 min interviewer-administered survey in Hindi assessing demographics, alcohol use, sexual risk behaviors, and health status. Instruments were developed in English, translated into Hindi and then reviewed by a study investigator fluent in both languages. Discrepancies were resolved with consultation with the US investigators. Participants were also provided with 100 rupees ($2.50) as compensation for their time in this study.

Demographic and Health Information

Demographic data were collected based on items modified or taken from the Demographic and Health Survey [8] and Population Council surveys [13] and included gender, age, level of education, income, religion, marital status, and number of children. The survey included questions on the use of antiretroviral medications, and health status was assessed using the Hindi language Short-Form 12 Health Survey Version 2.0 (SF-12) [14], whose summary measures include the Mental Component Score (MCS) and Physical Component Score (PCS) [15]. The PCS and MCS scores have a range from 0 to 100 and were designed to have a mean score of 50 and a standard deviation of 10 in a representative sample of the US population [16].

Alcohol Outcomes

The survey included questions on alcohol use in various contexts in the past 3 months and past year. Daily consumption in the prior 7 days was collected using a

validated calendar method, the Timeline Follow Back (TLFB) [17], and was categorized as heavy, moderate, or abstinent. The "heavy" category was derived from the National Institute on Alcohol Abuse and Alcoholism definition of amounts that risk consequences (>14 drinks per week or >4 drinks on a single occasion for men, and >7 per week or >3 on a single occasion, for women) [18]. Heavy alcohol use (yes vs. no) was the primary outcome for analyses evaluating predictors of heavy drinking. Alcohol dependence over the last 12 months was evaluated using the Composite International Diagnostic Interview (CIDI) [19]. The survey asked about alcohol use prior to sexual encounters (e.g., "In the past 3 months, on how many occasions did you have a drink containing alcohol prior to having sex with a paid sex worker?") [20].

Sexual Behavior Outcomes

The primary sexual behavior outcome was the number of unprotected transactional sex encounters in the past 3 months (e.g., "In the past 3 months, how many times did you have sex with a client(s)?" "Of the times you had sex with a client in the past 3 months, how many times did you use a condom?"). Secondarily, the survey asked about the proportion of transactional sex encounters when the respondent used a condom (e.g. "In the past year, how often did you use a condom with a paid female sex partner?" "In the past year, how often did you use a condom with a client(s)?") with the response options of "always," "usually," "sometimes," "rarely," or "never." The secondary outcome of interest, derived from this question, was thus inconsistent condom use (yes vs. no). For this outcome, all responses other than "always" were categorized as inconsistent use.

Data Management

Data quality and management involved immediate review by field staff of survey data following interviews to ensure accuracy and completion as well as same day review by the field coordinator. Data entry and verification of consistency and accuracy utilized SPSS 11.5 software (SPSS Inc., Champaign, IL). Double data entry of the survey forms was performed in India and all discrepancies were reviewed and reconciled. Data were transmitted via a secure internet data transfer site to the Boston University School of Public Health, where further data cleaning and analysis occurred using SAS version 9.1 (SAS Institute Inc., Cary, NC).

Data Analysis

Identification of Factors Associated with Heavy Drinking. Heavy drinking over the past week, as measured by the Timeline Follow Back survey questions, was defined as the primary outcome. We used an iterative model building procedure based on logistic regression models to identify factors associated with this outcome. The following factors of interest were evaluated: age, income, religion, education, marital status, and MCS and PCS from the SF-12 v2. Age and PCS were modeled using tertiles as the linearity assumption did not hold in the regression models. We first fit unadjusted logistic regression models for each factor of interest. Factors significantly associated with heavy drinking at a significance level of 0.15 were included together in a single multivariable model. Factors that were no longer significant at the 0.15 level in the multivariable model were removed one at a time. Finally, factors not significant in unadjusted analyses were included one at a time in the multivariable model to assess their significance in the presence of other variables. The final model was determined using this iterative approach. Prior to regression modeling, we assessed bivariate correlations between all independent variables and covariates. To avoid potential colinearity, no pair of variables with Spearman correlation coefficient greater than 0.40 was included in the same model. Although a significance level criterion of 0.15 was used for entry and retention in the model building process, a two-sided alpha level of 0.05 was used to test whether a factor was significantly associated with heavy drinking.

Association between Heavy Drinking and Risky Sexual Behavior. The distribution of number of unsafe sex acts in the past 3 months, a count variable, was skewed, with a considerable proportion of zeros and a long tail. Thus, the use of models assuming normality was not appropriate. Therefore, we used Poisson regression models with overdispersion to evaluate the association between heavy drinking and the number of unsafe sex acts in the past 3 months [21].

The Pearson chi-square correction was used to account for overdispersion in the data. The regression models controlled for the following potential confounders: age, income, religion, education, and marital status. The magnitude of association between heavy drinking and number of unsafe sex acts was quantified using an incidence rate ratio (IRR). The IRR is the ratio of number of unsafe sex acts for heavy drinkers compared to those who were not heavy drinkers, thus the null value of no association for the IRR is equal to 1. The binary outcome inconsistent condom use was analyzed using multiple logistic regression models and resulting odds ratios were reported. These analyses were also controlled for age, income, religion, education and marital status. All analyses were conducted separately by gender. Analyses were performed using SAS software (version 9.1; SAS Institute, Cary, NC).

Results

Participant Characteristics and Alcohol Use

The demographic characteristics of the participants are shown in Table 1. In addition, participants reported frequency and quantity of alcohol consumed over the last 30 days and the last week. In the last 30 days, 38% (80/211; 95% CI 32–45%) of women and 62% (127/205; 55–69%) of men drank on at least one occasion. Among all FSWs, 32% (95% CI 26–38%) met the study threshold for a "heavy" drinking in the past week and 11% (23/211; 95% CI 7–15%) met criteria for alcohol dependence. Among the 80 women who reported any drinking, 84% (67/80) met the study threshold for a "heavy" level of drinking; 29% (23/80) met criteria for alcohol dependence. Among the men, 44% (95% CI 37–51%) met criteria for heavy drinking in the past week and 29% (59/205; 95% CI 23–36%) met criteria for alcohol dependence. Among the 127 drinkers, 71% (90/127) met criteria for heavy drinking and 46% [59/127] met criteria for alcohol dependence. Seventeen percent of the women and 40% of the men said they "always" or "usually" drank before having sex with a client/FSW (Table 1).

Condom Use

The FSWs in this study had many more transactional sex encounters than the male clients, and condoms were used in a lower proportion of the women's encounters. Women reported having had an average of 127 sexual encounters with clients over the last 3 months, while the men had an average of three encounters with paid female partners; in this time period the average number of unprotected sexual encounters was 15 for women and 0.2 for men. When asked about transactional sex practices over the last year, 90% of women and 26% of men reported inconsistent condom use (Table 1).

Demographic and Health Characteristics Associated with Alcohol Use

For the female sex workers, the final multivariable model examining predictors of heavy alcohol use revealed that younger age (AOR 4.69 for youngest tertile [22–28 years] vs. oldest tertile [32–50 years], 95% CI 2.14–10.30; OR 1.62 for middle tertile [29–31 years] versus oldest tertile [32–50 years], 95% CI 0.72–3.64, overall $P < 0.01$) and better self-reported physical health as measured by PCS (AOR 2.43 for highest tertile [42.6–54] versus lowest tertile [24.2–38.4], 95% CI 1.09–5.45; AOR 2.53 for middle tertile [38.5–42.5] versus lowest tertile [24.2–38.4], 95% CI 1.14–5.60, $P = 0.04$) were significantly associated with heavy alcohol use (Table 2).

For the male clients, none of the demographic or health measures were significantly associated with heavy alcohol use in the final multivariable model, though there was a trend toward a relationship between a lower income (i.e., less than the median for the group) and heavy alcohol use (AOR 1.68, 95% CI 0.95–2.98, $P = 0.07$) (Table 2).

Relationship Between Alcohol Use and Risky Sexual Behavior

Among the FSWs, no significant association was observed between those with heavy alcohol use and the reported number of unsafe transactional sex encounters over the past 3 months. The median (25th, 75th percentiles) number of such encounters was 0 (0, 20) for the heavy drinkers and 0 (0–11) for those with no heavy alcohol use ($P = 0.37$). The percentage who reported inconsistent condom use over the last year was also similar in both groups (90% of heavy drinkers and 91% of those who drank less or not at all). In the multivariable Poisson regression model (Table 3) heavy alcohol use in the past week was not associated with more unprotected transactional sex acts compared to those without heavy drinking ($P = 0.58$). Among other covariates in the model, younger age was significantly associated with the number of unprotected transactional sex encounters (IRR 2.94 for youngest tertile [22–28 years] vs oldest tertile [32–50 years], 95% CI 1.37–6.37; IRR 1.43 for middle tertile [29–31 years] vs oldest tertile [32–50 years], 95% CI 0.61–3.34; $P = 0.01$). We also did not detect an association between heavy alcohol use and the secondary outcome of inconsistent condom use in the past year ($P = 0.59$). Based on the multivariable logistic regression model, being currently unmarried was the only variable associated with inconsistent condom use (AOR 4.59, 95% CI 1.20–17.59, $P = 0.03$) (Table 4).

Heavy alcohol use and age played different roles in the analytic models for the male clients. Among the male clients, those with heavy alcohol use reported more unprotected transactional sex encounters over the last 3 months (IRR 2.75 [0.93–8.19], $P = 0.05$), an association that was borderline statistically significant. In addition, being in the youngest tertile (20–29 years) was associated with fewer unprotected sexual encounters over the last 3 months (IRR 0.14 for youngest tertile [20–29 years] vs. oldest tertile [36–49 years], 95% CI 0.02–0.95; IRR 0.04 for middle tertile [30–35 years] vs. oldest tertile [36–49 years], 95% CI 0.003–0.48, $P < 0.001$) (Table 3). For the secondary outcome inconsistent condom use (Table 4), both heavy drinking (AOR 2.40, 95% CI 1.21–4.77, $P = 0.01$) and older age (for youngest

this country, and this use is commonly excessive. These findings sharply contrast with societal norms in which alcohol use is relatively uncommon in India as a whole, particularly among women. According to the 2005–2006 National Family Health Survey, which assesses behavioral risks in a nationally representative sample of adults in India, about 2% of women and 32% of men in India drink any alcohol [8]. The current data, however, are consistent with earlier data on the broader population of Indians involved in transactional sex, who have been found to be

more likely to drink than the average Indian. The largest study to report such data, the National Behavioral Surveillance Study 2006, interviewed 7417 FSWs and 6613 male clients of FSWs without regard to HIV status and found that 46% of FSWs surveyed across India, and one-fourth of FSWs surveyed in the state of Maharashtra (which contains Mumbai) drank alcohol, while three-quarters of male clients of FSWs in India and two-thirds of male clients in Maharashtra drank alcohol [2]. That the prevalence of alcohol consumption in the current study of HIV-infected FSWs and their HIV-infected male clients was similar to this national cohort (in which presumably the majority were not infected with HIV) is consistent with research from other countries that has shown that heavy alcohol use is common among those infected with HIV [22–24].

In addition, a high percentage of participants—11% of the women and almost one-third of the men—were alcohol-dependent. About two-thirds of American adults drink alcohol, up to one-third of them at heavy levels, but only 4% have alcohol dependence [25–27].

It appears that despite presumably being in poorer health, no detectable decrease in percentage of persons drinking alcohol is observed among HIV-infected FSWs or their HIV-infected male partner compared to the findings in the FSWs and clients alcohol consumption survey.

For men and women involved in transactional sex, alcohol may play a variety of roles that could explain its common use. In particular, female sex workers working in brothels in Mumbai often offer alcohol to their male clients [Saggurti N.[Personal communication]. 6 Oct 2009] and indeed in this study most of the men who drink and a significant proportion of the women reported doing so in the setting of transactional sex. The logistic regression analysis was performed to help illuminate other factors that may play a role in heavy alcohol use and to reveal possible avenues to pursue in order to mitigate such consumption. Among the women, those who were younger and those who reported greater physical health (represented by higher PCS scores) had a higher odds of heavy drinking. This latter finding may reflect the "sick quitter" phenomenon in which less alcohol use occurs as one becomes too sick to drink, and thus overall those still drinking appear to reflect better health [28].

Although no associations were statistically significant, a notable magnitude of association was observed between lower income and heavy alcohol use among the men. Other studies have found that depression, family history, and personality traits (e.g., antisocial behavior) are related to heavy drinking among women, factors that we did not assess [29–32].

We did not detect an association between heavy drinking and unprotected sex among the FSWs; this finding may have a number of potential explanations. A recent meta-analysis of 27 studies of people with HIV in North America, Africa, Europe, and Russia found there to be a significant association between alcohol consumption (at all levels) and unprotected sex across the examined data sets

[5]. However, it is notable that the association in this meta-analysis was strongest in samples of men only. In the Indian population we studied, one explanation for the difference between the men and the women could be that male clients, rather than the sex workers, may more often control the final decision about condom use in sexual encounters, even if, as has been suggested in another study, the FSW may be more likely to propose condom use [33].

If men do control the final decision, condom use may be less likely in situations when men drink heavily and become disinhibited than in situations in which only the women drink. Alternatively, or in addition, it may be that the study's methodology affected its ability to discern a relationship between heavy drinking and unprotected sex among the female sex workers. In particular, it is important to note that this analysis looked *globally* at the relationship between alcohol intake and inconsistent condom use and, given the high proportion of women who did not consistently have safe sex (90%), detecting an association between the two behaviors would thus be difficult. It is possible that event-level questions asking about individual sexual encounters might have allowed detection of an association between the two behaviors. However, similar questions to those in this study have detected associations between alcohol and unprotected sex in other settings, so the question format alone is unlikely to account entirely for the lack of association among the women [5]. Also of note, this analysis looked only at a self-reported high-risk sexual behavior (i.e., condom use); it is possible that biologic markers such as sexually transmitted infections, might reveal an association between alcohol and risky sex [34].

Beyond the issue of the association between alcohol consumption and increased risk of HIV transmission among HIV-infected men and women involved in transactional sex in Mumbai, it is important to remain vigilant about the fact that high levels of alcohol use have important health implications for HIV-infected persons. Heavy drinking is known to confer high risk for a spectrum of psychological, social, and health problems [27], including adverse HIV-related health behaviors such as poor antiretroviral medication adherence [35, 36], and poor attendance at medical appointments [37, 38]. Heavy alcohol use among HIV-infected persons has also been associated with increased risk of medical problems including worse depressive symptoms [39] and poorer HIV immunological function (i.e., CD4 cell count decline) [10, 11]. Thus, in addition to alcohol's effects on sexual behavior, the heavy alcohol use found so commonly among the drinkers in this study may negatively affect their HIV-related health outcomes, as well as viral suppression and CD4 cell count. Future research could help define these implications in this population and illuminate the potential benefits of an intervention to reduce alcohol use.

Findings from this study demonstrate a need for programs for those involved in sex work that address alcohol consumption and condom use. The findings also suggest that within care systems for HIV-infected Indians, providers should screen for alcohol problems with subsequent brief interventions for risky drinkers and link those with alcohol dependence to alcohol treatment. Venue based interventions (i.e., interventions in alcohol or sex work settings) may also be useful to address risky alcohol behaviors for both FSWs and male clients, regardless of HIV status, but alone these could be inadequate, as the majority of men are likely drinking prior to entry into the venue. Hence, among men, social norm campaigns are needed to encourage condom use even in social situations in which both alcohol use and transactional sex occurs. FSWs, in contrast, may be using alcohol less for social reasons and more as a means of coping with difficult work situations, as noted in other studies [40–42]. Thus, interventions to reduce FSWs' use of alcohol would require approaches that alter the working conditions for this population. Nonetheless, it is unclear if such an approach would additionally impact HIV risk, as current findings revealed no association between alcohol and condom use among FSWs.

There are several limitations to this study. First, as indicated above, it relied on self-reporting of both alcohol and sexual risk behaviors. Under-reporting of stigmatized behaviors, resulting in an underestimate of the prevalence of alcohol use and condom use, could lead to an under-appreciation of an association between heavy drinking and unprotected sex. By using trained interviewers rather than clinical staff, we sought to minimize this phenomenon. Another limitation is that although when possible we used standard research tools and instruments previously used in India, the survey did not exclusively include instruments validated in Hindi. A third limitation is that the study surveyed a group of HIV-infected men and women who were members of an HIV service network. They therefore may have been more organized or felt more responsible for their health than other HIV-infected individuals involved in transactional sex. In addition, these study participants had already received some HIV prevention education and health care services, which may have reduced their risky sexual behavior and potentially the extent of their alcohol use. If these possibilities were at play during the conduct of this study, the result again would be an underestimate, rather than an overestimate, of the alcohol use and risky sexual behavior among this population. It is noteworthy that even if this is a "best case scenario," much remains to be done to address excessive alcohol use and unsafe sex in these individuals who are at high risk for transmitting HIV infection. A fourth limitation is that the major outcomes for alcohol consumption and condom use had different

time-frames. The study used "alcohol consumption over the last week" to define heavy drinking, whereas the two questions about condom use asked about behavior over the last 3 months and last year, respectively. Thus, the analysis of the relationship between heavy drinking and risky sexual practices relies on the assumption that participants' drinking over the last week also reflects the alcohol consumption patterns over the last 3 months and past year. A final limitation, as noted above, is the use of global-level questions about alcohol and sexual practices in the survey; it is possible that more detailed examination of situation-level or event-level behaviors (e.g., of concurrent drinking and unprotected sex) might have revealed a stronger association between alcohol and high-risk sexual behavior.

In summary, the current study makes a novel contribution by providing a detailed characterization of participants' alcohol use, revealing a strikingly high prevalence of heavy drinking among HIV-infected female sex workers and their HIV-infected male clients in Mumbai, India, despite low levels of drinking nationwide. Heavy drinking by these men appears to be associated with lower rates of condom use. These findings raise the possibility that efforts to reduce alcohol use among HIV-infected men who purchase heterosexual sex in India may be an important component of secondary HIV prevention initiatives. In addition, given the known effects of heavy alcohol consumption on HIV-related health outcomes, interventions to reduce drinking among HIV-infected men and women involved in transactional sex may improve the health of this vulnerable group in India.

Acknowledgments Funded by the National Institute on Alcohol Abuse and Alcoholism (R01AA016059-S1 and K24AA015674) and the Indian Council of Medical Research. We would like to thank Ms. Shabana Patel from the Network in Maharashtra by People Living with HIV (NMP+) for her oversight of study implementation in terms of helping ensure safe, confidential, and respectful treatment of our HIV-infected participants. We would like to thank the members of our partnering community based organizations in Mumbai for their assistance in implementing this study in the field, including the recruitment sites—ASHA, District Level Network registry, Drop-in HIV Center at the King Edward Memorial Hospital. From the NPM+ in Mumbai, this includes Ms. Bharti Sonawane, Ms. Aruna Bhere, Ms. Sunita, Mr. Anil Dalvi, and Mr. Hement Pawar. From ASHA Mahila Sanshta, this includes Ms. Mailee Tamang, Ms. Rupa, and Mr. Santosh Patankar. We thank Ms. Victoria Churchill and Mr. Joseph Novotny for their assistance with manuscript preparation. Finally, we are immensely grateful to the participants of this study who have, without hesitation, given their time and narrated their experiences and views regarding alcohol use and sexual behaviors.

Pulmonary Vascular Resistance, Collateral Flow, and Ventricular Function in Patients With a Fontan Circulation at Rest and During Dobutamine Stress

Boris Schmitt, MD; Paul Steendijk, PhD; Stanislav Ovroutski, MD; Karsten Lunze, MD, MPH; Pedram Rahmanzadeh, MD; Nizar Maarouf, MD; Peter Ewert, MD; Felix Berger, MD, PhD; Titus Kuehne, MD, PhD

Background—The role, interplay, and relative importance of the multifactorial hemodynamic and myocardial mechanisms causing dysfunction of the Fontan circulation remain incompletely understood.

Methods and Results—Using an MRI catheterization technique, we performed a differential analysis of pulmonary vascular resistance and aortopulmonary collateral blood flow in conjunction with global ventricular pump function, myocontractility (end-systolic pressure-volume relation), and diastolic compliance (end-diastolic pressure-volume relation) in 10 patients with a Fontan circulation at rest and during dobutamine stress. Pulmonary and ventricular pressures were measured invasively and synchronized with velocity-encoded MRI-derived pulmonary and aortic blood flows and cine MRI-derived ventricular volumes. Pulmonary vascular resistance and end-systolic and end-diastolic pressure-volume relations were then determined. Aortopulmonary collateral flow was calculated as the difference between aortic and pulmonary flow. Compared to rest, dobutamine caused a small increase in mean pulmonary pressures ($P<0.05$). Collateral flow was significantly augmented ($P<0.001$) and contributed importantly to an increase in pulmonary flow ($P<0.01$). Pulmonary vascular resistance decreased significantly ($P<0.01$). Dobutamine did not increase stroke volumes significantly despite slightly enhanced contractility (end-systolic pressure-volume relation). Active early relaxation (τ) was inconspicuous, but the end-diastolic pressure-volume relation shifted upward, indicating reduced compliance.

Conclusions—In patients with a Fontan circulation, aortopulmonary collateral flow contributes substantially to enhanced pulmonary flow during stress. Our data indicate that pulmonary vascular response to augmented cardiac output was adequate, but decreased diastolic compliance was identified as an important component of ventricular dysfunction. **(*Circ Cardiovasc Imaging*. 2010;3:623-631.)**

Key Words: heart defects, congenital ■ pulmonary heart disease ■ heart failure ■ magnetic resonance imaging

Ventricular function and pulmonary vascular resistance (PVR) are important variables that determine the outcome of patients with a Fontan circulation. Impaired growth of the pulmonary arteries failing to match somatic growth was described in recent studies.[1,2] Other authors have reported significant left-to-right shunting through aortopulmonary collaterals.[3,4] Both factors may have a direct impact on the PVR that cannot be measured in the Fontan circulation by conventional techniques, such as thermodilution or oxymetry.

Clinical Perspective on p 631

In addition to pulmonary vascular factors, heart failure was identified as an important cause of morbidity, and the right-type systemic ventricle seems to carry a higher risk for developing heart failure than the left-type ventricle.[5,6] However, the onset, course, and predominant form of heart failure vary and remain unpredictable. Systolic dysfunction has been described, but the role and mechanisms of diastolic dysfunction are less known.[7–10] Diastolic filling is considered to be impaired due to low preload that by itself is at least partly controlled by PVR. In addition, ventricular compliance is likely to be altered because congenital abnormalities as well as prolonged cyanosis and volume load may have an impact on the fibrous matrix of the myocardium.[7,11]

In this study, we performed a differential analysis of PVR and aortopulmonary collateral blood flow in conjunction with global ventricular pump function, ventricular contractility, and diastolic compliance. Measurements were obtained at rest

and during dobutamine stress using an MRI catheterization technique. We hypothesized that exposure to dobutamine stress would have a specific impact on PVR and aortopulmonary collateral flow as well as on systolic and diastolic ventricular function and, hence, improve our understanding of cardiovascular pathophysiology in patients with a Fontan circulation.

Methods

Study Design

The study was conducted in 10 preselected patients with a Fontan circulation. The patients were experiencing decreasing exercise capacity at routine follow-up and, thus, were referred to our institution for cardiac catheterization and MRI to determine ventricular systolic and diastolic function and cardiovascular anatomy. The exercise capacity assessment was based on New York Heart Association classification and ergometry. Only patients with extracardiac total cavopulmonary connection that had no fenestration of the tunnel were included. Exclusion criteria were the presence of pulmonary artery stenosis, atrioventricular valve insufficiency, arrythmias, protein-loss syndrome, thromboembolism, effusion, or edema. In addition, patients on β-blocker medication were not included because β-blockers would have affected the impact of dobutamine infusion. All patients or their guardians gave informed consent for the study, which was approved by the responsible institutional review board and ethics committee.

Atrioventricular valvar function and ventricular inflow profiles (E/A-wave ratio) were evaluated by Doppler echocardiography. Exercise capacity was quantified by oxygen uptake during ergometry. During catheterization, ventricular pressures were measured with 4- to 5-F fluid-filled pigtail catheters and pulmonary pressures with 5-F wedge catheters. Catheters were advanced over a femoral artery and femoral or cubital vein approach, respectively. At the end of the study, a 24- to 36-mm sizing balloon was placed at the level of the tunnel-to-pulmonary artery connection. Patients then were transferred to the neighboring MRI laboratory, keeping all catheters in place. Details about the use of the catheters during MRI follow.

MRI Assessment of Blood Flow and PVR

All MRI studies were performed with a 1.5-T scanner, with a maximum gradient performance of 30 mT/m and slew rate of 150 T/m per second. A 5-element cardiac phased-array coil was used for signal acquisition. In all patients, MRI was performed without sedation. Quantitative blood flow was measured using velocity-encoded (VEC) MRI orthogonal to the dominating flow direction in the superior and inferior vena cave, left and right pulmonary artery, and the ascending aorta as reported elsewhere.[12–14] In the ascending aorta, flow was measured just distal to the coronary arteries and the semilunar valves. In the inferior and superior vena cava, flow was measured in a segment approximately 5 to 10 mm below or above their connection to the pulmonary artery. Pulmonary flow was measured simultaneously with invasive pulmonary pressure. Technical details for pressure recording follow. All measurements were performed during free breathing at rest and during continuous infusion of 10 μg/kg per minute dobutamine. Automated correction was performed for potential phase errors arising from the concomitant magnetic field. Sequence parameters were TR and TE shortest, acquired spatial resolution of 2×2×6 mm, 2 numbers of excitation, phase-encoding velocity of 70 cm/s for venous and pulmonary flow and 150 cm/s for aortic flow, and 35 reconstructed phases per cardiac cycle.

Data analysis was done with View Forum release 6.1 software. Antegrade and retrograde flows were measured as described elsewhere.[12,15]

Aortopulmonary collateral flow (mL) was defined as the difference between effective antegrade aortic flow and the sum of antegrade right and left pulmonary blood flow as measured with VEC MRI in the right and left pulmonary artery.

PVR was the quotient between transpulmonary gradient and effective antegrade pulmonary flow.[16,17] The transpulmonary gradient was calculated as the difference between mean pulmonary and ventricular end-diastolic pressures. Total effective pulmonary flow was defined as the sum of antegrade flow as measured with VEC MRI in the right and left pulmonary artery plus collateral blood flow.

The Nakata index was calculated as the sum of the cross-sectional areas of the left and right pulmonary artery divided by body surface area.[18] The areas were obtained from the magnitude images of the right and left pulmonary VEC MRI measurements.

MRI Assessment of Global Ventricular Function

Ventricular chamber volumes and myocardial mass were determined from axial stacks of multislice-multiphase steady-state free precession cine MRI covering the entire heart.[12,19,20] Sequence parameters were TR and TE, 3.4 and 1.7 milliseconds; slice thickness, 6 mm; no gap; in-plane resolution, 1.9×1.3 mm^2; 45 phases per cardiac cycle; number of averages, 1; and sensitivity encoding reduction factor, 2. Analysis was done using View Forum release 6.1 software. Biventricular endo- and epicardial borders were manually traced for computing ventricular volumes and myocardial mass, where the septum was accounted for as left ventricular mass. Papillary muscles and prominent right ventricular trabeculation were excluded for volume measurements. Stroke volume was calculated as the difference between the diastolic and systolic volumes. Ejection fraction was calculated as the ratio of stroke volume to end-diastolic volumes.

MRI Assessment of Myocontractile and Diastolic Function

Parameters of myocontractile and diastolic function were derived from pressure-volume loops that were measured by an MRI catheterization technique. This MRI method was previously validated in animal experiments and has been recently described in detail.[21] Briefly, ventricular volumes of the single ventricle were acquired over several cardiac beats with cine MRI. During MRI, invasive ventricular pressures were measured and averaged. At postprocessing, volumes and pressures were synchronized in time using a trigger signal. From these measures, a pressure-volume loop under steady-state conditions was constructed. The end-systolic pressure-volume relation was estimated from this loop using a single-beat approach as previously described.[22–24] Emax, which is the slope of the end-systolic pressure-volume relation, was defined as a measure of contractility and indexed to 100 mg myocardial muscle mass (Emax,i). Effective arterial elastance (Ea) was calculated as end-systolic pressure divided by stroke volume. Ventricular-arterial coupling was determined as the ratio of Emax to Ea.[23,25]

In a second step, instantaneous blood flows were measured using real-time VEC MRI in the ascending aorta just distal to the orifices of the coronary arteries.[13,21] The sequence parameters were TR and TE, 23 and 6.5 milliseconds; matrix, 128×256; field of view, 400 mm; slice thickness, 8 mm; encoding velocity, 150 cm/s; sensitivity encoding reduction factor, 3; half-scan factor, 0.6; and echo planar imaging factor, 41. The scan time was 31 milliseconds for the acquisition of 1 phase-contrast image. During flow measurements, ventricular preload was reduced by transient balloon occlusion of the vena cava. The balloon was inflated with isotonic saline solution. For each unloaded beat, we determined ventricular chamber volumes and synchronized them with ventricular pressures to generate a set of pressure-volume loops, as previously described.[21] The absolute end-diastolic volumes were determined by matching the VEC MRI-derived volumes with the intercept of the end-systolic pressure-volume relation. The resulting end-diastolic pressure-volume points were used to determine the end-diastolic pressure-volume relation. The stiffness constant ß, a load-independent measure of ventricular compliance, was calculated from the end-diastolic pressure-volume relation with an exponential regression as follows: $EDP = Ae^{ß \cdot EDV}$, where EDP indicates end-diastolic pressure; EDV, end-diastolic volume; and A, curve-fitting constant. ß was indexed to ventricular volumes to create a dimensionless index (ß, i). From

pressure measurements, we derived relaxation time constant τ as a parameter of early diastolic relaxation.

Pressure Recordings and Catheter Visualization During MRI

The fluid-filled catheters were connected to pressure transducers, and pressures were amplified, recorded, and analyzed with Ponemah software. An additional pressure transducer was positioned within the bore of the scanner to obtain a trigger signal for synchronizing measured pressures with cine and VEC MRI-derived ventricular and blood flow volumes.[21] The position of the catheters was visualized on cine MRI images (Figure 1). Appropriate inflation of the balloon catheter with saline solution was confirmed on interactive real-time MRI (Figure 1).[26]

Statistical Analysis

Measurements at rest and during dobutamine stress were analyzed with paired Student *t* test and Bonferroni-Holm correction for multiple comparisons of 20 parameters. Data are expressed as mean±SD. The correlation was determined among ventricular volumes, cardiac index, and aortopulmonary collateral flow. In addition, correlation was determined among measurements of collateral flow, PVR, and ergometry-derived parameters of functional capacity. The agreement between pulmonary and caval flow volumes was assessed using the Bland-Altman test.

Results

General Characteristics

We investigated 10 patients with a Fontan circulation (5 each with a right- and left-type single ventricle). Eight patients were white, and 2 were of Arabic ethnicity. All patients were compliant to the study. The duration of dobutamine exposure ranged from 15 to 25 minutes. There were no side effects to dobutamine. Due to the length of the study protocol, flow measurements in the inferior and superior vena cava were not performed in 2 patients at rest and in 4 patients during dobutamine stress.

All patients were New York Heart Association class I to II. Ergometry showed decreased functional capacity compared to published reference levels (Table 1).[27] Angiograms revealed no obstruction within the Fontan circulation and either no or only visibly small venovenous or aortopulmonary collaterals. Oxygen saturation at rest ranged from 91% to 97% and did not decrease significantly during dobutamine stress.

There were no statistically significant differences between parameters as measured for the left- versus right-type single ventricle. This finding also comprises the functional parameters as given in the next sections.

Blood Flow and PVR

The Nakata index of the pulmonary arteries was 150±45 mm^2/m^2 and, thus, substantially below published reference values of healthy controls.[1,18] Quantitative flow volumes measured in the inferior and superior vena cava were similar to those measured in the left and right pulmonary artery, and they all increased during dobutamine stress ($P<0.05$) (Table 2). In all patients,

*Significant differences after Bonferroni-Holm correction.

there was only trivial retrograde flow in the pulmonary arteries both at rest and during stress (Figure 2). The Bland-Altman analysis showed good agreement between flow measurements obtained in the vena cava and the pulmonary arteries (Figure 3). During augmented pulmonary flow, mean pulmonary artery pressure and transpulmonary pressure gradient only changed slightly, and consequently, vascular resistance was decreased (Table 3). Blood flow volumes were significantly larger when measured in the aorta than when measured in the pulmonary arteries, and compared to rest, this difference increased during stress (Table 2). Thus, the calculated collateral blood flow increased significantly during dobutamine stress ($P<0.01$). There was no significant correlation between collateral blood flow and ventricular end-diastolic volumes (at rest, $r=-0.072$;

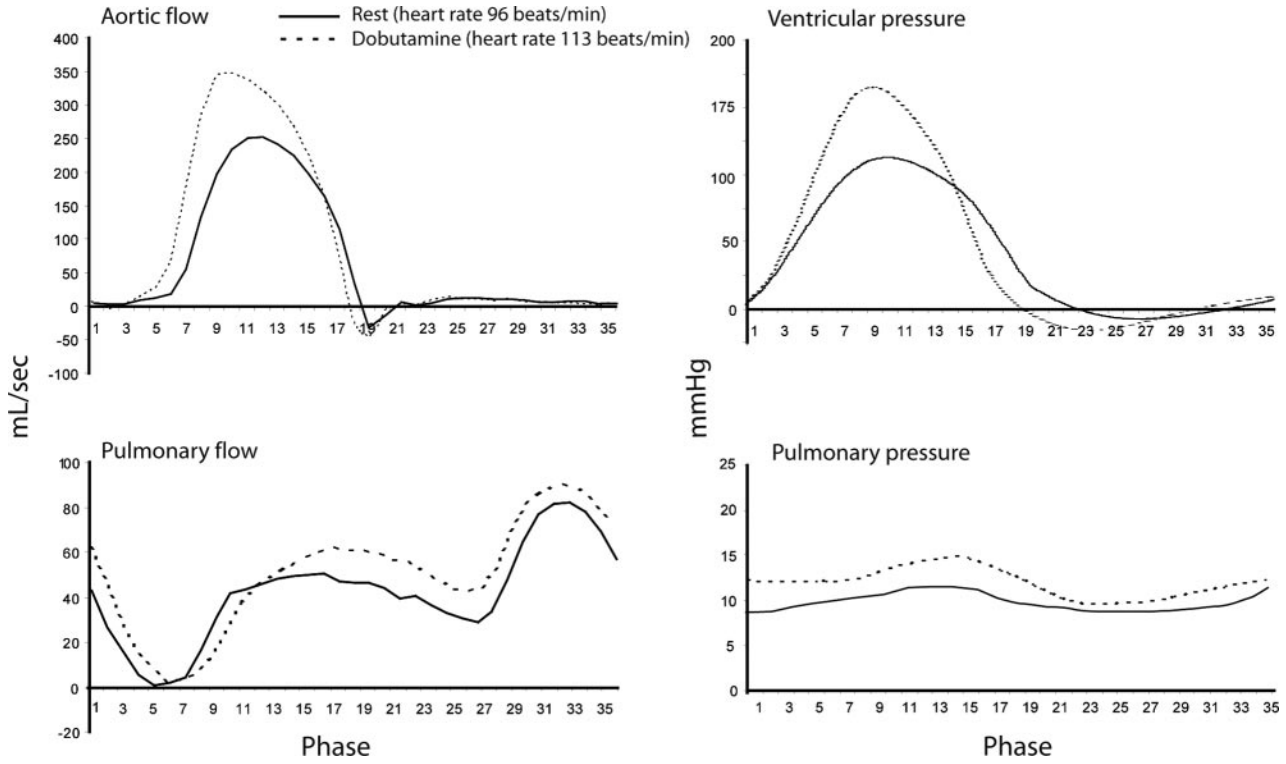

Figure 2. Representative flow volumes and pressures of a patient with Fontan measured at rest and during dobutamine stress. The pulmonary flow is shown as the sum of the flow measured in the left and right pulmonary artery. For illustration purposes, data measured at 2 different heart rates (rest and dobutamine stress) were scaled to 35 heart phases.

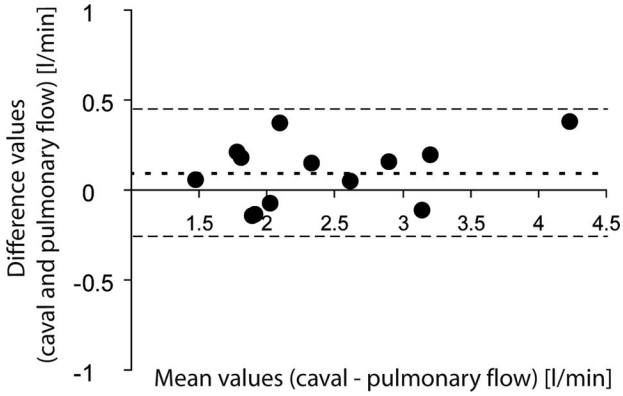

Figure 3. Bland-Altman plot of pulmonary and caval blood flow volumes (mL) for measurements obtained at rest and during dobutamine stress.

during dobutamine stress, $r=-0.062$) or between collateral blood flow and cardiac index (at rest, $r=-0.072$; during dobutamine stress, $r=-0.062$). However, there were statistically significant inverse correlations between collateral blood flow (aortopulmonary collateral) and both PVR ($r=-0.6$; $P=0.03$) and ergometry-derived peak oxygen uptake ($r=-0.7$; $P=0.01$). Blood flow patterns in the pulmonary arteries were similar at rest and during dobutamine stress (Figure 2). In concordance with other reports, the profiles showed some degree of interindividual variability.[28,29]

Global Pump Function

During dobutamine stress, heart rate and cardiac output increased significantly, but stroke volume did not (Tables 4 and 5). Differences in ejection fraction just fell short of being significant when using Bonferroni-Holm adjustments for multiple comparisons ($P=0.009$) (Table 5).

Myocontractile and Diastolic Function

During dobutamine stress, there was an increase of Emax,i that was not significant when adjusting for multiple comparisons ($P=0.026$) (Table 4). Efficiency of ventricular-arterial coupling did not improve during dobutamine stress due to a concomitant increase in Ea.[25] By echocardiography, the E/A-wave ratio was above 0.7 in all patients. During MRI catheterization at rest, the relaxation time constant τ was at published reference levels for healthy controls and shortened significantly during dobutamine stress (Table 4). At the same time, there was a decrease of end-diastolic volumes (Figure 4 and Table 5). End-diastolic pressure increased slightly but not significantly. There were no significant changes of the stiffness constant ß, but the pressure-volume loops shifted toward the left in the pressure-volume diagram in all patients (Figure 4 and Table 4).

Discussion

A progressive decrease of exercise capacity is commonly observed in patients with Fontan circulation, and at late follow-up, heart failure contributes importantly to morbidity.[5] The pathophysiologic causes for heart failure seem to be multifactorial. In this study, MRI catheterization was used at rest and during dobutamine stress to obtain information about PVR, global ventricular pump function, myocardial contractility, and diastolic function. The major findings are that left-to-right shunt through aortopulmonary collaterals increased during dobutamine stress, but PVR decreased. In addition, during stress, the single ventricle had signs for abnormal diastolic compliance.

Blood Flow and PVR

Several authors reported a diminished growth of the pulmonary arteries despite somatic growth and assumed that this might have an impact on PVR.[1,2] However, only sparse data are available

about the functional status of the pulmonary arteries at rest and during stress partly because vascular properties like PVR cannot be evaluated using conventional techniques, such as thermodilution or the Fick method, in patients with a Fontan circulation. In the present setting, MRI catheterization is a unique tool that combines invasive pressures and VEC MRI-derived flow data that also account for collateral aortopulmonary blood flow.[3,16,28] For reliable assessment of the PVR in the Fontan circulation, which is very susceptible to changes in volume load, pulmonary pressures and blood flow were measured in our study simultaneously but not sequentially.

The MRI method used in this study for measuring collateral blood flow was adopted from the work published by Grosse-Wortmann et al[3] and Whitehead et al.[14] In these studies, collateral flow was estimated by 2 approaches. Simplified, collateral flow was defined as the differences between flow volumes measured in the ascending aorta and the 4 pulmonary veins or, alternatively, as the difference between flow volumes in the ascending aorta and the systemic venous return. The latter was determined in the descending aorta[3] or the inferior and superior vena cava.[14] In both studies, the different methods had overall good agreement. In the present study, we modified the approach of Whitehead and colleagues slightly by directly measuring pulmonary arterial flow instead of caval flow. Comparing pulmonary with caval flow volumes showed good agreement (Figure 3).

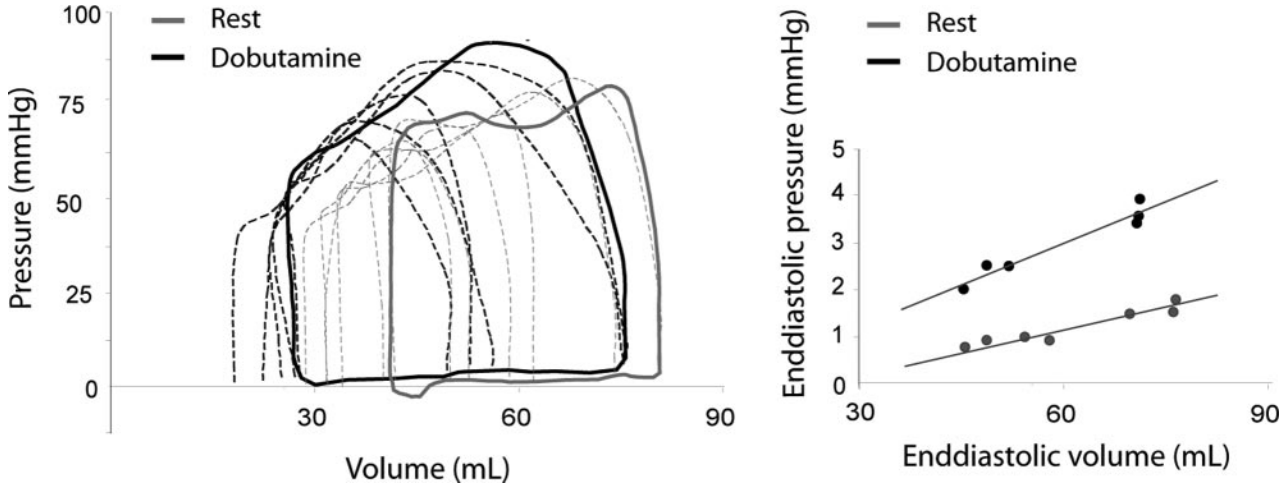

Figure 4. Pressure-volume loops (left) and end-diastolic pressure-volume points with regression line (right) in a representative patient at rest and during dobutamine stress. Note the left shift of the loops and end-diastolic pressure-volume points during dobutamine stress.

In concordance with the studies by Whitehead et al[14] and Grosse-Wortmann et al,[3] we noted an important contribution of aortopulmonary collateral flow to total effective pulmonary blood flow. The latter is considered being the amount of blood that passes through the pulmonary arteriole level, thus the sum of antegrade pulmonary and collateral flow. Recirculating blood through collaterals contributed about 13% to the total effective pulmonary flow at rest, and this percentage increased substantially to >25% during dobutamine stress. Interestingly, there was statistically significant inverse correlation between the amount of collateral flow and peak oxygen uptake during ergometry. Collateral flow also correlated inversely with PVR, but the relatively small sample size in the present study limits the clinical interpretation of this finding. This issue must be addressed systematically in future research.

In the studied patients, PVR at rest was slightly above published control values, which were determined in a previous study using the same MRI catheterization method.[16] During dobutamine stress, mean pulmonary pressures increased, but transpulmonary gradient did not, and thus, PVR decreased in the presence of augmented pulmonary throughput. PVR generally is considered a valid indicator of structural changes at the small resistive pulmonary arteriole level. Hence, we concluded that in the studied patients, there is at least a partially functioning pulmonary vasculature regulation to variation in pulmonary perfusion. However, one must keep in mind when interpreting these data that dobutamine was shown to increase pulmonary blood flow, but it does not affect the pulmonary vascular tone.[30,31] In addition, Hjortdal and colleagues[32] demonstrated that in patients with a Fontan circulation with total cavopulmonary connection, blood flow through the lung is driven by cardiac, respiratory, and peripheral muscular mechanisms. The relative contributions of these pumping mechanisms are influenced by many factors that include cardiac performance, physical exercise, body position, and respiratory patterns. These different mechanisms cannot be realistically simulated in the MRI environment.

Global Ventricular, Myocontractile, and Diastolic Function

Similar to earlier studies, we noted no substantial stroke volume augmentation under dobutamine stress in the patients with a Fontan circulation.[10,33] Myocardial contractility increased only slightly and not significantly during inotropic stimulation, and thus, the increase in cardiac output was mainly regulated by heart rate. This finding, again, is in line with earlier studies.[33] In conjunction with slightly improved parameters of contractility, end-systolic volumes decreased adequately, suggesting that systolic dysfunction is not the predominant cause of the abnormal response to stress. At the same time, end-diastolic volumes decreased, again similar to previous observations, and Emax/Ea, a parameter for the efficiency of ventriculoarterial coupling, remained at a low level.[10,23] These findings suggest an abnormal diastolic function of the single ventricle during dobutamine stress. In Fontan, diastolic filling is thought to be affected by a limited preload reserve because there is no subpulmonary ventricle actively pumping an appropriate amount of blood through the pulmonary system.[6,10,32] One also might speculate that in the presence of diminished preload recruitment, diastolic dysfunction is induced because the ventricle is not trained to be fully loaded. From elderly patients with atrial-septal defect, it is known that chronic underloading can lead to a small and stiff left ventricle.[34] In these patients, pharmacological priming before defect closure mostly improved diastolic function. On the contrary, recirculating blood through aortopulmonary collaterals contributes increasingly to ventricular filling under stress and, thus, would attenuate a deficient preload reserve. Other authors even discussed that collateral flow can impose a volume load on the single ventricle.[3,35,36] Overall, one should consider the important individual variations in the presence of collaterals and the resulting amount of collateral flow.[37]

In the present study, active early diastolic relaxation appeared to be normal, as indicated by a decrease of τ during dobutamine stress.[38] However, there was evidence of abnormal diastolic compliance. During dobutamine stress, the stiffness constant ß remained at similar levels as measured at rest, but the end-diastolic pressure-volume relation shifted toward the upper-left in

the pressure-volume diagram. Such a shift of the end-diastolic pressure-volume relation was not observed in recent studies that were performed in healthy pig left and right ventricles.[21,39] In addition, these studies showed that dobutamine has no major impact on the stiffness constant ß. It seems that chamber properties for filling do not improve during dobutamine stress; rather, filling must be accomplished in a system with increased stiffness. In the present study, we exposed the patients to moderate dobutamine stress that caused no substantial increase in end-diastolic pressures. In more severe stress situations, diastolic dysfunction might unmask even further, which could go along with more increased end-diastolic pressures. An abnormal ventricular stiffness could be explained by several reasons. The geometry of the single ventricle has a direct impact on its mechanical pump function and, thus, on its systolic and diastolic properties.[40] In addition, prolonged cyanosis and volume load during infancy are thought to induce myocardial fibrosis.[6,41] Finally, histopathologic studies in tricuspid atresia showed abnormal formation and arrangement of the fibrous matrix and the aggregation of myocyte chains.[11] Thus, the potential causes for the development of heart and pulmonary vascular dysfunction are multifactorial, as are the resulting forms of dysfunction, implying that it is essential to investigate these patients with methods that give a differential insight into the predominant form of failure that, in turn, will allow optimizing treatment concepts.

In summary, the findings of this study indicate that during dobutamine stress, blood flow through aortopulmonary collaterals contributes progressively to pulmonary perfusion. The pulmonary arteries had an abnormal growth index, but vascular regulation appeared to be unsuspicious. PVR decreased during stress and, thus, did not contribute to impaired diastolic filling in the patients studied. In contrast, we noted in the presence of normal early relaxation alteration of ventricular compliance during stress.

Limitations

There is no established animal model for studying the Fontan circulation. Additionally, extrapolating findings from healthy human controls to a univentricular physiology must be made with great care. Therefore, this patient study has a descriptive nature, and findings must be related to parameters that were obtained in other research. Care must be taken when comparing changes of ventricular and pulmonary vascular function induced by physical exercise with dobutamine stress.[30,32,42,43] Therefore, it would be inappropriate to directly translate our findings to exercise conditions. In addition, heart rate effects must be considered when interpreting our data of diastolic compliance. Collateral flow through intrapulmonary shunts and venovenous collaterals was not determined in our study. However, arterial oxygen saturation did not decrease significantly during stress, and thus, one can assume that flow through these types of shunts was relatively constant during the study protocol. Measuring blood flow in all 4 pulmonary veins would have allowed quantifying the amount of venovenous and intrapulmonary flow but at the expense of a substantially lengthened protocol that was judged too demanding. In general, VEC phase-contrast MRI flow sequences must be used with great care when measuring quantitative flow.

Finally, there is a broad range of varieties in Fontan regarding anatomic conditions and the onset and time course of cardiovascular dysfunction. Therefore, one cannot extrapolate our data of preselected patients to other forms of Fontan. However, the method used in this study allows differentiation among pulmonary, systolic, and diastolic dysfunction, which will potentially improve the planning of individual treatment strategies.

CLINICAL PERSPECTIVE

The pathophysiologic causes for failure of the Fontan circulation are multifactorial. Therefore, diagnostic tools are warranted that permit a differential analysis of ventricular and pulmonary vascular function. In this study, an MRI catheterization technique that enables simultaneous pressure and volume measurement in the single ventricle was used. From these measurements, parameters of global pump, myocontractile, and diastolic function can be derived. In addition, MRI catheterization allows determination of aortopulmonary collateral flow in conjunction with pulmonary vascular resistance. We found that pharmacological stress by dobutamine improved contractility, although without substantial augmentation of stroke volumes. At the same time, the single ventricle showed signs of abnormal diastolic performance. In the absence of a subpulmonary ventricle, these findings should be seen in the light of pulmonary vascular function. In the studied patients, blood flow through aortopulmonary collaterals contributed substantially to the total pulmonary blood flow. In addition, its proportion increased during stress. However, augmented total pulmonary blood flow was not associated with increased pulmonary vascular resistance, implying that resistance did not contribute to a limited preload reserve and, thus, impaired diastolic filling of the systemic ventricle. The method described in this study provides detailed and differential information of the cardiovascular function in Fontan, which will potentially improve the planning of individual treatment strategies. The findings of this descriptive study of preselected patients require further study in larger groups of patients with different types of Fontan circulation.

A dearth of literature exists on barriers to conducting research with Black male victims of community violence, despite the need for evidence-based postinjury interventions. This study used qualitative data from a cross-sectional interview study ($n = 16$) and a pilot intervention study ($n = 11$) conducted in Boston, MA to identify challenges and facilitators to conducting research with Black male victims of community violence, particularly with regard to recruitment and maintenance of a study sample. Qualitative methods, including Grounded Theory and ethnography, were used to analyze the data. Challenges included a fear of police involvement, an impression of "snitching" when disclosing personal information, mistrust of research motives, suspicion of the informed consent process, the emotional impact of the trauma itself, and logistical issues. Facilitators to research included monetary incentives and motivation to help oneself and others. Participant recommendations on recruitment methods relating to approach and timing are provided. Findings from this study may assist in the planning of research studies for Black male victims of community violence.

Keywords: African American, qualitative research, community violence, research participation

Morbidity and mortality from stabbing and shooting violence disproportionately affects young Black males. In 2006, the firearm homicide rate for Black males ages 18–25 was 100.4 per 100,000 persons, more than five times higher than the rate for any other group (National Center for Injury Prevention and Control, 2005). Despite potential for social, behavioral, and other hospital-based interventions to improve the treatment received by Black male victims of community violence, relatively few studies have been conducted in these settings (Becker, Hall, Ursic, Jain, & Calhoun, 2004; Cooper, Eslinger, Nash, al-Zawahri, & Stolley, 2000; Cooper, Eslinger, & Stolley, 2006; Zun, Downey, & Rosen, 2006). Moreover, little research is available to describe the specific barriers and facilitators to research participation in this population.

Two bodies of literature can help to inform this research gap. The first addresses conducting research with African Americans. This topic has been examined in a variety of samples, including cancer patients, general medical patients, and community members. Studies cite a lack of trust in medical research, particularly stemming from the Tuskegee Study, as a central barrier to conducting research with African Americans (Corbie-Smith, Thomas, Williams, & Moody-Ayers, 1999; McCallum, Arekere, Green, Katz, & Rivers, 2006; Rajakumar, Thomas, & Musa, 2009; Shavers, Lynch, & Burmeister, 2002). Other barriers include the belief that minorities have more risks in medical research, fear of risks to participating, inconvenience, perceived physician dishonesty, lack of perceived need for research, belief that African Americans would not benefit from any advancements a study may bring, fear of worsening health that may result in participation, and confusion of the purpose and meaning of informed consent (Corbie-Smith, Thomas, & St. George, 2002; Corbie-Smith et al., 91999; Dunlop,

E-mail: jane.liebschutz@bmc.org

Graham, Leroy, Glanz, & Dunlop, 2007; Shavers, Lynch, & Burmeister, 2002).

By contrast, there is much less published work on the second body of literature, barriers to research participation among community violence survivors. A study of a pharmacological intervention in acute trauma patients, including victims of violence as well as survivors of motor vehicle crashes and other accidents, showed difficulties enrolling trauma patients from the hospital; of the 569 accessible and potentially eligible patients, only 48 (8%) enrolled (Stein, Kerridge, Dimsdale, & Hoyt, 2007). The reasons for this difficulty in enrollment have not been explored, although informal discussions with patients by Stein and colleagues revealed several possible explanations, such as patients not wanting to participate in anything that may delay their discharge from the hospital and denial of possible mental health outcomes from a traumatic event (Stein et al., 2007). In a randomized controlled trial of victims of violent crime, only 243 (11.2%) of the 2161 patients responded to a letter sent by the study team (Rose, Brewin, Andrews, & Kirk, 1999). Investigators in that study felt that patients' unwillingness to share their experience of victimization with strangers may have played a large role in this low response rate.

Although these studies suggest issues that may be important when designing studies for Black male victims of violence, research is needed to examine whether there are unique barriers not previously identified, and how much previously identified issues impact research participation among victims of violence. To address these research gaps, we culled data from two studies to identify the challenges and facilitators to conducting interview and intervention studies with Black male victims of community violence. One was a cross-sectional qualitative study on interactions with health care after injury. The other study was a pilot intervention to link Black male victims of community violence to culturally appropriate mental health and primary care.

Methods

Participants

Participants from the cross-sectional study were recruited via flyers posted in community settings around Boston, MA through word of mouth from other participants, and via online posting (boston.craigslist.org). Interested people were screened for eligibility criteria, which included male gender, age 18–40 years, and history of a gunshot or stab wound injury for which they sought medical care. Although Black race was not an eligibility criterion, all participants who completed the study self-identified as Black. Thus, participants for the cross-sectional study included 16 Black males with a median age of 31 years (range 25–38). Three were victims of gunshot, five of stab wounds, and eight were victims of both injuries. The median length of time since the most recent injury was 5.5 years (range 4 months to 20.1 year). Eligible participants provided written informed consent. At interview completion, they received $25 compensation and a referral list for local mental health and substance use treatment centers.

The second study was a pilot intervention that linked participants to primary care and provided a five-session problem-solving counseling program. Participants in the intervention study were recruited through a violence intervention advocacy program of an urban academic medical center with the largest Level 1 trauma center in New England. Eligibility criteria included gunshot or stab wound that was treated via the Emergency Department in the prior 2 years, age ≥18 years, self-identified Black race, male sex, English language fluency, plans to stay in the area for the next 6 months, two forms of contact, and use of an illicit substance or hazardous amounts of alcohol in the prior month. Those who suffered a traumatic brain injury were excluded because of the need for participants to be able to engage in the counseling program. Participants for the intervention included 11 self-identified Black males with median age of 26 years (range 18–42). Two had been treated for a stab wound and nine for a gunshot injury that occurred a median of 23 days (range 1 day to 23 months) before study entry. One participant enrolled in both studies. Enrolled participants provided written informed consent and received $25 compensation for each of three research interviews completed.

Procedures

In the cross-sectional study, trained interviewers conducted 14 semistructured interviews from January through December of 2008 (2 paired and 12 individual interviews). Seven interviews were conducted by 2 Black, male, community-based mental health professionals, 3 by a White female research assistant, 3 by a Black male research assistant, and 1 by the White female principal investigator. To facilitate rapport, all interviews were scheduled with Black, male interviewers. However, two interviews occurred when participants showed up hours past the scheduled interview time, when the designated interviewer was no longer available. Two interviews occurred when the participants could not provide contact information to allow confirmation with Black interviewer schedules and thus were interviewed right at the time of inquiry by available trained staff. Interviews were digitally recorded and lasted 45−120 min. Audio recordings were professionally transcribed and identifying information was changed to preserve participant confidentiality.

The interview guide focused largely on experiences with health care during and after injuries. Once the investigators encountered recruitment difficulties, questions were added about views on research participation, particularly recruitment, starting with the third participant. The goals were to inform improvements to the recruitment protocol and to anticipate research conduct issues that might arise in the planned intervention study. Participants in later interviews were asked for clarification on concepts discussed in earlier interviews or about issues that came up during initiation of the intervention study.

In the pilot intervention study, data were drawn from detailed ethnographic field notes (Warren & Karner, 2005) taken by the research assistant on all contacts with participants over the course of their participation in this 6-month study. Notes explicitly focused on the process of research participation that could help assess feasibility of the program for future application. This included interactions relating to appointment scheduling, communication, family, transportation, and disability, as well as commentary on research from the participants.

Each study obtained approval from the Institutional Review Board at Boston University Medical Center and received Certificates of Confidentiality from the National Institutes of Health.

Analysis

Grounded Theory methods (Glaser & Strauss, 1967; Strauss & Corbin, 1990) were used to analyze the data, wherein themes found in earlier interviews were asked about in subsequent interviews for clarification if they were not spontaneously mentioned. The racially and professionally diverse research team represented a range of viewpoints for data interpretation. It included 3 White members and 3 Black members, and consisted of 2 physicians, 2 college-educated research assistants, 1 clinical psychologist, and 1 professor of public health. Team members listened to and read over the interview transcripts from the cross-sectional study and the field notes from the pilot intervention multiple times to create a coding scheme. At least two members coded each cross-sectional interview using NVIVO v. 7 software (QSR International Pty Ltd), resolving coding discrepancies through discussion with another team member. The pilot intervention field notes were coded by hand by at least two team members, resolving discrepancies with another team member. A full coding scheme was created from the cross-sectional interviews before analyzing the complete data from the pilot intervention. However, the field notes offered additional themes and ideas, and were integrated with the cross-sectional interviews. In some cases, the qualitative interviews explained observations made of the intervention. Questions on interpretation of data were clarified weekly with two violence intervention advocates, including one with a history of a gunshot wound. Throughout both studies, the team practiced reflexivity (Maruta, Swanson, & Finlayson, 1979) by continuously attending to the feelings and biases that emerged for them throughout the research process.

Results

Analysis of data from the cross-sectional and pilot intervention studies revealed challenges and facilitators to conducting research with Black male victims of community violence. Themes related to challenges, facilitators, and recommendations are described below along with the social context in which they occurred. Challenges to research centered on mistrust of the research process in several contexts, including fear of police involvement, an impression of "snitching" when revealing personal information, mistrust of research motives, and suspicion of the informed consent process. Other challenges included the emotional impact of the trauma itself as well as logistical issues. Facilitators to research included monetary incentives and motivation to help oneself and others. Participants' recommendations for recruitment are also presented. Unless otherwise noted, data came from the cross-sectional interview study. See Table 1 for a summary of these findings.

Challenges

Fear of police involvement. When asked about barriers to research participation, 7 (44%) of the 16 cross-sectional study participants voiced concern about police involvement in the research process. In particular, they feared that police could obtain information from the study to use against the participant or make a case in the injury investigation. One participant commented, "Like . . . maybe the undercover police, they're trying to find out the whole situation, what's going on with the story. Or, they might feel that you may give this story to the police." Another stated, "People think, 'Oh, they're trying to get some information from me. To get me caught up with the police or something like that."

One participant attributed this concern of being approached for research while hospitalized to the timing of the police investigation relating to his injury, ". . . 'cause most likely, the police usually come right after an injury. Then you guys come, so therefore, it's like, 'Well, the police just came. They might be connected to the police, too.'" This suspicion can lead some people to refuse speaking with anyone, as indicated by a participant who said: "I'm not talking to

Table 1
Recommendations for Conducting Research With Black Male Victims of Community Violence

Challenge	Recommendation
Fear of police involvement	Include on recruitment material: "Information will not be shared with police"; specify that you are not affiliated with police during initial approach and provide detailed information about the study to participant
Impression of snitching	Make privacy rules clear by reviewing rules again after consent, particularly relating to tape recorder or use of information
Mistrust of research motives	Provide information on purpose of research, funding and benefit to researchers Initial point of contact should be someone of similar background to potential participant-age, race, sex
Confusion of informed consent language (Principal) Investigator	Substitute with "research team member," "research director"
Privacy laws	Talk to IRB about ways to clarify language in consent form or through a consent script to make it easier to understand; explain specifically how data and forms are kept private—"This consent form will not go in the file with the other information you give us." or "We do not use your name on any of the forms other than the consent form"
Not open to discussing injury	Use mellow approach methods to first gauge the potential participants' willingness to talk
Logistical problems	Flexible scheduling, expect that many appointments will be missed, will start late, or will have to be rescheduled Provide taxi vouchers Use separate study telephone not attached to hospital line

Note. $n = 16$ for the cross-sectional study and $n = 11$ for the pilot intervention. The confusion of informed consent language, privacy laws, and logistical problems are informed by the cross-sectional and pilot intervention study. All other points are informed by the findings in the cross-sectional study.

anybody . . . "cause I don't know who they are, where they're from and what they're about."

Snitching. Five (31%) participants in the cross-sectional study spontaneously mentioned the perception that talking to researchers is a form of "snitching" or "ratting" on somebody. This included the fear that information would be shared outside of the research setting, and that participants were being "set up"; responses indicated misunderstanding the rules of privacy. One participant said:

> You don't want to talk about it. You get injured, you're like, "I'm not snitching. I'm not saying nothing to NOBODY. So, just talking to any study, or whatever, whatever, even though all the rules of the . . . of the study is . . . explain it's confidential and all that, but at the same time, some people just don't have their mind together and they think it's a form of snitching.

The use of recorders in the interviews played a role in the concern for information getting released, "Then you got a tape recorder right there, I'm like, 'Yo, what's that?' I don't want to swear but what the "f" are you going to do with that?"

Mistrust of research motives. Participants also noted that the motivation behind research was suspicious as exemplified by the language used to describe research, such as "there's always a catch" and "conspiracy." Two (13%) cross-sectional study participants identified research with lab animals, "You can't sit there and treat people from the inner city like a bunch of lab rats in a tank." Three (19%) participants discussed the belief that researchers have a "financial gain" in conducting studies:

> "The results of this research may be published in a medical book by White people for White people, to further benefit from your misery." That's what [the consent form] should state, like, [the research assistant] . . . is conducting this study, which is a LIE! So, why wouldn't she? She's . . . she's from [a hospital], right? With the rest of the White people that profit from all this misery? Very beneficial business.

This "profit" was assumed to benefit only the researchers, and not the participants or community, "Okay, it's a research study, they're gonna take my information and probably benefit, you know, from me, on a financial gain, and, you know, what am I gonna get out of it?"

Informed consent. Participants in both studies doubted the privacy protections provided by informed consent. It is important to note that all participants in both studies had undergone an informed consent process before the interview. One participant in the cross-sectional study said:

> 'Cause some people can say, "Yeah, this is a consent form, and we're not gonna give any information back," but then some people have different doubts, and they really think it's a situation like, "Well, I don't know, they might be trying to set me up in this situation."

Language of the consent form played a large role in this misunderstanding. During the pilot intervention, one participant signed the consent form. Later, he showed his copy to his mother. The next time the research assistant contacted the participant, he explained that his mother was concerned that his information would not be kept private and confidential AFTER she read the consent form, particularly the clauses that describe when researchers would be required to report private information. The research assistant explained the privacy laws again to both him and his mother, and the participant decided he would continue to participate. Additionally, the peer advocates working with the researchers noted that some study participants visibly tensed when hearing the words "principal investigator" read by the research assistant, as this term sounds similar to law enforcement terminology.

Not open to discussing injury. Another challenge to getting victims of community violence to participate in research relating to their injury was the emotional difficulty of talking about the injury. This concept was mentioned by 5 (31%) cross-sectional study participants. In the aftermath of the injury, victims of violence may understandably need time to sort out their feelings about the events. Feelings of fear, anger, disrespect, shock, and trauma were all mentioned as reasons why one may not want to participate in research soon after an injury, "After something happens to a person, depending on what happened and circumstances, it takes awhile for them to really get over the shocking point of it. You know what I mean? So it's like . . . 'give me time to BREATHE!'"

Participants mentioned the importance of taking into account the situations they encountered during the injury episode when approaching them about a study related to their injury, as this may affect their willingness to talk to unfamiliar researchers about what happened, "Like, Lord knows what might have happened when that person got shot. Like their best friend could have got killed and they just got injured, and they don't want to talk to nobody."

Because many victims of community violence are injured at a young age, one participant suggested that willingness to talk about the injury may also relate to the maturity level of the person at the time of the incident:

> Like, back then, I wouldn't have had time because I would rather be playing, than sitting up with somebody and talking for an hour. Like now, like, I'm grown, now. Like, I could sit here and conversate with you for an hour.

In addition to not wanting to discuss an injury right after it occurred, 4 (25%) of the cross-sectional study participants talked about the emotional pain that can come from bringing up the events of an injury that may have occurred several months or years ago, "You know, it hurts some people to think about it, you know? And their mind starts having flashbacks, you know? I'm dealing with them . . . memories that you're trying to suppress."

Logistics to research execution. During the intervention study, the field notes demonstrated a series of logistical challenges to working with this population, including scheduling appointments, telephone communication, and transportation. Appointments were scheduled to fit the needs of participants. Two (18%) of the 11 intervention participants had reversal of a day-night sleep cycle because of issues such as nightmares or an unstructured lifestyle, so they could only meet in the afternoons. Four (36%) intervention participants did not like to get home close to, or after, dark for fear of safety, so they requested morning appointments. Two (18%) intervention participants had childcare responsibilities and could only meet at certain times or days. Finally, on numerous occasions, participants did not show up at all or called at the time of the original appointment to change the time.

Telephone communication proved to be difficult throughout both studies. Participants rarely answered telephone calls when the caller identification showed a hospital telephone number. To address this issue, the study team purchased a cellular telephone for

the study, and noticed an immediate increase in the number of calls answered and returned. Of the 20 unanswered calls made using the hospital telephone for the intervention, just 4 (20%) were returned. By contrast, 4 out of the 9 (44%) unanswered calls from the study cellular telephone were returned. In addition, the hospital database of contact information was often incorrect. When asked about this in the cross-sectional study, one participant explained that providing inaccurate contact information reflected the "G-code," signifying a "gangster" code.

> That's . . . that's like sticking to what they call in the street, is like sticking to the "G Code." They . . . people just wanna get . . . get help that they need or whatever. But they don't want to . . . they don't want to participate in stuff, like the studies like this because they think this is like a form of snitching.

This participant explained that patients will be polite while getting treatment but may give a false telephone number to prevent any follow up contact.

Another issue stemming from telephone communication was the inability of some participants to maintain cellular telephone minutes. Three (27%) out of the 11 intervention participants lost their jobs after their injury and were unable to continue paying for their minutes. Four (36%) never had a steady income and it was unclear when cellular telephone minutes would be added back to the telephone. A second contact number was always taken at the screening for both studies, however, participants were not always available at the second contact, did not regularly stay at the location of the telephone, or it was the number of a person they might or might not see during the course of the study, like a parent or case manager.

A third logistical issue was transportation difficulty. Few participants had their own vehicles. All participants in the pilot intervention and 3 out of 16 (19%) in the cross-sectional study noted the fear of taking public transportation. At least one participant in each study was injured while on public transportation, and others were aware of the potential vulnerability while taking public buses or subways. One participant in the cross-sectional study describes his reaction to the police wanting him to take the bus down to the courthouse to testify as a witness:

> But, you know that, after . . . after something like this happen, there's no way you expect me just to get on the regular public transportation and come on down to the courthouse. That's unrealistic. That was like a death trap right there.

Physical disability can also affect transportation. Among the 11 intervention participants, 1 was paraplegic because of a spine injury, while 6 (55%) had leg injuries. This made traveling by public transportation or walking to the appointments challenging. To overcome both issues, taxi vouchers were provided in the pilot intervention for travel to and from appointments. Positive feedback was received from the pilot intervention participants regarding the vouchers, and none missed their medical appointments.

Factors Facilitating Research

Monetary incentives. When inquiring about facilitators to recruiting victims of violence for research, 7 (44%) of the 16 cross-sectional participants responded with some type of incentive, money being the most common. One participant stated, "I wouldn't do it if it was for free. I'd be like, 'I'm not gonna waste an hour of my time to like tell somebody about getting shot, and like get nothing out of the deal.'" Examples of nonmonetary incentives included counseling referrals ("So, you want to advertise, throw that out and say, 'Well, so, for our research, we'll also seek you help.'"), gift cards to toy stores ("I know that money's gonna go to my daughter"), movie passes, and food.

Participants mentioned not having a place to live, financial need, school loans, and the economy as some of the reasons for the importance of monetary incentives, "And it's sad to say that $25 might be life-altering at one time, another. They might need that money to go to work, or day labor, or whatever have you." One talked about the importance of compensation because it makes a person feel like they are participating in something meaningful: ". . . the money gives them the incentive to really feel like they're doing something."

Motivation to help oneself. Another reason why participants wanted to do research was they felt it would be beneficial to their own life. According to one participant, "You don't know what you might get out of it." Four (25%) cross-sectional participants believed that accessing resources through an intervention study, particularly counseling, would be a good incentive to participate in research.

> However, when you have a lot of people around you with a lot of feelings, you know what I mean, a lot of support . . . you know what I mean, it's gonna bring you to that point where you could get, you know, get . . . a little bit out of it. I'm not, I'm not saying all of it; a little bit out of it.

Conversely, not recognizing the personal benefits of research was also mentioned as a reason why one may not participate in a study. One participant said, "And I think most people'll go, 'Oh, f**k it. I ain't gonna go in there and tell them my God d**n life. Forget that. No, no, no. They, they ain't gonna do nothing, no way.'" Another explained, ". . . it's like, 'Well, I need my self-helped out. So, why would I want to help this person out if I can't get helped out?'"

Motivation to help others. Six (38%) cross-sectional participants also talked about wanting to help future victims of violence and their community as an incentive for participating in research, "At least you're being open to giving you suggestions and making things better for, not, maybe not yourself but somebody else later on down the line." One participant said he wanted to help researchers gather information with the hopes that more studies will develop from the new information. Seven (44%) cross-sectional study participants talked about the societal benefits that can come from someone participating in research, and six (38%) thought researchers should mention the potential societal benefits during the recruitment process to help people decide on whether or not to participate.

> I would say just, um . . . explain it in detail how, by their feedback, can contribute to the research study, to be beneficial for just . . . for society, in general, because it is a research study, and any research study that you do, if it's really successful, the whole . . . the society in general can benefit from it.

Participants' Recommendations for Effective Research Recruitment

Recruitment approach. Two main components to recruitment approach included specific behaviors and the demographic

make-up of researchers with initial patient contact. Participants suggested a mellow approach that begins with a brief introduction. It was important to acknowledge that the potential participant is injured by first inquiring about how they are feeling during the introduction, "I'd start off with flyers, and just giving them the brochure about, what we're about and what are we trying to do . . . Give them . . . and say, make them feel comfortable."

Two (13%) cross-sectional study participants suggested that family may play a role in recruitment. This was apparent in the intervention study, as several participants had their mothers or girlfriends present during the enrollment process and asked these women to come to appointments or help schedule appointments. "So, if you have a family member—somebody's mother, sister, girlfriend, wife—they could persuade them and point them in the right direction and tell them . . . without them have to think about it and evaluate the situation their self."

Two (13%) in the cross-sectional study suggested that the person approaching the potential participant should be someone who appears to come "from the same situation" or be of the same racial background so as to enhance the comfort level.

> Well, I can tell you, for . . . if there was a young Black male sitting in that hospital bed, you bet, you know, your chance would probably be better sending in the youngest Black male person you have workin' for you. 'Cause . . . I know for sure, man, it's all about eyes. And the first thing you see. Before you even open your mouth, I'm seeing you. And if you look different, or if you look, you know, something that I'm not used to seeing, I'm automatically gonna shut down about this much.

The researchers should take great effort to clarify that they are not affiliated with police officers when approaching potential participants in the hospital. Participants suggested providing information about the study to make this distinction.

> So it's all about . . . really . . . showing them that, "We don't mess with the police. That, we don't talk to them or give any information that you give to us TO the police." You know what I'm saying? If you really can prove that to that person . . . you'd get like . . . more people to come in and see you.

Participants also emphasized the importance of making the person feel like this is an "honest situation" and "productive." One talked about offering a study that fits the needs of this population,

> A lot of people need . . . need, need networking and, you know, resources. I mean, if you're just coming to sit there and talk to me, hold my hand, I mean, that's . . . I could call my girlfriend for that . . . a lot of these young cats feel like they don't have too many options. Or, you know, a lot of them don't have a direction yet. So, it all depends on what you're coming to the table with.

Participants said that in the initial contact, researchers should give patients a brochure with a telephone number where they can be reached. Leaving a number on the brochure may help recruit people who plan to follow through on the study. When discussing the content of the recruitment material, some talk about the language that should be included. One participant said the brochure should, "cater more to the actuality of their situation . . . You have to get them inspired first."

Timing. Timing of recruitment was also an important factor given the multiple stressors following an injury: "And reach out when the time is RIGHT. You know what I'm saying? You reach out when the time is right, you'll find people who . . . who are definitely sincere with their injuries and WANT to talk about it." Reasons cited as to why it might be difficult to recruit from the hospital included injury severity, adjusting to new medications, legal issues stemming from the incident, anger, maturity level, and trauma from the injury, "Under them circumstances? You, you are not trying to have that conversation. You know? You're just trying to get taken care of, and . . . you're probably tired, angry, confused . . . you know, just like, want to be left alone."

Eight (50%) cross-sectional participants talked about the emotional sensitivity they felt after their injury that likely would have inhibited them from signing up for a study in the immediate aftermath, with anger specifically mentioned by four participants, "Some people, when you talk to them about a situation, they just get more angry. And if you don't be careful, they'll take it out on YOU!" Participants suggested how long to wait when approaching potential participants that ranged from having time to "rest" and "get comfortable" in the hospital to after "recuperating and settling in" at home.

Discussion

This paper reports on challenges and facilitators to conducting research with Black male victims of community violence. Although some challenges are likely to be common to all populations (e.g., scheduling logistics), the most potent challenges for research participation seen in these studies relate to the inner city street culture in which many of these men are immersed. These barriers, including fear of police, an impression of snitching, and mistrust of institutions, may be explained by what sociologist Elijah Anderson refers to as the "Code of the Street" (Anderson, 1994). He defines this as a set of rules found among inner city Black communities in response to the perceived failure of mainstream institutions to serve their needs, including law enforcement agencies. This Code encourages youth to take control of their own safety by protecting themselves instead of seeking help from, or cooperating with, the police; speaking to the police is viewed as defying the Code. Instead, violent injury may lead victims to carry weapons or seek retaliation to protect themselves (Rich & Gray, 2005). Those who do seek help from law enforcement after an injury may be viewed as weak and unable to defend themselves and vulnerable to future attacks. Black male victims of violence may or may not be actively involved in gangs or street violence. According to Anderson, however, even those who do not have gang affiliations may have shared mistrust of police (Anderson, 1994). This emphasizes the recommendation that research personnel clearly show they are not affiliated with police in printed recruitment materials and via personal reassurance by those conducting recruitment so participants do not feel they are helping police build a case against the perpetrator of their injury by participating in research.

"Stop snitching" is a campaign started among inner city youth meant to discourage cooperation with police regarding investigations into criminal activity (Schorn, 2007). This slogan can be found in music, movies, and clothing. As many study participants mentioned, research participation can be viewed as a form of snitching, particularly if people believe the information is shared with police. Ensuring that participants clearly understand the privacy rules may help alleviate some concern that information can be shared outside of research teams. This may be particularly relevant among participants who use illicit substances, which was an entry criterion for the pilot intervention. However, as seen in this study, the current informed consent

process may not be clear to those who do not typically engage in research.

Concerns about privacy and informed consent are not a novel finding. In one study of African American patients from public and private primary care clinics, participants who reviewed a consent form containing Health Insurance Portability and Accountability Act (HIPAA) authorization were less likely to consider taking part in the study than those who reviewed a consent form with no HIPAA authorization because of mistrust toward the research, research personnel, or research institutions (Dunlop et al., 2007). Working with Institutional Review Boards to make privacy clauses more understandable may help recruit and maintain participants in research studies, particularly with populations that may have issues with trust and privacy. In addition, obtaining a Certificate of Confidentiality from the National Institutes of Health may alleviate some concern of information being shared with law enforcement agents because of the protections it provides. However, researchers need to use terminology that participants understand when explaining the Certificate's protections and be aware of similarities to terminology used by law enforcement.

Previous research has noted the barriers to conducting health care research with African Americans, particularly the mistrust in research institutions (Corbie-Smith et al., 1999; Rajakumar, Thomas, & Musa, 2009; Shavers, Lynch, & Burmeister, 2002). Contributing to this mistrust is knowledge of the Tuskegee study, which may negatively influence people's willingness to participate in research (Shavers, Lynch, & Burmeister, 2002). However, because none of the participants in these studies mentioned this as a reason for mistrust in research and they were not specifically asked about Tuskegee, it is unclear the role it plays among this particular population. Cultural mistrust, stemming from historic and current experiences with racism (Whaley, 2001), may also discourage African American research participation. Studies have shown that African Americans with high levels of cultural mistrust prefer working with Black clinicians and may not be comfortable disclosing personal information to White clinicians (Townes, Chavez-Korell, & Cunningham, 2009). This may relate to sharing personal information to a White research team member. Additionally, among Black male victims of violence, the mistrust in research may also relate to the Code of the Street and fear of getting arrested, reinjured, or killed if a participant discloses too much about the injury circumstances. The importance of cultural competency is often emphasized when conducting research with minority populations (Cooley, Boyd, & Grados, 2004). Awareness of and sensitivity to street culture should be considered when working with inner city populations who may be influenced by the Code of the Street, as well as the influence of cultural mistrust on African Americans' willingness to disclose information. Having a research team member that potential participants feel they can trust may help engage them in research.

Another challenge noted in this study was the difficulty recruiting patients in the early aftermath of the injury. Several factors may influence this, including emotional outcomes experienced after a traumatic event, such as peritraumatic distress and peritraumatic dissociation (Fein et al., 2002; Fein, Kassam-Adams, Vu, & Datner, 2001; Johansen, Wahl, Eilertsen, Hanestad, & Weisaeth, 2006). Logistical issues demonstrated a need for flexibility in scheduling follow-up appointments that related to an injury, such as sleep disturbances, because of physical and emotional outcomes of the injury. The challenge of recruiting victims of violence in the aftermath of the event corroborates findings in other studies working with trauma survivors (Stein et al., 2007). Scott and colleagues tested a study design that considers issues in research with trauma survivors that were found in this study, such as mobility and safety concerns (Scott, Sonis, Creamer, & Dennis, 2006). Similar to Scott's study, researchers should explore different research models for recruiting and randomizing victims of violence in the aftermath of the trauma.

Participants' desire to help others may be an avenue for which studies can increase recruitment. This has been seen among victims of other traumatic experiences (Campbell & Adams, 2009). In our study population, this desire may also stem from the idea of collectivism, the belief that the group or family is at the core of a society (Oyserman, Coon, & Kemmelmeier, 2002), a concept that has been found to be higher among African American populations (Kreuter, Lukwago, Bucholtz, Clark, & Sanders-Thompson, 2003). People with a strong sense of collectivism put their community before themselves and value loyalty, respect, and helping others (Kaniasty & Norris, 2000; Kreuter et al., 2003). Helping Black male victims of violence understand that participating in research can potentially help their community may help increase enrollment into research.

Findings from this study also reveal the high level of financial need among this population. While some may have had this need before their injury, because of the low-income environment from which they came, many were unable to work after their injury because of new physical and emotional disabilities. Communication was a common challenge with study participants, particularly because of the lack of steady income that may otherwise pay for a telephone or the unstable housing that would otherwise provide a steady telephone line. This made it difficult to stay in touch with participants and led to lost participants and rescheduled appointments. Participant availability has been an issue in other studies recruiting inner-city victims of violence because of the frequent mobility found in this population (Zun, Downey, & Rosen, 2006). A study looking at the psychosocial needs of victims of violence found the highest needs to be educational and occupational (Zun & Rosen, 2003). Study incentives catering to the needs of this population, such as money or telephone minutes, may play an important role in getting inner city victims of violence to enroll in studies. Using cellular telephone minutes as an incentive may have dual benefit, both for the participant, as well as for scheduling follow-up appointments.

Through the reflexivity practiced by the research team, investigators tried to be sensitive to what they were asking of participants, especially given the emotional trauma many participants had experienced. It may be appropriate for researchers working with this population to communicate empathy about the burden participating may place on potential subjects. Investigators may also want to emphasize that they are dedicated to preventing violence and assisting victims of violence, and not just there to "profit off participants' misery." They may also comment on the timeline for implementation of changes based on the results so participants do not feel that they provided information with no outcome for themselves or their community.

This study has several limitations. One is the small sample size, which in part may have been influenced by some of the barriers discussed in the results. Information was collected only from those who actually participated in research, thus, information on those who did not participate was gleaned from observation in the intervention component or by conjecture of participants who described how they felt when they were younger. However, a research bias exists toward those who were truly willing to participate in research. In addition,

this data has geographic limitations of an inner-city population in the Northeast, and may not generalize to other locations. The data also may not generalize to Black males who come from more educated, higher socioeconomic, or less urban backgrounds.

In the cross-sectional study, some participants were interviewed by White researchers, which may have influenced their willingness to disclose personal information if they had a high sense of cultural mistrust. The research team included both White and Black members, which may have had inadvertent bias toward the development of codes and themes based on racial or other experiences. To mitigate this, all members of the team reviewed all iterations of the manuscript to ensure that the views represented their own understanding of the issues. The team felt that the differing view points helped articulate, clarify, and interpret findings for each other. In particular, grasping the ramifications of the profound level of mistrust in research and health care systems in study participants spurred a change in consciousness among some team members.

Despite these limitations, this study attempts to provide information that will help in future research with Black male victims of community violence. As a qualitative study, the results provide information on which to base hypotheses for future testing. Future research should test study designs that incorporate the recommendations provided by our sample to see if they lead to greater recruitment, such as timing of recruitment, providing appropriate incentives, and creative communication avenues that may help with scheduling and follow-up. When working with this population in general, researchers should attempt to establish trust by involving peers in the recruitment process and by specifying that they are not affiliated with law enforcement; this may address some of the barriers to research participation. Finally, future research with Black male victims of community violence should be mindful of the cultural context in which these men have grown up and the emotional effects of the traumatic experience. Novel protocols should be adapted to fit within these contexts to maximize their effectiveness.

RESEARCH ARTICLE

Comparison of Health Outcomes for Male Seniors in the Veterans Health Administration and Medicare Advantage Plans

Alfredo J. Selim, Dan Berlowitz, Lewis E. Kazis, William Rogers, Steven M. Wright, Shirley X. Qian, James A. Rothendler, Avron Spiro III, Donald Miller, Bernardo J. Selim, and Benjamin G. Fincke

Objectives. To compare the Veterans Health Administration (VHA) with the Medicare Advantage (MA) plans with regard to health outcomes.
Data Sources. The Medicare Health Outcome Survey, the 1999 Large Health Survey of Veteran Enrollees, and the Ambulatory Care Survey of Healthcare Experiences of Patients (Fiscal Years 2002 and 2003).
Study Design. A retrospective study.
Extraction Methods. Men 65+ receiving care in MA (N= 198,421) or in VHA (N= 360,316). We compared the risk-adjusted probability of being alive with the same or better physical (PCS) and mental (MCS) health at 2-years follow-up. We computed hazard ratio (HR) for 2-year mortality.
Principal Findings. Veterans had a higher adjusted probability of being alive with the same or better PCS compared with MA participants (VHA 69.2 versus MA 63.6 percent, $p<.001$). VHA patients had a higher adjusted probability than MA patients of being alive with the same or better MCS (76.1 versus 69.6 percent, $p<.001$). The HRs for mortality in the MA were higher than in the VHA (HR, 1.26 [95 percent CI 1.23–1.29]).
Conclusions. Our findings indicate that the VHA has better patient outcomes than the private managed care plans in Medicare. The VHA's performance offers encouragement that the public sector can both finance and provide exemplary health care.

Key Words. Health outcomes, system comparison, quality of care

The Veterans Health Administration (VHA) is one of the largest integrated health care systems in the United States and provides health care to an aging veteran population (Ohldin et al. 2002). In 1995, VHA launched a major

health care transformation by adopting managed care principles (Flynn, McGlynn, and Young 1997). It included the use of information technology, measurement and reporting of performance, and integration of services and realigned payment policies (Kizer, Demakis, and Feussner 2000). By 2000, the VHA performance as measured by processes of care was better than that in the Medicare fee-for-service (FFS) program and in commercial managed care plans (Jha et al. 2003; Asch et al. 2004). However, whether this improvement has extended beyond processes of care and into patient outcomes has not yet been fully examined.

The few studies that have compared patient outcomes in the VHA with other health care systems used data collected in the early stages of the VHA transformation. The evidence on health outcomes for the VHA is mixed. For example, using data from 1993 to 1996, Rosenthal, Kaboli, and Barnett (2003) found that the VHA had higher mortality rates after coronary artery bypass grafting when compared with private sector hospitals serving the same health care market. Landrum et al. (2004) found that elderly male veterans hospitalized for acute myocardial infarction in a VHA facility between October 1, 1996, and September 30, 1999, had higher mortality when

compared with FFS Medicare patients. Studies that used data collected in the late 1990s found differences in risk-adjusted mortality that favored the VHA when compared with Medicare programs and private sector hospitals (Petersen et al. 2000; Selim et al. 2006; Vaughan-Sarrazin, Wakefield, and Rosenthal 2007). These contrasting findings leave unresolved questions regarding how outcomes in the VHA compare to that in other systems. The answer is likely to depend on which systems of care are studied, whether one compares overall outcomes for patients or outcomes regarding particular health conditions, as well as the specific metrics that are used.

In a prior study that used data collected between 1998 and 2000, we compared the VHA and the Medicare Advantage (MA) plans (Selim et al. 2007). This comparison was relevant because MA is a Medicare program that provides comprehensive health services to 4.6 million patients (12 percent of the Medicare population) through contracted private managed care organizations (MCOs) throughout the United States (Centers for Medicare and Medicare Services, HHS 2005). The MCOs are heterogeneous and we refer to them collectively as MA. We found that the adjusted probabilities of being alive with the same or better physical health at 2-years follow-up were comparable between the VHA and the MA (63.6 and 64.4 percent, respectively). The adjusted probability of being alive with the same or better mental health at 2-years follow-up in the VHA was significantly higher than in the MA; however, the magnitude of the difference was small (71.8 versus 70.1 percent, respectively). This cross-system comparison study was made at an early stage of the VHA transformation and was based on a limited number of patients. Given the continuing improvements in the VHA in the management of patients with chronic conditions (Asch et al. 2004; Kerr et al. 2004), it is possible that the results would be different with the use of contemporary health outcome databases (Higashi et al. 2005). A study with a larger number of patients might also reveal differences in outcomes for certain vulnerable subpopulations that may be more susceptible to variations in quality of care, such as older patients, patients with multiple medical problems, or racial/ethnic minorities.

In the present study, we sought to verify and extend the cross-system comparisons between the VHA and MA using more contemporary health outcome data and a larger number of patients. We gave special consideration to particular subpopulations that may be at the highest risk of poor health outcomes and in which the VHA has placed a special emphasis on improving care (Asch et al. 2006).

METHODS

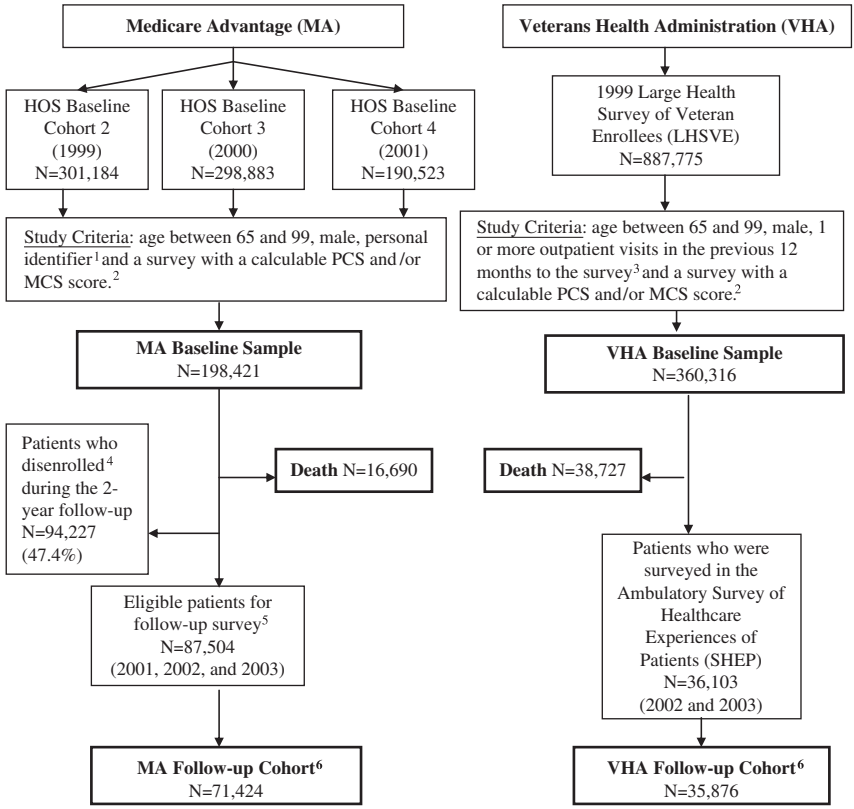
Study Population

The study population from each health care system was restricted to a comparable subset (Figure 1). The MA population was from three cohorts of the Medicare Health Outcomes Survey (HOS): cohorts 2 (1999–2001), 3 (2000–2002), and 4 (2001–2003). The Medicare HOS randomly selected a cohort of 1,000 beneficiaries who were continuously enrolled for at least 6 months from each of the Medicare MCOs (HEDIS® 2003). With the exception of a few specific contract types, all Medicare MCOs participated. The response rates were 66.5, 71, and 68.4 percent at baseline and 84, 77.1, and 78.4 percent at follow-up for cohorts 2, 3, and 4, respectively. The MA population was limited to those beneficiaries aged 65–99 who had person-level identifiers needed to link the HOS data to other databases. Given the disproportionate male representation in the VHA cohort (97.9 percent VHA male patients versus 51.6 percent MA male patients), both MA and VHA analyses were limited to male patients.

The MA population began with a baseline sample of 198,421 male seniors who had filled out the HOS survey and who had enough data to calculate physical (PCS) and mental (MCS) health scores using a previously validated modified regression estimation (MRE) algorithm for missing data (Centers of Medicaid and Medicare Services 2007a). Among the 198,421 Medicare beneficiaries, 16,690 (8.4 percent) died during a 2-year follow-up period. Only Medicare beneficiaries who remained in Medicare managed care ($N = 87{,}504$) were surveyed at 2 years. Among the 87,504 patients who were surveyed at follow-up, 71,424 had enough SF-36® data to calculate the PCS and MCS scores using the MRE algorithm.

The VHA population was derived from the 1999 Large Health Survey of Veteran Enrollees (LHSVE), a cross-sectional health survey administration (Perlin et al. 2000). The 1999 LHSVE randomly selected a total of 1.5 million veterans from the enrollment file of 3,613,877 individuals. The enrollment file consisted of all veterans registered with the VHA for medical care. The baseline survey administration took place between July 1999 and January 2000. The response rate was 63.1 percent. For the purpose of this study, the analyses were limited to male veterans aged 65–99 who had 1 or more outpatient visits in the previous 12 months and had enough data to calculate PCS and MCS scores using the MRE algorithm (Kazis et al. 2004b). Thus, the VHA baseline sample consisted of 360,316 elderly male veterans. Among the 360,316 veterans, 38,727 (10.6 percent) died during a 2-year follow-up

Figure 1: Medicare Advantage and Veterans Health Administration Populations



[1] Primary Medicare beneficiaries have a personal identifier (SSN) to link them with non-HOS databases in the analysis.

[2] Patients that responded a health survey (complete, partial complete) and had enough data to score the physical (PCS) or mental (MCS) component summary scores using the modified regression estimates (MRE) algorithms.

[3] This is a sampling strategy that the VHA applies for health care evaluations.

[4] Patients disenrolled from managed care organizations because their plan no longer participated in Medicare managed care or the beneficiaries themselves were no longer enrolled in the same plan.

[5] Patients were eligible for follow-up survey administrations only if they stayed in the same managed care organization in the two years follow-up period.

[6] Patients that responded a health survey (complete, partial complete) and had enough data to score the physical (PCS) or mental (MCS) component summary scores using the modified regression estimates (MRE) algorithms.

period. The VHA follow-up sample was derived from the Ambulatory Care Survey of Healthcare Experiences of Patients (SHEP), which is a patient-centered initiative by the Office of Quality and Performance to assess

satisfaction, functional status, and health behavior information from veterans who obtain care in the VHA (Wright et al. 2006). The SHEP had a response rate of 70.3 percent. Among the 360,316 patients from our baseline cohort, we found that 36,103 veterans were included in SHEP during the fiscal years 2002 and 2003. Only three patients did not respond to the survey. Of the 36,100 veterans, 35,876 had enough data to calculate PCS or MCS scores using the MRE algorithm (Centers of Medicaid and Medicare Services 2007b).

Tables SA1 and SA2 show the comparisons of baseline patient characteristics between the beneficiaries who stayed (enrollees) and those who did not stay (disenrollees) in MA at 2 years and veterans who were surveyed in SHEP and those who were not surveyed. Although the patient characteristics differences were statistically significant, the magnitude of the differences was very small, thus indicating that MA enrollees and disenrollees were similar as were veterans who were surveyed and not surveyed in SHEP.

Survey Methods

The Medicare HOS used the Medical Outcomes Study (MOS) Short Form-36 (SF-36®) Health Survey at baseline and at follow-up to measure health status (Gandek et al. 2004). For the VHA, the Veterans RAND 36-Item Health Survey (VR-36) was used for baseline health status, and the Veterans RAND 12-Item Health Survey (VR-12) was used for follow-up (Kazis et al. 2004a). They differ from the SF-36® in the use of five-point response choices for the role limitations due to physical problems and the role limitations due to emotional problems. There are validated conversion formulas that allow for comparisons of VR-36 and VR-12 scores to those from the SF-36® (Kazis et al. 2004b). We summarized the health surveys into physical (PCS) and mental component (MCS) scales by applying a linear *t*-score transformation with a mean of 50 and a standard deviation of 10 based on the 1990 U.S. population norms (Ware, Kosinski, and Keller 1994, 1995). We accounted for the differences in follow-up sampling strategies between the VHA and the MA by applying sampling weights to the PCS and MCS scores.

Outcome Measures

Based on the concept that patient health lies on a continuum from well-being to death, we used three outcomes: (1) the probability of being alive with the same or better (than would be expected by chance) PCS at 2 years, (2) the probability of being alive with the same or better (than would be expected by chance) MCS at 2 years, and (3) 2-year mortality. A 2-year follow-up was

selected because studies have shown significant changes in health status for this duration (Lorig et al. 2001). The composite outcome measures of being alive with "the same or better" PCS (or MCS) at follow-up were selected because they reflect the health care goal of maintaining or improving the physical and mental health status of elderly patients (Cohen et al. 2002). The cut-off points for the operational definition of change were "two standard errors of the measurement" (SEM) for a single score or 1.414 standard errors of change. We have applied this cut-off methodology for the outcome metrics because changes of this magnitude have been shown to be clinically relevant (Ware, Kosinski, and Keller 1994) and have been validated in previous studies (Ware et al. 1996). Mortality, our other outcome, is a measure that is particularly relevant to elderly patients and might reflect potentially poor quality of care (Reason 2000). We used the Death Master File from the Social Security Administration to ascertain vital status (Schall et al. 2001).

Case Mix Variables for Risk-Adjustment

Based on prior work (Selim et al. 2007), we used three domains of risk: sociodemographics, comorbidities, and baseline health status. Since the risk for health outcomes differs by demographic subgroup, we selected the following sociodemographic variables: age, race/ethnicity, marital status, education, and income (Williams 1996). Because substantial variations in health status among patients with different diagnoses exist, we selected a group of conditions that are commonly encountered in clinic visits and are known to be major indicators of health status (Bayliss et al. 2004). These are self-reported diagnoses of coronary artery disease (CAD)/myocardial infarction, angina, congestive heart failure (CHF), stroke, hypertension, diabetes, chronic obstructive pulmonary disease (COPD) and asthma, and cancer (other than skin cancer). We included baseline PCS and MCS scores in the risk-adjustment models for being alive because they are important predictors of survival (Dorr et al. 2006). The baseline health scores were not included in the change in PCS (or MCS) models because their coefficients are influenced by the baseline score measurement error and intertemporal correlation. All the case mix variables in our analyses correspond to characteristics of individual patients obtained in their baseline surveys.

Statistical Analysis

In order to examine the differences in patient characteristics between MA and VHA, we compared them in terms of sociodemographics, comorbid

conditions, and PCS and MCS scores. Because social circumstances are known to affect medical outcomes, a social disadvantage index was generated and included minority, unmarried, <12 years of education, and income less than U.S.$20,000 (Anand et al. 2006). To compare the differences in the two study groups at baseline, we used chi-square tests for categorical variables and *t*-tests for continuous variables.

To compare change in health status between the MA and VHA, we applied a previously validated methodology (Selim et al. 2007). We first calculated the change in PCS (or MCS) points per unit of time for each health care system. We took the difference between the PCS (or MCS) baseline and follow-up scores and divided it by the median difference, in years, between the baseline and follow-up surveys (in the MA and the VHA these numbers were 2.09 and 3.29 years, respectively). The reason for using the median time was that late surveys tend to be different (in the HOS they tend to be sicker respondents) and follow-up protocols vary. This gave us the change in points per year, which we multiplied by 2 to get the change in points per 2 years. If the change in points has mean μ_D and standard deviation σ_D and the percentage the same or better has mean μ_P and standard deviation σ_P, then the conversion formula to change an average point difference D into a percentage change P is

$$\frac{P-\mu_P}{\sigma_P}=\frac{D-\mu_D}{\sigma_D}$$

The terms were rearranged to a more familiar linear equation form, $P=aD+b$, where P is the probability of PCS (or MCS) the same or better; D is the mean change in PCS (or MCS) points per 2 years for each health care system, which was adjusted using least-squares means to control for sociodemographics and comorbidities; and a is the slope; and b is the intercept. We computed the "slope" and the "intercept" values using harmonic regressions because neither x (change in PCS [or MCS] points per 2 years) nor y (probability of PCS [or MCS] the same or better) is thought of as the dependent variable (Shalabh 2001). It is the harmonic mixture of regressing y on x and x on y. We applied the harmonic regressions to the HOS cohort because we needed to look to some unit of aggregation above the individual respondent in order to do the conversion and the HOS provides a large dataset naturally organized into managed care plans. For example, if PCS goes down by 1 point per year on the average, the converted probability of PCS the same or better is $5.03(-2)+80.61=70.55$ percent. We then combined the probability of PCS (or MCS) the same or better and the probability of being alive (or 1-probability of

death) using the following formulas (Diehr et al. 2003):

$$\text{Probability of being alive with PCS the same or better} = (1 - \text{Prob death}) \times (\text{Prob PCS the same or better})$$

$$\text{Probability of being alive with MCS the same or better} = (1 - \text{Prob death}) \times (\text{Prob MCS the same or better})$$

We computed the probability of being alive separately from the probability of having the same or better PCS (or MCS) at 2 years for two reasons. First, the population on which the vital status can be assessed with reasonable case mix controls consists of all persons who completed the baseline survey. This is a different sample from those who were followed up with survey administrations. Second, the vital status came from a source that was independent from the survey administrations, and therefore did not share any correlated error with baseline assessments. Thus, we used the full baseline sample of 360,316 VHA and 198,421 MA patients for the calculation of the probability of being alive, which was adjusted for sociodemographics (age, race/ethnicity, marital status, education, and income), comorbidities, and baseline health status (PCS and MCS scores). For the calculation of the probability of having the same or better PCS (or MCS) at 2 years, we used the follow-up sample of 35,876 VHA and 71,424 MA patients. We compared the adjusted probability of being alive with the same or better PCS (or MCS) at 2 years between the VHA and MA using tests of significance based on the standard error of the difference:

$$SE(p_1 - p_2) = \sqrt{\left(\frac{p_1(100 - p_1)}{n_1} + \frac{p_2(100 - p_2)}{n_2}\right)}$$

We also conducted additional analysis applying propensity score matching to examine patients who look alike in all observed characteristics.

We used Cox regression models to estimate hazard ratios (HRs) of dying with 95 percent confidence intervals (CI) for the MA compared with the VHA patients. We calculated the adjusted 2-year mortality rates for each health care system as its observed mortality rate divided by its expected mortality rate, multiplied by the mean of the observed mortality rate for all study patients across both systems.

We also examined subpopulations defined by specific patient characteristics since there might be especially large differences between the VHA and the MA, including age (75 and older), ethnicity/race (whites, African Americans, and Hispanics), and selected chronic conditions (diabetes,

hypertension, CAD/myocardial infarction, and CHF). The stratification variables were not included within the subgroup analyses as risk adjustors. The test of significance was adjusted for multiple comparisons using a Bonferroni correction. We divided 0.05 by the 20 group comparisons of the probability of being alive with the same or better PCS (or MCS) at 2-years follow-up between the MA and VHA, resulting in a significant level of 0.0025 as the cut-off.

RESULTS

Table 1 shows the sociodemographic characteristics of patients in MA and VHA. Mean age was 74.0 (SD ± 6) for the MA patients, while it was 73.7 (SD ± 5) for the VHA patients. The VHA patients, in comparison with MA plan patients, were significantly more likely to be nonwhites (17.8 versus 11.0 percent), were less likely to be married (68.9 versus 77.4 percent), were more

Table 1: Sociodemographic Characteristics of Medicare Advantage (MA) and Veterans Health Administration (VHA) Patients

	Medicare Advantage (N= 198,421)	*Veterans Health Administration (N= 360,316)*
Age, years (SD)	74.0 (± 6)	73.7 (± 5)
Race/ethnicity		
Whites	89.0%	82.2%
African Americans	6.4%	8.7%
Hispanics	1.8%	4.8%
Other	2.8%	4.3%
Marital status (married)	77.4%	68.9%
Education (<12 years)	30.7%	38.9%
Income (<U.S.$20,000)	41.9%	65.6%
Social disadvantage index*		
0	38.1%	17.5%
1	29.6%	33.5%
2	22.0%	31.2%
3	8.7%	14.6%
4	1.6%	3.3%

Note. All comparisons between MA and VHA were significant at <.0001

*The social disadvantage index includes minority, unmarried, <12 years of education, and income less than U.S.$20,000. A higher score indicates greater disadvantage.

likely to have <12 years of education (38.9 versus 30.7 percent), and were more likely to earn an income of less than U.S.$20,000 (65.6 versus 41.9 percent). Overall, the VHA had a higher level of social disadvantage than MA.

Table 2 shows the clinical features of patients in MA and VHA at baseline. The VHA patients had a significantly higher disease burden than the MA patients. The VHA patients were more likely to have four or more chronic medical conditions when compared with MA patients (23.5 versus 9.5 percent, respectively). VHA patients, in comparison with MA plan patients, were significantly more likely to have hypertension (65.7 versus 52.2 percent), coronary artery disease/myocardial infarction (28.3 versus 15.7 percent), diabetes (28.2 versus 19.8 percent), COPD/asthma (25.8 versus 13.5 percent), cancer (19.7 versus 15.1 percent), and stroke (15.3 versus 9.3 percent). VHA patients, in comparison with MA plan patients, had significantly worse physical health (PCS scores, 35.7 versus 43.3) and mental health (MCS scores, 45.2 versus 51.9) at baseline.

Table 2: Clinical Features of Medicare Advantage (MA) and Veterans Health Administration (VHA) Patients

	Medicare Advantage (N= 198,421)	*Veterans Health Administration (N= 360,316)*
Number of comorbidities (range 0–8)		
0	25.9%	12.6%
1	32.4%	25.1%

Cancer	15.1%	19.7%
Baseline physical health-PCS, points (SD)*	43.3 (± 11)	35.7 (± 10)
Baseline mental health MCS, points (SD)*	51.9 (± 10)	45.2 (± 13)

Note. All comparisons between MA and VHA were significant at <.0001.

*A lower number is indicative of poor health status for MCS and PCS.

Table 3 shows that the adjusted probability of being alive with the same or better PCS at 2-years follow-up was significantly higher in the VHA when compared with the MA (69.2 versus 63.6 percent, respectively). The adjusted probability of being alive with the same or better MCS at 2-years follow-up in the VHA was also significantly higher than in the MA (76.1 versus 69.6 percent, respectively). The propensity score matching analysis showed comparable results (the probability of being alive with the same or better PCS was 69.3 versus 63.5 percent and the probability of being alive with the same or better MCS was 75.9 versus 69.6 percent for the VHA and MA, respectively). The adjusted 2-year mortality rates were 11.8 and 9.9 percent for the MA, and VHA, respectively, with a significantly higher HR for mortality in the MA compared with the VHA (HR, 1.26 [95 percent CI 1.23–1.29]).

Table 3: Change in Health Status in the Medicare Advantage (MA) and the Veterans Health Administration (VHA)

Health Care System	*MA*	*VHA*
Baseline sample	198,421	360,316
Follow-up cohort	71,424	35,876
Adjusted probability of being alive at 2 years*	88.1%	90.1%

Probability of being alive with the same or better PCS at 2 years	63.5%	69.3%
Probability of being alive with the same or better MCS at 2 years	69.6%	75.9%
Mortality		
2-years adjusted mortality rates*	11.8%	9.9%
Odds ratio (95% confidence interval)	1.26 (1.23–1.29)	1

*The adjustment variables for survival/mortality included sociodemographics (age, race/ethnicity, marital status, education, and income), comorbidities (hypertension, diabetes, coronary artery disease/myocardial infarction, congestive heart failure, stroke, chronic obstructive pulmonary disease [COPD] and asthma, and cancer [other than skin cancer]), and baseline health status (PCS and MCS scores).

†The adjustment variables for PCS (or MCS) the same or better included sociodemographics (age, race/ethnicity, marital status, education, and income) and comorbidities (hypertension, diabetes, coronary artery disease/myocardial infarction, congestive heart failure, stroke, chronic obstructive pulmonary disease [COPD] and asthma, and cancer [other than skin cancer]).

‡All comparisons between MA and VHA were significant at p-value $< .001$.

We found that across the board, subgroups of vulnerable male patients had better outcomes in the VHA compared with those in MA (Table 4). The adjusted probabilities of being alive with the same or better PCS (or MCS) at 2 years in the VHA were also significantly higher than those in the MA across the very old patients (75 and older) as well as the race/ethnicity groups, including whites, African Americans, and Hispanics. Similar findings are also seen across patients with selected chronic conditions, including diabetes, hypertension, CAD/myocardial infarction, and CHF. The magnitude of the differences in the percentage of patients who were either "alive with the same or better PCS" or "alive with the same or better MCS" at 2-years follow-up ranged from 3 to 10 percent higher in the VHA when compared with the MA. The HRs for mortality in the MA were significantly higher than those in the VHA across all subgroups.

DISCUSSION

After adjusting for the higher prevalence of chronic disease and worse self-reported baseline health status in the VHA, we found significant differences in 2-year health outcomes that favor the VHA when compared with the MA. This was true for the average elderly male patient cared for in the VHA as well as for vulnerable subpopulations. This study, based on data collected on males between 1999 and 2003, extends our previous work using data collected between 1998 and 2000 (Selim et al. 2007).

One might argue that the "execution" of the VHA transformation may have contributed to the better health outcomes found in our study. Although each organizational transformation is unique, VHA's experiences offer a number of lessons for future transformations. The transformation framework included the creation of a vision for the future, the adoption of a new organization structure, careful planning and monitoring of performance to achieve system-wide coordination and accountability and the modification in rules and regulations for access to care (Young 2006). The VHA transitioned from a tertiary/specialty and inpatient-based care system delivering care in a traditional professional model into a system focused on ambulatory care. It developed integrated health care networks that have a collective goal of delivering services to a defined population in a coordinated and collaborative manner that maximizes the health care value of the service (Kizer, Demakis, and Feussner 2000). The VHA enhanced equity of access among ethnic minority veterans and mental health care services and implemented a

*The adjustment variables for survival/mortality included sociodemographics (age, race/ethnicity, marital status, education, and income), comorbidities (hypertension, diabetes, coronary artery disease/myocardial infarction, congestive heart failure, stroke, chronic obstructive pulmonary disease [COPD] and asthma, and cancer [other than skin cancer]), and baseline health status (PCS and MCS scores).

†The adjustment variables for PCS (or MCS) the same or better included sociodemographics (age, race/ethnicity, marital status, education, and income) and comorbidities (hypertension, diabetes, coronary artery disease/myocardial infarction, congestive heart failure, stroke, chronic obstructive pulmonary disease [COPD] and asthma, and cancer [other than skin cancer]).

The stratification variables were not included within the subgroup analyses as risk adjustors.

‡All comparisons between MA and VHA were significant at $p<.0025$ based on Bonferroni correction.

sophisticated electronic health record system that improved quality, efficiency, and costs of medical care (Wooten 2002; Chaudhry et al. 2006; Kressin et al. 2007).

The magnitude of the VHA's improved performance in the subgroup analysis is not better than in the full VHA sample, indicating that process improvements in the VHA are broad and not limited to an area in which special programs exist. Research studies in documenting and evaluating the transformation have found similarly broad effects when examining the progress and diverse impacts of the overall reorganization and several of its specific elements, including the creation of a seamless continuum of care, making superior quality consistent and demonstrating good value (Feussner, Kizer, and Demakis 2000; Berlowitz et al. 2001; Jha et al. 2003). Therefore, the creation of a clear vision of the future and a coherent transformation plan having concrete and concise goals and performance measures are essential to a successful health care system based on managed care principles.

There are a number of limitations in this study that might affect our results. First, the MA respondents started with higher scores than the VHA respondents. The reasoning might be that the scores have more to drop in MA because they are higher to start with and would suggest a model where all groups are progressing toward death at a fixed time. We have found that after correcting for regression to the mean effects, those individuals with lower scores start to decline at the same rate or faster than those with higher scores.

Second, the health survey instruments may be insensitive to further decline, which would bias against documenting worsening health status in patients who are already severely ill ("floor effect"). Against this is the finding of other investigators that over half of the patients with low health status were able to report that their health status subsequently declined further (Bindman, Keane, and Lurie 1990).

Third, the two surveys were conducted using different sampling strategies. The MA sample was based on sampling at the plan level, with follow-up survey data subject to continued plan participation in Medicare and the survey respondent's continuous enrollment in the plan. The baseline VHA sample was a population-based survey of all VHA patients and the follow-up sample were those in SHEP. Figure SA1 indicates that MA baseline cohort and those who were surveyed at follow-up were similar as were VHA baseline cohort and those who were surveyed in SHEP. The time between assessments was also different in the two systems. Therefore, the estimates of changes in health status at 2 years are a linear interpolation of changes.

Fourth, this study examines only male patients. There may be differences in outcomes between men and women within the VHA and MA, and for women, comparisons of outcomes between the VHA and MA may differ from that seen in men. Further research is needed to assess the effect of systems of care on outcomes for women.

Fifth, controlling for sociodemographics and comorbid illnesses explained only a fraction of the variance in the change in PCS and MCS. The pseudo R^2 was 0.0021 for PCS the same or better and 0.0039 for MCS the same or better. The same has been true in other studies (Bayliss et al. 2004). The mortality model had a *c*-statistic (discriminative power) of 0.747, which was equal or superior to values obtained in risk-adjusted mortality models for inpatient populations (Best and Cowper 1994; Schneeweiss et al. 2003). Our risk-adjustment methodology did not control for unobservable variables such as quality of care that could be correlated with the health care systems.

Sixth, our outcome measures combine respondents with good health status at baseline who do not decline over the time-frame with respondents in poor health status at baseline who improve. We broke down the composite outcomes into better and same. The categories of change in PCS were classified as (1) "the same" (or unchanged) between -5.66 points and $+5.66$ points, (2) "better" as $> +5.66$ points, and (3) "worse" as < -5.66 points. The categories of change in MCS were classified as (1) "the same" (or unchanged) between -6.72 points and $+6.72$ points, (2) "better" as $> +6.72$ points, and (3) "worse" as < -6.72 points. The cross-system comparison analysis yielded similar results (Table SA3).

Seventh, MA plans are independent and heterogeneous. In particular, there are those that probably look more like the VHA in terms of integration, use of health information technology, performance monitoring, and financial incentives and others that are probably closer to the unmanaged, FFS population. Further studies are needed to evaluate how differences in the organizational characteristics of variations in MA are associated with variation in and the impact on their performance.

Eighth, our work was limited to the comparison of patient outcomes in different settings of managed care. Some evidence suggests elderly patients with chronic conditions enrolled in Medicare managed care experienced greater declines in physical health than similar persons in Medicare FFS (Shaughnessy, Schlenker, and Hittle 1994; Ware et al. 1996). More recent studies of the elderly have found no differences between Medicare managed care and FFS with respect to functional declines and to mortality (Retchin et al.

1992; Riley 2000; Porell and Miltiades 2001). Further research is needed to better understand how these different systems of care affect outcomes.

In summary, our findings indicate that the VHA has better outcomes for men than MA. The VHA's performance offers encouragement that the public sector can both finance and provide exemplary health care. The VHA's experience provides some general, potentially transferable, and useful policy directions that might benefit other health care systems in the public as well as the private sectors.

BRIEF REPORT

How Researchers Define Vulnerable Populations in HIV/AIDS Clinical Trials

Sohini Sengupta · Bernard Lo · Ronald P. Strauss · Joseph Eron · Allen L. Gifford

Published online: 19 August 2010

Abstract In this study, we interviewed researchers, asking them to define vulnerable populations in HIV/AIDS clinical trials, and provide feedback on the federal regulations for three vulnerable populations. Interview data informed a conceptual framework, and were content analyzed to identify acceptability or disagreement with the regulations. Beginning with several characteristics of vulnerable enrollees identified by researchers, the conceptual framework illustrates possible scenarios of how enrollees could be considered vulnerable in clinical research. Content analysis identified barriers affecting HIV/AIDS researchers' ability to conduct clinical trials with pregnant women, prisoners, and children, for which the regulations specify additional protections. This study challenges current thinking about federal regulations' group-based approach to defining vulnerable populations.

Introduction

Vulnerability is a central concept in protecting human subjects in research, and the term, *vulnerable populations*, was introduced as part of the guidelines for medical ethics in the 1949 Nuremburg Code, World Medical Association Declaration of Helsinki (most recent update: 2008), and the 1979 Belmont Report to protect human subjects involved in research [1, 2]. The US federal regulations for protection of human subjects, in 45 Code of Federal Regulations Part 46 (45 CFR 46) require special protections for three categories of vulnerable populations—pregnant women, fetuses, and neonates (Subpart B), prisoners (Subpart C), and children (Subpart D) [1]. In addition, 45 CFR 46, in Subpart A (also known as the Common Rule), requires Institutional Review Boards (IRBs) to consider additional protections for those who are "economically," "educationally," or "decisionally" impaired, without specifying these terms [1].

Using a group-based approach—in which individuals are considered vulnerable if they belong to specified groups—has been criticized to be both too narrow and too broad in scope; too narrow because it does not take into account other factors that lead to vulnerability, or persons or populations with multiple vulnerabilities [3, 4], and too broad because some individuals who belong to these categories are not vulnerable in certain types of research [3,

5]. Another criticism with the group-based approach to identifying vulnerable populations is that the federal regulations do not provide adequate guidance about what additional safeguards should be taken with each of the groups identified [3]. For example, protecting vulnerable populations by barring them from participation in certain clinical trials may be doing more harm than good. Indeed, the current conceptualization of vulnerable populations has made access to clinical trials more difficult for underrepresented groups [1].

While the debate concerning defining vulnerable populations continues among bioethics scholars, only a few empirical studies examine how researchers think about and address vulnerability in clinical trials [6–8]. To date, however, no studies have examined issues of vulnerable populations in the context of HIV/AIDS clinical trials, particularly from the perspectives of frontline researchers. HIV/AIDS, unlike other diseases/conditions, includes individuals and populations with a wide range of vulnerability characteristics—including racial/ethnic minorities, women, and/or injecting drug users—not necessarily specified in the current definition and categories [9, 10]. HIV-positive subjects with one or more of these characteristics may not fit in 45 CFR 46's Subparts B,C, and D. Moreover, the terms, "educational, economic, and decisional impairment" in the Common Rule are not specific enough to assist HIV/AIDS clinical trial researchers to identify and protect subjects who they consider vulnerable.

The purpose of this study is twofold: The first part is to take a grounded-theory approach in developing a conceptual framework for understanding which enrollees are considered vulnerable from the perspectives of researchers working in HIV/AIDS clinical trials. The second part of the study explores HIV/AIDS researchers' perspectives on the subparts of 45 CFR 46 to gain a better understanding of the perceived utility and limits of these regulations for protecting pregnant women/fetuses, prisoners, and children from potential risks.

Methods

Sample and Recruitment

A sampling frame of AIDS Clinical Trials was obtained from the AIDS Clinical Trial Information Service (ACTIS), which was a resource of federally and privately-funded AIDS Clinical Trial information through the Division of Acquired Immune Deficiency Syndrome (DAIDS), National Institute for Allergy and Infectious Diseases (NIAID) [11]. A list of Principal Investigators (PIs) was created in an Excel spreadsheet and categorized by Adult or Pediatric AIDS Clinical Trials Groups (ACTGs), and comprised 31 Adult AIDS Clinical Trials Group (AACTG) sites and 18 Pediatric AIDS Clinical Trials Group (PACTG) sites. In addition, 16 HIV Prevention Trials Network (HPTN) PIs were included in the spreadsheet. HPTN—established in 1999 by DAIDS—is an international clinical trials network that develops and tests the safety and efficacy of primarily non-vaccine interventions designed to prevent the transmission of HIV [12].

All AACTG, PACTG, and HPTN PIs were sent an initial letter via regular mail requesting their participation in a telephone interview, and the names and contact information of their co-investigators or study coordinators so that they could be asked to participate. To PIs, co-investigators, and study coordinators who agreed to participate, a consent form was faxed to them; they were asked to sign the consent form and fax it back before the scheduled telephone interview. Several follow-up email or telephone contacts were made to both investigators and study coordinators to maximize the responses; both refusals and non-responses were documented. Once the interview was completed, investigator- and study coordinator-subjects were mailed a $50 incentive, or the $50 was donated to a charity of their choice. This study was approved by the UNC Biomedical Institutional Review Board.

Data Collection

A semi-structured interview guide was developed and used to conduct the audiotaped, telephone interviews with the investigators/study coordinator subjects. The interview guide included two conceptual domains to explore (a) their definitions of what constitutes vulnerability in HIV/AIDS clinical trial populations, and how they see their study population(s) as vulnerable; and (b) what they think of the current categories of vulnerable populations for which there are special protections in the 45 CFR 46.

Data Analysis

All audiotaped interviews from investigator/study coordinator subjects were electronically transcribed into Microsoft Word. Accuracy of the transcription was verified by a member of the research team, and any identifying information in the interviews was redacted to protect the confidentiality of subjects. The transcribed interviews were imported into the qualitative software program, Atlas.ti, v. 5.2. The first phase of qualitative data analysis involved identifying themes from the questions asked, and developing a codebook reflecting a thematic coding structure underlying the conceptual domains. Codes for each theme were assigned to text using Atlas.ti by a pair of coders per transcript, and inter-coder reliability was assessed by having the coders resolve any coding differences between

them. Thus, the first phase of the analytical process yielded discrete and systematically coded textual data.

Development of a Conceptual Framework

To develop the conceptual framework, we extracted coded textual data elicited from the questions (a) "What is your definition of a vulnerable population?", and (b) "In general, how are AIDS clinical trial (or HPTN) study populations considered vulnerable?" These data were reviewed in a 2-step process. The first step identified indicators of vulnerability elicited from these two questions and organized them into three broad categories reflecting social, treatment-related, and research participation-related vulnerabilities. The next step involved examining co-occurrences between the themes from these broad vulnerability categories that informed a conceptual framework to explore how HIV/AIDS clinical trial populations could be vulnerable in *clinical* research.

Investigator/Study Coordinator Views on 45 CFR 46 Subparts B, C, and D

To explore the perspectives of HIV/AIDS clinical trial researchers on the three categories of vulnerable populations for which there are special protections in the federal regulations, coded textual data were extracted from the following set of questions:

"IRBs identify three categories of vulnerable populations for which there are special protections. They are children, pregnant women/neonates/fetuses, and prisoners.

- Do you think each of these groups should be considered vulnerable populations with special protections, why or why not?
- Do these categories work well to help researchers understand vulnerable populations in HIV/AIDS clinical trials? Why or why not?"

Textual data were then collapsed into *why* or *why not* categories for each of the three vulnerable populations to create a matrix.

Results

Sociodemographics

Of the 65 sites (31 AACTG, 18 PACTG, 16 HPTN) contacted from the sampling frame, 27 (42%) sites' PIs agreed to participate: 14 (45%) representing AACTG, 5 (28%) from PACTG, and 8 (50%) from HPTN. Of the 38 sites that did not participate, 36 of the PIs from those sites never responded to our initial or follow-up requests, and two of the PIs declined to participate (no reasons were given). Furthermore, non-respondent PIs disproportionately represented the PACTG. Table 1 presents the sociodemographics of the 38 investigator- and study coordinator-subjects from the 27 participating sites. Investigators primarily were male (67%) and were physicians (72%), while the study coordinators primarily were female (65%) and were nurses (95%). The majority of the investigators and study coordinators were White (87%).

Conceptual Framework Defining Vulnerable Populations in HIV/AIDS Clinical Trials

The two initial, open-ended questions asking about how study populations in HIV/AIDS clinical trials are vulnerable elicited an array of indicators that we first organized into three broad vulnerability categories: social (e.g., substance/alcohol abuse, homeless), treatment-related (e.g., few options to treatment, newly diagnosed), and research participation-related (e.g., not understanding consent form, participating for inducement, physician-investigator influence). While organizing these vulnerable indicators into categories was useful, these indicators alone did not fully explain the possible circumstances in which HIV/AIDS clinical trial enrollees could be considered vulnerable in

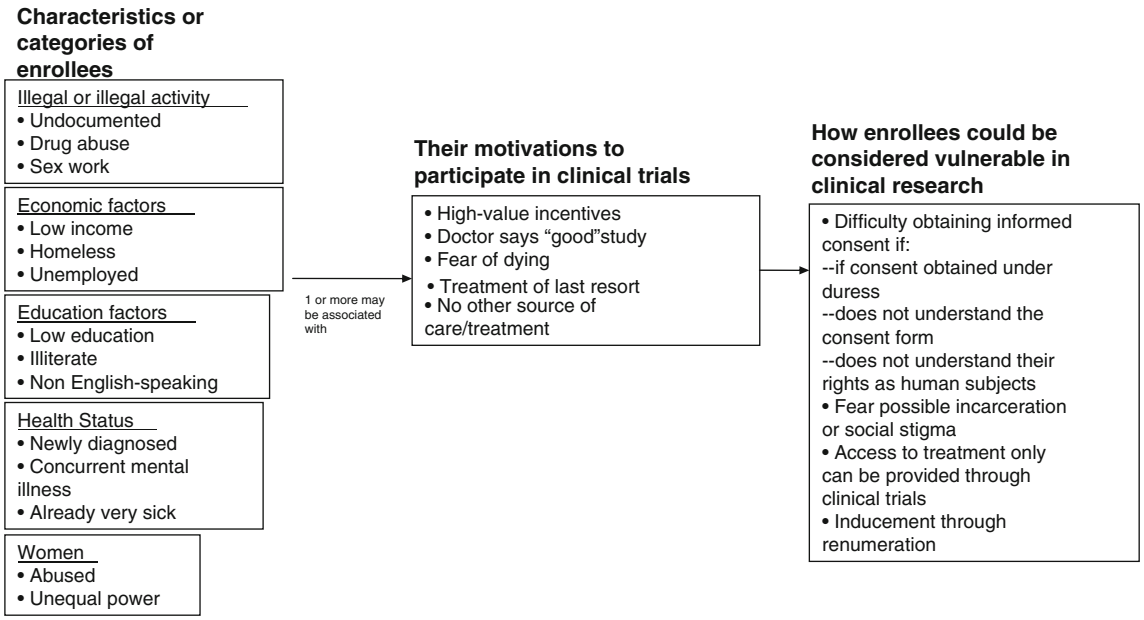

Fig. 1 Conceptual framework for understanding vulnerability in HIV/AIDS clinical trials

clinical research. To answer this question, we explored the thematic co-occurrences among these indicators, which were then used to develop a conceptual framework informing how researchers define vulnerable populations in HIV/AIDS clinical trials (Fig. 1).

The following quotation illustrates an example of the co-occurrences among some of the social, treatment-related, and research participation-related vulnerabilities depicted in Fig. 1; vulnerable population indicators are highlighted in italics. In this example, the study coordinator was sharing a story about a new enrollee who also just found out that he was HIV-positive:

> I'll take an extreme example where I was called into consent a patient…*They needed to be on meds years ago and just found out they're positive*. This individual was tearful through part of our consenting, *just overwhelmed with the new diagnosis, the pills, not understanding that they're not going to be dead in 2 years…And there's a lot of education there but they're only going to take home 10% of what you tell them*…So I mean that is a vulnerable person and I think they're informed as much as we can humanly inform them and they're making a legal consent, but they're vulnerable. *They have their faith in the physician that we're not going to lead them wrong. It's just my doctor said this would be a good study*. (HPTN study coordinator, male)

Relating back to Fig. 1, this quotation reflects the multiple vulnerabilities an enrollee can face in HIV/AIDS in clinical research. This particular enrollee had been sick for while, perhaps was motivated to participate because of the physician-investigator's influence, and believed that he was going to die given the HIV-positive diagnosis. The end result may be that this enrollee agreed to participate, despite understanding very little about the clinical trial during the consent process, because the trial in question may have been the only source of treatment/care available to him at that time.

Investigator and study coordinator subjects also described how their HIV/AIDS clinical trial sites have made efforts to provide special protections to enrollees who have one or more of the vulnerabilities presented in Fig. 1. One special protection that may not be required by IRBs, but was commonly cited by clinical trial researchers, was the implementation of various consent monitoring practices to improve informed consent comprehension at the time of enrollment. In this example, one AACTG female study coordinator stated:

> We do not enroll any study subject that we feel does not have a clear understanding. And we sort of give them like a little quiz…So, for example, we run studies for people that just got diagnosed and just found out they're HIV-positive…If we don't feel like they can handle not only the information of just being diagnosed with HIV and then on top of that a research study, we don't put them in the study.

Other special protections for HIV/AIDS clinical trial enrollees that were described included:

- Informed consent process could be re-visited periodically to make sure enrollees retain comprehension of key information in the clinical trial.

- Having trained staff to provide various services, such as translators to communicate with non-English speakers, social workers to help prevent crises in a patient's life arising from participating in a trial, or guardians present for the cognitively-impaired.
- Having a certificate of confidentiality approved by the IRB, especially for study populations involved in illicit activities.
- Working with high ranking officials and law enforcement officers to ensure research proceeds smoothly when there is illegal activity involved.

Thus, investigator and study coordinator subjects went beyond merely identifying different factors associated with vulnerability to suggesting specific measures to ameliorate the different types of vulnerability their participants faced.

Perspectives on 45 CFR 46 Subparts B, C, and D

Investigator and study coordinator subjects were asked how they felt about the current categories of vulnerable populations for which there are special protections in the Subparts of 45 CFR 46. Table 2 dichotomizes their perspectives by why or why not categories for pregnant women/neonates/fetuses, prisoners, or children should be considered vulnerable.

In general, investigator- and study coordinator-subjects agreed with the need for special protections for the categories of vulnerable populations identified in Subparts B, C, and D of 45 CFR 46 for the following reasons: women/neonates/fetuses because of the potential or known harms to the fetus (25 [66%]); prisoners given their captivity (24 [63%]); and children because of their age (33 [87%]). Yet, the investigators and study coordinator subjects did not view these study populations as always being vulnerable. Their reasons for why they should not be considered vulnerable further demonstrate how they consider vulnerability situational, thus rejecting the regulations' categorizing of these groups as vulnerable in all types of research. The following are sample quotes that illustrate how IRBs sometimes have made it difficult for researchers to enroll potential subjects who are pregnant, prisoners, or children.

For pregnant women:

> Well, the kinds of behavioral research I do, the interventions are applicable or more applicable for pregnant women. There's nothing that we do that would in any way harm the fetus…But I have to explain to the IRB why I'm including them…I don't get it. (HPTN investigator, male)

In this example, the regulations would deem behavioral intervention trials, such as the types described, as having minimal risk to the fetus, but the IRB made it more difficult

Table 2 Investigator and study coordinator subjects' perspectives on 45 CFR 46 subparts B, C, and D

45 CFR 46 subparts	Do you think each of these groups should be considered vulnerable populations with special protections?			
	Why?	*n*	Why not?	*n*
Subpart B: pregnant women/neonates/fetuses	• Experimental drugs could:	30	• Just because a woman is pregnant does not make her vulnerable	1
	1. Cause spontaneous abortion	5	• Becoming pregnant after starting a trial should not be the only reason to rule out a woman's ability to continue in the trial	3
	2. Interfere with fetus development	25		
	• Pregnant women only vulnerable if they are socioeconomically disadvantaged or affected by domestic violence	5	• Pregnant women should not be considered vulnerable in monitoring/observational trials, many prevention trials, and in clinical trials with medications that are proven non-teratogenic	13
	• Hormonal changes affect pregnant women's decision-making	7		
Subpart C: Prisoners	• Prisoners are a captive population. They do not have the ability to make their own choices	24	• Prisoners can make decisions for themselves since they are adults	3
			• Prisoners have better resources in prison than some populations on the outside	2
	• Co-morbid factors may be present, such as high rates of HIV infection or drug use that make them more vulnerable	4	• Entering prison post enrollment, prisoners not vulnerable—they already consented	13
Subpart D: Children	• Children cannot consent for themselves due to their age or lack of maturity	33	• Current age criterion is flawed given that it doesn't take into account cultural and maturity factors when qualifying someone as a child versus an adult	22
	• Parents can consent under duress or desperation and make bad choices for their children	3		

for this investigator's clinical trials site to include pregnant women.

For prisoners:

> We think it's a bad thing [considering prisoners a vulnerable population with special protections]. We would like to be able to continue their involvement in the clinical trial while they were in jail…but the logistics of actually being able to continue to provide research medications while somebody is in jail makes it very difficult. (AATCG investigator, male)

Investigators have to go though additional IRB procedures to be able to conduct clinical trials with prisoners. In this example, the investigator later explains when enrollees should be allowed to continue their participation in an HIV/AIDS clinical trial if they become incarcerated. Indeed, if enrollees are forced to withdraw from the trial, there is no guarantee that the antiretroviral medications they were taking before incarceration would be available to them during their jail time or imprisonment, which could have more harmful implications.

For children:

> In this country maybe if you're 15 and you want to go into a research study your parent or guardian would have to sign the consent as well. I don't think that's realistic in another country. I think that a 15-year-old who has been out working and might be married should be able to sign and consent to a study on their own. (HPTN study coordinator, female)

Similar to the quotation example for pregnant women, the regulations would permit minor assent without parental permission under certain conditions, but this researcher's experience with the IRB may not have allowed it.

Discussion

This exploratory study provides an in-depth and multi-faceted look at the ethical concept of vulnerable populations from the perspectives of researchers involved in HIV/AIDS clinical trials. A conceptual framework was developed that illustrates a combination of vulnerable population characteristics/categories identified from the broad definitions in the Common Rule (e.g., based on socioeconomics), and in prior reviews about HIV-infected and HIV-affected populations [9, 10], but organizes them to show possible circumstances in which HIV/AIDS clinical trial enrollees could be considered vulnerable in clinical research, and for which special protections could be warranted (e.g., consent monitoring in cases where there is educational, cognitive, or treatment-related vulnerabilities). In addition, barriers posed by Subparts B, C, and D of 45 CFR 46 were explored in the context of HIV/AIDS clinical trials, further demonstrating that applying group-based vulnerability can result in unnecessary exclusion of individuals in the vulnerable population categories of pregnant women/fetuses, prisoners, and children. The study's findings are consistent with concerns from bioethicists that vulnerability in research has not been clearly or uniformly defined in the federal regulations on human subjects research, and special protections delineated for select vulnerable populations often have made it difficult for these vulnerable populations to participate in HIV/AIDS clinical trials from which they could benefit [2, 5].

First, the study supports prior recommendations to look at vulnerability as situational, rather then group-based, as is typically used by IRBs in the United States and internationally [3, 4]. At a practical level, we hope that AACTG, PACTG, and HPTN researchers could use the conceptual framework as a guide to identify areas of vulnerability within their respective clinical trial populations, and implement appropriate protections to their informed consent process and/or recruitment procedures. Furthermore, we believe that the factors comprising the conceptual framework are not necessarily distinct to HIV/AIDS and may broaden the conceptual framework's potential to understanding vulnerable populations for other diseases or conditions, or that are distinct to minority groups (e.g., being undocumented). At an institutional level, we hope that local IRBs could use this conceptual framework to expand their thinking about what makes subjects vulnerable in HIV/AIDS clinical trials, and to consider innovative and alternative ways in which researchers could implement additional protections for clinical trial participants with one or more vulnerabilities.

Second, understanding the concerns among HIV researchers on why pregnant women, prisoners, and children should not be considered vulnerable for all types of clinical research strengthens the argument to examine vulnerability as situational. At an institutional level, we hope that these findings could encourage local IRBs to think of these three vulnerable populations more on a case-by-case basis, particularly in situations where clinical trial participants who represent these vulnerable populations stand to benefit from the results of the research.

This study has two main limitations. For the investigator/study coordinator sample, the response rate of 42% at the site level was low even though all 65 sites (31 AACTG, 18 PACTG, 16 HPTN) were asked to participate. Given that we were unsuccessful in interviewing PIs, other investigators, or study coordinators from 38 of the sites, our conceptual framework may be missing other important factors that contribute to vulnerability in clinical research. This is particularly true for PACTG that may have other vulnerable population indicators more relevant when

conducting clinical trials with children (and adolescents). Second, the conceptual framework for vulnerable populations in HIV/AIDS clinical trials is missing the perspectives coming from HIV/AIDS clinical trial enrollees with respect to how they consider themselves vulnerable. Future research may be useful to better explore vulnerability in clinical research from the enrollees' perspective.

In conclusion, the debate over vulnerable populations usually happens among bioethics scholars with little or no input from biomedical researchers about what they think, including if they agree with the current definitions, and their concerns with IRB regulations associated with vulnerable populations. The conceptual framework for understanding vulnerable populations in HIV/AIDS clinical trials was developed in this study from the perspectives of HIV/AIDS researchers to help us move beyond the broad categories of "economically," "educationally," or "decisionally" impaired, or the narrowly focused vulnerable categories of pregnant women, prisoners, and children for which there are special protections in 45 CFR 46. Indeed, the conceptual framework illustrates other plausible relationships of vulnerability, and this study's participants also identified interventions to address certain types of vulnerability, to which IRBs should pay greater attention. Future work on understanding vulnerable populations could expand the conceptual framework to include vulnerable population indicators for other diseases or conditions, and the conceptual framework could be used as a guide to develop interventions that address situational vulnerability in clinical research.

A Transitional Opioid Program to Engage Hospitalized Drug Users

Christopher W. Shanahan, MD, MPH[1,2], Donna Beers, RN, BSN, CARN[2,4], Daniel P. Alford, MD, MPH[1,2], Eileen Brigandi[4], and Jeffrey H. Samet, MD, MA, MPH[1,2,3,4]

[1]Clinical Addiction Research and Education (CARE) Unit, Section of General Internal Medicine, Department of Medicine, Boston University School of Medicine, Boston, MA, USA; [2]Boston Medical Center, Boston, MA, USA; [3]Department of Social and Behavioral Sciences, Boston University School of Public Health, Boston, MA, USA; [4]Division of Substance Abuse Prevention and Treatment Services, Boston Public Health Commission, Boston, MA, USA.

BACKGROUND: Many opioid-dependent patients do not receive care for addiction issues when hospitalized for other medical problems. Based on 3 years of clinical practice, we report the Transitional Opioid Program (TOP) experience using hospitalization as a "reachable moment" to identify and link opioid-dependent persons to addiction treatment from medical care.

METHODS: A program nurse identified, assessed, and enrolled hospitalized, out-of-treatment opioid-dependent drug users based on their receipt of methadone during hospitalization. At discharge, patients transitioned to an outpatient interim opioid agonist program providing 30-day stabilization followed by 60-day taper. The nurse provided case management emphasizing HIV risk reduction, health education, counseling, and medical follow-up. Treatment outcomes included opioid agonist stabilization then taper or transfer to long-term opioid agonist treatment.

RESULTS: From January 2002 to January 2005, 362 unique hospitalized, opioid-dependent drug users were screened; 56% (n = 203) met eligibility criteria and enrolled into the program. Subsequently, 82% (167/203) presented to the program clinic post-hospital discharge; for 59% (119/203) treatment was provided, for 26% (52/203) treatment was not provided, and for 16% (32/203) treatment was not possible (pursuit of TOP objectives precluded by medical problems, psychiatric issues, or incarceration). Program patients adhered to a spectrum of medical recommendations (e.g., obtaining prescription medications, medical follow-up).

CONCLUSIONS: The Transitional Opioid Program (TOP) identified at-risk hospitalized, out-of-treatment opioid-dependent drug users and, by offering a range of treatment intensity options, engaged a majority into addiction treatment. Hospitalization can be a "reachable moment" to engage and link drug users into addiction treatment.

INTRODUCTION

Opioid-dependent individuals are frequent users of hospital services for acute medical conditions.[1–3] When hospitalized, they are often not engaged in addiction treatment.[4] They avoid hospitalization for fear of withdrawal,[5] and if hospitalized, resume drug use at discharge.[6] However, hospitalization provides an opportunity to improve and coordinate addiction treatment. A hospital-based program could identify opioid-dependent patients, engage them in addiction treatment, and mitigate high-risk behaviors. Hospitalization is a "reachable moment"—to engage out-of-treatment individuals whose acute illness may render them willing to consider addiction treatment.[7,8]

Methadone is recommended for acute withdrawal in opioid-dependent patients to reduce early hospital departures and facilitate acute treatment.[4,9,10] However, brief methadone exposure does not improve low abstinence rates (e.g., 80% of opioid-dependant individuals relapse within 1 year of detoxification).[11,12] Moreover, opioid agonists administered during hospitalization do not result in adequate ongoing abstinence after discharge.[8]

Research programs targeting hospitalized opioid-dependent patients have combined engagement with intensive, structured substance use treatment.[13–15] However, patients ambivalent about formal addiction treatment may be disinclined to enroll or remain in these types of programs. We created a clinical model to improve comprehensive health and lifestyle outcomes (e.g., linkage and adherence to treatment, reduction in unhealthy substance use behaviors) and promote low-threshold access that might engage reluctant patients. In 2001, the Transitional Opioid Program (TOP) was created for out-of-treatment, opioid-dependent patients hospitalized in an urban teaching hospital in coordination with but independent of an affiliated Opioid Treatment Program (OTP). TOP had three aims: (1) improve access to opioid addiction treatment; (2) provide risk reduction strategies to prevent HIV, hepatitis, and sexually transmitted diseases; (3) increase hospital discharge plan adherence. TOP identified hospitalized out-of-treatment, opioid-dependent patients and linked them to outpatient,

interim opioid agonist addiction treatment, medical care, risk-reduction services, and individualized case management. Components of this clinical program and the initial 3-year experience are described.

METHODS

The program model was based on a conceptual framework that included the following important components: (1) interim opioid replacement therapy; (2) individualized case management; (3) group public health education; (4) principles of motivational interviewing and harm reduction.

Interim Opioid Agonist Treatment

Opioid agonists facilitated patient engagement in the program by mitigating withdrawal, craving, and illicit drug procurement. The program worked to reduce risk of harm from injection drug use and permit participants to reflect on their circumstances, consider behavior change, and formulate goals.

Individualized Case Management

Individualized case management marshaled resources for vulnerable participants temporarily stabilized on opioid-agonist therapy. After hospitalization, patients face additional barriers to recovery (e.g., lack of long-term treatment availability, lack of insurance, homelessness). Case management provided a safe environment for both formal and informal addiction counseling. Unstructured interactions provided opportunities to address ambivalence to counseling.

Group Health Education

Group health education was an essential program component as patients face many risk-laden decisions.[16,17] Drug users transmit information via "word-of-mouth" and may use knowledge gained through health education to reduce risky behaviors.[18] Group education maximized staff efficiency and reinforced therapeutic messages.

Principles of Motivational Interviewing and Harm Reduction

The program used principles recommended by the Institute of Medicine including engaging patients in all states of readiness to change, setting intermediate goals, working collaboratively with patients towards them, and responding to individual needs.[19] This approach was used to educate participants about prevention of sexually transmitted infections, increase linkage to mental health and primary medical care, and enhance adherence to medical treatment. Intermediate behavioral goals and harm reduction methods were employed to enhance readiness to change and decrease medical complications.[20,21]

The program nurse made frequent "check-in" visits during the hospitalization because experience suggested that repeated low-pressure engagement combined with motivational interviewing methods increased enrollment and enhanced outcomes for ambivalent participants. Incremental progress by achieving intermediate outcomes was considered productive and consistent with the transtheoretical model of behavior change.[22] Any reduction of harmful behaviors or increased involvement in treatment or assistance services was positively emphasized.[23]

Transitional Opioid Program Phases

Phase 1. Inpatient—Identification, Screening, Assessment, and Enrollment. Phase 1 (during hospitalization) included identification, screening, comprehensive medical and psychosocial assessment, social service evaluation, daily visitation, substance abuse treatment education, and methadone induction and stabilization. The program nurse employed clinical judgment while determining program eligibility in interested individuals.

Phases 2. Outpatient Days 1 Through 30—Stabilization and Maintenance. Phase 2 (at the OTP during days 1 to 30 after hospital discharge) included methadone dose reassessment and titration, individualized case management, and comprehensive care planning. The program nurse transferred medication and medical information (last methadone dose, admission documentation, laboratory results, PPD status, and urine toxicology) to the OTP. Patients received daily observed methadone at the OTP up to a maximum daily dose (80 mg) to relieve withdrawal symptoms and opioid craving. The dose of 80 mg was the highest dose from which a 60-day detoxification was estimated to be tolerable. The first day of outpatient methadone administration, the program nurse oriented patients to the OTP and daily administration staff.

Participation in case management, education emphasizing risk reduction, health education, and formal addiction counseling was encouraged but not required. Supervised urine drug testing and medical follow-up were recommended. The program nurse monitored patients, offered support and informal treatment counseling, made referrals, and managed psycho-social crises. A physician met participants the first week at the OTP. The program nurse facilitated weekly public-health oriented educational group discussions at the OTP addressing common challenges (e.g., relapse prevention). Participants also met the program nurse weekly for individual 15-min "check-in" sessions. Methadone was administered within 15 min of the group session to encourage attendance. OTP nurses monitored participants daily during methadone administration and were reminded by an electronic alert to direct participants to keep their weekly "check-in" appointment with the program nurse.

Phase 3. Outpatient Days 31 Through 90—Taper or Titration and Transition to Long-Term Addiction Treatment. Phase 3 (days 31-90) included initiation of a 60-day methadone taper or preparation for transfer to another OTP. The program nurse provided both scheduled and drop-in counseling sessions during Phases 2 and 3. As case manager, the program nurse

supported and guided participants, helping them clarify, define, and achieve personal treatment goals. Participants set measurable, achievable goals and identified action steps to meet them (e.g., decrease methadone dose 5 mg per week, keep next doctor appointment). The plan was reviewed weekly and revised based on progress, physical and mental health status, housing and legal status. The program nurse assisted and advocated for the participants to ensure that action steps were met as planned. Participants, in consultation with the program nurse, decided to taper or transfer to a long-term OTP based on individual preference, availability of treatment slots, insurance status, staff recommendations, and employment and family issues.

Outpatient Objectives During Phase 2 and 3. Phases 2 and 3 addressed educational issues, behaviors, and service utilization. Examples included discharge medical treatment adherence (obtaining prescriptions and medical follow-up); harm reduction (needle sharing avoidance, needle exchange program enrollment, vein care, overdose prevention); condom use; HIV counseling and testing; hepatitis C and HIV health education; and addiction treatment education (acupuncture, community resources, methadone, relapse prevention, smoking cessation, recovery tools, and 12-step groups).

Design and Implementation

The Program Nurse. The program nurse consistently engaged patients from hospital enrollment to program completion. Daily visits helped patients establish trust and rapport, address expectations and concerns, and optimize methadone dosing. The program nurse (DB), available to patients and all clinical staff by pager, was supervised by the program physician director (CWS). During Phase 2 and 3, the nurse reviewed treatment plans, assessed dosing, answered questions, and provided emotional support for participants at the OTP. OTP physicians oriented participants to opioid agonist treatment, performed assessments, and collaborated with the program nurse on the treatment plan. The program nurse provided ongoing education to the OTP clinic nursing staff about the philosophy and policies of the program to maintain support for TOP as a distinct program with specific goals within the larger OTP.

To determine program eligibility, hospitalized patients were screened for receipt of daily low-dose methadone (20–40 mg). Patients were identified through the inpatient computerized medication ordering system. The program nurse reviewed individual medical records and discussed the potential for enrollment with clinical staff. Eligibility criteria included: (1) active opioid use and dependence; (2) not currently enrolled in an opioid treatment program; (3) no chronic use of non-prescribed benzodiazepines; (4) no current alcohol-dependence; (5) no active psychosis or suicidal/homicidal ideation. Program participation did not guarantee the opportunity for long-term OTP enrollment. Methadone dosing in the OTP program was based on federal regulations authorizing up to 120 days of methadone without concurrent routine drug testing, counseling or rehabilitation services for individuals awaiting comprehensive treatment.[24]

Outcome Definitions. Important medical and psychosocial patient outcomes were determined after program design and implementation and were reported for descriptive purposes only. A comparison group was not available. Outcomes were defined in terms of whether or not treatment was provided to participants. All outcomes were classified as "Treatment Provided" (e.g., enrolled in long-term OTP), "Treatment Not Provided" (e.g., loss to follow-up), or "Treatment not Possible" because medical or psychiatric issues took precedence (e.g., too medically or mentally ill or incarcerated).

Data Collection. Data from the program case-management database and the hospital's information system were extracted and transferred to a research database. Unique patients from the program's first 3 years are reported. The Institutional Review Board of Boston Medical Center approved this study.

RESULTS

Patient Characteristics

Between January 2002—January 2005, 362 unique patients were screened from admissions to the medical service of Boston Medical Center that received methadone for opiate withdrawal treatment and were neither enrolled in an OTP nor prescribed methadone for pain control (Fig. 1). Average hospitalization was 5.7 days (SD 7.3; range 1-76 days). Average daily in-patient census (Phase 1) was 2, and average program census (Phase 1-3) was 17. The average length of participation

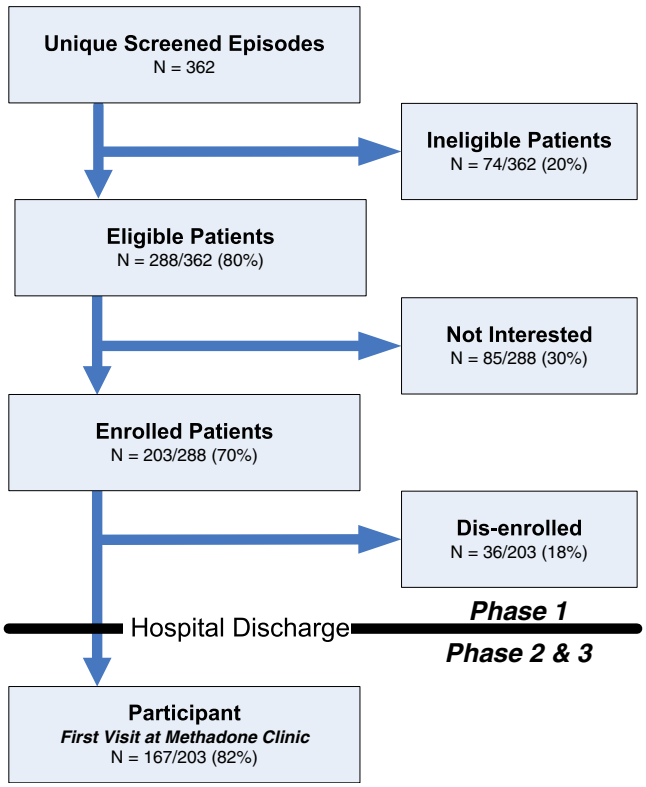

Figure 1. Screening and enrollment schema of the transitional opioid program.

in the entire program (Phases 1-3) was 60 days (SD 38; range, 1-154 days).

Unique Screened Patients

Of the 362 unique screened patients, there were 67% males: 50% White, 45% African-American, or 5% other; 24% self-reported Hispanic ethnicity. Mean age was 40 years. Medical conditions typical for this population were noted.[1,2] Housing information available from a subset of patients assessed in the latter period of follow-up revealed 60% (69/115) "any homelessness in the previous 6 months," 44% (51/115) "currently homeless," and 65% (75/115) "anticipated homelessness in the next 6 months."

Of the screened patients, 20% (74/362) were ineligible for the following reasons: active benzodiazepine abuse 24% (18/74); alcohol dependence with active alcohol use 24% (18/74); unstable psychiatric co-morbidity 14% (10/74); opioid use for less than 1 year 12% (9/74); medical illness severity 9% (7/74); non-daily opioid use 7% (5/74); other reasons 9% (7/74).

Eligible Patients

Of the 362 screened patients, 80% (288) were eligible for enrollment. However, 30% (85/288) declined program enrollment because they "desire residential treatment" 48% (41/85); "oppose methadone treatment" 24% (20/85); "have no interest in treatment at this time" 15% (13/85); "live too far away from the methadone clinic" 9% (8/85); or "want AA/NA only" 4% (3/85). Overall, 89% of those eligible (255/288) reported interest in addiction treatment.

Patients Enrolled in Hospital (Phase 1)

Of the remaining 203 patients that were eligible and accepted enrollment, 82% (167/203) became participants at the OTP clinic after hospitalization. Among the 18% (36/203) who "dropped-out" (failed to transition to the OTP—Phase 2), 44% (16/36) did not appear for the first dose, 22% (8/36) left the hospital "against medical advice," 11% (4/36) became too ill (e.g., transferred to ICU or long-term nursing facility), 8% (3/36) were discharged to another facility, and 14% (5/36) dropped out for other reasons.

Overall Outcomes of Participants Enrolled in Hospital (Phase 1)

Of 203 participants initially enrolled during hospitalization, treatment was provided to 59% (119/203), treatment was not provided to 26% (52/203), or treatment was not possible 16% (32/203).

Short-Term Substance Abuse Treatment Outcomes of Program Participants (Phase 2 and 3)

Among the 203 enrolled participants who entered Phase 2 and had treatment provided, 35% (71/203) enrolled in a long-term OTP, 15% (31/203) completed methadone taper, 4% (9/203) entered outpatient or residential substance abuse treatment, and 2% (5/203) entered an inpatient detoxification facility.

Among 52 participants initially enrolled but who were not provided treatment, 46% (24/52) did not show at the methadone clinic or left the hospital against medical advice, and 54% (28/52) did not show at the OTP clinic for 14 consecutive days or were discharged for behavioral issues.

Other Short-Term Outcomes

Phase 2 participants (n = 167) attained other outcomes including: obtained discharge prescriptions, 56% (94/167); attended primary care appointment, 54% (90/167); attended 2 or more group counseling sessions, 50% (84/167); enrolled in a needle-exchange program, 17% (28/167); attended a 12-step program, 16% (27/167); became employed, 16% (27/167).

DISCUSSION

The Transitional Opioid Program identified, recruited, engaged, and linked hospitalized out-of-treatment opioid-dependent patients to addiction care using interim opioid agonist treatment, individualized case management, and both scheduled and drop-in counseling. Most enrolled participants, 82% (167/203), presented for treatment at the OTP clinic after hospital discharge suggesting that an unmet need was addressed. The program employed minimal enrollment standards that did not require commitment to long-term OTP.

Other investigators have studied methods to engage opioid-dependent patients in addiction treatment. A randomized clinical trial targeting out-of-treatment opioid users identified and linked 126 selected individuals to methadone maintenance using four strategies: case management, free treatment voucher, case management plus voucher, or usual care for 6 months. At 3 months, long-term OTP enrollment was "usual care" (11%), case management alone (47%), treatment voucher (89%), and both case management and voucher (93%). Enhanced treatment access using a voucher was twice as effective as case management alone in linking hospitalized addicts to drug abuse treatment.[25] Vouchers also enhanced 6-month methadone treatment enrollment rates for patients seeking addiction treatment.[26] Schwartz et al. demonstrated that more than three-quarters of 319 heroin-dependent adults on an OTP waitlist randomly assigned to interim methadone remained engaged and entered a long-term OTP.[27,28]

TOP differs from previous reports in a few important ways. Populations identified by ours and other programs were similar in the range of need and readiness to change; however, TOP engaged non-treatment seeking, opioid-dependent patients ambivalent about substance abuse treatment. Moreover, the program approached ambivalence as a dynamic state and by use of interim opioid agonist therapy provided patients an opportunity to address indecision about addiction treatment and modify their readiness to change. Other "programs" described in the literature consisted of clinical trials that created linked but distinctly separate inpatient and outpatient services that were designed to test different methods and settings for engaging patients. These programs had different

objectives, enforced stricter eligibility requirements, or used longer duration and standard OTP structure. In contrast to reports in the literature, our program encouraged but did not require monthly urine drug testing or formal counseling (i.e., no minimum engagement requirements). Similarly, urine testing, if obtained and positive, did not impact program participation. Moreover, duration of participation in the program was roughly half that of other interim opioid-agonist therapy programs.[7–27] Similar to programs described by Aszalos and O'Toole, TOP participants were hospitalized; however, our program employed a single nurse who performed inpatient initial contact and screening through to final outpatient taper or referral to maintenance treatment in an OTP.[13–15]

The program provided the hospital-based clinical team an option for addressing opioid dependence. The TOP model appears sustainable and replicable using a modest staffing model (one nurse) and basic coordination within existing treatment services. The first 3 years of the program were supported by funding from the Massachusetts Department of Public Health. In year 4, the Boston Public Health Commission assumed program costs. Although data to examine health services implications of the program (e.g., hospital re-admissions) were not available, such analyses warrant further study.

Limitations

The program was not available for recruitment at all times but rather only 4 days/week, 8 h/day nor on all services (i.e., only medical service). The TOP model represents a single health care system's experience and awaits replication. Long-term outcomes of the model could not be determined because subjects did not receive long-term follow-up. Use of electronic medication reports was important and enhanced efficiency, but was not essential to the TOP model, and other enrollment screening methods could be devised to facilitate replication. Quantification of the relative improvement in addiction treatment and other outcomes was not possible because a comparison group was not available. However, most participants were not seeking treatment when hospitalized, and few would have received addiction treatment had they not been enrolled in the program.

CONCLUSIONS

The Transitional Opioid Program (TOP) program model is based on collaboration between a traditional acute inpatient facility and an outpatient addiction treatment program. This model of a transitional opioid program (TOP) engaged and linked many opioid-dependent patients to appropriate addiction and medical care by providing interim opioid agonist treatment while offering a range of treatment intensity options along with exposure to case management and health education focused on personal risks. Given the descriptive nature of this report, its findings should be considered preliminary and hypothesis-generating, and further study will be required to evaluate model efficacy and long-term outcomes.

Benefit-of-the-doubt approaches for calculating a composite measure of quality

Abstract Standard approaches for determining weights when calculating a composite measure of health care quality from individual quality indicators (QIs) include equal weighting, opportunity-based weights, and judgment-based weights. Benefit-of-the-doubt approaches have not been used in the health services area, though one has been used to calculate composite measures for profiling countries. Underlying these approaches is the assumption that relative performance on a set of indicators is, at least to some extent, a revealed preference by the organizational unit about the relative importance of the indicators. A benefit-of-the-doubt approach recognizes these revealed preferences by assigning higher weights to indicators on which performance is better and lower weights to indicators on which performance is poorer. We consider two benefit-of-the-doubt approaches. The first uses simple linear programming (LP) models; the second uses data envelopment analysis (DEA), the way in which the benefit-of-the-doubt approach has been previously implemented. In both cases, constraints are added to limit weight adjustments to some percentage of policy-determined baseline weights. Using both standard and benefit-of-the-doubt approaches, composite scores are calculated from data on five QIs from 32 Department of Veterans Affairs (VA) nursing homes. We examine the tradeoff between the

level of allowable weight adjustment and impact on facility rankings. If weights are constrained to be within 75% of baseline weights, all approaches identify pretty much the same high performing facilities. Weights from benefit-of-the-doubt approaches, because they are able to reflect local preferences and conditions, should be attractive to facilities and, in a collaborative environment, to policy makers.

1 Introduction

As efforts to improve measurement of quality of care expand, an increasing number of quality indicators (QIs) are being used to monitor progress. These QIs often capture different dimensions of quality that reflect the multiple objectives of provider organizations. However, when assessing overall performance, it is useful to aggregate individual QIs into a composite score (Institute of Medicine 2006). A composite score provides a useful summary of the extent to which top management has created a culture of quality and designed processes to ensure quality throughout the organization. Payers and consumers can use composite scores to compare performance across providers, and policy makers can use them to design incentives to encourage high quality, cost-efficient care.

Many different types of approaches for determining composite scores have been studied in the health services literature (Landrum et al. 2000; Lied et al. 2002; Zaslavsky et al. 2002; Jacobs et al. 2005; Jha et al. 2005; Werner and Bradlow 2006; Agency for Healthcare Research and Quality 2006; O'Brien et al. 2007; Lindenauer et al. 2007; Caldis 2007; Reeves et al. 2007; Shwartz et al. 2008). These approaches can be broadly distinguished by the way in which a construct (i.e., composite score) relates to the individual indicators which comprise it. There are two different types of relationships: first, the construct can be viewed as causing the indicators; or, second, the construct can be viewed as being formed from the indicators (Edwards and Bagozzi 2000). The first type of relationship is called *reflective* to indicate that individual indicators reflect or are manifestations of the underlying construct. A classic example of a reflective construct comes from educational testing: a student's underlying ability is reflected in answers to examination questions. The second type of relationship is called *formative* to indicate that the construct is formed from, or defined by, the individual indicators. Feinstein (1999) has highlighted this distinction in clinical medicine. Clinicians are often interested in combining multiple uncorrelated dimensions into a single score. The Apgar score, which measures the health of newborns, is an example of a widely used formative score.

Deciding whether a construct should be viewed as reflective or formative is based in part on conceptual considerations and in part on empirical evidence (Jarvis et al. 2003). If QIs are correlated, quality can be viewed as a reflective construct. In this case, factor analysis and other types of latent variable models are often used to estimate composite scores. Often, however, QIs are not highly correlated (Gandhi et al. 2002; Jha et al. 2005; Berlowitz et al. 2005; Ryan et al. 2009). In fact, the general trend in health services is to add QIs that broaden the definition of quality and reflect its different dimensions, not to add measures that are highly correlated with existing measures. Even though measures are not highly correlated, the QIs can be combined to create a composite score (a formative construct) by multiplying individual QIs by weights and then summing the results. In this paper, we treat the composite score as a formative construct.

Conceptually, one would like to weight QIs in a formative scale based on their contribution to overall patient health or well-being. However, there is rarely an empirical basis for determining the effect of changes in QIs on these ultimate patient outcomes. As a result, a number of practical approaches for weighting have been proposed, including equal weights, weights based on expert judgment, and weights based on the relative variance of each QI. When QIs are proportions (e.g., the proportion of eligible people who receive some intervention or who experience some adverse event), a common approach is denominator-based or opportunity-based weighting: each QI is weighted by the ratio of number eligible for the indicator to the sum of the numbers eligible for all indicators. None of these approaches is based on a set of underlying priorities or principles related to equity or efficiency and, if pressed, can be hard to defend.

Nardo et al. (2005) in their review of methods for constructing composite indicators discuss the "benefit-of-the-doubt" approach. As described by Cherchye et al. (2007), the conceptual basis for this approach is the following: relative performance on a set of indicators is a revealed preference by the organizational unit about the relative importance of the indicators. A benefit-of-the-doubt approach recognizes these revealed preferences by assigning higher weights to those indicators on which the organizational unit performs well and lower weights to indicators on which it performs less well. Specifically, weights are assigned in a way to optimize the composite measure, subject to a set of specified constraints. As noted by Cherchye et al. (2007, p 5), benefit-of-the-doubt weights "can be connected to a game-theoretic set-up: they can be conceived of as Nash equilibria in an evaluation game between a regulator and an organization." (Semple 1996). The benefit-of-the-doubt approach has been used to assess the relative performance of countries, mainly by researchers in Europe. For example, it has been used to assess macroeconomic performance (Lovell 1995), to reweight components of the Human Development Index (Mahlberg and Obersteiner 2001; Despotis 2005), to assess sustainable development (Cherchye and Kuosmanen 2004), and to evaluate technology achievement (Cherchye et al. 2008).

In the above examples, the benefit-of-the-doubt approach has been implemented through the use of Data Envelopment Analysis (DEA) (Charnes et al. 1978). DEA has been widely used to measure the performance efficiency of organization units (Cooper et al. 2007), where efficiency is the ratio of the weighted sum of different outputs to the weighted sum of inputs. For each organizational unit, weights for each of the outputs and inputs are chosen to optimize efficiency subject to the constraint that the efficiency measure is no greater than 1 for any of the units under consideration. The resulting efficiency measure for a specific organizational unit is relative to the best performing organizational unit(s), that is, the unit or units that are able to achieve an efficiency of 1 using the set of weights that optimize the specific unit's performance. Charnes et al. (1978) showed how this model can be converted to a linear programming model, which can be easily solved.

Benefit-of-the-doubt approaches have not been used to create composite measures in the health care area. However, in a system in which policy makers desire collaborative relationship with providers, the benefit-of-the-doubt approach has some appeal. Essentially, policy makers are saying to providers "We recognize that your relative performance on a set of QIs may reflect managerial decisions based upon the nature of your patients, staff, facility or local environment. Therefore, we will adjust to some extent our set of policy-determined baseline weights and assign somewhat higher weights to those QIs on which you do relatively well and somewhat lower weights on those QIs on which you do relatively less well." Since, within constraints resulting from the amount of adjustment

allowed, weights are assigned to optimize each facility's performance, facilities have less basis for complaints than if the initial policy-determined weights were used.

A criticism sometimes raised concerning benefit-of-the-doubt approaches is that once each organizational unit uses different weights, comparisons across units are no long possible. In response, consider students taking a course in which there are 5 different assignments, each of which is of equal importance. A common grading option is to allow students to drop the assignment with the lowest grade before calculating the final score. In this case, the weighting scheme is zero for the dropped assignment and one-fourth for the other assignments. A variation of this approach, which reduces the chance students will ignore 20% of the course material, is to allow students to place less weight on one of the assignments, e.g., only 12% weight on the assignment with the lowest score and 22% weight on the other 4 assignments. Assuming the assignment dropped (or down-weighted) occurs at random across students, only 20% of the class will be using the same set of weights. Nevertheless, there is no hesitancy in calculating a final score based on the 4 (or 5 if down-weighting is used) assignments and then assigning a grade based on this score. Hence, the principle of comparison when using a common rule that can result in "self-serving" weights is fairly well-accepted. DEA generalizes this principle. As illustrated by the extensive DEA literature, as long as all units "play under the same set of rules," the fact that the rules result in different weights in no way reduces the ability to fairly compare performance across the units.

There seems little doubt that students like the option of dropping their lowest assignment before calculating their final score. All students' final scores will be higher than if the final score were based on all five assignments. However, since final grading is usually done on a relative basis, it is not clear until all assignments are completed who has benefited and who has not from the policy. Nor is the extent to which the policy changes the relative performance of most students clear. If there is relatively little change in the final grade of most students, the policy of dropping the lowest assignment allows the teacher to "buy" student good will without much impact on final student rankings. If policy makers or regulators are seeking buy-in from providers, similar type policies, which can be implemented through benefit-of-the-doubt approaches, may be a way of "buying" provider good will.

In this paper, we apply benefit-of-the doubt approaches to calculating a composite measure of quality from individual QIs. To set the context, a particular reporting period has ended and performance on a set of QIs is available. Policy makers want to calculate a composite measure of performance for three possible purposes: (1) to facilitate choice among consumers by providing some "gestalt" sense of how good a facility is; (2) as part of a pay-for-performance program, to reward facilities whose performance has been particularly strong; and (3) to facilitate learning about policies and practices at high performing facilities in order to spread these to other facilities, thus raising the overall level of performance of all facilities. The weights that are used to calculate the composite measure for the recently completed period are of relevance only in that period. They will not be used prospectively to determine overall performance in the next reporting period.

We begin by describing several standard approaches currently used by central policy makers to establish weights when calculating a composite measure from QIs that are proportions. We then consider two benefit-of-the-doubt approaches. As noted, the benefit-of-the-doubt approach has been implemented previously using DEA. DEA does not require that specific outputs or inputs be on the same scale (e.g., quality and cost can both be outputs), thus eliminating the need to normalize measures before combining them into a

composite. Since different approaches for normalization can result in different rankings (Nardo et al. 2005), avoiding the need for normalization is an advantage of DEA. However, when all outputs are on the same scale, as they are in our example, there is no need to normalize measures. In this case, a reasonable alternative to DEA is a simple linear programming (LP) model that optimizes performance subject to the constraint that the sum of the weights is one. As we illustrate, the simple LP model is much more transparent than DEA. In what follows, we consider implementing the benefit-of-the-doubt approach using both simple LP and DEA. For both approaches for most of the analyses, we require that the weights remain within some range of baseline weights, thus limiting the extent of adjustment. We describe the models used to find the optimal weights for both approaches. Then, using data on 5 QIs from a sample of 32 nursing homes, we calculate the weights and composite scores using the different approaches. Finally, we examine the extent to which the relative performance of the 32 facilities is affected by the level of allowable weight adjustments.

2 Methods

2.1 Data

The data for this study are from an original set of 35 Department of Veterans Affairs (VA) nursing homes that were selected to represent a balanced sample of different sizes, locations and quality of care (Berlowitz et al. 2003). Data were available on 5 QIs that reflect changes in patients' status over time. All of these have been used previously as measures of nursing home quality: pressure ulcer development (Berlowitz et al. 1996; Porell et al. 1998; Mukamel 1997; Zimmerman et al. 1995); functional decline (Porell et al. 1998; Mukamel 1997; Zimmerman et al. 1995); behavioral decline (Arling et al. 1997; Porell et al. 1998); mortality (Braun 1991; Porell et al. 1998); and preventable hospitalizations (Carter 2003). Data used in calculating QIs were from semi-annual patient assessments performed for case-mix-based reimbursements. Pressure ulcer development was recorded if a patient who was ulcer free at one assessment had a stage 2 or deeper pressure ulcer at the subsequent assessment. Functional decline was measured by a change between assessments in a score measuring limitations in eating, toileting, and transferring. Behavioral decline was measured by a change in a score measuring extent of verbal disruption, physical aggression, and socially inappropriate behavior. Mortality was recorded if there was a death within 6 months of an assessment regardless of location. Preventive hospitalizations occurred if the patient was admitted to an acute medical unit within 6 months of an assessment for one of 13 conditions identified as a potentially preventable hospitalization (Agency for Healthcare Research and Quality 2004). Risk-adjustment models have been developed for these QIs: pressure ulcer development (Berlowitz et al. 1996), functional decline (Rosen et al. 2001), behavioral decline and mortality (Berlowitz et al. 2005), and preventable hospitalizations (Pizer et al. 2003). For each patient, the models give a predicted probability of the adverse event in a 6-month period based on risk factors at the time of initial assessment.

Data were collected in 1998 from the 35 nursing homes. However, data on all 5 measures were available for only 32 of 35 nursing homes, largely because 3 facilities switched to a new patient assessment instrument during the data collection period. These are the nursing homes considered in this study. For each patient, we know whether each

adverse event occurred (indicated by a 0 or 1) and the predicted probability of the adverse event from the relevant risk-adjustment model. Actual outcomes and predicted probabilities are summed for each facility, resulting in an *observed* number of cases (O) and an *expected* number of cases (E) for each QI. There are different ways in which observed and expected cases might be converted to an outcome measure, all of which have both strengths and weaknesses (Ash, Shwartz and Peköz 2003). We consider the ratio of observed cases to expected, i.e., the *O/E* ratio, a widely-used way of evaluating performance.

2.2 Calculating a composite score

2.2.1 Standard approaches: equal weights and denominator-based weights

Giving each indicator the same weight (an approach we call, not surprising, *equal weights*) has a great deal of intuitive appeal, but has the disadvantage that low prevalence indicators receive the same weight as high prevalence indicators. Denominator-based weights, the approach used by the Centers for Medicare and Medicaid Services (CMS) for combining individual process measures within clinical conditions (Premier 2003), weight indicators based on their relative prevalence. We modify the CMS approach slightly for our purposes. For each QI i at facility f, we know O_{if}/E_{if}. Similar to the CMS approach, we use the denominators as the basis for determining relative prevalence. Specifically, the weight for QI i at facility f is the ratio of the expected number for this QI to the sum of the expected numbers for all QIs, i.e., $E_{if}/\Sigma_i\ E_{if}$. Thus, each QI is weighted by its relative expected prevalence at the facility. More commonly expected QIs at a facility will have higher $E_{if}/\Sigma_i\ E_{if}$ ratios and hence will receive more weight. We refer to these weights as *facility-specific prevalence-based weights*. Note, that the composite score calculated using facility-specific prevalence-based weights $= \sum_i\ (E_{if}/\Sigma_i\ E_{if})^*\ (O_{if}/E_{if}) = \Sigma_i\ O_{if}/\Sigma_i\ E_{if}$. Hence, a reduction of one adverse event, regardless of QI, will have the same effect on the composite score. In this sense, facility-specific prevalence-based weights may be thought of as a form of equal weighting.

A modification of the above approach is to base weights not on facility-specific expected values, but on expected values summed across all facilities. This is the approach the Agency for Healthcare Research and Quality (AHRQ) uses to create composite measures from the individual Patient Safety Indicators. For each facility, the weight assigned to QI i is $\Sigma_f\ E_{if}/\Sigma_{if}\ E_{if}$. We refer to this approach as *overall prevalence-based weights*. For facilities with a patient mix (in terms of eligibility for the QIs) similar to the average, facility-specific and overall prevalence-based weights will be similar; for facilities with increasingly extreme patient mixes, weights will be increasingly different.

2.2.2 First benefit-of-the-doubt approach: simple LP models

The first benefit-of-the-doubt approach constrains the sum of the weights to equal 1. Thus, each weight represents the proportional importance of the QI.

Let w_{if} be the weight assigned to QI i at facility f. Then, the composite score at facility f is $\Sigma_i w_{if}\ (O_{if}/E_{if})$. Since low values of O_{if}/E_{if} represent high performance, facility f wants weights that minimize $\Sigma_i w_{if}\ (O_{if}/E_{if})$. The following linear programming model summarizes facility f's decision problem: find w_{if} to

$$\begin{aligned} &\text{minimize } \Sigma_i w_{if} \left(O_{if}/E_{if}\right) \\ &\text{subject to } \Sigma_i w_{if} = 1 \\ &\qquad w_{if} \geq 0 \text{ for all } i,\ i = 1, \ldots, 5 \end{aligned}$$

In addition, we want to ensure that at least some minimum weight is placed on each QI and that no more than some maximum weight is placed on any QI. We analyze the situation in which the weight for each QI is restricted to a proportional increase above and decrease below the overall prevalence-based weight (this analysis facilitates comparisons with results from the DEA model), using the following proportions: ±0.25, ±0.50, ±0.75, and ±0.90. When showing facility-specific results, we focus on the ±0.75 scenario, which we consider to be a moderate level of weight adjustment. In addition, we solve the model with no constraints. The solution to the unconstrained model is not practical, since all weight is placed on the one QI on which the facility performs the best. However, it does show the largest possible impact from allowing increased levels of weight adjustment.

2.2.3 Second benefit-of-the-doubt approach: DEA

In DEA, organizational units want to maximize efficiency, defined as the ratio of outputs to inputs. When applied to the problem of calculating a composite measure, the outputs are the QIs and the input for each facility is a "dummy variable" set equal to 1. To convert the problem of minimizing a weighted sum of *O/E* ratios (which we used in the simple LP model) to a comparable maximization problem, we maximize the quantity (K − *O/E*), where K is an arbitrary constant. (Note that in the simple LP model, in which the sum of the weights equals 1, maximizing $\Sigma_i w_{if}$ *(K − O_{if}/E_{if}) has the same solution as minimizing $\Sigma_i w_{if}$ (O_{if}/E_{if})). In DEA, the constraint is not on the sum of the weights, but on the composite score, which is constrained to be ≤1. Thus, a facility's composite score represents the proportion of the maximum possible score that the facility has achieved. In the same sense that the optimal weights for a facility in the simple LP model have to be feasible for all other facilities (i.e., they have to sum to 1), the optimal weights for any facility in DEA have to be feasible for all other facilities.

This gives rise to the following decision problem for facility f : find w_{if} to

$$\begin{aligned} &\text{maximize } \Sigma_i w_{if*} \left(\mathrm{K} - O_{if}/E_{if}\right) \\ &\text{subject to } \Sigma_i w_{if*} \left(\mathrm{K} - O_{ij}/E_{ij}\right) \leq 1 \text{ for all } j,\ j = 1, \ldots, 32 \\ &\qquad w_{if} > 0 \text{ for all } i,\ i = 1, \ldots, 5 \end{aligned}$$

Again, we want to ensure that the weights stay within some range of a set of baseline weights. The traditional way to do this in DEA is to constrain the ratio of the weights (Allen et al. 1997). We consider the ratios of the overall prevalence-based weights as baseline. Since in the simple LP model, weights are restricted to the range ± P of overall prevalence-based weights, in the DEA model, the ratio of weights is restricted to the range (1 − P)/(1 + P) to (1 + P)/(1 − P) times the ratio of the overall prevalence-based weights. We also solve the unconstrained model.

To solve the simple LP models efficiently, we use Solver in Excel plus an Excel Add-in, Solver Table (Winston and Albright 2001). To solve the DEA models, we use Excel-based DEA software called NUHOME (which also uses Solver) developed by Crystal Decision Systems, Inc. to enable nursing home managers to benchmark with DEA (Lenard et al. 2004).

3 Results

Table 1 shows the number of residents eligible for each QI, the number who experienced each type of adverse event, the ratio of the number who experienced the adverse event to the number expected to experience the adverse event (the *O/E* ratio), and prevalence-based weights. These data are shown for facilities ranked in the top 6 (high ranked facilities) or bottom 6 (low ranked facilities) by any of the standard approaches or the benefit-of-the-doubt approaches allowing ±0.75 adjustments to overall prevalence-based weights. As shown in Part A of the table, in most facilities, the mortality indicator has the largest number of eligible residents, which ranges from a low of 83 residents to a high of 817 residents (2 facilities not shown in the table also have more than 800 patients). The much lower number of residents eligible for pressure ulcers, functional decline and behavioral decline at some facilities results mainly from lack of a second assessment in many patients with short lengths of stay. Part B shows the number of people experiencing each adverse event. Part C shows the *O/E* ratios. There is wide variation in the *O/E* ratios, though less so for the mortality indicator. Part D shows both facility-specific prevalence-based weights and, in the last row, overall prevalence-based weights. The weight assigned to pressure ulcer development, the lowest prevalence condition, ranges from 0.013 to 0.091; the weight assigned to mortality, the highest prevalence condition, ranges from 0.195 to 0.747. Hence, there is substantial variation in the way in which QIs are weighted when using facility-specific prevalence-based weights. Using overall prevalence-based weights, pressure ulcer development receives relatively little weight (0.044) and mortality a very high weight (0.439).

Table 2 shows composite scores and facility ranks for each of the standard approaches and for the two benefit-of-the-doubt approaches (again with ±0.75 allowable adjustments). Facility-specific prevalence-based weights hurt facilities that do well on quality indicators on which they have a low prevalence (compared to the average prevalence over all facilities). For example, facility 8 does very well on pressure ulcer development, functional decline, and behavioral decline, indicators on which its facility-specific prevalence-based weights are much lower than the overall prevalence-based weights. Equal weighting hurts facilities that do well on high prevalence and poorly on low prevalence indicators (e.g., facility 11, that does particularly well on mortality and poorly on pressure ulcers) and helps facilities that do well on low prevalence indicators (e.g., facility 4). The benefit-of-the-doubt approaches assign more weight to those indicators on which facilities do particular well. This helps facilities that do particularly well on relatively high prevalence indicators (e.g., facility 30 and 32, that do particulary well on mortality, and facility 2 that does particularly well on both mortality and preventable hospitalizations.).

Perhaps most striking from this table is the minimal impact allowing adjustments of ±0.75 has on which facilities are ranked in the top 6. Using DEA, all of the high ranked facilities achieve a composite score of 1, indicating they are potential benchmarks for other facilities. The benefit-of-the-doubt approaches have a much larger effect on which facilities are ranked among the bottom 6. In this case, only 3 of the facilities ranked in the bottom 6 using overall prevalence-based weights are ranked in the bottom 6 using either of the benefit-of-the-doubt approaches. And, the facilities not ranked in the bottom 6 using benefit-of-the-doubt approaches sometimes move up many ranks (e.g., facilities 2, 30 and 32).

Figure 1a shows the effect of the amount of allowable weight adjustment on the average difference in ranks when using overall prevalence-based weights compared to each of the benefit-of-the-doubt weights. Most obvious from this figure is that for a given level of

* Results for the benefit-of-the-doubt approaches are for allowable weight adjustments of ±0.75 of overall prevalence-based weights

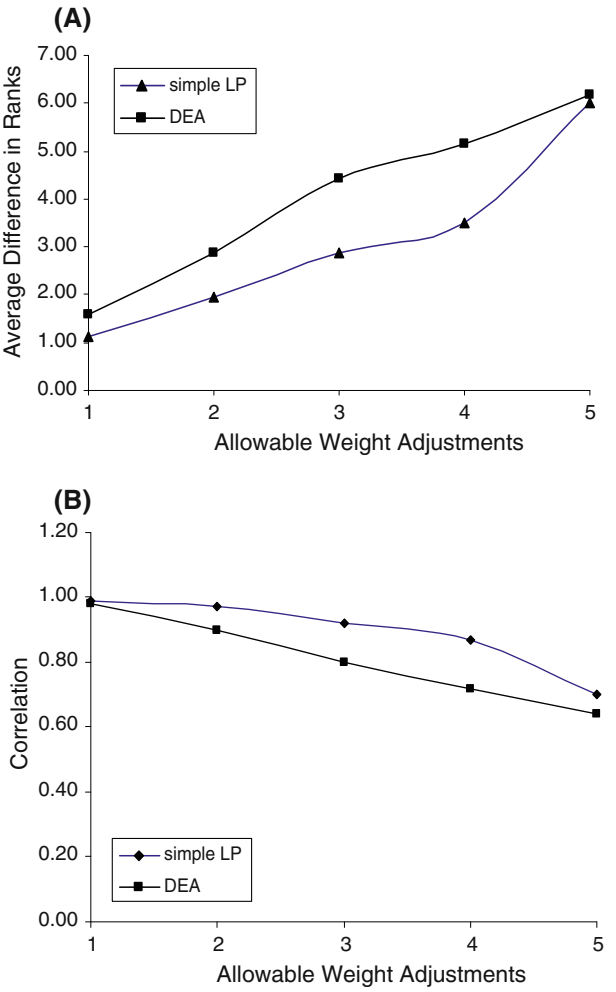

Fig. 1 Comparison of ranks using overall prevalence-based weights to ranks using each of the benefit-of-the-doubt approaches with different amounts of allowable weight adjustments*. Part A: Average difference in ranks. Part B: Correlation. * *Allowable weight adjustments*: 1: $\pm$0.25*overall prevalence-based weights, 2: $\pm$0.50* overall prevalence-based weights, 3: $\pm$0.75* overall prevalence-based weights, 4: $\pm$0.90* overall prevalence-based weights, 5: no constraints

flexibility, DEA has a larger impact on ranks than the simple LP models. For comparison purposes, when using facility-specific prevalence-based weights instead of overall prevalence-based weights, the average change in ranks is 2; when using equal weights instead of overall prevalence-based weights, the average change in ranks is 3. Thus, the simple LP models with allowable adjustments of $\pm$0.75 and the DEA model with a allowable adjustments of $\pm$0.50 would have less of an impact on ranks than switching from overall prevalence-based weights to equal weighting; the simple LP models with allowable adjustments of $\pm$0.50 and the DEA model with allowable adjustments of $\pm$0.25 would have less of an impact on ranks than switching from overall prevalence-based weights to facility-specific prevalence-based weights. At the extreme, when the models are solved without any constraints, the average change in ranks is about 6, which on average would move a facility from one quintile to another.

Figure 1b shows the effect of the amount of allowable weight adjustment on the correlation of ranks when using overall prevalence-based weights compared to each of the

benefit-of-the-doubt weights. Again for comparison purposes, the correlation between ranks using overall prevalence-based weights and facility-specific prevalence-based weights is 0.95; the correlation when using overall prevalence-based weights and equal weights is 0.90. In relation to comparisons with switching between standard approaches, findings are similar to those in Fig. 1. The correlation in ranks when using overall prevalence-based weights compared to equal weighting is no higher than the correlation when using overall prevalence-based weights compared to the simple LP models with allowable adjustments of ± 0.75 or the DEA models with allowable adjustments of ± 0.50. The correlation in ranks when using overall prevalence-based weights compared to facility-specific prevalence-based weights is lower than the correlation when using overall prevalence-based weights compared to the simple LP models with ± 0.50 adjustments or the DEA models with ± 0.25 adjustments.

4 Discussion

There is no gold standard that allows one to say that a composite measure calculated from one set of weights is a better than another. In this situation, the value of any particular approach rests upon its face validity: does it make sense to users? The two most widely used approaches—variants of equal weighting and use of "expert" or "policy maker" judgment—have some appeal. However, it is easy for providers to take "pot shots" at the resulting weights, often expressed by statements like the following: "These weights do not reflect what is important to our patients."

Since benefit-of-the-doubt weights apply to retrospective data, the above statement does reflect a self-serving tendency noted by Gormley and Weimer (1999) for organizations to "argue for favorable weights once they know their own position on the dependent variables underlying the scales." However, to the extent a facility's "position on the dependent variables" reflects its preferences about the relative importance of the dependent variables, there is a legitimate basis for this argument. Benefit-of-the-doubt approaches, by giving facilities the benefit-of-the-doubt about the reasons for differences in relative performance across QIs, recognize this legitimacy and thus should lessen tensions between policy makers and providers. In particular, these approaches should reduce the tendency noted by Gormley and Weimer (1999) for poorly ranked facilities to "blame the messenger." If this does happen, the messenger has a reasonable response: "Look, within the specified levels of allowable weight adjustments, we let you weight those QIs on which you performed well higher and those on which you did not perform well lower. Even after letting you do this, you still did not perform well compared to other facilities." Facilities might argue that the level of weight adjustments is not sufficient, but this has the potential to be a more productive conversation than one criticizing the fairness of the baseline weights.

There are a variety of legitimate reasons specific to providers' local context that might partially explain differences in relative performance on the QIs. For example, risk adjustment is not perfect. Poor performance on the mortality QI may reflect a particularly severe resident case mix that is not adequately captured by variables in the risk adjustment model. High rates of preventable hospitalizations (which can be reduced if there is adequate physician availability at a nursing home) may reflect an isolated rural facility with little physician availability in the community. For many QIs, the link between processes used in resident care and resident outcomes is weak. For example, for an indicator like functional decline, a particular facility may not believe that there is sufficient evidence that process improvements can lead to better outcomes among its particularly frail patient

population, and hence may not focus on this indicator even though its performance is poor. It is these types of factors that are taken into account by the allowable weights adjustments with benefit-of-the-doubt approaches. To the extent policy makers feel that factors like these exist and are important, more flexibility can be allowed in the weight adjustments; to the extent they do not, less flexibility can be allowed. And, to the extent they feel "legitimate" factors exist for some indicators but less so for others, different levels of allowable weight adjustments could be specified for different indicators.

It is interesting in our example that benefit-of-the-doubt approaches with moderate levels of allowable weight adjustment (e.g., ± 0.75) had little impact on which facilities were identified as top performers, but a larger impact on which providers were identified as poor performers. There is no particular reason to think this result generalizes. The more important lesson from our example is the benefit of examining the relationship between amount of allowable weight adjustment and impact on rankings. Understanding this relationship would be an important factor in deciding upon the amount of flexibility to allow when implementing a benefit-of-the-doubt approach.

We considered two benefit-of-the-doubt approaches. To the best of our knowledge, DEA is the only one of these approaches that has been used by others. As noted, one advantage of DEA is that quality indicators measured using different metrics can be combined without first normalizing the individual scores. In addition, DEA identifies for each facility performing below its potential, benchmark facilities (or a benchmark facility). The composite score has a clear interpretation: it is the percentage of a facility's potential that is being realized. Finally, benefit-of-the-doubt weights obtained through DEA have nice theoretical properties: as noted, they can be conceived of as Nash equilibria in a game theoretic formulation. However, there are some disadvantages as well. When the number of facilities is relatively small (as it is in our case), it can be difficult to reliably identify appropriate benchmark facilities. Also, if facility-specific prevalence-based weights were used as the baseline weights, the constraints on the ratio of weights would be different for each facility. This type of situation has not been considered in the DEA literature to the best of our knowledge and the implications for the efficiency frontier are not clear. In addition, and most important, it is difficult to determine exactly what it is about a facility's performance that results in the specific weights identified and the resulting composite score. The reason is that a facility's weights are determined not only by its own performance but by the performance of all other facilities (since the weights selected for a particular facility have to be feasible for all other facilities). The simple linear programming model approach can not handle indicators measured on different scale without first normalizing the scores. However, it has one big advantage: its transparency. It is easy to justify the resulting weights to policy makers and facility managers.

An important question is "when do facilities benefit from benefit-of-the doubt approaches?" The grading example discussed in the Introduction provides some insight. The student who has relatively similar scores on all 5 assignments will not receive value from being able to drop the lowest assignment and, unless all 5 scores are near the top, is likely to be negatively impacted by a policy that allows students to drop their lowest assignment. In the same sense, a facility that performs relatively similarly across indicators will not receive advantage from benefit-of-the-doubt weights and, in terms of rank relative to other facilities, is likely to suffer. Thus, benefit-of-the doubt approaches encourage managers to proactively consider which indicators are most important for their patients and which they believe they can most favorably impact, and to then focus on these QIs; or, alternatively, to identify those indicators that are less important for their patients, or particularly difficult or costly to change, and to de-emphasize these indicators.

Many pay-for-performance programs reward facilities both on the level of quality indicators at the end of the reporting period and on the amount of improvement in the indicators over the reporting period. Benefit-of-the-doubt approaches could be used to calculate a composite measure separately for absolute levels of the indicators and for changes in the indicators. These two composites could then be weighted using whatever weights policy makers decide upon. Or, alternatively, both absolute and change measures could be simultaneously weighted using benefit-of-the-doubt approaches.

We have illustrated our approach by making adjustment to baseline weights. However, there are a variety of alternative ways in which limitations might be placed on the weights. For example, policy makers might specify a rank ordering of the weights but then allow any specific weights consistent with this rank ordering; or, they might specify that the weight assigned to a particular indicator has to be 25% greater than the weight assigned to any other indicator. A more formal consensus process that uses modified Delphi or other similar methods to achieve consensus among stakeholders might be used to determine constraints on the weights. This is an example of a hybrid approach that combines expert judgment with benefit-of-the-doubt approaches.

Other forms of the outcome measures can be used. One disadvantage of *O/E* ratios is that they do not take account of differences in reliability of estimates from facilities of different sizes. As an alternative, one might consider z scores, e.g., $(O - E)$/variance (O). An advantage of converting a measure to a z score is that measures with very different scales can be easily combined. Or, instead of the observed performance on each indicator, one might use shrunken estimates of performance from hierarchical models (Arling et al. 2007).

We have illustrated benefit-of-the-doubt approaches for calculating a composite measure from individual indicators. However, the principle underlying the approach—that relative performance on a set of indicators reflects revealed preferences about the relative importance of the indicators—may have some value in the design phase of composite measures. CMS recently starting to post on its website results from the *Nursing Home Compare* Five-Star Quality Rating System. There is a fairly complex algorithm that leads to the final assignment of one to five stars to each nursing home. The people who contributed to the creation of the algorithm no doubt thought carefully about the relative importance of various components of the composite and developed an approach for arriving at a composite that reflected these judgments. In its current form, the algorithm does not lend itself to weight adjustments. As an additional consideration in the design phase, designers could have considered the question "Where might reasonable tradeoffs be made by nursing homes concerning elements of the composite?" This might have led to a different approach to calculating the composite, one that allowed some adjustments in weightings for those components of the composite about which facilities might reasonably make tradeoffs.

We studied only 32 nursing homes in a particular environment, the Veterans Health Administration. However, our purpose in this paper was not to undertake an actual evaluation. Rather, it was to use these data as an example to illustrate a potentially useful modification of existing ways that have been proposed for weighting individual QIs when calculating a composite score. In an environment like the Veterans Health Administration, nursing home chains, or perhaps in states, where policy makers desire to work collaboratively with providers, benefit-of-the-doubt approaches seem an option worth considering. These approaches should be attractive to facilities and may help reduce tensions between policy makers and facilities, which each have to live with the often implicit priorities imbedded in decisions about weights. Under benefit-of-the-doubt approaches, providers

who invest significant resources in achieving high performance on a particular set of QIs are assured baseline weights will be adjusted to reflect this success, as are other providers who focus on a different set of QIs. Further, as providers and policy makers better understand the implications of different amounts and different types of flexibility in choosing weights, an opportunity is created for healthy dialogue concerning future adaptations of the "rules of the game." Such dialogue can only improve the value of composite measures and perhaps increase trust and good will that may translate into better societal outcomes.

Acknowledgments This study was supported by VA Health Services Research and Development Service grant IIR 06-260. Findings and conclusions do not necessarily reflect the opinions or policies of the Department of Veterans Affairs.

A Single-Question Screening Test for Drug Use in Primary Care

Peter C. Smith, MD, MSc; Susan M. Schmidt, BA; Donald Allensworth-Davies, MSc; Richard Saitz, MD, MPH

Background: Drug use (illicit drug use and nonmedical use of prescription drugs) is common but underrecognized in primary care settings. We validated a single-question screening test for drug use and drug use disorders in primary care.

Methods: Adult patients recruited from primary care waiting rooms were asked the single screening question, "How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?" A response of at least 1 time was considered positive for drug use. They were also asked the 10-item Drug Abuse Screening Test (DAST-10). The reference standard was the presence or absence of current (past year) drug use or a drug use disorder (abuse or dependence) as determined by a standardized diagnostic interview. Drug use was also determined by oral fluid testing for common drugs of abuse.

Results: Of 394 eligible primary care patients, 286 (73%) completed the interview. The single screening question was 100% sensitive (95% confidence interval [CI], 90.6%-100%) and 73.5% specific (95% CI, 67.7%-78.6%) for the detection of a drug use disorder. It was less sensitive for the detection of self-reported current drug use (92.9%; 95% CI, 86.1%-96.5%) and drug use detected by oral fluid testing or self-report (81.8%; 95% CI, 72.5%-88.5%). Test characteristics were similar to those of the DAST-10 and were affected very little by participant demographic characteristics.

Conclusion: The single screening question accurately identified drug use in this sample of primary care patients, supporting the usefulness of this brief screen in primary care.

ILLICIT DRUG USE AND NONMEDICAL use of prescription drugs are common in the primary care setting and are underrecognized.[1,2] Screening for drug use allows clinicians to counsel patients and, when indicated, refer them to treatment. Because of this, the Substance Abuse and Mental Health Services Administration has promoted the integration of screening and brief intervention for substance use disorders into the primary care setting.[3] Screening for drug use is also useful as part of routine clinical care, for instance to aid in diagnosis and to avoid medication interactions. Few screening instruments for drug use or drug disorders have been validated, however, for use in primary care settings. Time is also limited during the primary care office visit, and commonly recommended drug screening instruments are composed of multiple questions, can be time consuming to administer, and may require scoring.[4,5] Practice guidelines currently recommend the use of a single screening question for the detection of unhealthy alcohol use in primary care settings.[6] Analogous single screening questions may also improve screening for drug use. We therefore set out to validate such a screening question in a sample of primary care patients.

METHODS

PARTICIPANTS

The study was conducted between October 2006 and June 2007 at an urban safety-net hospital-based primary care clinic at an academic medical center. The participant selection and data collection methods have been described previously.[7] Briefly, a sample of patients in the waiting room was selected by a research associate who systematically approached those waiting to be seen according to a predetermined pattern based on waiting room seating, which was varied daily. This was done to minimize biased selection of participants, because, owing to the large number of patients attending the clinic, all patients could not be approached. Prior to being approached for eligibility screening, patients saw no advertisement or indication by the research associate as to what the study was about. Patients who were younger than 18 years were excluded, as were those who, in the judgment of the research associate, would be unable to complete the questionnaire because of limited English, cognitive impairment, or acute illness. People in the waiting room accompanying patients who reported that they themselves were not patients of the clinic were also excluded. The institutional review board of Boston University Medical Center, Boston, Massachusetts, reviewed and approved all study procedures.

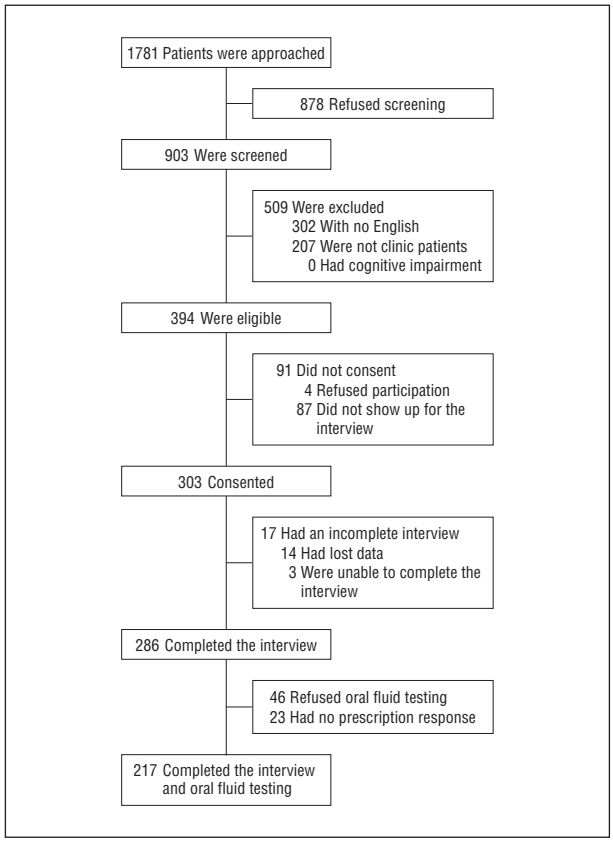

Figure. Flowchart of participant recruitment.

DATA COLLECTION

Interviews were conducted by trained research staff in a private setting, and data were recorded anonymously, unaccompanied by any unique identifiers. Participants were first asked the single screening question, "How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?" (where a response of ≥1 time was considered positive for drug use). If asked to clarify the meaning of "nonmedical reasons," the research associate added "for instance because of the experience or feeling it caused." After participants responded to the single screening question, they were asked if they had ever experienced any of a list of problems related to drug use. For this we modified the previously described Short Inventory of Problems–Alcohol and Drug (SIP-AD) questionnaire, which asks about problems ever experienced in the participant's lifetime related to alcohol or drug use.[8] We modified this by eliminating the word alcohol from the questions, a modification we hereafter refer to as the Short Inventory of Problems–Drug Use (SIP-DU). In a separate analysis (but in these participants) we determined the reliability and validity of the SIP-DU as a measure of drug use consequences.[9] The computerized version of the Composite International Diagnostic Interview (CIDI) Substance Abuse Module was used for the assessment of current (12-month) drug use disorders.[10] This structured interview yields a *Diagnostic and Statistical Manual of Mental Disorders (Fourth Edition)* diagnosis of drug abuse or dependence. In addition, as part of the CIDI, individuals were asked detailed questions about current (past year) use of illicit drugs (marijuana, cocaine, heroin, stimulants, or hallucinogens) and nonmedical use of prescription drugs. Following the interview, participants were asked to undergo oral fluid testing for the presence of common drugs of abuse (opiates, benzodiazepines, cocaine, methamphetamines, or tetrahydrocannabinol). Once collected, oral fluid was sent to an outside laboratory for analysis using methods that yielded results comparable to urine drug screening (Intercept immunoassay; OraSure Technologies, Bethlehem, Pennsylvania).[11-14] To aid in the interpretation of drug test results, individuals had been asked, as part of the interview, if they had recently been prescribed any drugs from a list of opiates or benzodiazepines. Because this question was added to the questionnaire during the study, responses were missing from 23 patients who underwent oral fluid testing. Participants were not told that they would be asked to undergo drug testing until the interview was complete. After completing the interview, they were compensated and thanked for their participation. They were then asked to undergo oral fluid testing, and a second informed consent process was completed. Following the single drug screening question, but before the other assessments, the 10-item Drug Abuse Screening Test (DAST-10) was administered for comparison.[4] As part of a parallel study on screening for unhealthy alcohol use, participants were also asked a single alcohol screening question (preceding the drug screening question), 2 other brief alcohol screening questionnaires, and a calendar-based assessment of past-month alcohol consumption (all after the drug screen and prior to the CIDI).[7]

REFERENCE STANDARD

Participants were considered to have current drug use if, during the CIDI, they reported the use of an illicit drug (marijuana, cocaine, heroin, stimulants, or hallucinogens), or the use of a prescription drug for nonmedical reasons, during the past 12 months. A second analysis included only individuals who consented to oral fluid testing. Participants in this analysis were considered to have current drug use if they met these criteria; if oral fluid testing was positive for cocaine, tetrahydrocannabinol, or methamphetamines; or if it was positive for opiates or benzodiazepines and they had not reported receiving a recent prescription for one of these medications. Participants were considered to have drug-related problems if they had current drug use and responded positively to any of the 15 SIP-DU questions. Those with drug abuse or dependence as determined by the CIDI and who reported experiencing symptoms within the past 12 months were considered to have a current drug use disorder.

STATISTICAL ANALYSIS

We calculated the sensitivity, specificity, likelihood ratios, and area under the receiver operating curve (AUC) of the single-question screen for the detection of drug use, drug use associated with problems, and a current drug use disorder as defined in the previous subsection. The AUC, a measure of a test's discriminatory power, can be interpreted as the probability, given 1 participant without drug use and 1 with drug use drawn at random from the population, that the person with drug use will score higher on the test. An AUC of 1.0 indicates perfect discrimination, an AUC higher than 0.8 indicates good discrimination, and an AUC of less than 0.7 indicates poor discrimination.[15] For comparison with the single-question screen, we calculated the sensitivity, specificity, likelihood ratios, and AUC of another longer screening test, the DAST-10, for the detection of the same conditions. The DAST-10 yields a score of 0 to 10. A total of more than 2 points is considered a positive screening test result.[4] We calculated 95% confidence intervals (CIs) using published formulas.[16] Statistical analyses were performed using SAS software (version 9.1; SAS Institute Inc, Cary North Carolina).

RESULTS

PARTICIPANT RECRUITMENT

Of the 1781 people approached, 903 (51%) agreed to be screened for study eligibility (**Figure**). Of these, 509 (56%)

Table 1. Participant Characteristics

Characteristic	No. (%)	
	Participants Consenting to Oral Fluid Testing (n=240)	Total (n=286)
Sex		
Female	135 (56.2)	155 (54.2)
Age, mean (SD), y	49.3 (12.8)	49.0 (12.3)

Opiates		
Reported no prescription	5 (2.1)	5 (1.7)
Reported prescription	5 (2.1)	5 (1.7)
Missing prescription response	2 (0.8)	2 (0.7)
Benzodiazepines		
Reported no prescription	4 (1.7)	4 (1.4)
Reported prescription	4 (1.7)	4 (1.4)
Missing prescription response	1 (0.4)	1 (0.3)

[a] For men, an average of more than 14 drinks per week over the past 30 days, or more than 4 drinks on any 1 day during the past 30 days (for women, >7 drinks per week, or >3 drinks per occasion), determined using a calendar-based reporting method.
[b] Lifetime and current alcohol and drug use disorders as determined by responses to the Composite International Diagnostic Interview (CIDI).
[c] "Current" refers to within the past year (12 months).
[d] As part of the CIDI interview participants are asked about their current use of illicit drugs or of prescription drugs for nonmedical reasons.
[e] Participants were considered to have drug-related problems if they were past-year drug users and responded positively to any of the 15 Short Inventory of Problems-Drug Use (SIP-DU) questions.
[f] A positive response to any of the questions from the SIP-DU questionnaire.

were ineligible for the study: 302 (33%) did not speak English and 207 (23%) were not clinic patients. Of the 394 patients who were eligible, 303 (76%) participated: 4 (1%) refused to participate, 87 (22%) did not show up for the planned interview after the visit with their physician, and of the 303 individuals who arrived and gave consent to participate, 3 (1%) were unable to complete the interview. The data of 14 participants (5%) were lost owing to an electronic error, leaving 286 whose data were analyzed (73% of those eligible).

After completion of the interview, patients were asked to undergo oral fluid testing for common drugs of abuse, to which 240 (84%) consented. Of these, 217 were asked about a recent prescription for opiates or benzodiazepines.

PARTICIPANT CHARACTERISTICS

Of the 286 participants, 54% were women, and the median age was 49 years (range, 21-86 years) (**Table 1**). Most

Table 2. Sensitivity, Specificity, and Likelihood Ratios for the Detection of Drug Use: Single Screening Question

Detection	Sensitivity, % (95% CI)	Specificity, % (95% CI)	Positive LR,[a] (95% CI)	Negative LR,[b] (95% CI)	AUC
Current use, self-reported (n=286)[c]	92.9 (86.1-96.5)	94.1 (89.8-96.7)	15.8 (8.9-28.1)	0.08 (0.04-0.2)	0.93
With drug problem or drug use disorder[d]	93.5 (86.5-97.0)	91.2 (86.4-94.5)	10.7 (6.8-16.8)	0.07 (0.03-0.2)	0.90
Current use, either self-reported or a positive oral fluid test result (n=217)[c]	84.7 (75.6-90.8)	96.2 (91.4-98.4)	22.4 (9.4-53.1)	0.2 (0.1-0.3)	0.92

Detection	Sensitivity, % (95% CI)	Specificity, % (95% CI)	Positive LR,[a] (95% CI)	Negative LR,[b] (95% CI)	AUC
Current use, self-reported (n=286)[c]	82.8 (74.2-89.0)	93.6 (89.1-96.3)	12.9 (7.4-22.5)	0.2 (0.1-0.3)	0.89
With drug problem or drug use disorder[d]	87.0 (78.6-92.4)	92.8 (88.2-95.6)	12.0 (7.2-20.1)	0.1 (0.08-0.2)	0.88
Current use, either self-reported or a positive oral fluid test result (n=217)[c]	80.0 (70.3-87.1)	93.9 (88.5-96.9)	13.2 (6.7-26.0)	0.2 (0.1-0.3)	0.89
With drug problem or drug use disorder[e]	83.5 (73.8-90.1)	92.8 (87.2-96.0)	11.5 (6.3-21.1)	0.2 (0.1-0.3)	0.89
Current drug use disorder (n=286)[c]	100 (90.6-100)	77.1 (71.5-81.9)	4.4 (3.5-5.5)	NC	NC

Abbreviations: AUC, area under the receiver operating curve; CI, confidence interval; DAST-10, 10-item Drug Abuse Screening Test; LR, likelihood ratio; NC, number could not be calculated (ie, the formula results in division by 0).
[a]Calculated as the probability of an individual with the condition having a positive test divided by the probability of an individual without the condition having a positive test.
[b]Calculated as the probability of an individual with the condition having a negative test divided by the probability of an individual without the condition having a negative test.
[c]"Current" refers to within the past year (12 months).
[d]Self-reported past-year drug use and either a positive response to one of the SIP-DU questions or a current drug use disorder.
[e]Self-reported past-year drug use or a positive oral fluid test and either a positive response to one of the SIP-DU questions or a current drug use disorder (excludes participants without an oral fluid test).

participants (63%) identified themselves as black or African American, with whites (17%) and Hispanics (16%) comprising most of the remainder. Most (78%) had completed high school, but only 14% had completed college. The prevalence of self-reported current (past-year) drug use was 35% (with 32% reporting at least 1 problem relating to use), and among those who consented to oral fluid testing, 40% either self-reported drug use or had a positive test result (38% with problem use). The prevalence of current drug abuse or dependence was 13%. The lifetime prevalence of alcohol use disorders (44%) and drug use disorders (47%) was high.

TEST CHARACTERISTICS

The single-question screen was 100% sensitive (95% CI, 90.6%-100%) and 73.5% specific (95% CI, 67.7%-78.6%) for the detection of a current drug use disorder (**Table 2**). It was slightly less sensitive (92.9%; 95% CI, 86.1%-96.5%) and was more specific (94.1%; 95% CI, 89.8%-96.7%) for the detection of current drug use (although CIs overlapped). If oral fluid test results were taken into account, the sensitivity for detecting current drug use was lower (84.7%; 95% CI, 75.6%-90.8%). The longer DAST-10 screen was also 100% sensitive (95% CI, 90.6%-100%) for the detection of a current drug use disorder and was 77% specific (95% CI, 71.5%-81.9%); overall, its test characteristics were similar to those of the single-question screen (**Table 3**). Participant education and primary language affected point estimates of the sensitivity and specificity of the single-item screen very little, although for some groups with small sample sizes there was insufficient power to exclude large differences (**Table 4**). The single-item screen may be less specific for the detection of a current drug use disorder in men and in Hispanic patients.

COMMENT

A single-question screen was sensitive and specific for the detection of drug use and drug use disorders in a sample of primary care patients. Its test characteristics were simi-

Table 4. Single-Question Screen for the Detection of Current Drug Use, in Selected Subgroups

Characteristic	No.	Sensitivity, % (95% CI)	Specificity, % (95% CI)	AUC
Female	155	100 (61.0-100)	80.5 (73.4-86.1)	0.93
Male	131	100 (89.0-100)	63.0 (53.2-71.8)	0.92
Non-Hispanic, white	45	100 (74.1-100)	79.4 (63.2-89.6)	0.94
Non-Hispanic, black	176	100 (80.6-100)	73.8 (66.4-80.0)	0.92
Hispanic	46	100 (70.1-100)	59.5 (43.5-73.6)	0.91
English primary language	223	100 (89.3-100)	72.8 (66.1-78.6)	0.93

lar to those of a longer screening tool in this sample, as well as in other studies reported in the literature.[4]

Drug use is prevalent in primary care.[1] While national guidelines do not currently recommend universal screening for drug use in primary care, recent evidence supports the effectiveness of brief intervention in this setting, and screening, brief intervention, and referral to treatment initiatives are widespread.[3,17] In addition to identifying patients who might benefit from brief physician counseling, drug use screening is likely worthwhile in many clinical circumstances, such as identifying potential medication interactions and prescribing risks (as when clinicians ask patients to report prescription and over-the-counter medication use and alternative medicines as part of routine care).

Time constraints in the primary care setting have been cited as a reason for failure to provide screening and prevention in general (according to one estimate, providing all recommended preventive services to an average primary care panel would require 7.4 hours out of each workday[18]). Successful screening and brief intervention programs therefore require a means of quickly selecting, from among all primary care patients, those most likely to benefit from further assessment and intervention. Single-question screening tests for unhealthy alcohol use have been validated, and one such test is currently recommended by the National Institute on Alcohol Abuse and Alcoholism in its most recent clinician's guide.[6] To our knowledge, no other single-question screening test for drug use has been validated in any setting. Such a screening test could facilitate early identification and brief intervention, as well as the avoidance of prescription errors and associated risks.

A number of drug use screening instruments have been proposed for use in general medical settings, ranging from 2 questions to more than 70.[5,19] Some of these are modified versions of alcohol screening tests, and some ask simultaneously about both alcohol and drugs (so-called conjoint screens). Conjoint screens may be more acceptable to some patients than direct questioning about drug use but also require more clarification of a positive screen result, and some of the questions, adapted from alcohol screening tests, may be less applicable to drug use (eg, the "eye-opener" question from the CAGE-AID ["Adapted to Include Drugs"] questionnaire).[20] A brief, 2-item conjoint screen (TICS) has been validated, representing a screening strategy of equivalent brevity to asking a single question about drug use and a single question about alcohol. The TICS was 79% sensitive and 78% specific for either an alcohol or drug use disorder. The sensitivity for a drug use disorder was similar, but specificity was not reported.[19] Two longer, but still brief, conjoint screens, the CAGE-AID and RAFFT, have been tested in adults, with similar test characteristics.[20,21] These conjoint tests target drug disorders but do not specifically identify drug use.

The DAST-10 (to our knowledge, not validated in a primary care sample until the present article), the Drug Use Disorders Identification Test (validated only in criminal justice and detoxification settings), and the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST), 3 screening questionnaires that ask about drug use specifically, have better test characteristics than the shorter conjoint screening tests and address part of the spectrum of clinical interest beyond drug diagnoses to include use and problems, but their length (10-28 questions for the DAST-10 and >70 questions for the ASSIST) and the need for scoring represent significant barriers to their use as screens in the primary care setting.[4,5,22] As a screening test (as opposed to an assessment of severity or a diagnostic tool), the single-question screen performed almost as well as the longer DAST-10 in the sample that we studied. Longer screening tools may, however, have promise as electronic medical record systems with decision support become more widespread (and as evidence for the validity of the ASSIST accumulates), potentially as a follow-up assessment after a positive single-question screen result, or even as a written previsit questionnaire. In summary, in terms of brevity, ease of scoring, and validity for detecting the spectrum of drug use conditions of interest in primary care, and therefore, likely greater widespread implementation, the single-question screen seems to have favorable characteristics.

For a screening test for drug use to be useful, it must be applicable to the broad range of people seen in primary care. The diversity of our participant sample allowed us to examine the effect of sex, ethnicity, primary language, and education on the accuracy of the single-question screen. While variations were seen in the sensitivity and specificity of the test across these groups, the differences were small.

Our study has several limitations. A higher than expected proportion of participants reported substance use disorders, likely reflecting the fact that they were re-

cruited from an urban safety-net hospital located in a community where the prevalence of such problems is high. While this potentially limits the generalizability of our results, it is this type of high-risk population that is typically targeted for screening and brief intervention (as mentioned, universal screening of all adults is not currently recommended, whereas targeted screening is recommended).[23] Nevertheless, additional study of the screening question in other settings (as well as in other language and in written and computer-based versions) is warranted. Participants were also assured anonymity, a condition that improves the accuracy of the reference standard interview but that may also serve to overestimate the accuracy of the screening test itself. This is consistent, however, with the methods of most other studies of screening tests for substance use disorders, thus allowing comparability of our findings with those of other studies.

The single-question screen accurately identified primary care patients who use drugs. Some patients who have positive tests results will have severe drug use disorders requiring referral to substance abuse treatment, while those who use drugs but have not experienced severe health or interpersonal problems might benefit from brief intervention by the primary care provider. The lack of an efficient way to distinguish these 2 groups is a challenge that must be addressed when implementing screening for drug use. The DAST-10 and the ASSIST screening tools, in providing scores, provide a measure of severity. Even though they may be too long for universal screening in many settings, they might be used for assessments after a single-item screening question is answered in the affirmative. However, this approach has not been tested or validated.

The single-question screen accurately identified a broad spectrum of drug use in this sample of primary care patients. The sensitivity and specificity of this single question was comparable with that reported for longer instruments in other studies. These findings support the use of this brief screen when identification of drug use is desired in primary care settings, which should, in turn, facilitate the implementation of screening and brief intervention programs in this setting.

Screening and Brief Intervention for Drug Use in Primary Care

Leah E. Squires, MA, Daniel P. Alford, MD, MPH, Judith Bernstein, PhD, ADN, MSN, Tibor Palfai, PhD, and Richard Saitz, MD, MPH

Key Words: primary care, drug use, substance use, screening, brief intervention, motivational interviewing

(*J Addict Med* 2010;4: 131–136)

This clinical case involves a man with unhealthy alcohol and drug use who presents for an initial visit to primary care with complaints of heartburn and a recent admission for chest pain. Four expert clinicians contribute their thoughts about the case.

CASE DESCRIPTION

A 45-year-old man (Mr. M) hospitalized 3 months prior for chest pain ("noncardiac," myocardial infarction [MI] ruled out) presents to a primary care physician (PCP) with heartburn worse after meals and not helped by antacids. He denies weight loss, vomiting, or bloody stools/melena. He has some trouble falling asleep because of worries about his job and sometimes forgets to pick up his kids from their activities. He is married and has 2 children (a son aged 9 yr and a daughter aged 11 yr) and working as a manager at an electronics store. His last visit to a PCP was 10 years ago. His father had a heart attack at the age of 50 years. Three years ago, he was injured in a motor vehicle crash and had facial lacerations and rib fractures; urine toxicology was positive for cocaine and tetrahydrocannabinol. Physical examination is notable for blood pressure 152/94 mm Hg and an S4. An electrocardiogram is normal, and the rapid plasma reagin, thyroid stimulating hormone, vitamin B12 level, liver enzymes, renal function, and complete blood count are normal.

Screening

Primary care presents an opportunity to screen for lifestyle habits that may impair health and provide intervention when warranted. A majority of individuals with substance use problems do not recognize their use as problematic. Based on considerable empirical support for screening and brief intervention (SBI) for risky alcohol use, and evidence suggesting that SBI for other drugs may be beneficial (Babor and Kadden, 2005; Madras et al., 2009), Mr. M's primary care clinic uses the NIDA-modified Alcohol Smoking and Substance involvement Screening Test (nm-ASSIST) (http://www.drugabuse.gov/NIDAMED/screening/). The nm-ASSIST is an adaptation of the World Health Organization-developed ASSIST (World Health Organization ASSIST Working Group, 2002) designed for use in primary care settings. The nm-ASSIST is easily scored and provides recommendations for intervention based on drug-specific scores. It also includes screening information to identify those who may be hazardous/harmful (vs dependent) drinkers. In this clinic, patients complete the nm-ASSIST "prescreen," which asks about lifetime use of substances, as part of a self-report intake packet, which is reviewed by the office nurse. Positive endorsement of any prescreen item leads to completion of the rest of the nm-ASSIST as a nurse administered interview during the review of vital signs, allergies, pain symptoms, medications, and other preventive services that might be due.

On the prescreen, Mr. M indicates lifetime use of alcohol, tobacco, marijuana, and cocaine. During the interview, Mr. M states he has used marijuana daily and cocaine monthly in the past 3 months. He also reports heavy drinking episodes on the days when he uses cocaine. He reports quitting tobacco 5 years ago. On the nm-ASSIST, Mr. M's receives a cannabis use score of 17 and a cocaine use score of 6. These "moderate risk" (4–26) scores, along with Mr. M's episodic heavy drinking prompt recommendation for a brief intervention. Based on the results of screening, the nurse conducts a brief intervention with Mr. M before the doctor's examination.

Brief Intervention-Treatment Framework

As practiced in Mr. M's clinic, brief intervention consists of one 20- to 30-minute counseling contact with the office nurse and the option of a follow-up visit or phone call.

After the intervention, the nurse flags the patient's chart so that the PCP is aware that the brief intervention was conducted before seeing the patient. The flag consists of a simple checklist indicating (1) which substances were reviewed; (2) whether a change plan was completed; and (3) whether a follow-up visit was scheduled. The nurse applies principles of motivational interviewing (Miller and Rollnick, 2002) to establish a collaborative atmosphere in which the patient is encouraged to discuss his/her substance use in the context of this health visit.

Intervention

After the administration of the nm-ASSIST, the nurse asks Mr. M whether they can spend a few more minutes discussing his substance use and health. Mr. M is initially reluctant to engage in the conversation and states that he doesn't perceive his substance use as problematic. The nurse reassures Mr. M that the goal of the discussion is for his health care team to get a better sense of how the patient understands the role that substances play in his life and how substance use is related to his health. The nurse asks Mr. M to review his current health concerns. Mr. M states that he had difficulty sleeping and lies in bed worrying about his job security. Since his hospital admission 3 months ago (and his father's MI at a young age), he is also been concerned about his health and sometimes worries about how his family would cope if he did have a serious health condition. He notes that smoking marijuana provides stress relief. The nurse encourages Mr. M to describe other "benefits" of marijuana use. Mr. M, pleasantly surprised at being asked, states that marijuana helps him fall asleep, and that after he smokes, he feels able to put his worries aside for the evening. The nurse then asks Mr. M to discuss the positive aspects of using cocaine. Mr. M notes that he uses it only occasionally with his friends, snorting cocaine and drinking beers while watching sports or playing video games.

After discussing these benefits, the nurse asks Mr. M to describe the "downsides to using." Mr. M states that in the past few months he has experienced some conflict with his wife over his smoking. The nurse asks for elaboration on these events, including emotional consequences of this conflict. Mr. M also states that he doesn't want his kids to pick up his "bad habit." He also notes that since having a car accident 3 years ago, he no longer drives after spending time drinking and using cocaine with his friends. In addition, Mr. M mentions that he occasionally noticed his heart "racing" after using cocaine, but it doesn't bother him.

The nurse summarizes the pros and cons of marijuana and cocaine use described by Mr. M and then asks permission to share information about the possible impact of Mr. M's substance use on his health. The nurse is careful to present the feedback as potentially useful information rather than a prescription for change. The nurse also points out that Mr. M's current episodic heavy alcohol use also places him at increased risk for accidents, such as his past car accident. The nurse highlights associations between substance use and reported health concerns identified by Mr. M, specifically concerns about his memory and cardiac health. During the delivery of this information, the nurse engages the patient and asks for reactions, comments, and thoughts about what is being presented.

When asked what led to him changing his past behavior, Mr. M endorses finances, concern for his children, and his wife's concern as the main reasons he cut back on both drinking and other drug use. He says change was "not too hard" at the time because he was busy working and helping his wife take care of their first child in the evening. After summarizing Mr. M's past change efforts, the nurse asks Mr. M for his thoughts about his current use. Mr. M states that he'd like to cut back on his marijuana but doesn't really see the need to change his cocaine use because it is infrequent. He states that he was comfortable with his current alcohol consumption. Mr. M and the nurse work on developing a change plan. Mr. M decides to reduce his marijuana smoking by engaging in other stress relieving activities, including spending more time with his children and a friend who doesn't use drugs. He identifies his friend Charlie and his wife as people he can enlist to help with this plan. The nurse expresses appreciation to Mr. M for his involvement in the discussion and offers him a follow-up visit if he thinks it would be helpful to him. Mr. M accepts the offer of a follow-up visit in 2 weeks to review his progress. The nurse also provides Mr. M with brochures summarizing the health information they discussed (impact of smoking, cocaine, marijuana, and alcohol use on the body) and a copy of his written plan for change. The nurse informs Mr. M that his PCP will see their discussion noted in his medical record and encourages Mr. M to speak to the doctor if he has additional questions.

Follow-Up Visit

Mr. M arrives on time for his follow-up visit and reports that he hasn't used cocaine for the past couple of weekends. He's also cut back on his marijuana use to 1 to 2 evenings. However, his drinking increased on weekend evenings. Mr. M states that thinking about smoking marijuana as similar to smoking cigarettes and the possibility of consequences that might affect his children made cutting back "something I want to do;" however, he notes that he still struggles to fall asleep at night and has on occasion gone outside to smoke to fall asleep.

The nurse and Mr. M review his progress and reformulate his change plan. Mr. M restates his intent to reduce his marijuana use. At the end of the follow-up visit, the nurse provides Mr. M with information about brief substance use treatment offered through the hospital and encourages him to contact the primary care team if he needs additional help making changes.

Record Keeping

In addition to the flag created for the doctor, the nurse notes in Mr. M's medical record the results of the substance use screening, his intention to cut back on his own, his change plan, and perceived barriers and supports to change. As part of standard practice, Mr. M will be asked about his progress at his next primary care visit and will be rescreened on an annual basis.

DISCUSSION

Daniel P. Alford, MD, MPH, FACP, FASAM

This case highlights the multiple important opportunities to screen patients for unhealthy substance use in general healthcare settings. Emergency room visits and hospitalizations are likely "reachable moments" (Shanahan et al., 2010) for patients with unhealthy substance use, especially when there is a link between their acute illness and their substance use. Before his primary care visit, Mr. M had previous emergency rooms visits and a hospitalization. These were all opportunities for healthcare providers to identify and address Mr. M's unhealthy substance use and draw connections between his substance use and his chief complaints (ie, motor vehicle crash and chest pain). Despite unhealthy substance use being a common problem in general healthcare settings, physicians are often reluctant or are inadequately trained to effectively screen or provide brief interventions (Isaacson et al., 2000).

An important question when implementing substance use SBI in general healthcare settings is who should perform it and when should it take place? During Mr. M's visit to primary care, a nurse administered the SBI for those patients who "prescreened" positive. Collaborative care in which staff other than the PCP screen and counsel patients is certainly one way to lessen the burden of multiple preventive agendas for PCPs. However, in this case, I am concerned about the low PCP involvement. In this SBI, the PCP was informed of the screening results, brief intervention conducted, and the patient's plan for change before the PCP visit. Ideally, this would be used by the PCP to emphasize the association between the patient's substance use and personally relevant health outcomes, reinforcing the feedback that the patient received and supporting any change efforts that the patient may wish to undertake; however, it is not clear that this occurred. The timing is also an issue in implementing SBI in primary care settings. With valid single-item screening tests for alcohol (Smith et al., 2009) and drugs (Smith et al., 2010) now available, it is feasible to "prescreen" patients before they see their PCP. However, for patients prescreening positive, a more extensive screening/assessment (eg, NIDA-modified ASSIST) is needed, followed by a brief intervention, all of which can be time consuming. The challenge with the nurse model in this case is how readily it could be implemented in a busy primary care practice where 20 to 30 minutes before a PCP visit is not available and may interfere with patient flow. Delaying the full screen/assessment and brief intervention until after the PCP visit is one possible solution but risks the patient leaving without having their unhealthy substance use addressed and excludes the PCP from the SBI process.

Finally, when a patient such as Mr. M screens positive for multiple substances (ie, cocaine, marijuana, and alcohol), which substance should the brief intervention focus on? Should it focus on all the substances, the substance the patient is most concerned about, or the substance that is most risky for the patient's health as determined by the healthcare provider? In Mr. M's case, despite having a lower nm-ASSIST score for cocaine, I could argue that his "occasional" intranasal cocaine use is putting his health at grave risk. He likely has preexisting heart disease with his elevated blood pressure and fourth heart sound. Cocaine use can cause increased myocardial oxygen demand, vasoconstriction, thrombosis, and premature atherosclerosis, which in combination with his family history of coronary heart disease put him a high risk for having a MI (Lange and Hillis, 2001). The occurrence of MI with cocaine is unrelated to the amount ingested, route of administration, or frequency of use (Lange, 2003) Moreover, the combination of cocaine and alcohol produces cocaethylene (Laizure et al., 2003), which increases the risk of cocaine-associated cardiac toxicity. I wonder whether Mr. M's comment that he "doesn't see the need to change his cocaine use" because it was "infrequent" was based on not being adequately informed about the potential risks that cocaine poses for him. It would have been helpful to first assess Mr. M's understanding of the potential health risks of his cocaine use before offering him feedback and information. Although it is important for brief interventions to be patient centered allowing patients to set goals, it would be unfortunate if the patient chose priorities for change without being fully informed of the risks associated with his/her substance use.

Judith Bernstein, PhD, ADN, MSN

Sometime it takes centuries to discover the obvious. As long ago as 1670, the French mathematician Pascal said, "people are generally better persuaded by the reasons which they have themselves discovered than by those which have come into the mind of others." Clinicians spend much valuable time lecturing patients about the negative imperatives for behavior change—risk factors and potential health consequences—but often overlook the uses of patient self-reflection and positive reinforcement. Motivational interviewing provides a toolbox for this type of patient-centered brief intervention in the course of a health care visit. Screening for unhealthy alcohol use is currently recommended in the primary care setting by the U.S. Preventive Services Task Force (2004), and moderate effect sizes for reductions in both quantity and alcohol-related consequences are well substantiated by a series of meta-analyses (Kaner et al., 2009). The evidence is not yet in for drug use, but preliminary research and program evaluation findings suggest promise (Bernstein et al., 2005; Madras et al., 2009).

As this case illustrates, motivational interviewing reflects "the rather simple notion that the way clients are spoken to about changing addictive behavior affects their willingness to talk freely about why and how they might change" (Rollnick, 2001). The nurse began by asking permission to discuss the subject, establishing respect for the patient and setting the stage for the patient to be the engine of change. The nurse then elicited the patient's perspective on the pros and cons of his substance use and only then offered nonjudgmental feedback about the possibility of connection between his substance use and his health concerns. If the nurse had begun by asking Mr. M what he understood about the risks of use, resistance and denial might have been encountered. Instead, by starting by eliciting positive effects of drug and alcohol use, the nurse was able to learn about the role cocaine

and alcohol played in important relationships and the patient's use of marijuana for stress reduction. Mr. M was then able to weigh these "benefits" against risks that he named for himself; the result was a plan for change that he believed he had the capacity to carry out. When he reported at follow-up that he had accomplished some but not all of these goals, he was received with positive reinforcement, rather than embarrassed about having "slipped." Brief intervention of this type is not a substitute for specialized treatment in those who exhibit dependence, but it can lead to behavior change over time, especially when reinforced in the context of continued primary care. Mr. M may still need a referral for counseling to examine sleep disruption and stress processing, but he has already changed his thinking about drug use and begun to alter negative health behaviors.

It is important to note that a nurse delivered this intervention. PCPs are often reluctant to begin complex conversations about behavior change because of time pressures. Use of a physician extender, a nurse, social worker, or an outreach worker who functions as a member of the clinical team could ensure that fulfilling U.S. Preventive Services Task Force (2004) recommendations does not take the 7.4 hours of physician clinical time each day that a landmark time-motion study demonstrated (Yarnall et al., 2003). Identification of unhealthy substance use during a clinical visit, followed by intervention to encourage healthier behaviors, is too important an opportunity to miss.

Tibor Palfai, PhD

With empirical support for the use of alcohol SBI in primary care (Kaner et al., 2009), investigators have adopted similar approaches for drug use with promising results (Madras et al., 2009). Although there are a variety of brief interventions that may be used to address substance use in medical settings (Babor and Kadden, 2005; Kaner et al., 2009), motivational interviewing (Miller and Rollnick, 2002) is particularly well suited for addressing substance use in the primary care setting where patients often do not identify their substance use as problematic or perceive the need to change. Moreover, motivational interviewing and its adaptations have received empirical support as a brief treatment for illicit drug use and marijuana use specifically (Hettema et al., 2005).

In this case, the patient presents with hazardous alcohol use, cocaine use, and frequent marijuana use. Among the challenges faced by the nurse is how to enhance motivation to change marijuana use in a patient who appears to view his use as nonproblematic and how to do this in a manner that may be enduring to support behavior change (eg, self-change and linkage to treatment). One of the features of motivational interviewing that makes it particularly valuable for this case is its emphasis on supporting patient autonomy (Markland et al., 2005). There is now considerable empirical support for the view that behavior change is facilitated to the extent that patients perceive their activity as autonomously controlled (Ryan and Deci, 2008). Autonomous sources of behavior include personally important values, goals, and beliefs and reflect the degree to which one experiences an action as willingly chosen. Autonomy support occurs through a number of processes including understanding and acknowledging perspectives, expressing regard, minimizing pressure and control, providing choices, and delivering a meaningful rationale for suggestions or requests.

The interview illustrates the variety of ways that the nurse provides autonomy support for the patient through the intervention. As detailed above, the nurse skillfully addresses initial patient reluctance by presenting the interview as a collaborative discussion that is intended to better understand substance use from the patient's point of view. By inviting the patient to first describe his current health concerns, the nurse is able to acknowledge what is most important for the patient, express empathy, and help the patient consider substance use in the context of overall health. The nurse's efforts to support autonomy are evident in the way that feedback about use and information about potential consequences are presented to the patient. These aspects of the intervention, which are common to a number of adaptations of motivational interviewing (Burke et al., 2003), may be particularly relevant for patients who are not aware of the association between substance use and presenting health concerns. Appreciating that the delivery of information about negative health effects may be perceived by the patient as an attempt to convince him to change, the nurse asks permission to deliver information about the effects of marijuana and cocaine on health, states that the information may or may not be experienced as important for the patient, and frequently checks with the patient about his perception of the information. Statements that indicate that the nurse values his perspective and appreciates his engagement are particularly important during this part of the intervention.

The nurse also seeks to identify, elaborate on, and reinforce instances in which the patient has been successful in promoting change. This includes both efforts to identify patient successes to enhance self-efficacy regarding current change, as well as efforts to highlight and elaborate on goals and values that have served as important sources of change in the past. As this patient indicates an interest in change, the nurse discusses options about how he might undertake change efforts and elicits sources of support and barriers to change. In addition, the nurse offers a follow-up session, which is presented as an option that the patient may use if helpful to him. The nurse further emphasizes choice and autonomy in the manner in which a follow-up session is offered in person or by phone. This follow-up session allows the nurse to explore the patient's experience with behavior change and continue support for autonomy while keeping the patient engaged with the change goal in a manner that he has chosen.

Richard Saitz, MD, MPH, FACP, FASM

It is noteworthy that Mr. M's PCP has implemented SBI for drugs. If drug SBI can improve primary care patient outcomes, then she/he will have been at the vanguard of practice. However, all universal preventive practices have opportunity costs, so each new practice should have proven efficacy. Guessing about efficacy, even when the practice seems logical, is not good enough—many good ideas have been later proven ineffective. We know that SBI for nondependent unhealthy alcohol use has modest efficacy (U.S. Preventive Services Task Force 2004); data are lacking for

single primary care visit drug SBI (Saitz et al., 2010). Also, there are reasons why it may not work, such as severity of those who use certain drugs, patient preferences against being referred to treatment, the wide range of substances used, and the complexity of prescription drug abuse. Brief adaptations of motivational interviewing similar to those used in this case are most likely to work.

In Mr. M's case, the practice wasn't screening (or its synonym "prescreening," whieh has somehow entered the vernacular in SBI programs but has no meaning distinct from "screening"). Screening quickly separates those at risk from those at lower risk and implies that the patient is asymptomatic with regard to the target condition. Yet, Mr. M had a hospitalization for chest pain, multiple trauma and positive urine drug tests, has insomnia and heartburn, and is sometimes forgetful. Screening was complete (and positive) before any questions were asked during this visit. Appropriate evaluation for Mr. M would include assessment relevant to the differential diagnosis of his symptoms and conditions, including alcohol and other drug use, which can cause or play a role in each.

Fortunately, Mr. M's PCP has implemented the nm-ASSIST, despite its length, need for scoring, less immediately relevant (to screening) questions about lifetime use, and inability to specify whether a patient is drinking risky amounts. Why then, fortunate? Because the benefit of such a tool is the assessment data it provides. Answers to individual questions give the clinician something to discuss. Scores give an estimate of severity and thus can inform brief intervention goals and urgency. Another fortunate feature of Mr. M's PCP's practice is having a nurse who can do brief counseling. This uncommon setup may be ideal for addressing a range of health behaviors in primary care. If drug SBI is proven efficacious, staff with behavioral expertise could step in after brief (eg, single question) validated screening. This approach seems most feasible and could result in wider dissemination of SBI.

I was surprised at Mr. M's response to the brief intervention. Although Babor (2004) found efficacy for marijuana brief intervention, their study was of people who sought the intervention. However, screening-identified primary care patients often do not perceive consequences or risks and have little ambivalence about their marijuana use for clinicians to work with. I might have prioritized differently. Mr. M had heartburn and hypertension, which could have been related to alcohol consumption, and chest pain (and possibly premature atherosclerosis) that could have been related to his cocaine use (and heart racing, which was related to it). I might have emphasized the link between these conditions of importance to him, and his alcohol and cocaine use, highlighting the discrepancy between what he values and his use, rather than spend precious time on his marijuana use.

The ability to make links between substanee use and medical conditions raises the question of the physician role in SBI. The best evidence for efficacy of alcohol SBI is for a PCP eounseling his or her patient on multiple occasions (Whitlock et al., 2004). If the physician isn't going to do the screening or the brief intervention, they should at least provide feedback and a warm handoff.

Finally, this case hints at another challenge for PCPs and patients. Information in medical records can have impact on insurability and potentially employment if the patient releases their records, which they often must do when applying for benefits. Federal substance dependence confidentiality regulations apply to programs that hold themselves out as providing treatment for addiction. In this case, there is no diagnosis of addiction, and the PCP was not representing the practice as an addiction treatment provider, so the regulations don't apply. The good news is that this PCP will be able to provide a safe, comprehensive eare for the patient including his substance use and other medical conditions. The bad news is that there will be potentially damaging information in the record. Privacy protections in primary care and addiction treatment programs should be reconsidered to prevent discrimination while encouraging high quality integrated healthcare.

Systematic Review: Treatment Agreements and Urine Drug Testing to Reduce Opioid Misuse in Patients With Chronic Pain

Joanna L. Starrels, MD, MS; William C. Becker, MD; Daniel P. Alford, MD, MPH; Alok Kapoor, MD, MSc; Arthur Robinson Williams, MA; and Barbara J. Turner, MD, MSEd

Background: Experts recommend opioid treatment agreements and urine drug testing to reduce opioid analgesia misuse, but evidence of their effectiveness has not been systematically reviewed.

Purpose: To synthesize studies of the association of treatment agreements and urine drug testing with opioid misuse outcomes in outpatients with chronic noncancer pain.

Data Sources: MEDLINE, PsycINFO, EMBASE, Cochrane Central Register of Controlled Clinical Trials (January 1966 to June 2009), reference lists, and expert contacts.

Study Selection: Original research addressing opioid medications, chronic pain, and treatment agreements or urine drug testing, with a sample size of 50 participants or more and published in English, Spanish, or French.

Data Extraction: Two investigators independently identified eligible studies, extracted data, and assessed study quality. The outcome of opioid misuse was defined as drug abuse, drug misuse, aberrant drug-related behavior, diversion, or addiction.

Data Synthesis: Of 102 eligible studies, 11 met inclusion criteria; 6 were in pain clinics and 5 were in primary care settings. Four primary care studies examined multicomponent strategies that included interdisciplinary support. All studies were observational and rated as poor to fair quality. In 4 studies with comparison groups, opioid misuse was modestly reduced (7% to 23%) after treatment agreements with or without urine drug testing. In the other 7 studies, the proportion of patients with opioid misuse after treatment agreements, urine drug testing, or both varied widely (3% to 43%).

Limitations: Diversity of interventions and opioid misuse measures precluded meta-analysis. Most studies evaluated combinations of interventions.

Conclusion: Relatively weak evidence supports the effectiveness of opioid treatment agreements and urine drug testing in reducing opioid misuse by patients with chronic pain. Further research on effective ways to monitor and reduce opioid misuse is needed, especially in primary care settings.

Primary Funding Source: Substance Abuse and Mental Health Services Administration, National Institute on Drug Abuse, and Robert Wood Johnson Foundation.

Chronic pain is one of the most common reasons for medical visits (1, 2), affecting 20% to 50% of patients who visit primary care providers (3–5). During the past 2 decades, opioid analgesics have been increasingly prescribed for chronic noncancer pain (1, 6, 7) and are now among the most frequently dispensed medications in the United States (8). The expansion of opioid prescriptions for chronic pain was initially supported by research from the 1980s and early 1990s, which reported a low risk for opioid addiction (9). However, treatment of chronic pain with opioids has continued to increase, despite a lack of rigorous research demonstrating the effectiveness of long-term treatment (10–13) and a burgeoning public health threat posed by opioid misuse, including abuse, addiction, diversion, and unintentional overdose (14–18).

To mitigate the risks for prescription opioid misuse, medical societies and regulatory agencies have published consensus guidelines recommending specific risk-reduction strategies, including written opioid treatment agreements and urine drug testing for patients with chronic pain who are prescribed long-term opioid analgesics (19–21). Because the adverse consequences of prescription opioid misuses including overdose or death, are severe and the risk for misuse cannot be reliably predicted, experts advise that "universal precautions" should be adopted when prescribing long-term opioid analgesics (22). Although most patients with chronic pain are managed in primary care practices (1), adoption of opioid treatment agreements and urine drug testing by primary care physicians has been limited. In 3 primary care studies of management of patients who were prescribed long-term opioids, only 23% to 44% of physicians completed treatment agreements with these patients, and only 8% to 30% obtained urine drug tests (23–25). Among the several reasons for limited use of these approaches by primary care physicians may be the lack of a clear evidence base for their effectiveness in reducing opioid misuse and other adverse outcomes (26, 27). This systematic review addresses this gap by evaluating the effectiveness of opioid treatment agreements and urine drug testing in reducing opioid misuse among outpatients with chronic noncancer pain.

Methods

Data Sources and Searches

We consulted with a research librarian and conducted a systematic literature search of MEDLINE, PsycINFO, EMBASE, and the Cochrane Central Register of Controlled Trials from the earliest index date to week 2 of June 2009 for relevant studies published in English, Spanish, or French. We used Medical Subject Headings and keywords to search opioid medications, chronic pain, and opioid treatment agreements or urine drug testing (**Appendix Table 1**, available at www.annals.org), combined by using the Boolean operator "and," as previously described (10, 28). To identify additional studies, we reviewed all reference lists from included studies, consensus statements, and relevant review articles. In addition, we consulted authors of included studies and experts in pain and opioid management.

Study Selection

Two reviewers screened abstracts identified by the literature search for potential eligibility. Articles were considered eligible for full review if they addressed opioid misuse outcomes after implementation of treatment agreements or urine drug testing; reported data from an original study (not a review or an editorial); were conducted in an outpatient setting in patients with chronic noncancer pain; included 50 or more participants; and were published as full manuscripts in English, Spanish, or French. Studies were not excluded on the basis of study design alone. We excluded studies in emergency departments because they do not provide longitudinal care, as well as studies of patients with cancer-related, acute, or postoperative pain. In a random sample of 100 abstracts, the observed agreement between reviewers on this first screening was 95%, which corresponded to substantial agreement ($\kappa = 0.76$).

To define the final set of eligible studies, 2 physician–researchers retrieved and independently reviewed full manuscripts. Eligible studies were conducted in a relevant study population and included patients who were prescribed at least 3 months of opioids or who received opioid treatment described as "long-term" or "chronic." Studies of opioid treatment agreements had to describe a written document that used any of 3 terms for the medication (opioid, controlled substance, or pain medication) and any of 4 terms for the type of document (agreement, contract, treatment plan, or informed consent). Because of the wide variation in the description and inclusion of the treatment agreement documents in identified studies, we did not further specify the type of treatment agreements for inclusion in the review. Studies of urine drug testing needed to use testing routinely as part of a management strategy and not as a single test to detect misuse for research purposes. The urine drug test needed to assess for controlled substances, but we did not define the type of assay or the specific drugs tested.

Context

Some experts recommend treatment agreements and urine drug testing to discourage misuse when opioids are prescribed for chronic noncancer pain, even though the effectiveness of these strategies is uncertain.

Contribution

This systematic review identified 11 poor- to fair-quality observational studies of treatment contracts and urine drug testing and found only weak, heterogeneous evidence that these strategies were associated with less misuse.

Implication

Careful studies of strategies to promote safe use of opioids for chronic noncancer pain are needed. Unless evidence becomes available to support a benefit of treatment contracts and urine testing, the absence of these strategies should not be considered a mark of poor-quality care.

—The Editors

With regard to opioid misuse outcomes, eligible studies needed to evaluate behaviors described as aberrant or indicative of abuse, misuse, or diversion, consistent with the terminology recommended by Ballantyne and LaForge (29). Examples of such behaviors include overuse of prescribed opioids, repeatedly lost or stolen prescriptions, receipt of opioid medications from multiple providers or sources, prescription adulteration or forgery, or concomitant use of nonprescribed controlled substances (licit or illicit) (29). Outcomes could have been measured from patients, providers, medical charts, or laboratory tests. Urine drug tests indicative of opioid misuse included those that were positive for a nonprescribed controlled substance or negative for the prescribed controlled substance and confirmed with gas or liquid chromatography and mass spectrometry. The observed agreement between reviewers was 94.2% ($\kappa = 0.83$). A third reviewer resolved disagreements about eligibility.

Data Extraction and Quality Assessment

Two reviewers used a standardized instrument to independently extract data from each study. They extracted data on the patient sample, outpatient setting, intervention, opioid misuse outcome measures, and results.

By using a quality assessment checklist that was derived from the ECRI Institute (13), Downs and Black (30), and Jadad and coworkers (31), 2 reviewers assessed the quality of included studies in 3 domains: sample, design, and a global assessment (32) (**Table 1**). We modified these measures to address features of observational studies. The quality checklist assigned a maximum of 15 points to each study: 3 for sample (external validity) and 12 for design (internal validity). In addition, each study was evaluated by using the modified GRADE (Grading of Recommendations Assessment, Development, and Evaluation) quality

Table 1. **Assessment of Study Quality**

Sample domain (maximum 3 points)*
- Persons with diverse types of chronic pain conditions included
- Persons with history of substance abuse included
- Persons with mental health disorders included

Design domain (maximum 12 points)*
- Prospective design
- Control group included
- Control participants from a similar population
- Intervention described clearly
- Intervention consistent among groups
- Outcome described clearly
- Outcome objective
- Completion or response rate ≥85%
- Distribution of potential confounders provided
- Multivariate analysis conducted
- Adequate adjustment for confounding
- Results clearly presented

Global assessment (maximum 4 points)†
- Very low = 1
- Low = 2
- Moderate = 3
- High = 4

* 1 point was assigned for each.
† Based on the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) algorithm (33).

assessment criteria, which consider the rigor of the design, biases, and limitations on a scale of 1 to 4 (33). On the basis of scores on the quality checklist and GRADE, we assigned 1 of the following ratings to each study: excellent (score ≥11 and GRADE ≥3), good (score ≥11 and GRADE ≥2), fair (score = 6 to 10 and GRADE ≥2), or poor (score ≤5 or GRADE = 1). Ratings between reviewers had 73% agreement ($\kappa = 0.48$), and a third independent reviewer resolved disagreements in quality assessment. We did not exclude studies on the basis of quality. **Appendix Tables 2** and **3** (available at www.annals.org) provide a detailed quality assessment for each study, including scores for individual domains.

Data Synthesis and Analysis

For each study, we calculated the absolute risk reduction (ARR) and 95% CIs for opioid misuse in the intervention versus control or comparison group. Consistent with options described in the Cochrane Handbook for Systematic Reviews (34), we dichotomized a continuous outcome variable in 1 study to calculate the ARR; the study reported the mean number of opioid prescribers per patient per quarter, and we selected a cutoff of 2 or more as indicative of receiving opioids from multiple sources (35). The interventions evaluated and the measures of opioid misuse were too variable to permit meta-analysis, so we summarized results descriptively.

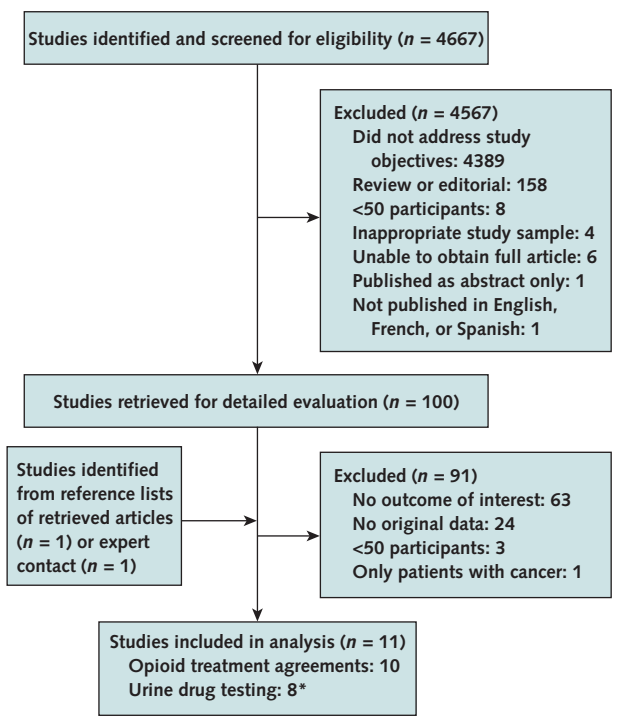
Role of the Funding Source

The Substance Abuse and Mental Health Services Administration, the National Institute on Drug Abuse, and the Robert Wood Johnson Foundation funded the study through the Treatment Research Institute's Program of Research to Integrate Substance Use into Mainstream Healthcare (PRISM). The funding sources had no influence on the analyses, preparation of the manuscript, or the decision to submit the manuscript for publication.

RESULTS

Of 4667 abstracts identified, 100 studies met criteria for full review, and 2 additional articles were identified from reference lists and expert contacts. Of these 102 studies, 11 met our inclusion criteria (35–45) (**Figure**). No studies evaluated opioid overdose, abuse, or dependence, as they were defined by the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*. Six studies were conducted in pain specialty settings (37, 38, 42–45). Of the 5 studies in primary care settings, 3 evaluated interdisciplinary programs that integrated care by pain specialists, psychiatrists, nurses, or pharmacists on a referral basis for patients suspected of opioid misuse (36, 39, 40). Another primary care study included a secretary-based patient tracking system (35). Overall, 7 studies evaluated opioid treatment agreements as part of multicomponent management strategies that included routine urine drug testing (36–41, 44), and 1 study evaluated urine drug testing alone (45). Disparate outcome measures of opioid misuse were used, as described in **Table 2**.

Figure. **Study flow diagram.**



* Seven studies evaluated management strategies incorporating both treatment agreements and urine drug testing.

The description of treatment agreements and urine drug testing interventions varied widely among studies. Six of 10 studies evaluating treatment agreements provided a copy of the agreement (35, 39–42, 44), but the remaining 4 studies offered little or no description of it. The same treatment agreement was used in 2 studies in the same setting (39, 40), yielding 5 agreements available for review. All 5 of these agreements listed the conditions necessary for continuation of opioid medications. Although these conditions varied, all agreements required patients to agree not to sell or share opioid medications and to provide urine or blood specimens for drug testing at their providers' request. In most agreements, patients agreed not to abuse illicit drugs or alcohol, obtain opioids from more than 1 provider or pharmacy, or request a refill before the previous prescription should have been completed. Although 3 agreements informed patients that opioid medications may not improve their pain or function, only 1 stated that a lack of response would indicate that these medications should be discontinued (42). Among the 8 studies that evaluated urine drug testing, the frequency of and indications for testing varied. Testing was described as "regular" or "random" in 4 studies (37–39, 41), and 1 study defined a protocol for testing before enrollment and on a monthly basis thereafter (40). Three studies described a minimum frequency of urine testing (at enrollment, annually, or both), with more frequent testing according to the physician's judgment (36, 44, 45). The assay used in urine drug testing interventions was specified in 5 of 8 studies; 1 study used an immunoassay screen alone (38), and 4 used confirmatory gas chromatography and mass spectrometry (39, 40, 44, 45).

All 4 studies that included a control group reported a decrease in opioid misuse after treatment agreements as part of the opioid management strategy (35–38). Two of these studies were conducted in Veterans Administration primary care clinics that provided monthly visits with a clinical pharmacist (36) or tracking by a secretary (35) as part of the monitoring program. One Veterans Administration study (36) found that opioid misuse among the 335 study participants decreased from 51.0% before the intervention to 28.1% afterward (ARR, 22.9% [95% CI, 17.3% to 28.7%]) (36). The other Veterans Administration study (35) reported a decrease from 47.3% to 26.4% (ARR, 20.9% [CI, 10.6% to 31.2%]) in opioid misuse among 209 intervention patients compared with no change in matched control participants. The remaining 2 controlled studies were conducted in the same sample of patients in a pain specialty setting and used historical control participants (37, 38). These studies found statistically significant decreases in obtaining opioid medications from an outside source from 17.8% to 9.2% (ARR, 8.6% [CI, 4.4% to 12.8%]) and in detection of illicit drug use from 22.5% to 16.0% (ARR, 6.5% [CI, 1.3% to 11.7%]). The quality of the 4 controlled studies was rated fair for 2 (35, 36) and poor for 2 (37, 38). Quality concerns include unrepresentative and high-risk samples (35–38), use of pre–post design (35, 36), and historical control groups (37, 38). **Appendix Tables 2** and **3** provide a detailed quality assessment.

Seven uncontrolled studies found wide variation in the proportion of patients with opioid misuse after treatment agreements, urine drug testing, or both (3% to 43%) (39–45). Of the 3 primary care studies, 2 were conducted in the same interdisciplinary referral-based program for patients with suspected substance abuse (39, 40) and reported that 32% of patients misused opioid medications, despite completing opioid treatment agreements. Another uncontrolled primary care study found that 17% of patients misused opioid medications after a treatment agreement (41). Two studies in pain specialty settings reported misuse of opioids during the year after an agreement in 24% to 28% of patients (43, 44). A study of patients in a pain specialty setting without a history of substance abuse found that only 3% misused opioids (42). The only study of opioid misuse after implementing routine urine drug testing without an opioid treatment agreement, conducted in 2 pain centers, found that 43% of patients misused opioids over nearly 4 years (45). The quality of these studies was rated as fair for 5 (39–41, 43, 45) and poor for 2 (42, 44). In addition to lack of a control group, a common quality concern is sampling bias because 2 studies excluded patients with known substance abuse (42, 43), whereas another 2 included patients who received referrals because of substance abuse concerns (39, 40).

Discussion

Despite an increasing reliance on prescribed opioids to treat chronic noncancer pain and a concurrent increase in diversion and overdose deaths (17, 18), this systematic review found that few studies have been conducted on the use of opioid treatment agreements and urine drug testing to reduce opioid misuse. Opioid misuse outcome measures varied substantially across studies, with none examining the clinically important outcomes of opioid abuse, dependence, overdose, or death. Moreover, all 11 studies used observational designs that are vulnerable to several threats to validity, such as unmeasured confounding. In the 4 studies that included comparison groups, multicomponent management strategies were associated with a 7% to 23% reduction in patient misuse of opioids when compared with preintervention conditions or historical control participants.

These studies were not representative of practice settings in which most patients are prescribed long-term opioids for chronic noncancer pain. Although we searched for studies conducted in any outpatient setting, most were conducted in pain specialty settings or in primary care practices that offered complex management strategies, including monitoring by ancillary or interdisciplinary staff. However, most patients with chronic pain are managed in

Table 2. **Studies Evaluating Opioid Misuse After Implementation of OTAs or UDT**

Study, Year (Reference)	Study Design	Setting	Sample Characteristics*	Management Strategy
Wiedemer et al, 2007 (36)	RCS	VA-based primary care with consultative support	335 patients referred by a PCP	OTA and routine UDT, with regular monitoring visits with clinical pharmacist
Goldberg et al, 2005 (35)	RCS	VA-based primary care	91 patients with an OTA in their medical record; mean age, 52 y; 88% men; 66% white	OTA‡
Manchikanti et al, 2006 (37)	PCS	Pain clinic	500 consecutive patients receiving stable opioid regimen; mean age, 48.5 y; 41% men; mean pain duration, 10.7 y	OTA and routine UDT
Manchikanti el al, 2006 (38)	PCS	Pain clinic	500 consecutive patients receiving stable opioid regimen; mean age, 48.5 y; 41% men; mean pain duration, 10.7 y	OTA and routine UDT
Chelminski et al, 2005 (39)	PCS	Primary care with consultative support	85 patients referred by a PCP to a pain program; mean age, 51 y; 60% men; 78% white; 75% had a history of alcohol use; 44% had a history of substance use	OTA, routine UDT, monthly visits in the context of a multidisciplinary pain management program††
Ives et al, 2006 (40)	PCS	Primary care with consultative support	196 patients referred by a PCP to a pain program; mean age, 52 y; 55% men; 75% white; 28% had a history of alcohol abuse; 29% had a history of cocaine abuse	OTA, routine UDT, monthly visits in the context of a multidisciplinary pain management program††
Hariharan et al, 2007 (41)	RCS	Primary care	330 patients; median age, 49 y; 52% men; 50% white; 48% black	OTA and UDT
Compton et al, 2008 (43)	PCS	VA-based pain clinic	135 patients without current substance use disorder defined by DSM-IV; mean age, 53 y; 94% men	OTA and monthly visits
Burchman and Pagel, 1995 (42)	RCS	VA-based pain clinic	81 patients with no known history of substance use, followed in clinic ≥1 y	OTA and monthly visits
Vaglienti et al, 2003 (44)	RCS	Pain clinic	Approximately 780 patients with OTA; of 184 patients with infractions, 51% were men	OTA with monthly UDT
Katz et al, 2003 (45)	RCS	Pain clinic	All 122 patients receiving long-term opioid therapy at 2 academic pain centers; mean age, 45 y; 51% men; 89% white; 17% had a history of substance abuse	Routine UDT¶¶

ARR = absolute risk reduction; BEH = behavioral monitoring (includes overuse, lost or stolen prescriptions, and provider impression of misuse); DSM-IV = *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*; GRADE = Grading of Recommendations Assessment, Development, and Evaluation; iUDT = urine drug test results inappropriately positive for an illicit or nonprescribed drug or negative for a prescribed opioid; MS = receipt of opioid medications from multiple sources; OTA = opioid treatment agreement; PCP = primary care physician; PCS = prospective cohort study; RCS = retrospective cohort study; RxA = prescription adulteration or forgery; UDT = urine drug testing; VA = Veterans Administration; VIOL = other or unspecified violation of OTA.
* Sample characteristics provided, as available.
† Quality rating: excellent (score ≥11 and GRADE ≥ 3), good (score ≥11 and GRADE ≥2), fair (score = 6–10 and GRADE ≥2), or poor (score ≤5 or GRADE = 1).
‡ Terms of OTA included UDT.
§ Matched on age, sex, race, and duration and dose of opioid treatment.
‖ Mean number of opioid prescribers per patient per quarter >2 (yes or no) during the 1.5 y after OTA compared with 2 y before OTA.
¶ Obtaining opioids either illegally or from another physician in nonemergency circumstances (yes or no).
** UDT detected the presence of cocaine, marijuana, methamphetamines, or amphetamines.
†† Multidisciplinary team included the patient's PCP, a clinical pharmacist, program assistant, pain psychiatrist, and nurse.
‡‡ A single marijuana-positive UDT result was not included in the definition of "opioid misuse."
§§ UDT detected the presence of cocaine or marijuana.
‖‖ Attempted to fill opioid prescriptions from an outside source.
¶¶ UDT frequency varied at the 2 sites (at one, at least annually or more if the physician found it to be indicated; at the other, at approximately every visit).
*** Behaviors included lost or stolen prescriptions, opioid overuse, visits without appointments, intolerance and allergies to several drugs, and frequent telephone calls.

primary care settings (1) that probably lack the staffing and support to implement these complex strategies.

In 7 studies that did not have control groups, we observed wide variation in opioid misuse after implementation of treatment agreements, urine drug testing, or both (4% to 32% in primary care and 3% to 43% in pain clinics). This variation probably reflects differences in the underlying risk for misuse in the study samples. Hariharan and colleagues (41) examined a representative sample of primary care patients and, after treatment agreements, identified opioid misuse (for example, prescription adulteration, several opioid sources, or other opioid-related over-the-counter violations) in only 4% of patients. In comparison, a literature review by Kahan and coworkers (46) reported that 7% to 31% of primary care patients who received treatment with long-term opioid medications but without treatment agreements exhibited signs of opioid misuse, such as repeatedly requesting early refills or reporting lost or stolen medications. Unfortunately, differences in the measures of opioid misuse limit the conclusions we can draw about the effect of the agreement itself.

A recent review by Chou and colleagues (47) examined a broad range of issues about opioid management and found little support for monitoring strategies, such as opioid treatment agreements and urine drug testing, but cited only 1 relevant study. In our systematic review, we identi-

Table 2—**Continued**

Control Condition	Follow-up	Misuse Measure	Results	Limitations	Quality†
Pre–post analysis	2-y observation	iUDT and BEH	ARR, 22.9% (95% CI, 17.3%–28.7%)	Sampling bias	Fair

fied 11 relevant studies and provide a comprehensive synthesis of the available evidence base. Our finding of limited evidence for the effectiveness of opioid treatment agreements should be viewed in the context of findings from a Cochrane review of treatment agreements (contracts) between patients and health care providers for clinical indications other than chronic pain, such as addiction, hypertension, and obesity (48). In that review, 16 of 30 randomized, controlled trials found statistically significant improvements in outcomes, including abstinence from substance abuse and adherence to medications and behavioral regimens.

Despite the lack of rigorous evidence supporting the use of treatment agreements and urine drug testing, these strategies have been endorsed by pain and addiction experts, professional societies, and regulatory agencies (19–21), and their use has been proposed as a quality indicator (49). Even in the absence of strong evidence, several compelling reasons for physicians to consider implementing these strategies exist. First, primary care providers who use opioid treatment agreements report improved satisfaction, comfort, and sense of mastery in managing chronic pain (50, 51). Second, management strategies that include treatment agreements have been associated with reductions in emergency department visits in observational studies (35, 36). Third, cross-sectional studies and a case series have demonstrated that urine drug testing is a valuable tool to detect use of nonprescribed drugs and confirm adherence to prescribed medications beyond that identified by patient self-report or impression of the treating physician (45, 52–57). Finally, implementing routine urine drug testing may improve the provider–patient relationship and clinic morale, as suggested in a letter to the editor (58).

In addition to lack of a strong evidence base, barriers to implementing treatment agreements and urine drug testing exist, particularly in primary care practices. Clinicians may be concerned about the time required to complete a treatment agreement with the patient (36) or that committing to a treatment agreement will restrict their clinical decision making. Furthermore, some clinicians may regard it as unethical to require treatment agreements for patients who take opioid analgesics but not for patients who take other potentially dangerous therapies, such as warfarin or insulin (59). Barriers to conducting urine drug testing in primary care practices include discomfort with discussing testing with patients, lack of access to appropriate tests (60), confusion about how to interpret or respond to test results (61, 62), and belief that one's patients are not at risk for opioid misuse and urine drug testing would be unnecessary. Misinterpretation of test re-

sults can lead to falsely accusing patients of opioid misuse and consequently harming the provider–patient relationship (60). Future research must address barriers and potential harms when evaluating the effectiveness of implementing these strategies.

Our review is limited by the considerable variation in the definition of opioid misuse in identified studies. Measures of opioid misuse ranged from subjective (provider impression of misuse) to the more objective finding of a positive urine drug test for an illicit substance. These measures also vary in severity; experts believe that adulterating a prescription is more likely to indicate addiction than obtaining opioids from multiple sources, which could represent undertreatment of pain (63). Unfortunately, no measure of opioid misuse has been demonstrated to be clearly superior in predicting clinically important outcomes, such as opioid abuse, dependence, overdose, or death. Research on defining optimal measures for opioid misuse is necessary because the use of clinical outcomes, such as opioid dependence, overdose, or death, would require large study populations and long time frames to identify events.

Another limitation is the multicomponent nature of most opioid management strategies, which does not distinguish the most effective components. Even among opioid treatment agreements, wide variation exists (64, 65). Experts have promoted goal-directed agreements that acknowledge the lack of evidence supporting long-term opioid treatment of chronic pain by defining functional goals to be achieved by the patient in order to continue the opioid analgesics (66, 67). In this review, we identified only 1 study that used a goal-directed agreement (42), and we could not draw any conclusions about its superiority over other approaches. Similarly, the implementation of urine drug testing interventions (for example, frequency, or type of assays) varied among studies and was reported inconsistently. Finally, publication bias and language bias may have limited the evidence available for our systematic review.

Our systematic review reveals that weak evidence supports the use of opioid treatment agreements and urine drug testing to reduce opioid misuse, despite the theoretical benefits of these strategies. This lack of evidence may explain in part why they have not been widely adopted in primary care. However, serious consequences of opioid misuse are on the rise (14–18) and affect all age groups (68, 69). Urgent attention is necessary to address this glaring deficiency in research, as are studies on the effectiveness of long-term opioid therapy for noncancer pain. Future research on effective risk-reduction strategies needs to be conducted in diverse primary care settings and use standardized measures of misuse, ideally those associated with clinical outcomes. In addition, this research should assess not only the benefits but also the potential harms of these strategies, such as patients forgoing pain treatment because of a perceived stigma or clinicians undertreating pain because of the perceived burden of opioid risk management. Studies of opioid management strategies need to be conducted as part of a larger initiative to improve the safety and effectiveness of long-term opioid treatment of patients with chronic noncancer pain.

Annals of Internal Medicine | PERSPECTIVE

Concierge Medicine: A "Regular" Physician's Perspective

Michael Stillman, MD

Concierge medical practices, which advertise expanded access to care and individualized attention, collect charges both from insurance companies and directly from their patients. Some bill hundreds of dollars for one-time "executive" physicals, whereas others have patients pay annual retainer fees. Yet, virtually no data are available about these "luxury" practices. It is not known how many physicians have "turned concierge," whether they have altered their testing and prescribing patterns, or whether their clinical outcomes are superior to those of their colleagues in traditional practices. Although some have voiced concern that concierge physicians create a 2-tiered system and may contribute to the difficulty that many patients have with access to care, the medical community has largely remained silent on the matter. The mere existence of concierge medicine may reflect our need as physicians to do better by our patients. Yet our responsibility as a professional community is to engage in—not run from—that monumental challenge.

Ann Intern Med. 2010;152:391-392. www.annals.org

Late last week, Marc, a fit, middle-aged patient, sent an e-mail telling me he was joining a concierge practice. Marc, his wife, and several of his siblings—all patients in my office for nearly 20 years—had always received same-day attention for any concerns, promptly returned calls, evidence-based and ethical care, and warm service from my staff. My relationship with him had at times seemed as much friendly as professional, and he had once invited me to his vacation home for dinner. So what precipitated this breakup?

Several weeks previously, 1 day before departing for vacation, Marc had called to tell me he felt something "stuck in his throat." He denied fevers, chills, or night sweats; had no new lumps in his neck; and had no difficulty swallowing food or breathing. Apart from this minor complaint, in fact, he felt perfectly well. Although Marc did not want to come to the office, he wondered what I thought might be wrong. I told him that he probably had postnasal drip or acid reflux, but that we could certainly arrange for neck ultrasonography and, if the result was negative, laryngoscopy. I called his local hospital, scheduled the ultrasonography for the day he returned from vacation, and called Marc to let him know.

Two weeks later, I called Marc and left a message inquiring whether he had had the ultrasonography, because I had not yet seen a report. In response, Marc penned the following e-mail: "I want you to know," he wrote, "that I have enormous regard for your capabilities as a doctor . . . and have always felt you were extremely caring and thorough. It is simply," he continued, "that I have a slight tendency toward obsessive worrying, and it has been my experience that waiting in line in the world of medicine can be torture." Marc told me that when he found he could not obtain same-day ultrasonography, one of his friends had directed him to a concierge practice. He had paid an $1800 fee, been seen within an hour, gone directly for an endoscopy, and received a diagnosis of . . . acid reflux. Marc had received the prompt diagnosis he felt he needed and had therefore decided to stay with his new physician.

This is not the first time a patient has left me for a concierge practice.

Gary, a healthy man 44 years of age, called to tell me he had subacute hand and arm numbness, and I offered him a same-day visit. His symptoms and physical examination suggested ulnar neuropathy—a peripheral nerve entrapment—but one of his nonmedical friends had convinced him he had a bulging disk and needed an imaging study. I scheduled Gary for a confirmatory nerve study, and only realized he had switched physicians when he did not attend. Disappointed with my reluctance to order magnetic resonance imaging, Gary found a more accommodating "luxury" physician who had done so promptly.

Mary, a pleasant woman 60 years of age, told me at our first visit that she had lupus. She had been hospitalized several times for "autoimmune flares," received immunomodulators intermittently, and had become so accustomed to her diagnosis that she "blamed all her sickness on it." After closely reviewing Mary's records, I found no evidence of an autoimmune disorder, but when I told her this good news and offered her a reevaluation from my favorite rheumatologist, she left me for a concierge physician. Rather than being overjoyed, she felt I had "pulled a rug out from under her," and in transferring physicians cited her need for "more personal" care.

Tim, a delightful man 21 years of age, presented with lymphadenopathy, weight loss, and night sweats. At our first visit, I admitted him to my service, arranged for an expedited metastatic workup, and unfortunately diagnosed lymphoma. Although I visited Tim several times after work hours and communicated closely with his oncology team, his parents enrolled him with a concierge physician who charges a $5000 annual "membership fee." Tim's father wrote that although he appreciated my efforts and attention, he was looking for "more proactive care." I have wondered since whether Tim's father had chosen that uniquely American approach of throwing money at a problem to buy a solution.

Despite the recent explosion of luxury practices, very little is known about them. No reliable statistics report the number of physicians who have "gone concierge" (or how many patients these transitions have displaced), and their clinical outcomes remain uninvestigated. A single study in

2005 (1) reported that patients at concierge practices are less ethnically diverse than the general population and have lower rates of diabetes, heart disease, and hypertension.

Several authors have expressed their ethical misgivings over concierge medicine in well-written articles. Donohoe (2) questions how physicians trained with public monies could limit their practices to a wealthy few and argues that associations between academic medical centers and "executive" practices undermine our efforts to produce clinically and morally thoughtful trainees. Carnahan (3) suggests that concierge physicians are cherry-picking the wealthiest and healthiest patients, "leaving behind a comparatively sick population to be absorbed by others in the community." Brennan (4), however, argues that the "luxury style of practice" allows physicians to spend ample time with patients and to "undertake the ethical responsibility to put [their] welfare above everything else." Kirkpatrick (5) describes how his retainer practice—which grosses $2.5 million per year—has satisfied patients, physicians, and medical center leadership and staunched an outflow of "*important patron patients*" (italics mine) who favor the "high-service benefits of belonging to a concierge practice."

It is understandable that patients want the best care possible, and practices that advertise 24-hour physician availability, lengthy appointments, and expedited access to subspecialists and procedures are naturally appealing. Marc, perturbed by having to wait a reasonable amount of time for a nonemergent evaluation, felt gratified to receive immediate care, whereas Gary, convinced that he needed magnetic resonance imaging, must have felt his new physician was doing "everything possible" to evaluate his symptoms.

I am less charitable, however, toward concierge physicians and am surprised by the neutrality with which the medical community has addressed their work. First, each of us has vowed to "treat without exception all who seek [our] ministrations," and limiting one's practice to several hundred wealthy patients undermines this tenet of our profession. Even though economic realities and schedule limitations dictate that some physicians maintain a certain payer mix or eventually close their panels to new patients, I am certain that the legendary physicians of our profession would be embarrassed by the criteria some of our colleagues have used in selecting which patients they will and will not see.

Second, Donohoe (2) correctly asserts that many retainer practices use a "buffet approach to diagnosis which makes a mockery of evidence-based medical care." A patient with a "lump in his throat" without dysphagia need not be sent for same-day ultrasonography and a man with hand numbness, no neck pain, and a negative Spurling test result does not require cervical magnetic resonance imaging.

Third, without proof that concierge medicine is clinically superior to traditional care, any suggestion that ill patients will be more tightly managed or that they will live longer or healthier lives is specious. Some patients may be willing to pay retainer fees simply for expanded access to their physicians or for receiving their care in a well-appointed office. Yet until data demonstrate that the longer visits, "executive" physicals, or annual ancillary testing offered by so many luxury practices yield better clinical outcomes, no one should not be allowed or led to believe that prompt or expensive care is necessarily the best.

Patients deserve and desire our fullest attention and consideration. They want to be listened to, to feel that we understand and appreciate their concerns, and to know that we are their staunchest advocates. Perhaps the emergence of concierge medicine will remind us of these tenets and force us to redouble our professional efforts. Broad adoption of the "medical home" model, which emphasizes the physician–patient relationship and enhanced access to care, may one day obviate luxury care. This being said, physicians who opt out of the current system by expending their energies catering to "patron patients" rather than helping reform a deeply flawed health care system or energizing a beleaguered professional community should reenter the fray. There are patients to be cared for, both wealthy and underprivileged; ideas to be proposed and exchanged; and policymakers to be educated and persuaded. These difficult times call for engagement, not isolation and retreat.

For Those on Whom We Rely

FIVE MONTHS AGO DEB—MY OFFICE MANAGER—developed pain in her right armpit. It was initially mild, yet over a course of weeks it had become severe enough that she had difficulties with typing and filing. I never pried nor insisted that she be seen by her physician, and Deb is so accustomed to minimizing her own concerns—so reluctant to "bother a doctor"—that she did not seek formal consultation until quite recently. One month ago she visited her primary care physician and was prescribed a ten-day course of ibuprofen. Two weeks ago she saw a physiatrist, who ordered magnetic resonance imaging—a study that was ultimately canceled.

Deb and I have a tacit understanding that I am not to meddle in her medical management; she deserves her privacy, and she and I are so close that my interventions would be subjective and therefore faulty. There is simply no way I could offer her my most clear-headed opinion. When her pain peaked, however, and she wondered aloud how she would get through the day, I quickly palpated her armpit and shoulder, found that no area was unusually tender, and sent her around the corner for a chest film. By the time Deb returned to our office, a radiologist had called me with unwelcome news. The film revealed a large right upper lobe mass, most likely with pleural extension.

Overriding Deb's objections, I canceled our patients for the day, brought her to our hospital's emergency department where we were met by her family, and had her admitted to the medicine service. During a two-day hospital course, she underwent a transthoracic biopsy, had both brain magnetic resonance imaging and a PET scan, and was diagnosed with squamous cell carcinoma. She returned to work the day after discharge, feeling guilty about a stack of paperwork she had left undone, but during her brief absence a pall hung over the office. It was not simply that she was not there; she does occasionally take vacation. Rather, it was that my staff and I had a jolting glimpse into what it would be like were Deb to become too ill to continue working with us. We felt amputated from some essential source of strength and goodness. We felt diminished and dull.

My first job after completing residency was at a community hospital. Eager for general internists, the chief medical officer had hired me on a guaranteed salary, given me an advertising budget with which to attract new patients, and placed me in an office with a well-established local internist. Deb was the lead secretary in that office, and she adopted me as if I were her own son. During my first weeks in practice, I knew very few of the physicians and staff who would prove essential to my ability to attract patients. Deb escorted me around the hospital, introduced me to her friends and colleagues, and had lunch with me every day so I would not be lonely. She was so thorough in handling administrative tasks, so hard-working, and so unusually sensitive in her dealings with patients, I later begged her to leave a position she had held for more than 20 years in favor of managing my own practice. The day she agreed to join me was one of the most important of my life.

Deb and I have shared many humorous moments. We have bantered with our favorite patients and giggled over how awkwardly our medical students behave (then marveled at how quickly they mature). We also share interests outside work and have compared notes on play-off games, disastrous runway couture, and the previous night's performances on *Glee* and *American Idol*. Deb was once so horrified to hear that a patient had disappeared into our private office bathroom to collect a sample for semen analysis, she dubbed the room the "Cave of Iniquity." Many years later, she and I still speak of "The Cave," and our new hires never know to what we are referring.

We have also shared a good number of tragedies. Deb and I have jointly attended patients' wakes, supported people who have struggled after a spouse's or child's death, and written sympathy letters to families of patients for whom we once cared. We have seen one another though personal and family troubles with illness, addiction, and crumbling relationships and have shared, in the first hour of our workdays before our staff and patients arrive, a great many sensitive revelations.

Deb has been my stout pillar of support—an insightful woman who will unobtrusively correct me when I am wrong and who will stand with me, even when others desert, when she feels I am right. Deb proofreads and edits my journal submissions and most sensitive correspondences before I mail them, often altering and improving on both tone and content. She seems to know exactly what I want to say, yet words my thoughts more gracefully and polishes my pieces' rough edges. Once, when I was just months out of residency, I became angry at and hung up on a woman who had had me paged and awakened at 3 o'clock in the morning for a mild cough. The woman's family threatened me—both physically and legally—and several hospital administrators called me in for a disciplinary conference. Deb's pithy response: "I would never wake someone up for a cough."

A Piece of My Mind Section Editor: Roxanne K. Young, Associate Senior Editor.

Finally, Deb has been the staunchest of patient advocates, treating them, as we all should, as if they were family. Her formal job description is simply to manage our office's finances and staffing, yet she has found struggling patients transitional housing, enrolled elderly patients in publicly funded transportation programs, arranged for nursing visits for people without adequate medical support at home, and argued down insurance companies that have wrongly billed our patients or inappropriately denied payment for our services. Patients often thank me for my care and tell me I am unusual in that I see to both their medical and nonmedical needs. I deflect this praise toward Deb. She is our patients' first point of contact, their guide through an often-baffling health care system, and their unyielding defender who takes upon herself the burden of setting injustices right.

This essay is not a remembrance. Deb, her family, and I know she has difficult months and years ahead, yet we both hope and expect that she will emerge from these menacing times and retake her place as the enthusiastic and essential hub about which so many lives revolve. Rather, I wrote this in appreciation specifically of a woman who has quietly and with extraordinary humility made my career, and more broadly about the people on whom we physicians rely.

In practices large and small, general and subspecialty, and in urban, suburban, and rural settings, some fortunate physicians' careers blossom based largely on the efforts of our managers, nurses, secretaries, and medical assistants. These people who can never be adequately compensated for their energy, enthusiasm, and investment in our work are not diagnosticians yet are every bit as important to our ill patients and their loved ones as we are. They are our public faces, projecting and amplifying only our best intentions. They are our soundings boards, our moral compasses, and our confidants. They are our part-time "spouses," coming to know us so well they can read and manage our moods at least as deftly as can our own families. They become our dear and trusted friends.

Intimate Partner Aggression Perpetration in Primary Care Chronic Pain Patients

Casey Taft, PhD
VA Boston Healthcare System, and
Boston University School of Medicine

Sonia Schwartz, BA
Boston Medical Center, and
Boston University School of Medicine

Jane M. Liebschutz, MD, MPH
Boston Medical Center, Boston University School of Medicine, and
Boston University School of Public Health

This study examined the prevalence and correlates of partner aggression perpetration in 597 primary care chronic pain patients. Approximately 30% of participants reported perpetrating low-level aggression, 12% reported injuring their partner, and 5% reported engaging in sexual coercion. Women reported more low-level aggression perpetration than men, and men reported more engagement in sexual coercion than women. Substance use disorders (SUD) were associated with all outcomes, and both aggression victimization and lifetime ratings of posttraumatic stress disorder (PTSD) were associated with low-level aggression and injuries. In multivariate analyses, gender, aggression victimization, PTSD, and SUD evidenced associations with one or more outcomes. Findings indicate a need for aggression screening in this population and highlight avenues for intervention.

Keywords: chronic pain; aggression; primary health care; substance use; posttraumatic stress disorder

An extensive literature documents the scope and impact of intimate partner aggression victimization among medical populations, including those experiencing chronic pain (Balousek, Plane, & Fleming, 2007). Relative to this research, little work has examined rates of perpetration of partner aggression in primary care medical settings, and none has focused on patients with chronic pain. Therefore, in the current investigation, we set out to examine the prevalence of behaviors reflecting intimate partner aggression perpetration among a sample of chronic pain patients, as well as potential correlates associated with these forms of aggression.

Chronic pain has been linked to psychiatric factors that are characterized by negative affect and impulsive behavior, and that confer risk for aggression. In particular, patients with chronic pain are likely to evidence heightened posttraumatic stress disorder (PTSD),

DOI: 10.1891/0886-6708.25.5.649

depression, and substance use problems (Larson et al., 2007; Liebschutz et al., 2007; McWilliams, Cox, & Enns, 2003), all of which are strongly linked to relationship aggression perpetration in other populations (Jordan et al., 1992; Stuart, Moore, Gordon, Ramsey, & Kahler, 2006; Taft et al., 2005). Seminal theories of aggression, such as Berkowitz' cognitive-neoassociationistic model (Berkowitz, 1990), hold that those who experience more frequent and severe negative affect also experience heightened feelings, thoughts, and memories related to anger and have a higher propensity for aggressive behavior. Problematic substance use is further likely to decrease positive communication behaviors and disinhibit aggressive behavior (Leonard & Roberts, 1998), particularly in the presence of anger and heightened negative affect (Eckhardt, 2007).

While no theoretical or empirical models have been developed to explain the possible association of chronic pain with relationship aggression, Fishbain and colleagues (Fishbain, Cutler, Rosomoff, & Steele-Rosomoff, 2000) have developed a clinical model of patient violence toward physicians that describes some potential explanatory mechanisms. Specifically, this model, which has received some recent empirical support (Bruns, Disorbio, & Hanks, 2007), highlights the role of problematic and stressful interpersonal relationships with those involved in the patients' care, negative affect, physical symptom factors such as level of pain and perceptions of functional health and disability, and potential substance abuse. Analogous processes are likely to occur within the context of an intimate relationship, which has its own set of stressors, such as pain-related occupational and family role changes, financial difficulties, and impaired sexual functioning (Schwartz, Slater, & Birchler, 1996). Such relationship strains are likely to independently or jointly increase risk for aggression along with negative affect and possible substance abuse problems that accompany chronic pain.

We expected that variables reflecting negative affect and behavioral disinhibition would distinguish primary care chronic pain patients who report intimate partner aggression perpetration from their nonaggressive counterparts. Specifically, we examined PTSD, depression, and substance use disorders (SUD) as potential correlates of aggression. Consistent with the Fishbain model (Fishbain et al., 2000), it was also hypothesized that chronic pain severity and indices of physical and mental health disability would be associated with higher relationship aggression. Demographic and background correlates (age, gender, and race/ethnicity) were also explored, and we considered the role of victimization experience since much intimate aggression is bidirectional in community-based samples (Johnson & Ferraro, 2000) and individuals may aggress out of self-defense (White, Smith, Koss, & Figueredo, 2000).

METHODS

Participants

Participants were 597 patients who were 18 to 60 years of age, spoke English, endorsed pain of 3 months or more, reported use of any analgesic medication (over-the-counter or prescription) in the prior month, and had a scheduled primary care appointment. Of the 825 who met eligibility criteria for the study, 597 (76%) agreed to participate. When comparing screening questions responses between those who enrolled and those who declined, enrollees were more likely to be African American (61% vs. 55%, $p < .05$), less likely to take over-the-counter pain medication (67% vs. 79%, $p < .001$), and more likely to take

opioid pain medication (41% vs. 30%, $p < .01$). Age and gender were not different. Overall, the sample averaged 45.8 years of age and was 58.6% female, 60.8% African American, 27.8% with less than a high school education, 61.1% with a reported income less than US$20,000, 60.5% unemployed, and the majority experienced high pain limitation.

Trained research interviewers consecutively approached patients in primary care waiting rooms of an academic, urban, safety-net hospital primary care practice. Potential participants were asked to complete a written screening instrument about their pain, analgesia use, and demographic characteristics. Written informed consent was obtained from eligible and interested patients. All study measures were administered via interviews that lasted 45 to 90 min and participants were compensated US$10. Recruitment occurred between February 2005 and August 2006. The Boston University Medical Center Institutional Review Board approved the study, and National Institutes of Health issued a Certificate of Confidentiality.

Measures

Aggression perpetration was assessed with three questions taken from Wave III of the Add Health Home Questionnaire (Carolina Population Center, n.d.; Fang & Corso, 2007). Each question represented separate dependent variables: (1) Low-level aggression: Have *you* ever threatened your partner with violence, pushed or shoved [him or her], or thrown something at [him or her] that could hurt? (2) Injury: Has your partner ever had an injury, such as a sprain, bruise, or cut because of a fight with you? and (3) Sexual coercion: Have *you* ever insisted on or made your partner have sexual relations with you when [he or she] didn't want to? Participants reported on each outcome using a yes/no dichotomous scale. After each positive response, participants were asked the year of the last perpetration behavior. Each perpetrating behavior was analyzed as a separate outcome. Partner aggression perpetration assessed using the Add Health Questionnaire has been shown to be significantly associated with an index of general aggression perpetration in young adulthood, attesting to the construct validity of this outcome measure (Herrera, Wiersma, & Cleveland, 2008). Intimate partner victimization was measured using the same three questions. Any of the three victimization experiences constituted victimization in bivariate and regression analyses.

The Composite International Diagnostic Interview (CIDI; World Health Organization, 1997) was used to measure PTSD ever (lifetime) or in the past year (current). The CIDI has been shown to have good test-retest and interrater reliability and good validity (Andrews & Peters, 1998; Wittchen, 1994).

Major depression was measured using the Patient Health Questionnaire (PHQ) for Depression (Kroenke, 2002). The PHQ is a nine-item measure examining past 2 week major depression with items rated on a 4-point scale and total scores ranging from 9 to 27. The psychometric properties of the measure have been previously demonstrated (Kroenke, 2002).

SUD was defined as meeting *DSM-IV* criteria for any drug abuse or dependence ever, and/or past year alcohol dependence as measured by the CIDI version 2.1 for drug disorder (World Health Organization, 1997) and Short-Form (SF) for alcohol dependence (World Health Organization, 1997). Past year SUD included active diagnosis in the past 12 months.

Pain-related disability (limiting or nonlimiting) was measured using the Graded Chronic Pain Scale, a seven-item validated measure of pain and disability that includes

two subscales: Chronic Pain Intensity and Disability Points (Von Korff, Ormel, Keefe, & Dworkin, 1992). Scoring involves categorizing the participant into one of five pain grades: pain free, low disability-low intensity, low disability-high intensity, high disability-moderately limiting, and high disability-severely limiting.

Health-related quality of life was measured with the SF-12 Mental Health and SF-12 Physical Health composite scores (Ware, Kosinski, & Keller, 1996). This measure is derived from the SF-36 Health Survey and is scored using norm-based scoring. Several studies in both medical and general populations have shown the SF-12 to have good reliability and validity (Gandek et al., 1998; Salyers, Bosworth, Swanson, Lamb-Pagone, & Osher, 2000; Ware et al., 1996).

Analysis

This is a secondary analysis of a cross-sectional study of primary care patients with chronic pain designed to look at correlates of pain, SUD, and violence-related mental health problems. After computing descriptive statistics for the aggression outcomes, bivariate analyses were performed examining differences in characteristics associated with each perpetrating behavior. Logistic regression models were created using those variables found to be significantly associated with aggression perpetration at the bivariate level, as well as victimization for all models.

RESULTS

Descriptive Statistics for Aggression

Descriptive statistics for the study correlates are reported in Table 1. As is shown in Table 2, almost one-third of participants (30%) reported perpetrating low-level aggression toward their partner, and less than half of the sample (44%) reported low-level aggression victimization. The prevalence of injury stemming from intimate partner physical aggression victimization (33%) was approximately 3 times greater than was the prevalence of participants reporting that they injured their partner (12%). Five percent of participants reported engaging in sexual coercion, and 20% of participants indicated that their partners sexually coerced them. Participants reported a mean of about 10 years since the last perpetration behavior (9.9 for low-level aggression and sexual coercion and 13.2 for injuring partner) and 12 years since last victim experience (11.2 for low-level aggression, 12.1 for injury by partner, and 11.8 for sexual coercion).

We further examined intimate partner aggression prevalence by victim–perpetrator status (victim-only status, perpetrator-only status, or both victim and perpetrator). As Table 3 indicates, most participants who reported aggression perpetration also reported victimization (of any type). For example, 85% of participants who reported low-level intimate partner aggression perpetration also reported victimization. It is not known whether this was bidirectional in the same relationship or victimization and perpetration in different relationships.

Correlates of Intimate Partner Aggression Perpetration

Several potential correlates were examined as factors that may distinguish those who report intimate partner aggression perpetration versus those who do not. Results from these analyses are presented in Table 4. A gender effect was found, such that women were more

TABLE 1. Descriptive Statistics for Study Correlates (*N* = 597)

Variable	*N*	%

SF-12 mental health	42.2	12.7

Note. Victimization includes at least one of the three forms of aggression (i.e., low-level aggression, injury, sexual coercion). PTSD = Posttraumatic Stress Disorder; SUD = Substance Use Disorder; SF-12 = Short Form-12 Physical and Mental Health Related Quality of Life.

likely to report perpetration of low-level aggression, and men were more likely to report sexual coercion of a partner. Partner aggression victimization was strongly associated with both low-level aggression and partner injury, and its association with sexual coercion approached significance. Lifetime PTSD represented a significant correlate of low-level aggression and partner injury, whereas a current diagnosis of PTSD was associated only with low-level aggression. Current major depression, on the other hand, was not significantly associated with any form of aggression, though its association with low-level aggression approached significance. SUD represented a significant correlate for all three outcomes. Mental health–related quality of life score was lower (worse) in perpetrators of low-level aggression but not the other types of aggression.

Regression Analyses

Table 5 reports the outcomes of regression models predicting the three outcomes. In Model 1, female gender, any victimization, lifetime PTSD, and SUD were associated with low-level aggression perpetration, whereas mental health–related quality of life was not. When we substituted current PTSD for lifetime PTSD, it was not statistically significant (data not

shown). For Model 2, any victimization and SUD were associated with higher infliction of injury, whereas lifetime PTSD was not. For Model 3, female gender was associated with less sexual coercion, while any victimization experience was associated with more sexual coercion and SUD was not associated with this outcome.

DISCUSSION

High rates of intimate partner aggression perpetration and victimization were reported in this sample of primary care patients with chronic pain recruited from an urban academic practice, with almost one-third reporting perpetration of low-level aggression and almost one half of the sample reporting low-level aggression victimization. More than 12% of the

sample reported the infliction of injuries on their partner, and rates of injury victimization were almost 3 times higher. Approximately 5% of this sample reported engaging in sexual coercion, while rates of sexual coercion victimization were 4 times higher. Considering data on relationship aggression rates obtained from representative sample studies of the general population (Coker et al., 2002), and being mindful of the use of different aggression measures across studies, current findings suggest elevated rates of aggression occurring in the intimate relationships of patients experiencing chronic pain.

Reports of higher rates of intimate partner aggression victimization than perpetration are consistent with the focus of the broader literature that has emphasized associations between abuse victimization experiences and chronic pain (Bailey, Freedenfeld, Kiser, & Gatchel, 2003; Balousek et al., 2007; Walsh, Jamieson, Macmillan, & Boyle, 2007). It is important to note, however, that individuals tend to underreport their intimate relationship perpetration behavior relative to their victimization due to social desirability and other biases (Moffitt et al., 1997). Thus, perpetration reports in this study are likely to represent underestimates, and the true rates of aggression victimization and perpetration are likely to be more comparable than current study findings indicate. In addition, study findings indicate that a number of correlates were associated with intimate relationship aggression perpetration in this sample, even when controlling for victimization experiences, suggesting that aggression perpetrated in this sample was not exclusively due to acts of self-defense or bidirectional aggression.

TABLE 5. Characteristics Associated With Intimate Partner Aggression Perpetration

Model	Odds Ratio (95% CI)
1. Low-level aggression	
Female vs. Male	1.97 (1.25–3.11)
Any victimization—Yes vs. No	7.18 (4.45–11.59)
Lifetime PTSD—Yes vs. No	1.81 (1.18–2.77)
Any SUD—Yes vs. No	2.23 (1.43–3.47)
SF-12 mental health score	1.01 (0.99–1.02)
2. Injury	
Any victimization—Yes vs. No	7.12 (3.40–14.90)
Lifetime PTSD—Yes vs. No	1.12 (0.66–1.89)
Current/lifetime SUD—Yes vs. No	2.42 (1.42–4.13)
3. Sexual coercion	
Female vs. Male	0.22 (0.09–0.53)
Any victimization—Yes vs. No	2.34 (1.04–5.30)
Current/lifetime SUD—Yes vs. No	1.54 (0.68–3.47)

Note. Victimization includes at least one of the three forms of aggression (i.e., low-level aggression, injury, sexual coercion). PTSD = Posttraumatic Stress Disorder; SUD = Substance Use Disorder; SF-12 = Short Form-12 Physical and Mental Health–Related Quality of Life.

Consistent with the Fishbain model (Fishbain et al., 2000) adapted for intimate partner aggression, it was predicted that variables reflecting negative affect and behavioral disinhibition, as well as chronic pain severity and disability would emerge as significant correlates of aggression perpetration. Among these predictors, SUD generally emerged as the strongest relative predictor. This correlate was associated with each of the three aggression perpetration outcomes at the bivariate level and both measures reflecting nonsexual aggression when statistically accounting for the other significant correlates. Problematic substance use leads to disinhibition of aggressive impulses (Eckhardt, 2007; Leonard & Roberts, 1998), and previous research indicates that substance abuse is associated with violent ideation in this population (Bruns et al., 2007). Substance use may be particularly problematic in the context of PTSD and poor mental health functioning, which were also associated with aggression perpetration at the bivariate level. PTSD and not poor mental health functioning was associated with low-level aggression perpetration in the context of the other significant correlates.

Women appeared to report more low-level aggression than men, while men reported more engagement in sexual coercion behavior. These findings are generally consistent with the broader literature on intimate partner aggression perpetration. A meta-analysis by Archer (2000) indicated that women engage in slightly higher rates of

noninjurious intimate aggression than men, particularly in community-based samples (Archer, 2000). Men's aggression is more likely to lead to victim injury, though current study findings did not find such gender differences. Regarding differences in sexual coercion, previous research indicates that men engage in higher levels of sexual coercion or sexual aggression than women (Hartwick, Desmarais, & Hennig, 2007; Stets & Pirog-Good, 1987).

The current investigation has some important clinical implications. Intimate partner aggression victimization as well as perpetration appears to be heightened in the chronic pain population, suggesting that increased screening, prevention, and intervention efforts focused on partner aggression are warranted for these individuals. Such efforts should target both men and women, as current study findings suggest that although some gender differences were noted, both genders may engage in or experience intimate partner aggression. It appears that interventions that target SUD in particular, as well as symptoms of PTSD, may be especially effective in reducing aggression. Couples-based interventions also appear warranted for this population, as the aggression reported in this study suggests that it may frequently be bidirectional in nature, and victimization was a robust predictor of perpetration. Previous work indicates that the response of the intimate partner to a patient's negative pain behaviors can serve as powerful determinants of adjustment and the maintenance of such behaviors, lending further support for couples-based intervention approaches (Burns, Johnson, Mahoney, Devine, & Pawl, 1996; Cano, Gillis, Heinz, Geisser, & Foran, 2004; Cano & Leonard, 2006; Newton-John & Williams, 2006; Romano et al., 1992; Schwartz et al., 1996). However, couples therapy may be contraindicated in cases of moderate- to severe-aggression or in the presence of a pattern of coercive control in the relationship.

The cross-sectional nature of this study precludes us from drawing firm conclusions regarding the directionality of obtained associations. Findings that much of the aggression may have occurred several years prior to study participation (taking into account the previously described possible deflated self-reported rates of aggression) suggest that aggression victimization led to the experience of chronic pain in this sample. Moreover, aggression perpetration may also lead to higher levels of chronic pain because anger expression may alienate patients from their partners and other sources of support (Burns et al., 1996), and several other psychological, biological, and genetic mechanisms have been proposed for this relationship (Bruehl, Chung, & Burns, 2006). Prospective designs are needed to more fully examine the directionality of associations among the variables investigated in the current study. It is perhaps most likely that associations among chronic pain, aggression victimization and perpetration, and the correlates of interest are bidirectional in nature. Future research in this area should also utilize more comprehensive measures of different forms of physical, psychological, and sexual intimate partner aggression and should obtain reports from both members of the couple. Finally, sampling was limited to one primary care setting in one locale. It is possible that findings would not generalize to other settings or study sites.

Despite these limitations, this study represents an initial attempt to examine reports of intimate relationship aggression perpetration in a sample of chronic pain patients, including correlates of such aggression. Findings suggest relatively high rates of aggression perpetration and victimization in this sample and highlight the role of substance use problems in particular as a correlate of perpetration. Additional work is needed to better understand the nature and scope of the relationship aggression problem in patients experiencing chronic pain and to ultimately reduce aggression and enhance intimate relationships in this population.

ABSTRACT

Background: Health literacy affects the acquisition of health knowledge and is thus linked to health outcomes. However, few scales have been developed to assess the level of health knowledge among the general public.

Methods: The 15-item Japanese Health Knowledge Test (J-HKT) was developed by using item response theory to score an item pool. We examined the construct validity of the J-HKT in relation to health literacy items, and analyzed the sociodemographic and behavioral factors associated with poor health knowledge.

Results: We enrolled 1040 adult participants (mean age, 57 years; women, 52%). The 15 items that best identified people with poor health knowledge were selected. For all items on the J-HKT, the information function curves had a peak in the negative spectrum of the latent trait. As compared with participants reporting high levels of income, educational attainment, and literacy, those with low levels of income, education, and literacy had a lower total score on the J-HKT. As compared with non/light drinkers, moderate and heavy drinkers had lower total scores on the J-HKT.

Conclusions: The J-HKT may prove useful in measuring health knowledge among the general public, and in identifying and characterizing those with poor health knowledge.

Key words: health knowledge; health literacy; socioeconomic status

INTRODUCTION

A growing body of evidence supports the impact of low health literacy on the health of individuals[1]; therefore, recent attention has focused on the elucidation of potential causal pathways linking low health literacy to poor health.[2,3] Among the mechanisms that mediate the influence of health literacy on the health of individuals, the effect of health literacy on health knowledge may be one of the most consistent and critical factors.[4–6] It has been proposed that low health literacy leads to poor health knowledge and, ultimately, to worse health outcomes, because people with low health literacy have difficulty in acquiring the health knowledge necessary to navigate the healthcare system and to practice effective self-care.

Patients with poor knowledge of illness prevention and chronic diseases have lower adherence to medical instructions and are more likely to have high-risk health behaviors.[7–10] Thus, these individuals are less likely to utilize healthcare services, such as recommended vaccination and health screening programs.[11–13] In addition, during both acute and chronic illnesses, the quality of self-care is poor among those with limited knowledge, which may manifest in the greater use of potentially harmful complementary or alternative medicine.[14]

Many studies have evaluated the relationship between health literacy and health knowledge.[4,5,7,8,15,16] These have mostly focused on patients with specific illnesses, such as asthma, diabetes, congestive heart failure, hypertension, and human immunodeficiency virus infection; few have evaluated the association between low health literacy and poor health knowledge in the general public. In patients with chronic diseases, the relationship between health literacy and health knowledge of a particular disease has been confirmed.[4,5,7,8,15,16] In order to better understand the relationship between health literacy and health knowledge, and to help target education and guide disease prevention for the general public, it would be useful to examine the

relationship between health knowledge and health literacy in the general public. However, this objective cannot be realized without a tool to assess general health knowledge. Such a tool would be particularly useful if it were short, if it could differentiate among people at the low end of the health knowledge spectrum, and if it could be administered in a mode other than in-person interview. Thus, in the present study, we used nominal categories modeling of item response theory (IRT) analysis to develop a test of general health knowledge for Japanese adults. To evaluate construct validity, we examined the association between this health knowledge test and health literacy. In addition, we identified the sociodemographic and health behavioral factors that were significantly associated with poor health knowledge.

METHODS

Study participants

The data for this study were collected from responses to a national cross-sectional online survey conducted from 3 July to 8 July 2008. Institutional review board approval was obtained from the National Institute of Japanese Language. Japan was divided into 10 regions: Hokkaido, Tohoku, Kanto, Tokai, Keihin, Hokuriku, Kyouhanshin, Chugoku, Shikoku, and Kyushu. The number of potential participants was determined within each region from a panel of people registered by Yahoo JAPAN Co. (Tokyo, Japan) by means of probability sampling proportionate to age and sex, using Japanese national census data of population distributions for people aged 30–90 years in 2007. People younger than 30 years were excluded because our aims included evaluation of the potential association between health knowledge and final educational attainment. In addition, health care workers, such as physicians, nurses, hospital workers, and public health workers, were excluded. No gifts or payments were given for participating in the survey.

Data collection

The survey gathered demographic and socioeconomic data, as well as responses to the questionnaire for health literacy and the test of health knowledge. Demographic data included age, sex, annual income, education, and occupation. Regarding annual income, cutoff points of 2, 4, 6, and 8 million Japanese Yen (JY) were used to generate 5 income categories (the average exchange rate for 1 US dollar in July 2008 was about 100 JY). We used these income cutoffs because the National Tax Agency regards an income of 2 million JY as the cutoff level for low-wage workers and reports the income distribution in this fashion. For educational attainment, 5 categories were used (did not graduate high school, high school graduate, vocational school, short-term college, and undergraduate/postgraduate degree). For occupational status, 5 categorical levels were included: working full-time, homemaker, working part-time, retired, and not currently working. Survey items also assessed current and past smoking, current alcohol use, and chronic conditions (cancer, cardiovascular disease, hypertension, diabetes, arthritis, asthma or chronic obstructive pulmonary disease, and depression), as previously described.[2]

Current alcohol consumption was categorized into 3 categories: non/light, moderate, and heavy. Non/light drinkers were defined as those who drank less than once a week; moderate and heavy users included those who drank at least once a week. In addition, heavy users were defined as those who drank in a day ≥3 glasses of beer, ≥540 ml of Japanese sake (*nihonshu*), three-quarters of a bottle or more of wine, or ≥180 ml of whisky. All remaining participants were defined as moderate users.

Health literacy was measured by self-report using 2 validated screening questions.[17,18] Specifically, we asked: "How often do you have problems learning about your medical condition because of difficulty understanding written information?" (Item 1: "Problems learning") and "How often do you have someone help you read hospital materials?" (Item 2: "Help reading"). The 5-point Likert response scale was, "Never", "Occasionally", "Sometimes", "Often", or "Always". These 2 items have been shown to predict scores on commonly used English-language measures of health literacy: the Short Test of Functional Health Literacy in Adults (STOFHLA) and the Rapid Estimate of Adult Literacy in Medicine (REALM).[17,18] Due to the linguistic differences between English and Japanese, English-language instruments for measuring health literacy cannot be simply translated. Thus, we used these 2 self-report items as surrogate measures of health literacy.[17–19]

Development of the Japanese Health Knowledge Test (J-HKT)

The first phase of development included item generation by a group of experts in healthcare, literacy, linguistics, and mass media. This 25-member group included physicians, nurses, pharmacists, linguists, journalists, university researchers in communication, and representatives of patient advocate groups. Each item was developed with a single correct response among a list of 4 choices. When providing the item test to the study participants, they were advised that there was a 2-minute time limit for each item. Each item was scored as correct or incorrect.

In the second phase of development, the 48-item pool was shortened using item response theory (IRT) analysis, specifically the nominal categories model. This model was proposed by Bock[20] as an extension of IRT analysis for nominally scored items. As compared with the use of a graded categories model or a binary logistic model, the nominal categories model is more effective in examining the full spectrum of contributions for each item and the possible responses in an instrument. For this purpose, we used a sample size large enough to meet the requirements of nominal categories modeling.

In the nominal categories model, the response probability p_{ijk} that respondent i with a latent trait θ_i response to category k ($k = 1, 2, \ldots, K_j$) of item j is described as follows[21]:

$$p_{ijk} = \frac{\exp(\alpha_{jk}\theta_i + \gamma_{jk})}{\sum_{k'=1}^{K_j} \exp(\alpha_{jk'}\theta_i + \gamma_{jk'})}$$

where K_j denotes the number of the category of item j. We cannot interpret the parameters of the categories independently in the nominal categories model because the equation defined for a response probability to the category contains other parameters. Thus, in order to estimate item parameters, Okubo suggested that a restriction be imposed as follows[22]:

$$\alpha_{j1} = \gamma_{j1} = 0$$

The role of the alpha parameter is that of a slope in the linear function. A larger slope implies that the item clearly discriminates the latent trait θ_i, while a smaller slope implies low discrimination. The role of the gamma parameter is that of an intercept. A larger intercept gamma suggests that the item is difficult to solve, while a smaller intercept gamma suggests it is easy to solve.

Next, the item response category characteristic curve (IRCCC) is determined by the relative relations among parameters; thus, each parameter cannot be interpreted alone. The usual method to analyze the characteristics of items is to draw the IRCCC by using the estimated parameters. The IRCCC is a multinomial logistic regression curve whose independent variable is a factor—in this case, health knowledge.

Item information functions were then generated for each item. Item information function curves were derived from the response probabilities from the IRCCCs. The standard error of measurement curve can be calculated as the reciprocal of the square root of the item information function. Item information functions describe responses at different levels of a latent trait—health knowledge in this study. A combination of all items together was used to generate the test information function, and an item reduction procedure was performed based on the item information functions. Participants with a score that was ≥1 standard deviation lower than the mean were classified as having a low score.

Phase 3 of development sought to support the validity of the J-HKT. The face validity of the J-HKT was confirmed by the aforementioned expert panel. Next, for construct validity, we hypothesized that health literacy would be associated with improved J-HKT scores and thus the association between literacy and J-HKT scores was examined by using the nonparametric test for trend across ordered groups developed by Cuzick.[23]

Associations between sociodemographic characteristics and J-HKT scores were evaluated by a logistic regression model that included age and sex, as well as additional variables found to be significant in univariate analyses. Statistical analyses were performed using R version 2.6.6 (R Foundation for Statistical Computing) and STATA 10.0 (College Station, Texas, USA), and graphics were generated using Mathematica version 6.0 (Wolfram Research, Illinois, USA). A 2-tailed P value <0.05 was considered statistically significant.

RESULTS

Of 2500 subjects randomly selected from the online panel, 1074 participated in the study (response rate, 43.0%). Among these, after deleting data from participants working in the health care industry, data for 1040 persons were available for our analysis and were considered as the final sample. Table 1 shows the sociodemographic characteristics of all participants; 52% were women and the mean age was 57 years (range, 30–90).

Table 1. Characteristics of participants (n = 1040)

Characteristic	Meen (SD) or n, %
Age (years)	57 (15)
Sex	
Male	497, 48%
Female	543, 52%
Income (Japanese Yen)	
<2 million	92, 9%
2–3.99 million	264, 25%
4–5.99 million	290, 28%
6–7.99 million	160, 15%
8 million or more	234, 23%
Education	
<Grade 12	51, 5%
High school graduate	379, 36%
Vocational school	107, 10%
Some college	139, 13%
University or graduate degree	364, 35%
Working status	
Working full-time	445, 43%
Homemaker	273, 26%
Working part-time	91, 9%
Retired	135, 13%
Currently not working	96, 9%
Smoking	
Current	200, 19%
Former	247, 24%
Never	593, 57%
Current alcohol use	
None/light	588, 57%
Moderate	407, 39%
Heavy	45, 4%
Chronic condition	
Cancer	38, 4%
Cardiovascular disease	21, 2%
Hypertension	221, 21%
Diabetes	55, 5%
Arthritis	45, 4%
Asthma or COPD	29, 3%
Depression	33, 3%

COPD = chronic obstructive pulmonary disease.

Table 2. Estimated parameters for the 15 items of the Japanese Health Knowledge Test

Item number	Alpha (slope parameter) Category				Gamma (location parameter) Category			
	1	2	3	4	1	2	3	4
1	0.00	0.07	0.46	0.36	0.00	0.88	2.04	−0.41

10	NA	0.00	1.53	NA	NA	0.00	3.54	NA
11	0.00	0.56	NA	0.32	0.00	2.53	NA	0.89
12	0.00	−0.74	−0.87	0.24	0.00	−1.42	−0.71	−0.17
13	0.00	−1.52	0.96	NA	0.00	−2.56	0.88	NA
14	0.00	0.81	−0.33	−0.25	0.00	1.37	−0.50	−0.06
15	0.00	−1.18	−0.21	0.69	0.00	−0.91	−0.34	1.12

Values for category 1 were set to 0 for estimating parameters.
NA, not available.

The initial item pool contained 48 items that covered knowledge of body parts, diseases, hospitals, drugs, healthcare systems, health policy, and home care. The expert panel considered these 48 items to have adequate content validity, and to represent the range of patient knowledge required to understand common medical problems. Based on the item information functions of the IRT analysis for health knowledge testing in the 1040 participants, a 15-item J-HKT was produced from the initial 48-item pool (Table 2 and Supplement).

Regarding each response to individual items of the J-HKT, all IRCCCs of the J-HKT satisfied the assumption of monotonicity, ie, scores for each item were higher among participants with a higher overall J-HKT score. For most items, a greater number of intersections of probability curves of item responses was shifted to the negative spectrum of the latent trait. Figure 1 shows the item information function for individual items of the J-HKT.

To better discriminate between people with poor health knowledge and those with intermediate or higher levels of health knowledge, 15 items with the highest information function at −0.85 (those with the lowest percentile of 20% of overall scores in all participants) of latent trait θ_i were included in the J-HKT. Thus, we chose items able to differentiate among people at the low end of health knowledge; as such, the curves for all items of the J-HKT show a peak of the information functions in the negative spectrum of the latent trait.

Figure 2 shows a histogram of total scores for the 15-item J-HKT. The mean score was 4.7 and the standard deviation was 1.6; the median score was 5.0 and the mode was 4.0. The score is normally distributed, with a skewness of −0.37 and a kurtosis of −0.38. Figures 3 and 4 show the proportions of participants with poor health knowledge, by responses to the 2 health literacy items ("Problems learning" and "Help reading"). There were statistically significant associations between responses to the health literacy items and total score on the J-HKT (ie, construct validity). Figure 5 shows the item information function curve of the 15-item J-HKT, and Figure 6 depicts the standard error curve of the item information function of the 15-item J-HKT (the standard error is the reciprocal of the item information function).

Table 3 shows the distributions of total score on the J-HKT by sociodemographic characteristics, smoking, and alcohol use. Overall, 36% of participants had a score of 0–3, which was defined as poor health knowledge (ie, more than 1 standard deviation below the mean, 4.7 − 1.6 = 3.1). Age, sex, and employment status were not associated with test scores; however, participants with low income and low educational attainment were more likely to have a lower score on the J-HKT. Although smoking status was not associated with J-HKT score, those with higher current alcohol use had a lower total score on the J-HKT.

Table 4 presents the results of the logistic regression model for poor health knowledge on the J-HKT (0–3, yes versus no) adjusted for age, sex, income, education, and current alcohol use. Compared with those with an income >8 million JY, those with income ≥2 and <4 million JY were more likely to have poor health knowledge (odds ratio [OR], 1.68; 95% confidence interval [CI], 1.08–2.62) and those with an income <2 million JY were also more likely to have poor health knowledge (1.84; 1.02–3.31). In addition, as compared with university degree holders, those who had not graduated high school were also more likely to have poor health knowledge (2.08; 1.05–4.14). Regarding current alcohol use, as compared with non/light drinkers, poor health knowledge was more likely among moderate drinkers (1.53; 1.12–2.09) and heavy drinkers (2.28; 1.16–4.47).

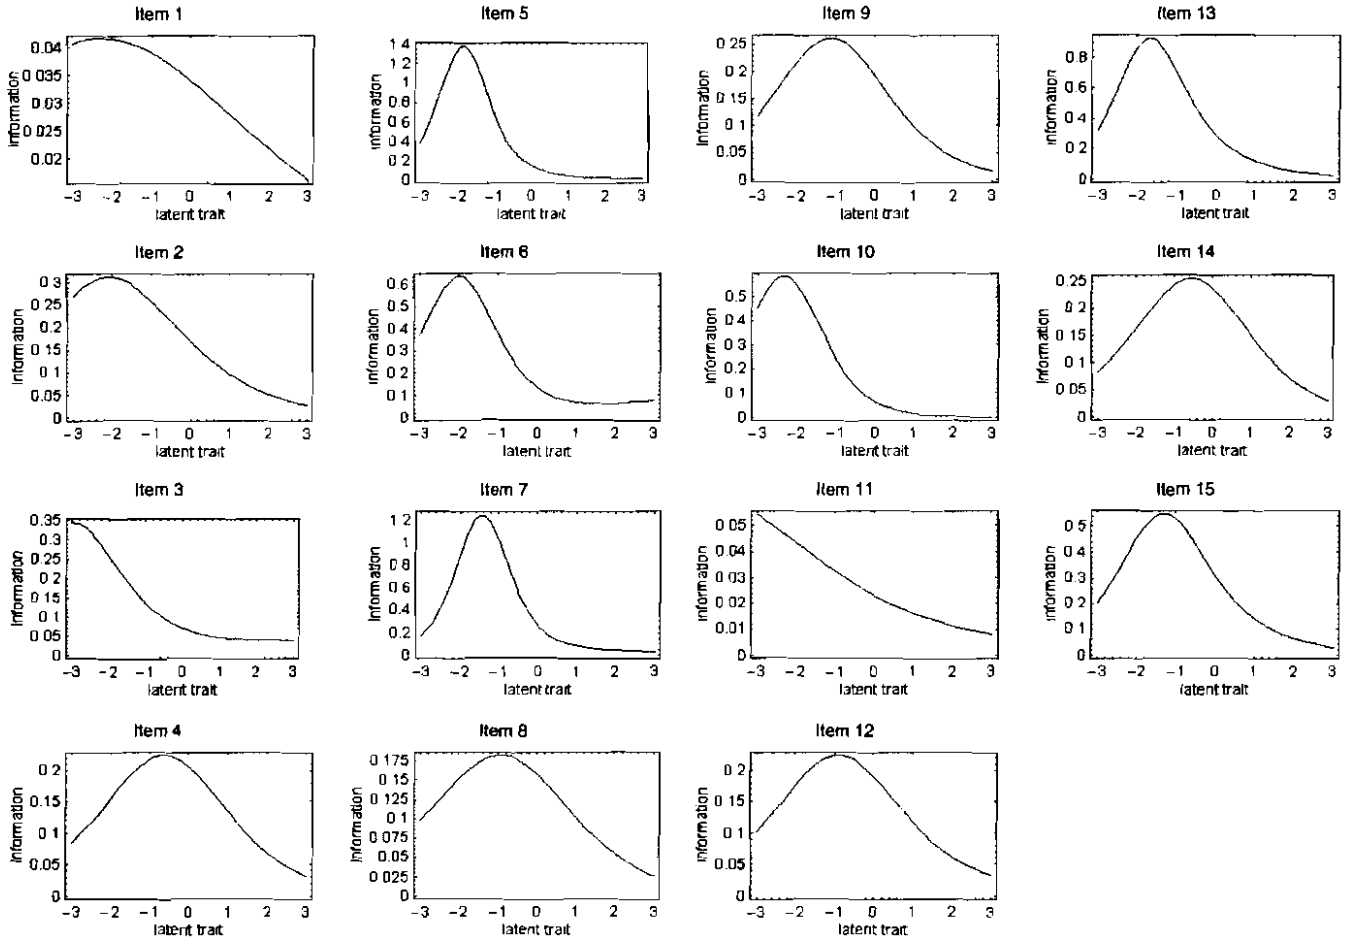

Figure 1. Item information function curves for each item of the Japanese Health Knowledge Test were generated by analysis of data from 1040 Japanese adults. The curves were derived from the response probabilities from the item response category characteristic curves. The standard error of measurement curve was calculated as the reciprocal of the square root of the item information function. Note: the scales for the y-axis differ among items.

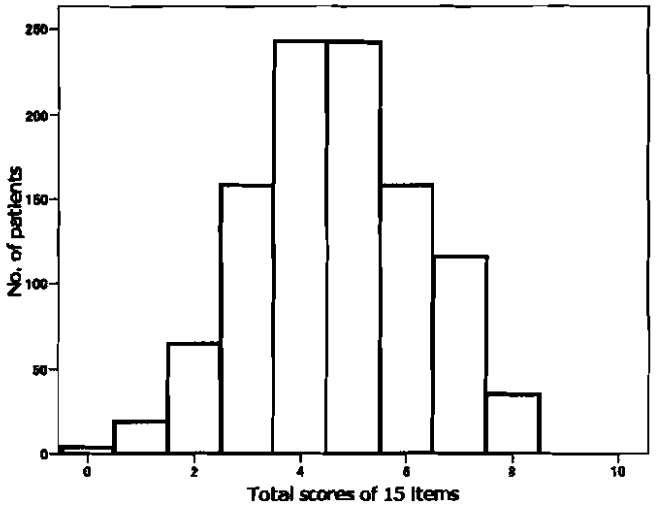

Figure 2. Histogram of total scores on the Japanese Health Knowledge Test.

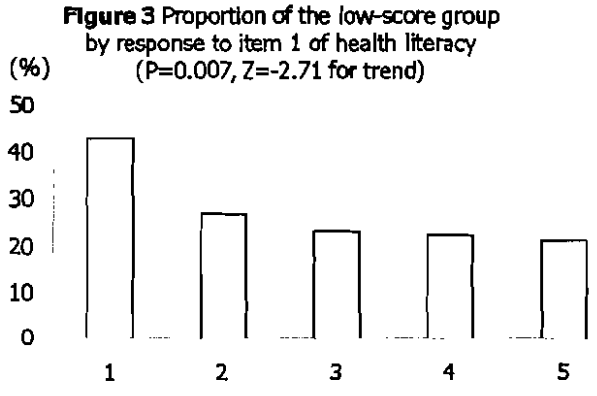

Figure 3. Proportion of participants with poor health knowledge, by response to item 1 ("Problems learning") on the health literacy test. The question was, "How often do you have problems learning about your medical condition because of difficulty understanding written information?" The 5-point Likert response scale was, "Always" (1), "Often" (2), "Sometimes" (3), "Occasionally" (4), and "Never" (5). Participants with lower literacy represented a higher proportion of those with a low score on the Japanese Health Knowledge Test.

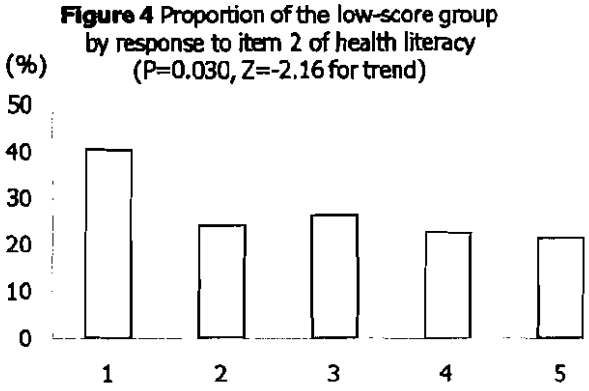

Figure 4. Proportion of participants with poor health knowledge, by response to item 2 ("Help reading") on the health literacy test. The question was, "How often do you have someone help you read hospital materials?" The 5-point Likert response scale was, "Always" (1), "Often" (2), "Sometimes" (3), "Occasionally" (4), or "Never" (5). Participants with lower literacy represented a higher proportion of those with a low score on the Japanese Health Knowledge Test.

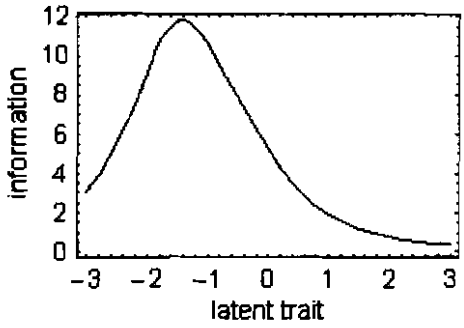

Figure 5. Item information function curve for the 15-item Japanese Health Knowledge Test.

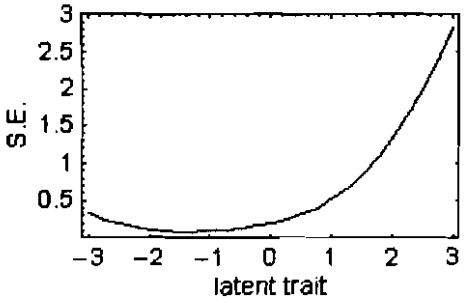

Figure 6. Standard error of the item information function for the 15-item Japanese Health Knowledge Test. S.E. indicates standard error.

Table 3. Score results of the 15-item Japanese Health Knowledge Test (n = 1040)

Characteristic	Total score			Group with low score[a]	
	Mean	SD	P-value	n (%)	P-value

DISCUSSION

Using nominal categories modeling of item response theory analysis, we developed the 15-item J-HKT for Japanese adults. The instrument had a good ability to discriminate among those with poor health knowledge. In addition, items on the J-HKT and health literacy instruments were significantly correlated. The proportion of respondents with a low score on the J-HKT was higher among those with low literacy, which provides evidence of construct validity. Further, fully 36% of the participants had poor health knowledge (defined as a score of 0–3 of a possible 15 on the J-HKT). Finally, we found that poor health knowledge was

Table 4. Logistic regression analysis of the odds of a low score on the Japanese Health Knowledge Test (n = 1040)

Characteristic	Odds ratio	95% CI of odds ratio	P-value

associated with low income, low educational attainment, and heavier current use of alcohol.

We used nominal categories modeling to elueidate the individual discriminating power and the effect of item position in the initial 48-item pool. This allowed us to identify items with good psychometric characteristics for inclusion in the 15-item J-HKT. Therefore, it is likely that we successfully developed a test that performs well in assessing health knowledge level among people with moderately poor health knowledge.

We chose to focus the discriminating capacity of this test at the low end of health knowledge, for several reasons. First, people with the lowest levels of health knowledge are those who have the worst health outcomes.[16,24,25] An increase in health knowledge among people who already have relatively greater knowledge is desirable, but is not likely to provide the biggest health impact. Next, focusing health resources on people with poor health knowledge is a means of minimizing health disparities.[26] People with poor health knowledge are likely to have more complex illnesses, and management of complex illnesses requires proper adherence to regimens via active patient involvement in treatment, which is more likely when illnesses are better understood.[5]

Several limitations should be noted. First, the results of our study were based on an online survey. A high proportion of Japanese adults use the internet, and while this mode of testing is much less expensive and much more convenient than in-person household interviews, it is possible that people in the sampling frame were younger, wealthier, and more educated than the general public.[27] As such, caution should be used in extrapolating our results.

Similarly, while the participation rate in this project is satisfactory for online research, it is likely that the participants were different from nonparticipants. Different methods for sampling the general population or patient populations with experience of frequent visits to clinicians (eg, due to chronic illness) might result in different distributions of J-HKT scores. There might also have been issues related to differential item functioning between participants and nonparticipants.[27] Although this paper presents a careful psychometric evaluation of the 15-item J-HKT, additional research is needed to ensure appropriate calibration.

Third, since this was an online survey, we do not know if the participants had help or discussed the questions with anyone else. The online panel registration system required a personal identification number and password, and did not allow participants to test more than once. However, participants had to read the questions, and poor reading skill may have resulted in an incorrect answer for an item that would have been answered correctly had it been read aloud. Further research in the form of a test-retest evaluation is needed to determine if the results of verbal administration differ from those of the written test.[28]

Fourth, based on the item information functions of the IRT analysis for each response to individual items, the content of several responses must be improved. For instance, on item 10, no participants selected responses 3 or 4, and, on item 1, nearly all participants selected response 3. Moreover, several items will require revision because of dynamic changes in the public's awareness of health information, due to rapid turnover in health-related knowledge in this era of rapid technological advance.

In summary, the current study described an online test of health knowledge among Japanese. We carefully evaluated the psychometric properties of this test and produced an instrument that can accurately discriminate among participants with poor health knowledge. The J-HKT is a convenient and valid measure of health knowledge, and can be used for the general Japanese public. Japanese public health practitioners and clinicians can easily use this quick test for the purposes of health education and disease prevention.

SUPPLEMENTS

How to answer the items below

Below are some medical terms that you may encounter or have encountered on various occasions in medical settings or situations. Please select the sentence that you think best describes each term. The objective of this test is to evaluate your awareness of healthcare terms. It is NOT a test to determine the number of correct responses. Please answer each Item based on your knowledge, even if you are unfamiliar with the terms.

Item 1 Please select the sentence that best describes the term "Tumor."

1. A state of cancer that can be life-threatening.
2. Early treatment, such as surgery, is necessary because it often metastasizes throughout the body.
3. A growth of tissue (mass of cells) that arises from abnormal cellular proliferation.
4. Growth is slow, and it does not spread to other parts of the body or invade surrounding tissue.

Item 2 Please select the sentence that best describes the term "Anti-tumor Drug."

1. It works for all forms of cancer, so it is given to almost all cancer patients.
2. Because this drug does not cure cancer, it is predominantly used for terminal cancer.
3. This drug suppresses cancer cell proliferation and eliminates cancer.
4. Due to its numerous adverse effects and limited therapeutic effect, this drug is used only when requested by patients.

Item 3 Please select the sentence that best describes the term "Ileus."

1. It has almost the same meaning as intestinal obstruction.
2. It does not occur to people who have had abdominal surgery in the past.
3. A condition where the passage of bowel contents is excessively rapid.
4. A small, sac-like protrusion that develops on the intestinal wall.

Item 4 Please select the sentence that best describes the term "Ulcer."

1. Because it is benign, there is no need to worry about cancer.
2. Duodenal ulcers may develop into cancer.
3. A condition where the surface of mucous membrane or skin is injured and deeply gouged.
4. Stomach ulcer usually heals on its own.

Item 5 Please select the sentence that best describes the term "Renal Failure."

1. Because it is asymptomatic and painless, treatment is generally not required.
2. A condition where the kidney is diseased and requires or almost requires dialysis (artificial kidney).
3. It is caused by chronic nephritis, not diabetes or hypertension.
4. It is caused by long-term, heavy alcohol consumption and causes jaundice (yellowish pigmentation of the skin).

Item 6 Please select the sentence that best describes the term "Influenza."

1. It is what we call the "common cold."
2. A bacterial infectious disease caused by the influenza bacteria.
3. It is 100% preventable by vaccine.
4. Antibiotics are ineffective.

Item 7 Please select the sentence that best describes the term "Arteriosclerosis."

1. Changes in the artery associated with old-age.
2. It is caused by diabetes and/or hypertension but progresses with age.
3. It is not caused by smoking.
4. It happens less in men than in women.

Item 8 Please select the sentence that best describes the term "Remission."

1. It is when an illness has been completely cured.
2. It is a phenomenon in which symptoms worsen due to chronic diseases.
3. It is when no further hospitalization or examination is necessary.
4. It is when symptoms are gone but the illness is not completely healed.

Item 9 Please select the sentence that best describes the term "Terminal Care."

1. Medical practice that emphasizes QOL enhancement more than life-sustaining treatment.
2. It is only for terminal cancer patients.
3. Medical services provided at train stations.
4. It refers to "Care of the Dying"

Item 10 Please select the sentenee that best describes the term "Hospice."

1. A hospital ward where once you enter, you never leave.
2. Hospitalization fees at a hospice cost more than fees at a regular hospital ward.
3. Palliative care is provided to ease physical, psychological and spiritual pain of terminally-ill patients.
4. A place for dying where no treatment is provided.

Item 11 Please select the sentence that best describes the term "Death with Dignity."

1. Administering a lethal injection for the purpose of stopping the heart and hastening death.
2. Choosing to die peacefully and naturally, maintaining one's dignity.
3. Committing suicide by ingesting poison.
4. It is when the patient refuses life-support for not wanting to cause his/her family any trouble.

Item 12 Please select the sentence that best describes the term "Clinical Pathway."

1. Comprehensive and standardized plan of care in which care categories, such as exam, surgery, administration of medication, treatment, nutrition, etc., are organized and sequenced over a specified course of time.
2. A schedule that specifies outpatient clinic physicians based on days and specialty.
3. An identification card required for hospital consultations.
4. Individually-developed care schedules that emphasize each physician's unique treatment protocol.

Item 13 Please select the sentence that best describes the term "Metabolic Syndrome."

1. An overweight person with greater-than-standard abdominal girth measurement.
2. An obese person who has a high level of "bad" cholesterol.
3. There is an increased risk of diabetes, hypertension, hyperlipidemia and complications due to accumulation of visceral fat.
4. Its cause is more due to heredity than life-style habits.

Item 14 Please select the sentence that best describes the term "EBM."

1. A standard medical practice that eliminates a physician's experience and instincts.
2. To practice medicine based on scientific evidence but also being considerate of each patient's situation and values.
3. To conduct research based on assumption and imagination.
4. To use treatment that has been reported to be effective in a small number of study cases.

Item 15 Please select the sentence that best describes the term "Evidence."

1. Treatment methods that are subjectively chosen and widely recommended by specialists.
2. A large majority of home remedies have "evidence" and is proven effective.
3. Treatment methods that have been proven effective in animal experiments.
4. Scientific evidence and proof that explain the effectiveness of treatment methods and medications.

Abstract

This study determined the frequency of reporting being introduced to opioids by a physician among opioid-dependent patients. Cross-sectional analyses were performed using baseline data from a cohort of opioid addicts seeking treatment with buprenorphine. The primary outcome was a response to the question: "Who introduced you to opiates?" Covariates included sociodemographics, depression, pain, and current and prior substance use. Of 140 participants, 29% reported that they had been introduced to opioids by a physician. Of those who were introduced to opioids by a physician, all indicated that they had initially used opioids for pain, versus only 11% of those who did not report being introduced to opioids by a physician ($p < .01$). There was no difference in current pain (78% vs. 85%, $p = .29$); however, participants who were introduced to opioids by a physician were more likely to have chronic pain (63% vs. 43%, $p = .04$). A substantial proportion of individuals with opioid dependence seeking treatment may have been introduced to opioids by a physician.

Keywords: Opioid dependence; Pain; Physician

1. Introduction

Based on 2008 national data, nearly 2 million individuals in the Unite States abuse or depend on opioids, with most reporting abuse of prescription opioids (Substance Abuse and Mental Health Services Administration, 2009). Individuals may be introduced to opioids through a variety of nonmedical and medical situations. Patients who are introduced to opioids through a physician may subsequently develop abuse or dependence either through continued use of prescription opioids or heroin. However, most persons who have misused prescription opioids report receiving them from a friend or relative (Substance Abuse and Mental Health Services Administration, 2009), and others may purchase diverted opioids from other sources (Inciardi, Surratt, Cicero, & Beard, 2009). Therefore, prescription opioid abuse and dependence may develop without provision of script from a physician. At the same time, physician prescribing rates for opioids are increasing (Caudill-Slosberg, Schwartz, & Woloshin, 2004; Gilson, Ryan, Joranson, & Dahl, 2004; Olsen, Daumit, & Ford, 2006; Sullivan et al., 2008), raising concern that the medical providers may share the responsibility for the rise in opioid abuse and dependence.

The risk of developing opioid abuse or dependence after being prescribed opioids for acute or chronic pain by a physician is unknown. A meta-analysis of iatrogenic addiction (defined as an "addiction of a patient to a drug initially prescribed for a medical condition") concluded that the literature could not establish whether the risk was high (>10%) or low (<0.1%) (Wasan, Correll, Kissin, O'Shea, & Jamison, 2006). However, the practice of prescribing opioids for pain is fairly common: research suggest that up to one

fifth of adults are prescribed opioids annually (MMWR, 2010; Williams, Sampson, Kalilani, Wurzelmann, & Janning, 2008). Even if the true risk is low, the widespread practice of prescribing opioids could still result in a substantial absolute number of cases of opioid abuse and dependence, thereby contributing to the problem. Therefore, the relatively common practice of prescribing opioids could still result in a substantial absolute number of cases of opioid abuse and dependence. Furthermore, it is important to examine the phenomenon of physician introduction to opioids among a population of prescription and nonprescription opioid users because (a) patients who were initially introduced to opioids by a physician may have shifted their use to heroin and (b) prescription opioids can be procured without use of a physician script.

This study examined the prevalence of reporting being introduced to opioids by a physician among a cohort of patients with opioid dependence who were seeking addiction treatment with buprenorphine. In addition, we performed descriptive analyses to understand how participants who reported opioid introduction through a physician differed from those who did not. We hypothesized that opioid-dependent participants who had been introduced by a physician would be more likely to use prescription opioids as opposed to heroin and would be more likely to have pain because this would be an underlying reason for an initial introduction to opioids by a physician.

2. Methods

2.1. Study sample and design

This cross-sectional study used baseline data from participants in a randomized, controlled trial to determine whether treatment for depressive symptoms increases treatment retention among opioid-dependent patients initiating buprenorphine (Stein et al., 2010). Participants were recruited through community advertising, physician referrals, and word-of-mouth. Study inclusion criteria included the following: age 18–65, *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* diagnosis of opioid dependence, score on the Modified Hamilton Depression Revised Scale greater than 14 (Miller, Bishop, Norman & Maddover, 1985), absence of significant suicidal ideation, willingness and ability to complete a 3-month treatment with buprenorphine, no history of severe mental illness (bipolar disorder, schizophrenia, schizo-affective, or paranoid disorder), no currently prescribed medications for depression (participants were not specifically excluded if they were taking a tricyclic antidepressant only for pain), and ability to complete the study assessment in English. The study was approved by the Rhode Island Hospital and Butler Hospital Institutional Review Boards.

Between November 2006 and May 2009, 932 individuals were screened by telephone, and of those, 394 callers appeared eligible for the study and were invited for an in-person screening visit. Of the 226 who attended this visit, 147 fully met criteria and agreed to enroll the parent study. Seven participants (4.8%) were missing data on the question that asked whether a physician had introduced them to opiates and were excluded from the analyses, leaving a final study cohort of 140.

2.2. Measures

The primary outcome examined was participants' responses to the question: "Who introduced you to opiates?" Possible responses included physician, sexual partner, friend, family member, stranger, and no one. Covariates included the demographic variables age, gender, race (White vs. non-White), current (past 30 day) employment, and insurance status. Clinical variables included severe depression, current pain, chronic pain, self-report of starting opioids for pain, having a primary care provider, and regular use of alcohol, marijuana, or cocaine prior to opioid use. Severe depression was defined as a score greater than 28 on the Beck Depression Inventory II (Beck, Steer, & Brown, 1996). Current pain was defined as having any pain in the past week; chronic pain was defined as pain that had been present for at least 6 months. Current pain was rated in severity by using the Visual Analog Scale (VAS; Melzack, 1987). Chronic severe pain was defined as pain experienced 6 months or longer that (a) caused at least moderate interference (defined by a single question from the Short Form-12 Questionnaire (Ware, Kosinski, & Keller, 1996) or (b) was of at least moderate in intensity (defined as a score above the median VAS score for the group). This definition was adapted from a study of chronic severe pain in methadone maintenance patients by the Rosenblum et al. (2003). Initiation of opioids for pain was defined as positive response to the question: "Do you believe that you started using your primary opiate of addiction to relieve physical pain?" Information on current (last 30 days) and past use of prescription opioids and heroin (including route of administration) was obtained using the Addiction Severity Index (McLellan et al., 1992). Regular use of alcohol, marijuana, and cocaine was determined by the question: "Prior to starting opiates, did you ever have daily or regular use of (drug)?"

2.3. Statistical analysis

All analyses were performed using baseline study data. The prevalence of physician introduction to opioids was determined by calculating the proportion with that report from the total sample. Descriptive analyses were performed comparing individuals who reported a physician introduction to opioids to those who did not report a physician introduction. We examined differences in demographic, clinical, and substance use-related variables between participants using Student's *t* tests and Pearson's chi-square tests.

Table 1
Characteristics of opioid-dependent patients who do and do not report a physician introducing them to opioids

Characteristics	Physician Introduced (n = 40) % or M (±SD)	Physician Did Not Introduce (n = 100) % or M (±SD)	p
Age	38 (±9)	37 (±10)	.87
Female	28	22	.49
Non-White	15	22	.35
Married	10	7	.52
Employed	45	56	.24
Has health insurance	44	33	.24
Has a primary care provider	38	37	.96
Duration of opioid use	9 (±8)	9 (±7)	.74
Prior injection drug use	38	76	<.01
Regular use of alcohol prior to opioids	35	34	.91
Regular use of marijuana prior to opioids	53	72	.03
Regular use of cocaine prior to opioids	23	45	.01

All statistical analyses were conducted using Stata version 10.0 (College Station, TX).

3. Results

Of the 140 opioid-dependent participants seeking treatment in the sample, 40 (29%) reported that they had been introduced to opioids by a physician. The mean age in the sample was 38 years (SD ± 10), 24% were female, and the average duration of opioid use was 9 years. There were no significant differences in gender, age, race, marital status, employment, or insurance status among individuals who did and did not report being introduced to opioids by a physician (Table 1). Individuals who were introduced to opioids through a physician were less likely to have injected drugs. Regular use of alcohol prior to starting opioids was equally reported among those who were and were not introduced by a physician to opioids. However, individuals who were introduced by a physician were significantly less likely to report prior use of marijuana and cocaine.

All of the participants who reported being introduced to opioids by a physician indicated that they had started using opioids to treat pain as compared to only 11% of those not introduced to opioids by a physician (Table 2). The prevalence of any current or chronic pain was high in the overall sample (83% and 49%, respectively). There were no significant differences in the proportions reporting current pain (any pain in the past week) between individuals who had and had not been initially introduced to opioids by a physician (Table 2). Among individuals who reported pain, the mean VAS score between the two groups did not significantly differ (57 [SD ± 4] for physician introduced vs. 60 [SD ± 3] for not physician introduced; p = .57). Individuals who had been introduced to opioids by a physician were more likely to have chronic pain and chronic severe pain. The percentage of individuals with severe depression did not differ between the two groups. Participants who were introduced to opioids by a physician were more likely to admit to using a physician to procure a prescription for opioids to get high with and to seek out a physician who "gives opiate prescriptions without asking too many questions."

Participants introduced to opioids by a physician were more likely to be currently using prescription opioids only (Fig. 1) compared with participants who were not introduced by a physician (chi-square, p < .01). However, 32% of opioid-dependent individuals who were physician-introduced reported currently using heroin in combination with prescription opioids, and 10% were using heroin exclusively. Likewise, participants who were introduced to opioids by a

Table 2
Pain, depression, and drug-related aberrant behaviors among opioid-dependent patients who do and do not report a physician introducing them to opiates

Behaviors	Physician Introduced (n = 40), %	Physician did not introduce (n = 100), %	p
Introduced to opioids for pain	100	11	<.01
Current (past week) pain	78	85	.29
Chronic (>6 months) pain	63	43	.04
Chronic severe pain	53	30	.01
Severe Depression	38	48	.26
Regular opioid use was prescribed by a physician	85	14	<.01
Ever used a physician to procure a prescription for opioids to get high	50	32	.05
Ever used a physician to procure a prescription for opioids to sell to others	10	4	.17
Ever sought out a physician known to easily prescribe opioids	33	17	.04

physician were half as likely to currently inject drugs (28% vs. 57%, $p < .01$).

4. Discussion

Opioids are prescribed in medical settings for acute and chronic pain, and physicians may provide an introduction to opioids in individuals who subsequently develop opioid abuse and dependence. This study found that among a cohort of opioid-dependent patients who were seeking addiction treatment with buprenorphine, 29% reported that they had been introduced to opioids through a physician treating their pain. To our knowledge, this is the first study to assess this question in a population of opioid-dependent patients who were users of both prescription and nonprescription opioids. This study, although it does not define the risk of developing opioid abuse or dependence among patients who are prescribed opioids in a medical setting, provides insights on the fraction of patients whose opioid dependence can be linked to a medical introduction to opioids.

This study expands the current understanding of physicians' roles in the growing trend of opioid abuse and dependence. Prescription opioid misuse is reportedly increasing (Gilson et al., 2004; Zacny et al., 2003), as are overdose deaths related to prescription opioids (Hall et al., 2008; Warner, Chen, & Makuc, 2009). Concurrently, physician prescribing rates for opioids are increasing (Caudill-Slosberg et al., 2004; Gilson et al., 2004; Olsen et al., 2006; Sullivan et al., 2008), raising concern that the medical providers may share responsibility for the current trend. Physicians are encouraged to screen for and treat pain, and opioids are effective in treating pain (Ballantyne & Mao, 2003), although the risk for subsequent addiction is not known (Wasan et al., 2006). Even if the risk is low, the widespread practice of prescribing opioids among physicians could still result in a substantial absolute number of cases of opioid dependence and thereby contribute to the problem of opioid dependence. This study suggests that physician introduction to opioids is a factor for a sizeable proportion of individuals who have opioid dependence requiring addiction treatment.

The finding that participants who reported being introduced to opioids through a physician were more likely to have chronic pain is consistent with prior research. Studies of opioid-dependent patients on methadone maintenance show that more than a third report chronic pain (Rosenblum et al., 2003; Rosenblum et al., 2007). At least two prior studies have found a higher prevalence of chronic pain among opioid-dependent patients who were primarily prescription drug users compared to nonprescription drug users (Brands, Blake, Sproule, Gourlay, & Busto, 2004; Rosenblum et al., 2007). However, it is interesting to note that the proportion of individuals with current pain was similar among those who did and did not report a physician introduction to opioids. It is possible that some participants who did not initiate opioids for pain may have developed pain for reasons related to their opioid use. Such causes for pain in this cohort might include injuries from trauma, depression (Bair, Robinson, Katon, & Kroenke, 2003), chronic medical conditions that are associated with pain such as hepatitis C virus (Barkhuizen et al., 1999; Silberbogen, Janke, & Hebenstreit, 2007; Thompson & Barkhuizen, 2003), or opioid-induced hyperalgesia (Chu, Angst, & Clark, 2008).

Our study cohort included both current users and nonusers of prescription opioids, and results demonstrated that most individuals who were introduced to opioids by a physician for pain continued to use prescription opioids over heroin. Still, 42% of participants who reported that a physician introduced them to opioids were currently using some heroin (either exclusively or in combination with prescription opioids), and more than a quarter were injecting opioids, which confirms prior research that suggest shifting trajectories of opioid abuse among individuals who are initially prescribed opioids. A study of opioid-dependent patients in a methadone treatment program in Canada found that 24% of participants reported using prescription opioids (medically or nonmedically) initially and heroin later (Brands et al., 2004), and a study of 72 methadone maintenance treatment programs in the United States found that 69% of primary heroin users had ever used prescription opioids (Rosenblum et al., 2007). Our finding that opioid-dependent individuals who are initially introduced to opioids for pain are more likely to admit to prescription drug aberrant behaviors (telling a doctor they had pain to obtain opioids so that they could get high, or seeking out a physician known to prescribe opioids "without asking too many questions")

suggests that the patients who display drug aberrant behaviors are more likely to have developed their opioid addiction in the context of pain management through a physician, as opposed to initiating use through illicit opioids. This may be relevant to dispelling the bias against use of effective pain medicines for injection drug users (Breitbart et al., 1996).

There are several limitations to this study. The relatively small sample size limited power to detect statistically significant differences. The study questionnaire asked whether the participant was introduced to opioids by a physician but did not obtain detailed information on the setting (e.g., office or emergency department), the respondent's ongoing relationship with that prescribing physician, or the amount and duration of the initial opioid prescription. Furthermore, this question relied on patient recall, which could be subject to bias in either direction, and patients' conceptions of what constitutes an "introduction" to opiates may have differed. Second, our study was conducted among a sample of opioid-dependent individuals with depressive symptoms who were seeking treatment with buprenorphine, which may limit generalizability. However, depression is common among opioid-addicted patients: Studies estimate that approximately a third to one half have depression (Brienza et al., 2000; Croughan, Miller, Wagelin, & Whitman, 1982; Khantzian & Treece, 1985; Rounsaville, Weissman, Crits-Christoph, Wilber, & Kleber, 1982). Furthermore, our sample appears to be similar to other populations of buprenorphine-treated patients with regard to the proportion currently using heroin versus nonheroin opioids, supporting its overall general representativeness (Stanton, McLeod, Luckey, Kissin, & Sonnenfeld). Finally, by excluding individuals on antidepressants, which may include a small subset on tricyclic antidepressants for depression and pain, ours may be an underestimate of the true proportion of opioid-dependent individuals who are introduced to opioids by a physician for pain.

In summary, this study found that 29% of patients who were presenting for treatment for opioid dependence reported that a physician had introduced them to opioids. This finding reinforces the need for physicians to carefully select patients before initiating an opioid therapeutic trial and, once prescribing, to monitor patients regularly for opioid misuse, abuse, and dependence (Passik, 2009). More prospective research is needed to examine the trajectories of opioid use that occur among individuals who introduced to opioids through a physician and to develop strategies to prevent patients from developing addiction to opioids.

Improving Decision Making at the End of Life With Video Images

Angelo E. Volandes, MD, Michael J. Barry, MD, Yuchiao Chang, PhD, Michael K. Paasche-Orlow, MD, MA, MPH

Background. *Decision making at the end of life is frequently complex and often filled with uncertainty. We hypothesized that people with limited health literacy would have more uncertainty about end-of-life decision making than people with adequate literacy. We also hypothesized that video images would decrease uncertainty.* ***Design.*** *Before and after oral survey.* ***Participants.*** *Subjects presenting to their primary care physicians.* ***Methods.*** *Subjects were asked about their preferences for end-of-life care after they heard a verbal description of advanced dementia and were asked to rate the level of their uncertainty. Subjects then viewed a video of a patient with advanced dementia and were asked again about their preferences and uncertainty. Uncertainty was measured using the Decisional Conflict Scale with score ranges from 3 (***high uncertainty***) to 15 (***no uncertainty***). Health literacy was measured using the Rapid Estimate of Adult Literacy in Medicine, and subjects were divided into 3 literacy categories: low (0–45, 6th grade and below), marginal (46–60, 7th–8th grade), and adequate (61–66, 9th grade and above).* ***Results.*** *A total of 146 patients completed the interview. Prior to the video, the average uncertainty scores for subjects with low, marginal, and adequate health literacy were 10.8, 12.4, and 13.5, respectively (*$P < 0.0001$*). After the video, the 3 groups had similar uncertainty about their decisions. The average uncertainty scores for subjects with low, marginal, and adequate health literacy were 13.6, 14.1, and 14.5, respectively (*$P = 0.046$*).* ***Conclusions.*** *Subjects with limited health literacy expressed more uncertainty about their preferences for end-of-life care than did subjects with adequate literacy. Our video decision aid improved end-of-life decision making by decreasing uncertainty regarding subjects' preferences, especially for those with limited literacy.* ***Key words:*** *end-of-life decision making; video; decision aids; uncertainty; advance care planning; health literacy; ethics; palliative care; dementia; Alzheimer's disease.* ***(Med Decis Making 2010;30:29–34)***

Decision making at the end of life is frequently complex and often filled with uncertainty.[1] Patients are increasingly asked to describe their preferences for medical care in advance of having a disease such as dementia.[2,3] Physicians use verbal or written descriptions to communicate future health states, but serious doubts have been raised regarding whether patients can realistically envision future health states on the basis of verbal descriptions alone.[4]

Received 16 October 2007 from the General Medicine Unit, Massachusetts General Hospital, Boston (AEV, MJB, YC); Harvard Medical School, Boston, Massachusetts (AEV, MJB, YC); and Department of Medicine, Boston University School of Medicine, Boston, Massachusetts (MKP-O). Revision accepted for publication 28 February 2009.

DOI: 10.1177/0272989X09341587

Limited health literacy is a prevalent barrier to accurate communication that can pose significant obstacles to informed decision making at the end of life.[5] Although more than 90 million American adults have limited health literacy,[6,7] techniques that can be used to overcome communication barriers posed by limited health literacy are frequently not employed. For example, visual images have been shown to improve communication of information with patients.[8–11] The medium of video allows patients to envision health states in a manner not easily captured with verbal communication and can both engage people and efficiently communicate information about the experience of illness.[12]

One measure of improved decision making at the end of life includes decreasing uncertainty regarding decisions.[1] We hypothesized that people with limited health literacy would have more uncertainty about end-of-life decision making than people with adequate literacy. In addition, we hypothesized that

video images would decrease uncertainty and that this improvement would be greatest for people with limited health literacy. We conducted a before-and-after trial to examine whether a video of a patient with advanced dementia could improve decision making by decreasing uncertainty.

METHODS

Participants

Patients at 6 study sites who were older than 40 y and were scheduled to see a general internist were eligible to participate. The study sites consisted of urban and suburban primary care clinics affiliated with 2 teaching hospitals in the greater Boston area. Subjects were excluded if they had previously had a close relationship with a person with advanced dementia because they would likely have had 1st-hand experience and knowledge of the disease. Subjects were also excluded if, in the judgment of the physician interviewer, they lacked medical decision-making capacity at the time of the interview or if they did not speak English, the language of our validated tools. Each interview was conducted by 1 of 2 physicians between 1 December 2005 and 31 January 2007. Approval for the project was granted by the Institutional Review Boards of the affiliated hospitals.

Design

A structured questionnaire was developed for this study. Survey questions were generated from a review of the medical ethics literature and consultations with medical ethics, palliative care, geriatric, and neurology experts. Early versions of the survey were pretested with subjects recruited from primary care clinics.

After obtaining verbal informed consent, interviewers defined advanced dementia in simple language, highlighting functional impairments based on the Functional Assessment Staging[13] criteria, including inability to communicate understandably with others, inability to ambulate without assistance, and inability to feed oneself (see the Appendix for text of the verbal description). We then outlined 3 levels of medical treatments and the goals associated with each level: life-prolonging care, limited care, and comfort care.[12] Subjects were then asked 3 questions measuring uncertainty regarding their preferences.

Each subject next viewed a 2-min video of a patient with advanced dementia. The video depicts the salient features of advanced dementia. The narrative that accompanies the video is identical to the verbal description used to assess subjects' initial preferences. The design, content, and structure of the video intervention were reviewed for accuracy by 3 geriatricians and 5 neurologists, all of whom specialize in the care of patients with dementia. The video was also designed with the close collaboration of caregivers of patients with advanced dementia. (The film clip is available online at www.ACPdecisions.com.) Each subject was then asked the same questions as before regarding preferences and uncertainty.

Measures

Answers to sociodemographic questions (age, race, gender, etc.) were self-reported by the subjects. Health literacy was measured at the end of the interview using the validated Rapid Estimate of Adult Literacy in Medicine tool (REALM).[14] The survey is available on request.

The main outcome measures were the difference of uncertainty regarding individual preferences for medical care across the 3 levels of health literacy before and after viewing a video of advanced dementia. Our measure for uncertainty was the uncertainty subscale of the Decisional Conflict Scale.[15] This validated subscale uses 3 questions to elicit the level of uncertainty regarding a subject's decision making. The subscale ranges from a score of 3 (*high uncertainty*) to a score of 15 (*no uncertainty*).

Our measure for health literacy was the 66-word REALM.[14] This is a 2- to 3-min English test of medically relevant vocabulary. The REALM is a valid test of word pronunciation and has been shown to correlate well with tests that evaluate a range of literacy skills. As others have done, we defined 3 categories for literacy: low literacy (REALM score of 0–45, 6th grade and below), marginal literacy (REALM score of 45–60, 7th–8th grade), and adequate literacy (REALM score of 61–66, 9th grade and above).[7]

Statistical Analysis

Means, standard deviations, and 95% confidence intervals were used to summarize the uncertainty scores before and after the video as well as the changes in uncertainty. Changes in preferences from before to after the video were analyzed with McNemar's test. Analysis of variance techniques were used to compare the prevideo uncertainty level, postvideo uncertainty level, and the change in uncertainty level among 3 ordered categories of health literacy in 3 separate models.

Multivariable regression analyses were used to examine the effect of health literacy on level of uncertainty, adjusting for other potential confounding factors. Factors significant at univariate $P < 0.20$ were tested in these models. Our independent variable of interest, health literacy, was designated to remain in each of our models. We further excluded variables that were highly associated with the variable of interest, health literacy, using χ^2 tests for association. Two-sided P values <0.05 were considered statistically significant. Data were analyzed using SAS software, version 9.1 (SAS Institute, Cary, NC).

RESULTS

Study Participants

A total of 146 subjects were interviewed for the study. Table 1 describes the characteristics of the survey sample. Of the 146 subjects, 82 (56%) were African American and 64 (44%) were white. African Americans had significantly lower health literacy, lower education, more religious attendance, and poorer health (all with $P < 0.001$).

Table 1 Characteristics of the Study Sample

Characteristic	Total
No. of subjects	146
Age in years, mean (SD)	57 (12)
Women, *n* (%)	93 (64)
Race, *n* (%)	
African American	82 (56)
White	64 (44)
Health literacy, *n* (%)	
Low	27 (18)
Marginal	30 (21)
Adequate	89 (61)
Education, *n* (%)	
High school or less	82 (56)
College or beyond	64 (44)
Marital status, *n* (%)

Christian (other)	46 (32)
Other	28 (19)
Religious attendance, *n* (%)	
Two times per month or more	63 (43)
One time per month or less	23 (16)
Never	60 (41)
Self-reported health status, *n* (%)	
Very healthy	77 (53)
Somewhat healthy	63 (43)
Not healthy	6 (4)

Outcomes

After hearing a brief verbal description of advanced dementia, 102 (69%) subjects preferred comfort care, 23 (16%) desired life-prolonging care, 14 (10%) chose limited care, and 7 (5%) were unsure of their preferences (Figure 1). The subjects' preferences changed significantly after the video: 136 (93%) of the subjects chose comfort care, 1 (1%) desired life-prolonging care, 8 (5%) chose limited care, and, 1 (1%) was unsure ($P < 0.001$).

Before watching the video, the mean score for uncertainty was 12.8 ($s = 2.6$; 95% confidence interval [CI] = 12.4–13.2). After watching the video, the mean uncertainty score improved to 14.3 ($s = 1.7$; 95% CI = 14.0–14.5). The mean change in uncertainty score after viewing the video was 1.5 ($s = 2.4$; 95% CI = 1.1–1.9; $P < 0.0001$).

Health literacy level was associated with uncertainty level before ($P < 0.001$) and after ($P = 0.046$) watching the video and with the change in uncertainty between the 2 time points ($P = 0.002$). Of the 27 subjects with low health literacy, the mean prevideo uncertainty score was 10.8 ($s = 3.0$; 95% CI = 9.6–12.0) and the mean postvideo uncertainty score was 13.6 ($s = 2.8$; 95% CI = 12.5–14.7). The mean change in uncertainty score in this group was 2.8 ($s = 3.5$; 95% CI = 1.4–4.2).

Of the 30 subjects with marginal health literacy, the mean prevideo uncertainty score was 12.4 ($s = 2.2$; 95% CI = 11.6–13.2) and the mean postvideo uncertainty score was 14.1 ($s = 1.7$; 95% CI = 13.4–14.7). The mean change in uncertainty score in this group was 1.7 ($s = 2.3$; 95% CI = 0.8–2.5).

Of the 89 subjects with adequate health literacy, the mean prevideo uncertainty score was 13.5 ($s = 2.2$; 95% CI = 13.1–14.0) and the mean postvideo uncertainty score was 14.5 ($s = 1.1$; 95% CI = 14.3–14.7). The mean change in uncertainty score in this group was 1.0 ($s = 1.9$; 95% CI = 0.6–1.4).

In addition to health literacy, race, education, religious affiliation, and health status were found to be associated with level of uncertainty before or after watching the video. Race and education were highly correlated with health literacy and were dropped from the model. Overall, 88% of Caucasians had adequate health literacy compared with 40% of African Americans; 72% of those with a high school or higher education had adequate health literacy, whereas only 4% of those with less than high

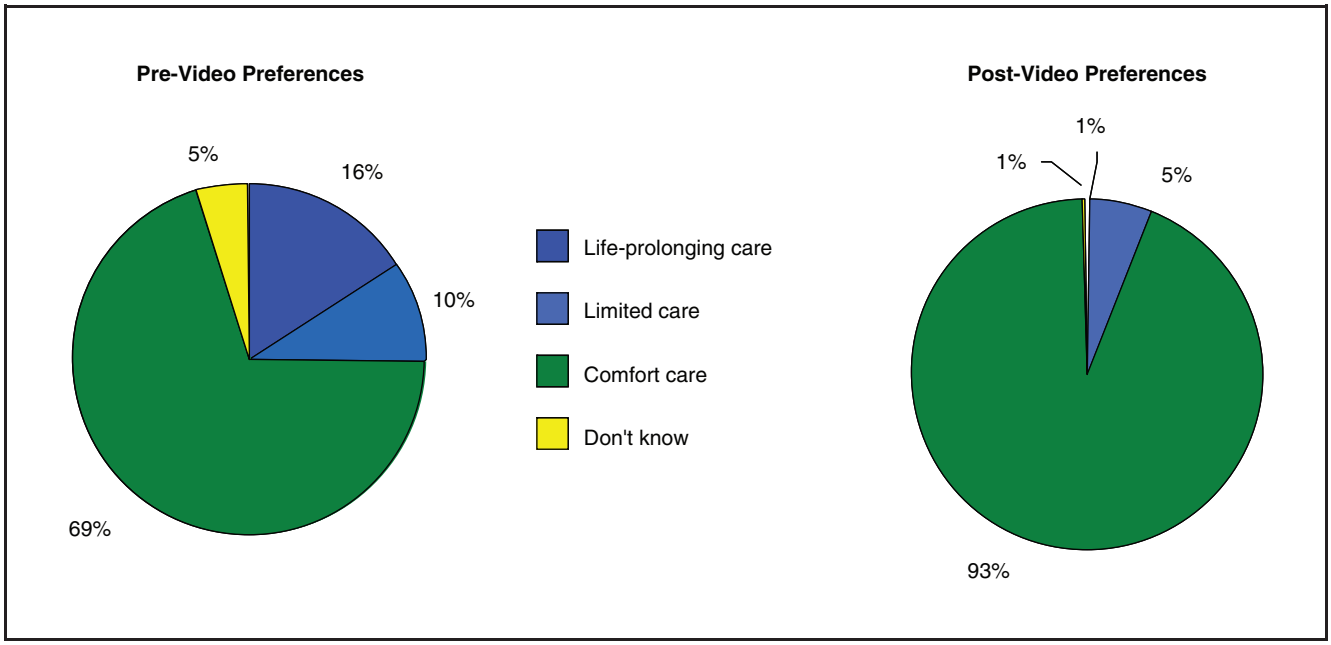

Figure 1 Prevideo and Postvideo preferences.

school education had adequate health literacy (both with $P < 0.001$).

The 3 final multivariable regression models of uncertainty prior to the video, uncertainty after the video, and the change in uncertainty included health literacy, religious affiliation, and health status. The adjusted mean scores from these 3 models are summarized in Table 2. Health literacy remained a significant predictor for the uncertainty prior to the video ($P < 0.001$) and the change in uncertainty ($P = 0.023$) but was no longer statistically significant in the prediction of uncertainty after the video ($P = 0.22$).

DISCUSSION

Multiple studies have shown that decision aids improve the quality of subjects' decisions, including video decision aids at the end of life.[12] Our study suggests that patients with limited health literacy—a significant portion of our patient population—have more uncertainty regarding their decisions at the end of life than those with adequate health literacy and benefit from the use of video decision aids at the end of life more than patients with adequate health literacy. Indeed, after the video, health literacy was no longer independently associated with uncertainty. Decreasing uncertainty remains a significant sphere in which to improve decision making for patients.

The observed changes in overall uncertainty scores and uncertainty scores for the low-literacy group after the video are likely to be clinically important. As others have noted,[16] changes in health-related quality-of-life measurements that exceed 50% of the baseline standard deviation can be considered clinically significant. The changes observed in our study overall and especially for the low-literacy group were well above this cutoff (overall change in uncertainty score divided by standard deviation at baseline = 1.5/2.6 = 0.58; change in uncertainty score in the low-literacy group divided by the standard deviation at baseline = 2.8/3.0 = 0.93). As we hypothesized, the clinical importance of the observed changes was greatest in the group with low health literacy.

The Cochrane database[17] includes multiple decision aids in a variety of clinical contexts in which uncertainty is improved. To our knowledge, this is the 1st study to examine the influence of health literacy on the uncertainty of end-of-life decision making. Our study needs to be interpreted in the context of end-of-life decision making and the study design.

Video clips can be manipulated to favor a particular perspective. To minimize the introduction of bias in the filming of the patient, the video was filmed and edited with close collaboration from expert geriatricians and neurologists. All filming and editing was done by the principal investigator in the cinema verité style of documentary film

Table 2 Adjusted Mean Uncertainty Scores for Prevideo, Postvideo, and Change in Level of Uncertainty by Level of Health Literacy (Adjusted for Health Status and Religious Affiliation)

		Prevideo	Postvideo	Change
Health Literacy	**Subject (*n*)**	**Mean (95% CI)**	**Mean (95% CI)**	**Mean (95% CI)**
Low	27	10.3 (9.3–11.4)	13.9 (13.1–14.6)	3.5 (2.5–4.6)
Marginal	30	11.9 (10.8–12.9)	14.4 (13.6–15.1)	2.5 (1.5–3.5)

making, avoiding the use of special effects or staging. Nonetheless, the use of video inherently involves aesthetic biases, and we have addressed the controversies involving visual media elsewhere.[18] We also did not test the robustness of our findings using other video clips varying features of the patient, such as race/ethnicity, gender, and nursing home setting.

We used a before-and-after study design in which individual subjects heard the description of dementia twice, verbally and then with the video. Subjects may have benefited merely from the repetition of the information for comprehension. It is possible that subjects with limited literacy had more uncertainty in this study because they had less knowledge about dementia. We did not measure knowledge of dementia or goals of care options. Furthermore, although we did conduct multivariable analyses that exhibited the independent predictive value of limited literacy for uncertainty prior to the video, we were unable to fully evaluate the relationship between literacy, education, and religion. Future randomized studies can further evaluate these issues, manage unmeasured confounders, and isolate the effect of the video.

Our study group also did not include the largest minority group in this country, namely, Latinos. Studying the use of video in other languages and other large minority groups would be helpful. Proceeding with such research, however, will require further validation of tools to measure uncertainty and literacy.

We did not analyze subjects' uncertainty in relation to their preferences for end-of-life care nor examine level of uncertainty in those subjects who changed preferences after the video. Such analyses require large numbers of subjects, and research on the relationship between stability of preferences and uncertainty would be interesting. Similarly, although the overall change in uncertainty represented more than a half standard deviation, it is important to note that the true clinical significance of even this large change in uncertainty has not been elucidated.

Our present study asked questions about uncertainty relating to advanced dementia, a common end-of-life scenario. Uncertainty for end-of-life care in other disease states may be different; however, we suspect this to be unlikely. If our results are found to be generalizable to other health states and other populations, this would have important implications for research and practice relating to decision making.

Our data support the idea that the level of uncertainty is more like a state than a trait; that is, people with limited health literacy do not appear to be constitutionally less certain. To the extent that uncertainty may lead to more passivity overall regarding health promotion and self-care activities, our observations may represent an important direction for future research, as the level of uncertainty has not yet been explored as a mechanism for how limited health literacy leads to worse health outcomes. Research evaluating these connections may identify important opportunities for intervention.

Video decision aids are widely accessible and easily disseminated. Research relating to end-of-life decision making may need to focus on decision aids that are proven to benefit patients with limited health literacy. Research of this kind has the potential to improve the quality of decision making for patients.

APPENDIX

Narrative Describing Advanced Dementia

I am going to describe to you an illness called advanced dementia, like advanced Alzheimer's dementia, that you may or may not be familiar with. Advanced dementia is an incurable disease of the brain in which one is not able to communicate with others. People in advanced

dementia are not able to move around or walk, get out of bed independently, eat by oneself, or communicate understandably with others. People with advanced dementia often have difficulty chewing or swallowing and require assistance with feeding oneself. Advanced dementia is an incurable disease and most commonly occurs after many years of Alzheimer's disease or as the result of strokes. People are not able to answer any questions or tell you about themselves.

Physical Health and Drinking Among Medical Inpatients With Unhealthy Alcohol Use: A Prospective Study[1]

Emily C. Williams, Tibor Palfai, Debbie M. Cheng, Jeffrey H. Samet, Katharine A. Bradley, Thomas D. Koepsell, Thomas M. Wickizer, Patrick J. Heagerty, and Richard Saitz

Objective: Unhealthy alcohol use is common in medical inpatients, and hospitalization has been hypothesized to serve as a "teachable moment" that could motivate patients to decrease drinking, but studies of hospital-based brief interventions have often not found decreases. Evaluating associations between physical health and subsequent drinking among medical inpatients with unhealthy alcohol use could inform refinement of hospital-based brief interventions by identifying an important foundation on which to build them. We tested associations between poor physical health and drinking after hospitalization and whether associations varied by alcohol dependence status and readiness to change.

Methods: Participants were medical inpatients who screened positive for unhealthy alcohol use and consented to participate in a randomized trial of brief intervention (n = 341). Five measures of physical health were independent variables. Outcomes were abstinence and the number of heavy drinking days (HDDs) reported in the 30 days prior to interviews 3 months after hospitalization. Separate regression models were fit to evaluate each independent variable controlling for age, gender, randomization group, and baseline alcohol use. Interactions between each independent variable and alcohol dependence and readiness to change were tested. Stratified models were fit when significant interactions were identified.

Results: Among all participants, measures of physical health were not significantly associated with either abstinence or number of HDDs at 3 months. Having an alcohol-attributable principal admitting diagnosis was significantly associated with fewer HDDs in patients who were nondependent [adjusted incidence rate ratio (aIRR) 0.10, 95% CI 0.03–0.32] or who had low alcohol problem perception (aIRR 0.36, 95% CI 0.13–0.99) at hospital admission. No significant association between alcohol-attributable principal admitting diagnosis and number of HDDs was identified for participants with alcohol dependence or high problem perception.

Conclusions: Among medical inpatients with nondependent unhealthy alcohol use and those who do not view their drinking as problematic, alcohol-attributable illness may catalyze decreased drinking. Brief interventions that highlight alcohol-related illness might be more successful.

Key Words: Hospital-Based Brief Intervention, Physical Health, Readiness to Change, Unhealthy Alcohol Use, Alcohol Dependence.

MEDICAL ILLNESS AND poor physical health status are common among patients with unhealthy alcohol use (Blow et al., 2000; Bridevaux et al., 2004; Chou et al., 1996; Green et al., 2004; Rehm et al., 2003; Room et al., 2005; Saitz et al., 2006; Solberg et al., 2008; Stein, 1999; Williams et al., 2010), a term which is used to describe a spectrum from drinking amounts that risk health consequences (e.g., above recommended limits), to drinking amounts

associated with consequences but not yet meeting criteria for a disorder, to meeting diagnostic criteria for alcohol abuse or dependence (Saitz, 2005). Approximately 25% of all persons admitted to general hospitals have alcohol use disorders or are being treated for the consequences of their drinking, making hospitalization a potentially opportune time for interventions to reduce unhealthy alcohol use (Smothers et al., 2003). However, the evidence in support of brief counseling interventions in hospital settings is mixed, often showing lack of efficacy (Chick et al., 1985; Elvy et al., 1988; Emmen et al., 2004; Freyer-Adam et al., 2008; Heather et al., 1996; Holloway et al., 2007; Persson and Magnusson, 1989; Saitz et al., 2007, 2009). This lack of efficacy may be due in part to the high prevalence of dependence among patients with unhealthy alcohol use in hospitals (Saitz et al., 2006), although studies that excluded dependent patients have also had mixed results (McQueen et al., 2009). Improvements in opportunistic counseling interventions for hospitalized patients identified with unhealthy use, including dependence, are sorely needed.

Qualitative studies have identified factors responsible for catalyzing change in patients with unhealthy alcohol use (Orford and Hawker, 1974; Orford et al., 2006, 2008), which include "awareness of accumulating harms" and "triggering occurrences" (Orford et al., 2006). As such, poor physical health may serve as a catalyst of change. Further, in the context of a hospitalization, which has been hypothesized to provide a "teachable moment," patients with unhealthy alcohol use may recognize the link between their drinking and health and be particularly amenable to making changes in their drinking (Figlie et al., 2005; Stewart and Connors, 2007), with or without intervention. As such, patients with the physical health consequences from alcohol use would be more likely to change than those without such consequences.

Factors that may catalyze change among patients with unhealthy alcohol use may operate differently for patients based on both the severity of dependence symptoms and their readiness for or commitment to change. Specifically, patients with alcohol dependence, who typically exhibit impaired control over their drinking, or those who are not ready to change may be less likely to decrease drinking after a catalyst than those without dependence or those with greater readiness to change (DiMartini et al., 2002; Kelly et al., 2006; Moos and Moos, 2006; Orford et al., 2008; Saitz et al., 2009; Vielva and Iraurgi, 2001; Walton et al., 2003).

Evaluating associations between physical health and subsequent drinking among medical inpatients with unhealthy alcohol use could help to inform further refinement of hospital-based brief interventions by identifying whether they should specifically focus on physical health. This study sought, in a secondary analysis of data collected prospectively, to evaluate whether, independent of an intervention, 5 different measures of physical health were associated with two drinking outcomes 3 months after hospitalization and to explore whether associations between physical health and drinking vary by alcohol dependence or readiness to change.

METHODS

Study Design

We studied a prospective cohort of adult medical inpatients with unhealthy alcohol use who were first identified by screening in the hospital and then enrolled in a randomized trial of brief alcohol counseling. Although the intervention was not associated with decreased drinking or receipt of alcohol-related treatment in this trial (Saitz et al., 2007), some subgroups, including patients without alcohol dependence, appeared to benefit from the brief intervention (Saitz et al., 2009). The study represents a secondary analysis of data collected during this trial and was approved by the institutional review boards of Boston Medical Center and the University of Washington. Subjects provided informed consent to participate in the trial and were compensated for each completed interview. A federal government certificate of confidentiality was obtained to protect participant privacy.

Participants

Participants included 341 adult medical inpatients who reported drinking risky amounts in the past month defined as >14 standard drinks per week or ≥ 5 drinks per occasion for men (>11 and ≥ 4, respectively, for both women and people ≥ 66 years (i.e., screened positive for unhealthy alcohol use) based on the screening strategy recommended by the National Institute on Alcohol Abuse and Alcoholism (National Institute on Alcohol Abuse and Alcoholism et al., 2007). Participants also were fluent in English or Spanish, provided names of 2 contacts to assist with follow-up, had no plans to move away from the study area in the following year, scored 21 or more points on the Mini-Mental State Examination (Smith et al., 2006), and consented to participate in the trial (Saitz et al., 2007).

Assessments

Participants were assessed via in-person interviews by trained research associates at enrollment and a 3-month follow-up visit. Also at enrollment, a physician-researcher reviewed each participant's medical record to determine medical diagnoses, including the principal reason for admission (principal admitting diagnosis).

Measures

Drinking Outcomes. Alcohol use in the 30 days before each interview was assessed using the validated Timeline Follow-Back calendar method (Sobell et al., 1988), which identifies the number of standard drinks consumed on each of the past 30 days. Two drinking measures derived from the Timeline Follow-Back were used as study outcomes: (i) 30-day abstinence and (ii) number of heavy drinking days (HDDs) reported in the 30 days prior to the 3-month assessment. HDDs were defined as drinking ≥ 5 drinks per day for men and ≥ 4 per day for women.

Independent Variables. Five measures of different dimensions of physical health, the independent variables for the study, were derived from interview and structured record review at the time of enrollment: (i) recent medical comorbidity, (ii) lifetime medical comorbidity, (iii) self-reported physical health status, (iv) any alcohol-attributable medical diagnosis, and (v) alcohol-attributable principal admitting diagnosis. Medical comorbidities were assessed using a questionnaire validated by Katz, et al., which is similar to the Charlson Comorbidity Index (Charlson et al., 1994) but is based on patient report instead of administrative data and assesses the presence of medical illnesses including kidney disease, diabetes, heart disease, chronic obstructive pulmonary disease, AIDS, and others using both recent (past 3 months) and lifetime timeframes (Katz et al., 1996). We categorized the number of recent and lifetime comorbidities (0, 1, or ≥ 2). The

physical component summary (PCS) score from the 12-item Short Form Health Survey (Ware et al., 1996) measured physical health status. The PCS score ranges from 1 to 100 and is standardized to the U.S. population mean with 1 representing poor and 100 representing perfect physical health status (Ware et al., 1996). To avoid an assumption of linearity, PCS scores were categorized into quintiles with the highest quintile (best health) used as the referent category. Finally, a physician-researcher reviewed each patient's medical record at enrollment for any medical diagnoses that are 100% alcohol-attributable, and for whether any of these were the principal admitting diagnosis. Diagnoses included alcohol intoxication, alcoholic pellagra, alcoholic polyneuropathy, alcoholic gastritis, alcohol cardiomyopathy, alcoholic liver damage, acute alcoholic cirrhosis of the liver, alcoholic hepatitis, alcoholic fatty liver, alcoholic amnestic syndrome, other alcoholic dementia, alcohol withdrawal, alcohol withdrawal hallucinosis, alcohol withdrawal delirium, other alcoholic psychosis, alcohol withdrawal convulsion, or alcoholic pancreatitis (Adams et al., 1993).

Potential Effect Modifiers. DSM IV diagnosis of current alcohol dependence (American Psychiatric Association, 1994) was made at enrollment based on the Composite International Diagnostic Interview (CIDI) Alcohol Module (Robins et al., 1988). Readiness to change drinking was assessed via interview with the validated Stages of Change Readiness and Treatment Eagerness Scale (SOCRATES), which was developed to assess readiness among individuals presenting for specialty alcohol treatment (Miller and Tonigan, 1996). Two SOCRATES components (*Problem Perception* and *Taking Action*) were used rather than the 3 factors originally described based on results from a previous factor analysis in this patient population (Bertholet et al., 2009b), because it is consistent with another prior study (Maisto et al., 1999) and because these factors more aptly describe change readiness among patients not actively seeking or receiving specialty alcohol treatment. The two components yield continuous scores (range: 10–50 for Problem Perception, 6–30 for Taking Action) with higher scores representing more readiness. The readiness scores have been previously modeled using quartiles of the distribution because of nonlinear associations with drinking outcomes (Bertholet et al., 2009b). For this study, each score was dichotomized based on the observed associations with the outcomes of interest for this study and for ease of interpretation. Based on results of preliminary analyses categorizing readiness scores using quartiles of the distribution, Problem Perception was dichotomized at the 50th and Taking Action at the 75th percentile; residual plots and likelihood ratio tests evaluating goodness-of-fit suggested adequate fit.

Covariates. Covariates representing potential confounders were selected based on known associations between medical illness or health status and alcohol use and included: demographic characteristics (age in years, female gender, and race including Hispanic, Black, White, and other); smoking status [never, current, and past (Fagerstrom Tolerance Test), and quantity/frequency questions] (Pomerleau et al., 1994), and alcohol use reported at enrollment. Number of drinks per day (continuous variable) was included in models with abstinence as the outcome, and the number of heavy drinking days in the 30 days prior to baseline (categories: 0–1, 2–14, and ≥15 heavy drinking days) was included in models with number of heavy drinking days as the outcome. For evaluating the association between measures of physical health and abstinence, alcohol dependence was considered a potential confounder (in addition to a potential effect modifier) because of its strong associations with both medical illness and abstinence (Dawson et al., 2005). Despite the negative main trial results, randomization group was also included as a covariate because we sought to identify associations independent of intervention, subgroup analyses suggested some intervention effect, and the intervention may have resulted in differences in drinking or readiness to change between groups (Saitz et al., 2009).

Analyses

Subjects lost to follow-up were compared with those assessed at 3 months on all patient demographic and drinking characteristics using chi-square statistics, two-sample *t*-tests, and nonparametric (two-sample Wilcoxon rank-sum or Mann–Whitney) tests as appropriate. Separate logistic regression models were fit to evaluate the association between each of the 5 independent variables and 30-day abstinence. Negative binomial regression was used to model the association between each of the independent variables and the number of heavy drinking days reported at 3 months, because days are counts with a skewed distribution (large numbers of zeros from abstinent subjects, and some extreme numbers of days). Negative binomial regression generates estimates of the incidence rate ratio (IRR), which is interpreted as a multiplicative increase or decrease in the number of days for each 1-unit difference in the predictor variable (similar to a relative risk). A robust variance correction was used to allow for over-dispersion. Preliminary unadjusted models were fit first and then adjusted models controlling for all covariates were used as the primary analysis. Multiplicative first-order interactions between each measure of physical health and potential effect modifiers (dependence status and readiness to change) were tested in both unadjusted and adjusted models. Stratified analyses were conducted when interactions were significant ($p < 0.05$). We did not formally adjust for multiple comparisons because this secondary analysis was exploratory and intended to assess whether a single concept—physical health—was associated with drinking 3 months after hospitalization. All analyses were performed using Stata Version 10.1 (StataCorp., 2007) .

RESULTS

Participants had a mean age of 44 years and were racially diverse (45% Black, 39% White, and 9% Hispanic) (Table 1). Only 14% of participants reported never smoking; 75% reported current smoking. At baseline, patients reported consuming a median of 3.6 drinks per day, 38% of patients reported 15 or more heavy drinking days, 4% met diagnostic criteria for current alcohol abuse, and 77% met criteria for current alcohol dependence. Patients generally reported high levels of recognition of unhealthy drinking and efforts to change. Mean problem perception score was 35 (SD 11, range 10–50), and mean Taking Action score was 21 (SD 6, range 6–30). Participants had poor average physical health status [Physical Component Summary score of 38 (SD 9)]; 22% reported 2 or more recent medical comorbidities, and 33% reported 2 or more lifetime comorbidities. Forty-six percent of participants had any alcohol-attributable medical diagnosis in their medical record, while 15% had an alcohol-attributable principal admitting diagnosis.

Overall, 272 patients were interviewed 3 months after hospitalization (80% follow-up). No statistically significant differences (at $p < 0.05$) in demographic or drinking characteristics were identified between those with and without follow-up. However, a nonsignificantly greater proportion of patients with follow-up, compared to those without, met diagnostic criteria for alcohol dependence (79% vs. 68%,

p = 0.06). There were no significant differences in measures of physical health between those who did and did not complete follow-up.

At 3 months, 60 participants (22% of those with follow-up) were abstinent, and the median number of heavy drinking days was 5 (range 0–30). Most measures of physical health were not significantly associated with either abstinence or the number of heavy drinking days reported at 3 months in both unadjusted and adjusted regression models (Table 2). However, in unadjusted models, patients in the lowest quintile of self-reported physical health status (worst health) had significantly greater odds of abstinence at 3 months compared to those in the highest quintile (OR 3.35, 95% CI 1.25–8.96). The significance of the association was attenuated after adjustment (Table 2).

Table 3 displays p values for all tests of effect modification. Alcohol dependence significantly modified the association between having any alcohol-attributable medical diagnosis and abstinence and between having an alcohol-attributable principal admitting diagnosis and the number of heavy drinking days reported at 3 months but did not modify any other associations between measures of physical health and either drinking outcome. For the 58 participants without alcohol dependence, having an alcohol-attributable medical diagnosis (n = 13) was significantly associated with increased abstinence in unadjusted analyses (OR 4.36; 95% CI: 1.12–17.03) but not after adjustment for potential confounders (OR 3.83; 95% CI 0.75–19.59). For those who were alcohol dependent (n = 214), there was no significant association between having an alcohol-attributable diagnosis (n = 114) and abstinence in unadjusted or adjusted analyses (ORs 0.90; 95% CI 0.47–1.70 and 0.78; 95% CI 0.41–1.62, respectively). For the 58 participants who were not alcohol dependent, having an alcohol-attributable principal admitting diagnosis (n = 4) was significantly associated with fewer heavy drinking days in unadjusted and adjusted models (Table 4). For the 214 participants who were alcohol dependent, there was no significant association between having an alcohol-attributable principal admitting diagnosis (n = 37) and number of heavy drinking days (Table 4).

Neither measure of readiness to change modified any of the associations between measures of physical health and abstinence in unadjusted or adjusted analyses (Table 3). In contrast, both measures of readiness to change modified associations between having an alcohol-attributable principal admitting diagnosis and the number of heavy drinking days at 3 months (Table 3). Associations in unadjusted and adjusted analyses stratified by levels of Taking Action were not significant. However, among subjects with low Problem Perception (n = 132), those with an alcohol-attributable principal admitting diagnosis (n = 9) had 0.36 times the number of heavy drinking days compared to those without such a diagnosis (95% CI 0.13–0.99) (Table 4). No association was detected between having an alcohol-attributable principal admitting diagnosis (n = 30) and heavy drinking days among participants with high Problem Perception (n = 137). Problem Perception also modified the association between self-reported physical health status and heavy drinking days (Table 3). Among the 132 patients with low Problem Perception, those in the second Quintile of health status (n = 20) had 2.06 times the number of heavy drinking days (95% CI 1.17–3.62) compared to those in the referent group with the highest health status [5th Quintile (n = 33)] in unadjusted analyses. However, associations in stratified adjusted analyses were all not significant. No other significant interactions were found between readiness to change and the independent variables in models of heavy drinking days at 3 months (Table 3).

[a]Medical comorbidities (both recent and lifetime) modeled categorically (0, 1, ≥2) with 0 the referent; Physical Health Status modeled categorically in Quintiles (Quintile 5 referent); Alcohol-Attributable diagnoses (both any and principal admission) modeled dichotomously.
[b]Adjusted models included age, gender, race, smoking status, randomization group, alcohol dependence, and drinks per day at baseline.
[c]All models were adjusted for heaving drinking days at baseline; adjusted models also include age, gender, race, smoking status, randomization group, and alcohol dependence.

DISCUSSION

In this study of medical inpatients with unhealthy alcohol use, most participants had alcohol dependence and reported substantial medical comorbidity. Among all participants, there were no significant associations between measures of physical health and either abstinence or heavy drinking days 3 months after hospitalization, though we did observe a borderline significant association between worse physical health status and abstinence. However, among participants with nondependent unhealthy alcohol use and those who were less aware of their drinking as a problem regardless of dependence status, having an alcohol-attributable principal admitting diagnosis was associated with less heavy episodic drinking at follow-up.

Table 4. Associations Between Alcohol-Attributable Principal Admitting Diagnosis and Number of Heavy Drinking Days Stratified by Alcohol Dependence and Problem Perception (Significant Results are Bolded)

	Nondependent (*N* = 58)	Dependent (*N* = 214)	Low Problem Perception (*N* = 132)	High Problem Perception (*N* = 137)
	N (%)	*N* (%)	*N* (%)	*N* (%)

[a]Adjusted for heaving drinking days at baseline.
[b]Adjusted for age, gender, race, smoking status, randomization group, heaving drinking days at baseline, and alcohol dependence.

Several previous studies have explored the idea that medical illness or one's perception of their physical health may be associated with or lead to changes in drinking. Multiple successful alcohol-related interventions have focused on addressing a medical issue via ongoing monitoring of abnormal alcohol-related lab tests or blood pressure (Fleming et al., 2004; Kristenson et al., 1983, 2002; Maheswaran et al., 1992; Willenbring and Olson, 1999). One study of patients with HIV and past alcohol problems found that those who were told they had hepatitis C were more likely to reduce drinking at follow-up than those who were not (Tsui et al., 2007), and interventions in patients identified as heavy drinkers based on physical health problems were associated with reduced drinking and improved health outcomes (Israel et al., 1996; Kristenson et al., 1983; Willenbring and Olson, 1999). Finally, three randomized trials of interventions for unhealthy alcohol use found that the intervention was associated with improved outcomes for patients with an alcohol-related diagnosis but not for those without (Saitz et al., 2009; Walton et al., 2008; Weisner et al., 2001). Only one previous study that examined physical health and alcohol outcomes was conducted in medical inpatients with unhealthy alcohol use (Stewart and Connors, 2007). That study identified associations between readiness to change drinking and self-reported health status and alcohol-related physical consequences but found that only alcohol-related physical consequences were significantly associated with taking steps to change drinking (Stewart and Connors, 2007). Together, findings of previous studies suggest that poor physical health may motivate patients to consider changes in drinking and that, in combination with an intervention, alcohol-related illness can be a strong motivator of actual changes in drinking.

Our findings support and extend findings of previous studies in two ways. First, while the previous study in medical inpatients evaluated associations between self-reported physical health and readiness to change drinking (Stewart and Connors, 2007), our study evaluated associations between both self-report and medical-record-derived measures of physical health and patients' self-reported drinking 3 months after hospitalization. Though not statistically significant, estimates of associations between physical health and drinking went in the expected direction such that poorer physical health was associated with decreased drinking at follow-up. Second, we found that, independent of an intervention, admission to a hospital for a problem resulting from drinking was associated with less heavy drinking for nondependent patients and those who did not perceive their excessive drinking to be problematic at the time of their hospitalization.

Several previous studies have demonstrated that high levels of readiness to change when defined as problem recognition are strongly correlated with more severe unhealthy alcohol use (Maisto et al., 2001; Samet and O'Connor, 1998; Williams et al., 2006, 2007). And, although some measures of readiness to change predict decreases in drinking (Heather et al., 1993; Williams et al., 2007), greater Problem Perception has previously been demonstrated to predict *increases* in drinking (Bertholet et al., 2009a). Further, decreasing drinking may be more difficult for and require more intensive interventions with patients with alcohol dependence (Bischof et al., 2008; Fleming and Manwell, 1999). As such, our finding of decreased incidence of heavy drinking days among participants with nondependent unhealthy alcohol use who may have become aware of consequences of their drinking, but not among participants with alcohol dependence, is consistent with prior research.

We expected but did not find that poor physical health would be associated with decreased drinking among all participants. It could be that the relationship between health and drinking is more complex or that the expected associations are weaker than expected and thus were not statistically significant in this relatively small sample. Our finding that having an alcohol-attributable principal admitting diagnosis was associated with decreased drinking in subgroups of patients may have clinical implications. Brief alcohol counseling interventions that have reliably decreased alcohol consumption in primary care patients do not have confirmed efficacy for medical inpatients with unhealthy alcohol use (Emmen et al., 2004; Freyer-Adam et al., 2008; Holloway et al., 2007; Saitz et al., 2007, 2009). Although further research is needed to confirm this, our findings suggest that being hospitalized for

an alcohol-attributable illness may serve as a catalyst of change (Orford et al., 2006) for someone whose drinking or perception of drinking is more malleable to begin with (i.e., patients without dependence or who have little recognition upon hospital admission of their unhealthy drinking). As such, it could be that hospitalizations for alcohol-attributable illness may be a meaningful aspect to focus on during brief interventions for inpatients with less severe unhealthy alcohol use. But, most patients identified by alcohol screening in hospital settings are alcohol dependent (Saitz et al., 2006), a phenomenon which could account for lack of efficacy of brief interventions in this population (Guth et al., 2008). Further, 45 of the 51 (88%) patients who were hospitalized for alcohol-attributable illnesses in this study met criteria for alcohol dependence, and results of this study suggest that alcohol-attributable illness was not a strong catalyst of change for these patients. However, the study did not address whether an *intervention* focused on poor physical health impacted drinking outcomes. It could be that building upon the presence of an alcohol-attributable illness, or focusing on alcohol-related symptoms or problems (such as trauma) in the absence of alcohol-attributable illness, during brief interventions in hospital settings would help catalyze change for all patients along the spectrum of unhealthy alcohol use.

This study is limited in several ways. First, these analyses were conducted in a cohort of patients who consented to participate in a randomized controlled trial, which may limit the generalizability of findings. However, those who enrolled were identified by screening all medical inpatients. In addition, the parent study was not designed to answer the questions posed and, therefore, our ability to detect associations of the observed magnitude was limited both in the overall analyses and particularly in subgroup analyses exploring effect modification. In particular, the group of patients who were not alcohol dependent, for whom changes in drinking may be easier than they are for alcohol-dependent patients, was small, which may have limited our ability to detect important associations (although it was in this group that we did find an association between physical health and drinking). Future research should be pursued to confirm the results of this exploratory study. However, we found that, in exploring whether multiple dimensions of physical health were associated with changes in drinking, point estimates generally went in the expected direction, some results were significant, and consistent patterns emerged in subgroup analyses. Finally, the observational nature of our data makes us unable to determine a causal association between poor physical health and subsequent drinking. However, because it is impossible to randomize patients to medical illnesses or perceptions of their physical health status as poor, prospective data collection and adjusted analyses as in this study may be the best way to answer the research question.

Despite the limitations, some conclusions can be drawn from these findings, which merit further research. Some dimensions of physical health (e.g., medical illness) may not be associated with subsequent drinking among medical inpatients with unhealthy alcohol use. However, among participants with nondependent unhealthy alcohol use and those less aware that they are drinking at unhealthy levels, being admitted to the hospital for an alcohol-attributable diagnosis was associated with less heavy drinking. Although further research should confirm these findings, they suggest that, among medical inpatients with less severe unhealthy alcohol use, medical illness attributable to alcohol use may serve as a catalyst for positive changes in drinking. Hospital clinicians may be uniquely positioned to offer assistance to inpatients with less severe unhealthy alcohol use by helping patients to recognize a link between their drinking and medical diagnoses.

Summary. *Background:* For patients on warfarin therapy an international normalized ratio (INR) recall interval not exceeding 4 weeks has traditionally been recommended. For patients whose INR values are nearly always therapeutic, less frequent INR monitoring may be feasible. *Objective:* To identify patients with stable INRs (INR values exclusively within the INR range) and comparator patients (at least one INR outside the INR range), compare occurrences of thromboembolism, bleeding and death between groups, and identify independent predictors of stable INR control. *Methods:* The study was a retrospective, longitudinal cohort study using data extracted from electronic databases. Patient characteristics and risk factors were entered into multivariate logistic regression models to identify variables that independently predict stable INR status. *Results:* There were 533 stable and 2555 comparator patients. Bleeding and thromboembolic complications were significantly lower in stable vs. comparator patients (2.1% vs. 4.1% and 0.2% vs. 1.3%, respectively; $P < 0.05$). Independent predictors of stable INR control were age >70 years, male gender and the absence of heart failure. Stable patients were significantly less likely to have target INR ≥3.0 or chronic diseases. *Conclusion:* A group of patients with exclusively therapeutic INR values over 12 months is identifiable. In general, these patients are older, have a target INR <3.0, and do not have heart failure and/or other chronic diseases. Our findings suggest that many patients whose INR values remain within the therapeutic range over time could be safely treated with INR recall intervals >4 weeks.

Received 11 September 2009, accepted 29 December 2009

Introduction

Warfarin is effective for the prevention and treatment of arterial and venous thromboembolic disorders. Intra- and interpatient variability in dose response, susceptibility to drug–drug and drug–food interactions and a narrow therapeutic index necessitate periodic monitoring of physiologic response to warfarin using the international normalized ratio (INR) [1]. In addition, to provide the best combination of thrombosis reduction and bleeding avoidance, target INR ranges are varied by therapeutic indication (e.g. an INR target range of 2.0–3.0 for atrial fibrillation or venous thrombosis and 2.5–3.5 for patients with mechanical heart valves) [1]. While the INR is used to monitor the impact of warfarin therapy, few studies have addressed the optimization of INR measurement frequency or INR recall interval. Current guidelines suggest an INR recall interval not exceeding 4 weeks between measurements [1,2]. However, this suggestion is not evidence-based, having evolved instead from regional differences in routine clinical practise and expert opinion [3].

Frequent INR testing, perhaps as often as weekly, has been suggested for patients who self-monitor warfarin using point-of-care technology [1,4,5]. High frequency INR testing raises the likelihood of measuring slightly out-of-range INR values (which often leads to unnecessary warfarin dose changes) [6], increases the costs associated with warfarin therapy, and is probably unnecessary in those patients who demonstrate long-term INR stability (i.e. minimal INR deviation and longitudinal warfarin dose stability). Less frequent INR monitoring should be possible for patients with a stable warfarin dose, as

suggested by routine clinical practise in the United Kingdom where INR recall intervals of up to 90 days are employed in such patients [7]. Recent evidence suggests that longer INR recall intervals may also be associated with improved INR control [8,9], which has in turn been associated with reduced risk for anticoagulation therapy-related adverse events [10,11]. Moreover, anticoagulated patients with 6-month stable INR control have been identified [12]. Patients with such stable INR control experienced significantly fewer anticoagulation therapy-related complications compared with anticoagulated patients who did not have 6 months of stable INR control.

The objective of this investigation was to expand on previous research by identifying anticoagulated patients with very stable (i.e. all INR values in the therapeutic range during a 12-month time interval) INR control. In addition to identifying patient characteristics associated with very stable INR values, we compared the rates of anticoagulation therapy-related adverse events with those from a group of comparator patients whose INR control was less stable.

Patients and methods

Study design and setting

The study was a retrospective, longitudinal cohort study conducted at Kaiser Permanente Colorado (KPCO), an integrated health care delivery system that provides services to over 450 000 members in the Denver–Boulder metropolitan area. Anticoagulation services at KPCO are provided by a centralized Clinical Pharmacy Anticoagulation Service (CPAS) [11]. Working collaboratively with the referring physician and using standardized dosing algorithms [13], CPAS clinical pharmacists initiate, adjust and refill anticoagulant medications and order relevant laboratory tests. Dosing algorithms utilized during this study at KPCO specified a maximum INR recall interval of 6 weeks. Integrated, electronic medical, pharmacy and laboratory records systems and the CPAS database (Dawn-AC®; 4S Systems, Ltd., Milnthorpe, UK) were utilized to identify patients, treatments and outcomes for this study. Approval to conduct this study was obtained from the KPCO Institutional Review Board.

Patients

Patients with a duration of warfarin therapy in excess of 90 days during the study timeframe (January 2000 through to December 2005), an age of greater than 18 years and warfarin therapy continuing throughout at least one 12-month observation period were included in the study. Stable patients were defined as having all INR values within each patient's strictly defined therapeutic INR range for the first identifiable continuous 12-month period (i.e. 100% INR control) during the study timeframe. Comparator patients were those who did not have any continuous 12-month period where all INR values were within the therapeutic range. In order to ensure a minimal standard for compliance with ongoing INR monitoring, both stable and comparator patients had to have at least one INR determination every 8 weeks during the 12-month observation period. For example, a patient who had an INR target range of 2.0–3.0, at least one INR measurement every 2 months for a minimum of six measurements, and all INR values recorded during the 12-month observation period between 2.0 and 3.0, would be assigned to the stable group.

Data collection

Variables collected for analysis included the primary warfarin indication, age at start of the 12-month observation period, gender, INR target, duration of warfarin therapy, and INR values. Patient-specific factors that could influence the risk for anticoagulant-related complications also were recorded, including a history of diabetes, hypertension, heart failure, venous thrombosis, hemorrhage, stroke, cancer, and/or use of estrogen therapy. Risk factors were considered present when a coded assessment for a given factor during a KPCO healthcare visit was identified in the 180 days prior to the start of the observation period. Estrogen therapy was defined as a prescription for a systemic estrogen-containing product sold within 90 days prior to the start of the observation period. A validated measure of patient acuity, the chronic disease score (CDS), was calculated for each patient by using ambulatory prescription drug data from the observation period [14]. Chronic disease scores can range from 0 to 35, with increasing scores indicating an increasing burden of chronic diseases under treatment. Use of the CDS allows for the accounting of each patient's risk of mortality and future health care utilization [14,15].

The first occurrence of anticoagulant-related complications (thromboembolism, bleeding and death) requiring admission to the hospital or emergency department were sought using ICD-9 discharge diagnostic codes (available upon request) within KPCO electronic administrative databases. All events were subsequently confirmed through independent review of the patient's electronic medical record by two investigators. Events were scored using a modified Naranjo Scale to quantify the relationship of the adverse event with warfarin therapy [16]. A third reviewer was employed to resolve disagreements.

Thromboembolic complications were defined as any deep vein thrombosis, pulmonary embolism, cerebral vascular accident, transient ischemic attack, systemic embolism, or heart valve thrombosis. Bleeding complications included episodes such as intracranial bleeding, gastrointestinal hemorrhage, hematoma, hemoptysis, epistaxis and hematuria. All bleeding episodes resulting in admission to the emergency department or hospital were included regardless of severity. Fatal events were assessed for direct relationship to bleeding or thromboembolism using the medical record and/or a death certificate.

Statistical analysis

Data analyses were performed utilizing SAS 9.1.3 (SAS, Cary, NC, USA) statistical software. Patient characteristics were

reported as means and standard deviations for interval-level variables (e.g. age, warfarin dose, length of warfarin therapy, etc.) and percentages for categorical variables (e.g. gender, target INR, occurrence of anticoagulation therapy-related complications, etc.). Group associations between categorical variables were assessed using the chi-square test and continuous variables were compared between groups using the independent samples *t*-test or Wilcoxon rank sum test (depending on the distribution of the data). Patient characteristics and risk factors with an overall incidence of ≥1% were entered into a multivariate logistic regression model to identify variables that independently predicted INR stability. The alpha was set at 0.05.

Results

Records from 4701 patients were screened; of these, 3088 patients had a period where at least one INR was measured every 8 weeks for 12 months. The stable group comprised 533 patients with INR values within the desired reference interval on all determinations and the comparator group comprised 2555 patients with at least one INR outside the desired reference interval.

Baseline characteristics of stable and comparator patients are presented in Table 1. Stable patients were older and more likely to have had a target INR < 3.0, heart failure or prior venous thrombosis, and been receiving warfarin for atrial fibrillation, compared with non-stable comparator patients (all $P < 0.05$). Stable patients were less likely to have been receiving warfarin for heart valve replacement, taking concurrent estrogen therapy, and their mean CDS was lower ($P < 0.05$). Differences in the duration of warfarin therapy prior to inclusion in the study were not statistically significant between groups ($P = 0.552$). The mean percentage of INR values in the therapeutic range for the comparator group was 42.1% [standard deviation (SD) = 5.7]. The stable patients had a lower mean number of INRs measured during the observation period, 12.6 (SD = 1.9) INRs per patient compared with 21.8 (SD = 8.0) for comparators ($P < 0.001$).

Compared with stable patients, the rate of overall mortality was higher in the comparator group ($P < 0.01$) (Table 2). However, the anticoagulation therapy-related mortality rates were not statistically significantly different ($P = 0.518$). The rates of anticoagulation-related thromboembolic ($P = 0.022$), bleeding ($P = 0.026$) and combined bleeding or thromboembolic ($P = 0.003$) complications were higher in the comparator group. Additionally, patients in the comparator group were more likely to require co-administration of heparin or low-molecular-weight heparin ($P < 0.001$).

Independent predictors of INR stability were age > 70 years [odds ratio (OR) = 1.93, 95% confidence interval (CI) 1.56–2.38], male sex (OR = 1.44, 95% CI 1.16–1.78), target INR of 2.0 (OR = 2.80, 95% CI 1.83–4.28), and the absence of co-morbid heart failure (OR = 2.08, 95% CI 1.36–3.17) (Table 3). Conversely, an increasing burden of chronic illness (i.e. higher CDS) (OR = 0.92, 95% CI 0.88–0.95) and a target INR ≥3.0 (OR = 0.28, 95% CI 0.17–0.47) were independent predictors of INR instability.

Discussion

In this large retrospective cohort study, we identified 533 patients with very stable long-term INR control. We found that patients with stable INR control were significantly less likely to develop complications related to anticoagulation therapy. We identified that age > 70 years, male gender, target INR of 2.0 and the absence of co-morbid heart failure independently predicted INR stability. Patients with a target INR ≥3.0 and those with a greater burden of chronic diseases were less likely to have long-term INR stability. On average the proportion of comparator patients' INRs in the therapeutic range was 42.1%. The time in therapeutic range for all patients managed by the KPCO CPAS is typically about 65% [11].

The results presented here are similar to those we observed in a study that evaluated patients with stable INR control over a 6-month observation period [12]. As would be expected based on a definition of stability that required exclusively therapeutic INRs, fewer patients were able to maintain 100% INR control

*With all things being equal between two patients, for every 1 point increase in chronic disease score there is an 8% reduced likelihood of being stable.

over 12 months compared with 6 months of observation (533 vs. 2504, respectively). However, both studies found that age > 70, absence of heart failure, target INR < 3.0 and a lesser burden of chronic illness independently predicted stable INR control, increasing confidence in the observed association of these variables with INR stability. The two analyses differ in that male gender was identified as an independent predictor of stability in the current study, while estrogen therapy was not.

Based on the mean number of INRs measured in stable patients during the 12-month observation period (12.6), the observed frequency of INR monitoring was consistent with the current North American standard 4-week recall interval in stable patients. However, as study patients were required to have at least one INR measured every 8 weeks, it is reasonable to conclude in retrospect that stable group patients could have been safely monitored with 8-week INR recall intervals; so doing would have reduced the count of INR measurements by approximately half without compromising therapeutic outcomes. Less frequent INR monitoring would probably be well received by patients on chronic warfarin therapy and would reduce the utilization of healthcare resources. Changes in health status, dietary vitamin K intake or co-administered medications would require more frequent INR monitoring [1]. The utility of 8-week recall intervals should be confirmed in prospective, controlled trials. The observation that comparator patients were monitored significantly more frequently (mean INRs per patient 21.8) than stable patients probably reflects the standard CPAS procedure of scheduling 1–2-week INR recall intervals for out-of-range INR values. While it is possible that more frequent interaction with the healthcare system in comparator patients increased the chances of identifying bleeding or thromboembolic complications, we believe this is unlikely. Our definition of complications required admission to the hospital or emergency department (see Table 2), and most encounters for INR testing in our system involve only a visit to the laboratory for phlebotomy and do not include formal evaluation by a healthcare provider.

The finding that age > 70 predicted long-term INR stability argues against innate INR variability associated with advancing age. Although not specifically assessed, we speculate that better adherence to warfarin treatment regimens among older patients may have been a factor. We do not fully understand the association between a lower target INR (2.0) and INR stability. However, this observation could merely be a consequence of the non-linear association between INR and clotting factor activity [17]. Thus increasing INR target intervals of equal width such as those observed in our study (e.g. 1.5–2.5, 2.0–3.0, 2.5–3.5) may in effect have narrower therapeutic intervals. This is consistent with our observation that INR

targets of ≥3.0 independently predicted INR instability. For patients with atrial fibrillation, INR values < 2.0 have been associated with an increased risk for thromboembolic complications and more serious sequelae from these complications [18,19]. In light of this, and the absence of high-quality evidence showing that a target INR = 2.0 significantly lowers the risk of major hemorrhage, we recommend against targeting a lower INR range as a way to extend INR recall intervals.

Our results are likely to be valid. The dataset used to complete this study was robust, includes real-world patients with a variety of indications for warfarin and therapeutic INR targets, and has been used previously in health records and data extraction research [11,12,20] The large number of patients included in our analysis increases the generalizability of our results and reduces the likelihood that unmeasured bias may have influenced them. Clinical events were comprehensively collected and described and INR measurements were performed by a single laboratory and systematically captured in an integrated electronic medical record. All clinical events were independently assessed for causality using a validated scoring system by two expert reviewers. The long-term stable cohort was carefully established using a strict definition for stability. Most patients observed in our study had been on warfarin therapy for several years. Potential adherence and survivor biases were minimized by the fact that both groups observed in our study could appropriately be termed 'prevalent' warfarin users.

This study does have important limitations. Not all variables likely to enter into clinical decision making or known to affect INR control were collected due to the retrospective, observational design. The retrospective nature of the study also precludes definitive establishment of cause and effect relationships between study variables and outcomes. It is possible that some clinical events were missed. However, given that KPCO patients are either seen within an affiliated hospital or the costs of care are billed to KPCO when care is provided at non-affiliated hospitals, it is likely that the vast majority of clinically important events were captured. Any failure to capture such events would have been random across groups. Our study was conducted within an integrated healthcare delivery system with a specialized anticoagulation service using standardized warfarin dosing protocols and, thus, the observed results may not directly translate to other healthcare settings.

In conclusion, our work proves that a subgroup of anticoagulated patients with therapeutically stable INR values over 12 months can be identified. In general, these patients are older, with a target INR < 3.0 and lower chronic illness burden. Additionally, patients with highly stable INR values appear to experience significantly fewer anticoagulation therapy-related complications. Our findings support the suggestion that INR recall intervals should be individually tailored based on demonstrated INR control rather than being fixed at some arbitrary minimum frequency, such as 4 weeks [8]. We acknowledge that, before widespread change in the frequency of INR monitoring can be recommended, our findings will need confirmation in future prospective evaluations.

Addendum

D.M. Witt, T. Delate and N.P. Clark designed the research and extracted information from medical records; T. Delate performed the statistical analysis; D.M. Witt, T. Delate, N.P. Clark, M.A. Crowther, D.A. Garcia, W. Ageno and E.M. Hylek interpreted the analysis and revised the manuscript; D.M. Witt wrote the initial draft of the manuscript; T. Tran and C. Martell extracted information from medical records and reviewed the manuscript.

Quality of US Primary Care Delivered by Resident and Staff Physicians

Leah Zallman, MD[1], Jun Ma, MD, PhD[2], Lan Xiao, PhD[2], and Karen E. Lasser, MD, MPH[3]

[1] Department of Medicine, Cambridge Health Alliance and Harvard Medical School, Cambridge, MA, USA; [2]Palo Alto Medical Foundation Research Institute, Palo Alto, CA, USA; [3]Section of General Internal Medicine, Boston Medical Center, Boston, MA, USA.

BACKGROUND: Few population-based data are available on the quality of outpatient care provided by resident physicians in the US.

OBJECTIVE: To assess the quality of outpatient care delivered by resident and staff physicians.

DESIGN: Cross-sectional analysis. We used chi-square tests to compare resident and staff physician performance on 19 quality indicators. Using multivariable logistic regression, we controlled for sex, age, race/ethnicity, insurance, and metropolitan status.

PARTICIPANTS: 33,900 hospital-based outpatient visits from the 1997-2004 National Hospital Ambulatory Medical Care Survey (NHAMCS).

MEASUREMENTS: Resident and staff physician performance on 19 quality indicators.

RESULTS: Resident physicians were more likely to care for younger, non-white, female, urban, and Medicaid-insured patients. In both adjusted and unadjusted analyses, residents outperformed staff on four of 19 measures including angiotensin converting enzyme inhibitor use for congestive heart failure (57.0% vs. 27.6%; p=<0.001), diuretic use for hypertension (57.8% vs. 44.0%; p=<0.001), statin use for hyperlipidemia (56.3% vs. 40.4%; p=0.001), and routine blood pressure screening (85.3% vs. 79.6%; p=0.02). Residents and staff performed at similar levels for counseling (range 15.7 to 32.0%). Residents and staff performed similarly well on measures capturing inappropriate prescribing or overuse of diagnostic testing (range 48.6 to 100%). Residents and staff performed similarly on measures of appropriate prescribing (range from 30.9% to 69.2%).

CONCLUSIONS: Primary care provided by resident physicians is of similar or higher quality than that provided by staff physicians. Significant opportunity remains to improve quality of outpatient care provided by all physicians. Residency training programs should devote attention to improving outpatient quality of care delivered by residents.

BACKGROUND

Despite ongoing efforts to improve the quality of primary care in the United States, deficiencies persist.[1] In recognition of the importance of residency training in ambulatory medicine, the Accreditation Council for Graduate Medical Education (ACGME) increased the required time residents spend in primary care continuity clinics starting in July 2009 [2] and has supported involvement of residents in quality improvement efforts. Targeting trainees is prudent, as practice patterns are largely determined during the residency training years. Quality of care delivered by internal medicine residents is particularly important with respect to addressing health care disparities, as residents provide a substantial amount of care to minority and uninsured patients.[3,4]

Studies have shown increased quality of inpatient care delivered in teaching hospitals relative to non-teaching hospitals.[5,6] However, few population-based data are available on the quality of outpatient care provided by resident physicians in the United States. Although prior studies have reported comparable or increased quality of outpatient care delivered by residents, these studies have been limited by their lack of a comparison group [7] or by their focus on specific diseases or geographical areas.[8,9] We analyzed data from the National Hospital Ambulatory Medical Care Survey (NHAMCS). Our objective was to compare the quality of outpatient care delivered by resident physicians and staff physicians in the United States, across a spectrum of previously defined and published quality measures.[10]

METHODS

Data Source

We analyzed data from the Outpatient Department component of the NHAMCS collected between 1997 and 2004. The NHAMCS is administered by the National Center for Health Statistics (NCHS). It uses a multistage stratified probability sampling procedure to obtain nationally representative estimates of outpatient visits to hospital-based clinics on an annual basis. Hospital-based physicians (with staff assistance) or hospital staff complete NCHS standard encounter forms, including data on visit diagnoses, over a four-week period. The survey contains items on patient demographics (with the patient's race and ethnicity determined by the physician), up to three reasons for the visit (in the patient's own words), visit diagnoses (primary diagnosis plus two 'other' diagnoses), diagnostic and screening services ordered, counseling and education provided, and up to six medications. Listed medications included prescription and nonprescription medications that the physician prescribed on the day of the visit or prior to the visit and that the physician expected the patient to continue taking. In addition, the physician indicates whether she is the patient's primary care physician and whether she is a staff or resident physician. We did not analyze NHAMCS data after 2004 because the later surveys did not identify resident physicians. Ninety percent of the selected hospitals participated, and item non-response rates were generally 5% or less.

Description of Quality Indicators

We examined a set of 20 outpatient quality indicators, which was previously described in detail for use in NHAMCS.[10] Briefly, the quality indicators were developed in accordance with the Institute of Medicine's criteria[11] of clinical importance, scientific soundness, and feasibility for indicator selection as well as criteria specific to the limitations of the data source. Limitations of the data source included visit-based data, unreliable data elements and subpopulations, and inconsistent inclusion of variables over years. Indicators were selected if they were meaningful when measured at individual patient visits and did not rely on data elements or subpopulations that are considered unreliable according to NCHS standards. The quality indicators fall into five categories: 1) medical management of chronic diseases (ten measures; e.g. beta blocker use for coronary artery disease); 2) appropriate antibiotic use (two measures; e.g. no antibiotic use for upper respiratory tract infection); 3) preventive counseling (three measures; e.g. exercise counseling in adults at moderate to high risk for coronary heart disease defined as having two or more risk factors including a history of smoking, men >45 years old or women >55 years old, hypercholesterolemia, hypertension, or obesity and excluding those with known CAD or diabetes mellitus); 4) screening tests (four measures; e.g. routine blood pressure screening), and 5) inappropriate prescribing in elderly patients, defined as age $\geq$ 65 (e.g. avoiding use of 33 inappropriate medications such as benzodiazepines). We defined performance on quality indicators as the percentage of eligible visits receiving recommended care (i.e., the higher the percentage the better the performance), based on practice guidelines or, in the absence of authoritative practice guidelines, consensus expert statements. We excluded visits from both the numerator and denominator of a measure if the patient had clinical contraindications to a recommended treatment. For example, we computed the measure 'angiotensin converting enzyme (ACE) inhibitor use for congestive heart failure (CHF)' as the number of visits by adults with a visit diagnosis of CHF who had a documented prescription of ACE inhibitors or angiotensin receptor blockers divided by the number of visits by adults diagnosed as having CHF. We excluded visits by adults with diagnoses of hyperkalemia or angioedema from both the numerator and the denominator. We could only capture disease conditions and exclusions if the diagnosis in question was listed on the day of the visit, and if the medication in question was listed on the day of the visit. Because this study used publicly available anonymous data, the Institutional Review Board of Boston University Medical Center deemed it exempt from review.

Statistical Analysis

Using SAS Enterprise Guide 4.2 (SAS Institute, Cary, NC), we performed analyses using the patient visit as the unit of analysis. We calculated standard errors for all results as recommended by the NCHS, which accounts for the sampling weights and the complex multi-stage sampling design of the NHAMCS.[12] According to the NCHS, estimates with greater than a 30% relative standard error (i.e. the standard error divided by the estimate expressed as a percentage of the estimate) or based on fewer than 30 sample cases may be unreliable. In accordance with the NCHS analytical guidelines, we combined data from 1997-2004 in order to generate reliable national estimates. We excluded one quality indicator (antithrombotic therapy for atrial fibrillation), because it had a sample size that was too small to be considered reliable, leaving us with 19 quality indicators.

The primary outcomes were mean performance rates on quality indicators analyzed according to physician status (resident vs. staff physician). We compared mean performance rates with chi-square analyses (PROC SURVEYFREQ), followed by multivariable logistic regression analyses (PROC SURVEYLOGISTIC) controlling for patient sex, age, race/ethnicity, medical insurance, and metropolitan status. We selected these variables because they have been shown to be associated with differences in quality of care.[13,14]

RESULTS

Patient and Visit Characteristics

Table 1 shows characteristics of patient visits made to resident and staff physicians. Resident physicians were more likely to care for younger, non-white, female, and urban patients, as well as patients with Medicaid. Resident and staff physicians cared for patients with similar numbers of comorbid medical conditions and from similar regions of the United States. The proportion of visits to resident and staff physicians for preventive care versus treatment was similar.

[a]denotes that significance remains after adjusting for sex, age, race, insurance, and urban location
[†]treatment of depression is defined as: prescribing antidepressants, psychotherapy or mental health counseling
[‡]high risk adults is defined as having two or more of the following risk factors for coronary heart disease: a history of smoking, men >45 years old or women >55 years old, hypercholesterolemia, hypertension, or obesity and excluding those with known CAD or diabetes mellitus
[§]Data only available for 2003 and 2004

Performance on Quality Indicators

Table 2 shows mean performance rates on quality indicators for resident and staff physicians. In both unadjusted and adjusted analyses, residents outperformed staff physicians on four measures: ACE inhibitor use for congestive heart failure (57.0% vs. 27.6%; adjusted p=<0.001), diuretic use for hypertension (57.8% vs. 44.0% adjusted p=<0.001), statin use for hyperlipidemia (56.3% vs. 40.4% adjusted p=0.001), and routine blood pressure screening (85.3% vs. 79.6%; adjusted p=0.024). Residents and staff performed at similar levels for counseling on smoking cessation, and for exercise and nutrition counseling among moderate to high-risk adults; performance rates ranged from 15.7 to 32.0%. Residents and staff performed similarly well on measures capturing inappropriate prescribing or overuse of diagnostic testing. These measures included avoiding inappropriate prescribing in elderly patients, benzodiazepine use for the treatment of depression, antibiotic use for upper respiratory tract infections, and ordering routine complete blood counts, urinalyses and electrocardiograms; performance rates varied from 48.6% to 100%. Residents

and staff performed similarly on measures of appropriate prescribing including: treatment of depression (prescribing antidepressants, psychotherapy or mental health counseling), trimethoprim-sulfamethoxazole or quinolone use for urinary tract infections, aspirin and beta blocker use for coronary artery disease, and inhaled corticosteroid use for asthma. Performance rates on these measures of appropriate prescribing were between 30.9% and 69.2%.

COMMENT

Compared with staff physicians, resident physicians provide primary care that is of similar or higher quality. Residents outperformed staff physicians on four of nineteen quality indicators including ACE inhibitor use for congestive heart failure, diuretic use for hypertension, statin use for hyperlipidemia and routine blood pressure screening. Residents and staff perform similarly on preventive counseling, measures of avoiding inappropriate prescribing or overuse of diagnostic testing, and on measures of appropriate prescribing.

Our results are congruent with previous studies that have demonstrated increased quality of care provided by resident physicians on specific measures or at single sites.[8,9] As in previous studies, we found that resident physicians are less likely than staff physicians to prescribe antibiotics for respiratory conditions where antibiotics are rarely indicated.[8] Both resident and staff physician performance revealed deficits in quality of care. This confirms previously identified gaps in compliance with evidence-based guidelines for blood pressure screening,[15] diet and exercise counseling,[16] statin use for moderate to high risk patients,[17] and aspirin use for primary and secondary prevention of cardiovascular disease.[1,18,19]

Resident physicians provide a disproportionate amount of care for vulnerable populations. In our study, residents were more likely than staff physicians to care for non-white and Medicaid patients, which is consistent with prior studies.[3,4] This finding suggests that improving the quality of resident outpatient care might improve the quality of care delivered to underserved populations and hence potentially reduce disparities in care.

Our analyses are limited because physicians were only able to list a limited number of diagnoses (up to three) and medications (up to six). Thus, some diagnoses and medications may not have been captured on the day of the NHAMCS study visit. The six-medication limit would cause us to underestimate quality for indicators that call for use of a specific drug, but overestimate quality when the measure suggests drug avoidance. Hence, we would expect measures capturing inappropriate prescribing (avoiding inappropriate prescribing in elderly patients, benzodiazepine use for the treatment of depression, and antibiotic use for upper respiratory tract infections) to be somewhat overestimated in our comparisons, while measures of appropriate prescribing (treatment of depression, trimethoprim-sulfamethoxazole or quinolone use for urinary tract infections, aspirin and beta blocker use for coronary artery disease, and inhaled corticosteroid use for asthma) would be underestimated. Similarly, lack of complete diagnostic information might cause us to underestimate valid contraindications to otherwise indicated drugs. This problem seems most likely for ACE inhibitor in CHF, beta-blocker for CAD, diuretic use for HTN, and statin use for hyperlipidemia. However, these problems would only affect our conclusions regarding the relative quality of care by the two groups of physicians if these limitations applied differentially to residents or staff physicians. We know of no a priori reason to believe this is so and in fact believe that patients cared for by resident physicians have a similar burden of illness as those cared for by staff physicians, as evidenced by our finding that patients in each group were as likely to have a comorbid condition and had a similar number of comorbid conditions. Thus, we doubt that the absence of data on additional diagnoses and medications has introduced bias.

Our analyses are also limited by underreporting of preventive counseling behaviors in physician-report-based studies such as the NHAMCS, in which counseling behaviors are underreported for two reasons: 1) physicians underreport counseling behavior as compared to procedural behaviors,[20] and 2) visit-based data are unable to capture counseling behaviors that did not occur at the index visit. We doubt that staff physicians are more likely than residents to underreport counseling behaviors; however, because staff physicians have most likely seen their patients over a longer period of time, counseling is more likely to have occurred at a prior visit. One of the quality measures, blood pressure screening, is often carried out by medical assistants and may therefore reflect a difference in practice performance rather than individual physician performance. However, as it is incumbent upon the physician to ensure that screening tests be performed, the difference in blood pressure screening may still reflect a difference in physician attention to this screening test. Our study data were limited to hospital-based clinics and do not include visits to community-based clinics. Thus our findings may not be generalizable to those settings. Finally, because our study period preceded the ACGME-mandated increased ambulatory requirements, we have not captured any improvements in quality of care that may have resulted from this change.

Why are there differences in the quality of outpatient care provided by resident and staff physicians? Resident physicians are in the midst of training, thereby increasing the likelihood that they have learned current evidence-based based guidelines. Residents are also closely precepted by faculty, who may be more likely than non-teaching staff physicians to practice according to current guidelines. Residents performed particularly well on measures that are reinforced by their inpatient training, such as ACE inhibitor use for CHF and statin use for hyperlipidemia. Finally, since we were unable to control for the type of institution (academic vs. non-academic), the higher quality of care delivered by residents may reflect differences in systems of care provided at academic versus non-academic institutions.

This study highlights the significant opportunity that remains to improve quality of outpatient care in the United States, including within residency training programs. While ongoing quality improvement projects aimed at staff physicians target the majority of care delivered in the US, quality improvement programs targeting residency training sites are an important area for future interventions. Despite the fact that the majority of care is delivered in ambulatory settings, residents spend the majority of their training years in inpatient settings. Residency training programs should devote attention not only to augmenting time spent in the ambulatory setting as mandated by the ACGME but also on improving outpatient quality of care delivered by residents. Residents might participate in quality improvement projects in order to learn more about quality measurement and process improvement. Such efforts could be

guided by the development of a standard curriculum. As more emphasis is being placed on performance-based compensation, this is an increasingly important area to which residency programs should devote attention. Quality improvement interventions that address specific barriers at the system, provider, and patient level are necessary in order to reduce the discrepancy between clinical practice and best evidence.[21,22] Research on factors contributing to deficiencies and disparities in quality of care will inform the design of tailored interventions.

Despite increasing prevalence of HIV among U.S. Latinos, participation in HIV clinical trials is low. Barriers to HIV clinical trial participation in U.S. Latinos are not well understood. Using in-depth, semistructured interviews with HIV care providers serving HIV-positive Latinos and focus groups with HIV-positive Mexican-origin Latinos, we assessed cross-cultural barriers (e.g., stigma and linguistic) to HIV clinical trials in San Diego, California, bordering Mexico. Cross-cultural barriers were explored using grounded theory analytical techniques. Patient-provider concordance on the nature of HIV-related stigma, linguistic barriers, the impact of U.S.-Mexico border on Latino patients and participation in clinical trials were found. Providers described care access challenges faced by patients of Mexican-origin, particularly in light of immigration and U.S. border policy. HIV-related stigma and communication barriers among Latinos remain important obstacles to clinical trials participation and care access in the United States.

KEYWORDS U.S.-Mexico border, immigrants, HIV/AIDS, health care access, clinical trials

To live on the border is to live in the center: to be at the entrance and the exit; to inhabit two worlds, two cultures and to accept both.

—José Antonio Burciaga

INTRODUCTION

HIV prevalence is increasing in the U.S.-Mexico border region (Brouwer et al., 2006) and HIV has been identified as a health priority by the U.S.-Mexico Border Health Commission and Pan American Health Organization (United States-Mexico Border Health Commission, 2003; Pan American Health Organization [PAHO], 2007). National HIV surveillance data in the United States indicate a notable increase in the proportion of Latinos among new HIV infections and AIDS diagnoses, as well as increasing rate of HIV diagnosis among Latinos—three times higher than in non-Latino Whites in 2005 (Centers for Disease Control [CDC], 2006). Latino participation in HIV clinical trials, however, remains low (Gifford et al., 2002; Getz & Faden, 2008). Broadly defined, clinical trials are biomedical (e.g., development of new medications and treatment options or improvement of medication dosing) or behavior-related (e.g., assessment of new behavioral interventions to prevent disease transmission) research studies with individuals who are assigned by the investigator to a treatment or other intervention, and their outcomes are measured (U.S. National Institutes of Health [NIH], 2009).

Clinical trials are designed to determine new ways of improving patient health, including comparison of existing treatments to determine relative effectiveness.

Participation in clinical trials may allow for access to new therapies and treatment modalities, of particular importance for minority populations most affected by the HIV epidemic who may have limited access to care. Participation in clinical trials may not guarantee access to better treatment modalities; however, it improves a patient's access to monitoring of their disease state by clinicians specialized in the field of HIV. Equitable access to clinical trials may also improve generalizability of study findings to minority populations, and may reduce health disparities among those most affected by HIV. The National Institutes of Health (NIH) has issued a directive to promote recruitment of racial and ethnic minorities into research in order to identify potential differences in effects among ethnic/racial groups (NIH, 2001). Attention to ethnic and culturally-mediated barriers to HIV care and participation in clinical trials among Latinos in the U.S.-Mexico border region is warranted given the region's rapid demographic growth and substantial daily cross-border interaction (San Diego Association of Governments [SANDAG], 2003; U.S. Census Bureau, 2007).

Barriers to clinical trials include system-level barriers that may impede access to care and clinical trials (King et al., 2007). Examples of system-level barriers include provider preconceived notions or stereotypes about willingness to participate among Latinos and African Americans; language differences (e.g., clinicians are less likely to discuss clinical trials with patients who do not speak English); and level of effort that clinical trials personnel may make to recruit members of underrepresented communities (King et al., 2007; Stone, Mauch, Steger, Janas, & Craven, 1997; Stone, Mauch, & Steger, 1998; Stone, 2005). Ethical issues related to voluntary and informed consent, participation and coercion are appropriate areas of concern when enrolling members of traditionally underserved communities, including Latinos of Mexican origin living with HIV. To this end, Institutional Review Boards and NIH require detailed researcher explanation of how study recruitment will uphold the rights of participants including training of key personnel in protection of study participants (NIH, 2000). Provisions to improve linguistically-competent and ethically sound enrollment of traditionally disenfranchised ethnic groups include projects such as Project TRES (2009) an ethnically and linguistically-tailored ethics training course for Latino/a community-level research recruitment staff. Notwithstanding, continued attention is needed on potential ethical problems, particularly language-related issues, in recruitment of underserved populations. Our preliminary work in clinical trials participation barriers among Latinas living with HIV indicated that personal factors, such as fear, shame, and stigma are the most commonly perceived barriers to clinical trials participation (Zúñiga, Blanco, Martínez, Strathdee, & Gifford, 2007). This same study found that HIV service providers,

reported system-level barriers (Zúñiga et al., 2007). HIV-related stigma has been well documented in other studies as a significant barrier to HIV care and treatment in U.S. Latino populations (Zúñiga, Brennan, Scolari, & Strathdee, 2008; Vanable, Carey, Blair, & Littlewood, 2006), yet its role in clinical trials participation for U.S. Latinos has not been well established. Furthermore, although HIV-related stigma has been implicated as a barrier to HIV vaccine clinical trials recruitment among uninfected populations (Brooks, Newman, Duan, & Ortiz, 2007) there is limited research on the role of HIV-related stigma in clinical trials recruitment of persons living with HIV. As the prevalence of HIV increases in Latino populations along the U.S.-Mexico border region, lack of access to HIV-related care, including clinical trials, may further widen observed disparities in health.

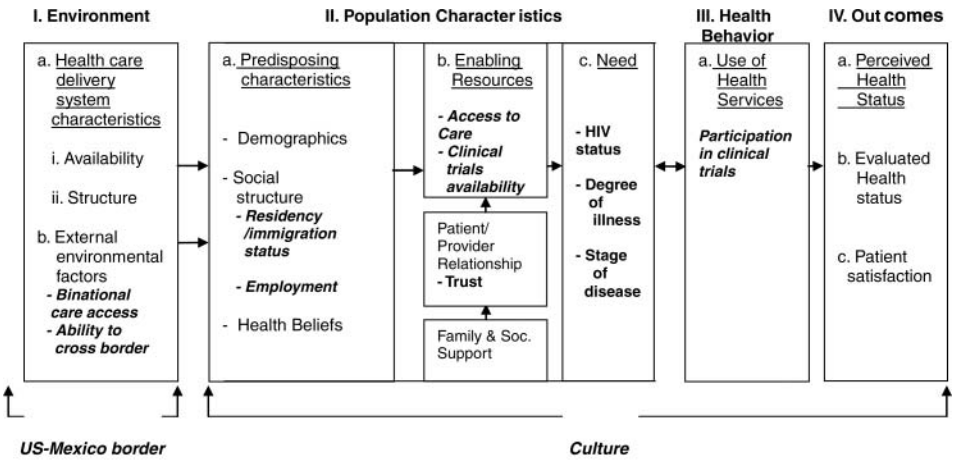
The current qualitative study was conducted in San Diego, California, which borders Tijuana, Baja California, Mexico. We examined barriers to HIV clinical trials participation among U.S. Latinos living with HIV and HIV care providers who serve Latino patients with a specific focus on stigma and system-level barriers. An in-depth understanding of patient and clinician contextual realities and perceived barriers to clinical trials is important to increase the effectiveness of clinical trials recruitment and inform the design of new approaches to improve access to HIV clinical trials and health care in Latino populations.

METHODS

Conceptual Framework

The behavioral model of health services utilization developed by Andersen, Aday, and others was adapted for the present study and served as the theoretical framework to explore and define factors associated with barriers to HIV clinical trials and HIV care in HIV-positive Latino populations in the U.S.-Mexico border region (see Figure 1; Phillips, Morrison, Andersen, & Aday, 1998; Andersen, 1995). Specifically, we applied the model's framework to include access to clinical trials as a factor of enabling resources within population characteristics (see Figure 1). The Behavioral model provides a framework in which factors associated with access to clinical trials can be contextualized within a broader access to care framework. This model has been used effectively to predict behavior in studies with HIV-positive persons and other vulnerable populations (Andersen, 1995; Gelberg, Andersen, & Leake, 2000; Dobalian et al., 2006) and was particularly well suited for the study as it has been successfully applied to access of vulnerable groups to antiretroviral therapy in the United States (Andersen, 1995).

The current study recruited two different populations (HIV providers and Latino patients living with HIV), employing sequential qualitative methods to first conduct in-depth interviews with HIV providers and later using



* Based on work from: Andersen RM, 1995; Phillips KA, Morrison KR, Andersen R, Aday LA, 1998.

FIGURE 1 Study Conceptual Framework using the Behavioral Model of Health Services Utilization.

these findings to inform focus group questions used with Latino patients living with HIV. Since there has been little research with clinicians who serve Latinos living with HIV (Zúñiga et al., 2007), it was imperative to conduct in-depth interviews with clinicians to understand their perspectives on barriers to care as part of potential structural barriers faced by patients. Furthermore, given that our previous research indicated that there may be a disconnect between perceptions of barriers to clinical trials between clinicians and patients (Zúñiga et al., 2007), we chose to conduct subsequent focus groups with Latino patients in order to allow for detailed discussion of patient agreement or disagreement with provider perspectives. This study was reviewed and approved by the University of California, San Diego (UCSD) Human Research Protection Program. Consent was obtained from all participants prior to participation.

Recruitment

In-depth, key informant interview participants included a purposive sample of 15 HIV physicians, pharmacists and nurses from affiliated university research centers, clinics and hospitals who actively served Latino populations living with HIV. Potential participants were chosen based on recommendations of key members of the UCSD HIV clinical trial system including clinical trials recruitment coordinators who work directly with clinicians. Potential key informants were contacted via e-mail and phone by a member of the research team; of the 33 persons contacted, 15 agreed to participate (45%). Our sample included clinicians who are integrally

involved with HIV clinical trials, including study principal investigators and co-investigators. Low clinician response rate is common in busy clinical environments where schedules may make it difficult for clinicians and study staff to participate; King and colleagues indicated low response rates among HIV clinical trials study staff, with rates ranging from 56% to 58% in an internet-based survey (King et al., 2007).

Focus group participants were Latino patients living with HIV in the San Diego region. Eligibility criteria included: ≥18 years of age, Latino, English- or Spanish-speaking, and living with HIV. Thirty-seven persons participated in a total of four focus groups (two male and two female groups). Of the four focus groups, two focus groups (one female and one male group) were comprised of persons who had participated in a clinical trial, and two (one female and one male group) were conducted with persons who had never participated in a clinical trial. Focus group participants were recruited by volunteer peer advocates from a partner community clinic as well as by outreach workers from the UCSD HIV clinical trial research groups.

Data Collection

The in-depth interviews were conducted using a guide that included 29 open-ended and 6 closed-ended items, based on research generated from patients living with HIV and HIV service providers that indicated specific difference in perspectives on barriers to entry into clinical trials (Zúñiga et al., 2007). Questions such as: "Do you think low acculturation influences an HIV-positive Latino's willingness or ability to participate in a clinical trial?" and "Do you think Latino patients are worried that someone will find out they are HIV-positive if they participate in a clinical trial?" wer were followed by prompts for the participants to expand on why or why not they thought the statement was correct. Trained study interviewers conducted the hour-long interviews with providers at a mutually convenient time and location. Providers did not receive an incentive for participating in the study.

Provider interview data were used to generate patient focus group questions and to ask patients about their perceptions of patient-provider communication, its role as a potential mediator of health choices, satisfaction with HIV medical services and care, and how these items may influence clinical trial participation. Draft focus group questions were presented in Spanish to a peer advocacy group for evaluation and feedback. Peer advocate review contributed to identification of errors and resulted in substantial improvements in clarity of questions in the interview measure. Focus group questions (12 total) were designed to provide participants with sufficient background information to understand the context of provider comments derived from key informant interviews and promote focus group reflection; elicit agreement or disagreement; and contribute their own thoughts on the

subject. Questions framed the issue and were followed by prompts for the participants to expand on their statements. Examples include: "For persons living with HIV who are undocumented, do you think that for those people their citizenship status is a barrier to participation in clinical trials?;" and "Do you think that the role of your family or partner could influence your participation in a clinical trial?" A 12-item demographic survey, including questions on education level, language preferences, and income, was also administered to study participants. All focus groups were conducted in Spanish and lasted between 1.5 and 2 hours; two were conducted at a collaborating community clinic and two at a UCSD clinical trial research office. Participants were read a consent form and allowed to ask questions during the entirety of the process. Participants received a $25 grocery store voucher. (Study measures and protocols are available upon request from the study's lead author).

DATA ANALYSIS

We followed the principle of *microanalysis* as described by Strauss and Corbin (1990), which is the detailed analysis of text that is necessary at the beginning of analysis to generate initial themes and suggest relationships between themes. Two members of the study team reviewed all interviews and focus group transcripts to identify themes.

Subsequent analysis was conducted independently by three study team members using open coding procedures on a sample of 5 of the 15 clinician/provider interviews to generate concepts, properties, and dimensions discovered in the data (Strauss & Corbin, 1990). The study team then met to discuss categories and reach consensus on coding themes. Next, the study team independently reviewed and coded two open-ended questions to reach consensus on how codes had been applied and whether there were emerging themes that merited new codes.

Using the revised coding scheme, two members independently coded five pages of two focus group transcripts. Coded questions were independently reviewed by third team member, who determined inter-rater reliability and met with study team to resolve coding discrepancies. Inter-rater reliability was >80%. The qualitative text analysis software, ATLAS.ti (version 7; ATLAS.ti Scientific Software Development GmbH), was used to facilitate visualization and organization of coded categories (concepts that stand for phenomena/central ideas in the data) and their properties, dimensions, and subcategories (Strauss & Corbin, 1990) as well as to facilitate generating frequencies of coded categories. Using the method of constant comparison, (Glaser & Strauss, 2006; Strauss & Corbin, 1990) a final coding taxonomy was reached through study team consensus.

RESULTS

Demographics

HIV care providers participating in in-depth interviews included 10 physicians, 3 nurses, and 2 pharmacists; were mostly non-Hispanic (66.7%), male (73.3%), and worked with HIV-positive Latinos for >10 years (73.3%). Slightly less than half of provider respondents were comfortable communicating in Spanish (47%), with one provider preferring to respond to the in-depth questions in Spanish.

Of 37 Latino focus group participants, 57% were male; and mean age was 43 years (range 22–59 years). Most participants were born in Mexico (92%) and about 60% of persons born outside of the United States had lived in the United States ≥10 years; 41% made at least one round-trip border crossing per month. About 38% had completed ≤8 years of schooling; nearly 70% reported an annual family income <$15,000/year and 27% reported no medical insurance. Most (78%) preferred receiving health information in Spanish. Eighty-eight percent of participants were exposed to HIV through sexual contact and 50% had lived with HIV for ≥10 years; about half (49%) having been diagnosed in Mexico. Additional focus group sociodemographic data are provided in Table 1.

Key Emergent Themes

Major themes identified in both in-depth provider interviews and patient focus groups were: (a) HIV-related stigma, (b) Communication/language; (c) Cross-cultural issues; and (d) U.S.-Mexico border and immigration. Findings are presented by major theme with HIV provider perspectives first, followed by patient perspectives.

HIV-Related Stigma

Providers described manifestations of HIV-related stigma as barriers to clinical trials participation among their Latino patients, noting the influence of individual-level stigma (e.g., fear of losing social support if seen entering an HIV research center) and community-level stigma (e.g., family adversely influenced their desire to seek medical care out of concern that others will learn of patient's status). Internalized stigma, both HIV-related stigma and stigma about sexual orientation, was expressed by providers who indicated that Latino patient discomfort with disclosure could serve as a barrier to participate in an HIV clinical trial. Providers conveyed that some patients felt guilty about being infected with HIV. Internalized stigma overlapped with patient concern about the number of additional clinic visits that clinical trials participation entails and having to explain to family members the reason for

going to the doctor more often. Stigma was also raised in the context of trusting providers (e.g., patient concern over who will have access to their clinical trials information), although the broader influence of HIV stigma on the patient appeared to be more of a concern than patient mistrust of providers.

Providers felt that patients were concerned about being seen at sites where only persons living with HIV receive care. One provider indicated that a patient was anxious about being identified as someone living with HIV so the provider made recommendations as to other clinics where the patient could seek care. Co-occurring themes with HIV-related stigma were

disclosure and family social support. Although providers observed Latino patient reticence to be seen walking into an HIV research center, providers felt that it would be beneficial to have clinical trials centers closer to where Latinos reside. Some patients feared that they may be seen and somehow compromise the social support provided by their family if the patient's HIV status became known. As one provider described:

> But the problem is that they [families] are supportive [and] they try to cover the issue; one of the young ones die of HIV they will say they die of pneumonia . . . or something other than complications related to HIV. If you tell them it is an HIV clinic then they will try to skip appointments. If you say that this is a place they do HIV studies they will be labeled and for sure try to avoid us.

The increase in number of care visits related to clinical trials participation was also perceived as problematic for patients who are concerned about stigma and having to explain to family and/or employer the reason for increase in visits. Increase in number of visits associated with clinical trials participation was specifically noted as a problem for employment, where patients feared having to disclose to employers the reason for needing time off for additional medical appointments and for school, where families may feel uncomfortable about explaining to teachers why the child will need to visit the doctor so often.

When the HIV-related stigma question was posed to Latino focus group participants, two individuals in different groups asked for clarification of the word *stigma*. The facilitator allowed participants who were familiar with this term to define it for their peers in order to observe how HIV-related stigma is understood and identified within the community. For example, in the women's group one participant stated, "Stigma is, for example, when you are ashamed to talk about it, you don't want to talk about it as if it were taboo for you or others."

Upon clarification of the term, participants engaged in discussion of their personal experiences with how perceived and felt HIV-related stigma and discrimination had affected their lives and that of their families. Female participants discussed how they have coped with HIV-related stigma over time. Upon reflecting on her experiences of living with HIV, navigating feelings of stigma, and HIV clinical research, one participant noted:

> At first, HIV stigma makes one starts to become paranoid . . . you receive a letter, "we invite you to participate in a study of HIV," and you want to burn the page or rip it up due to fear of that . . . and then you start to close your doors, when it should not be like that. You should talk with your family and overcome that barrier, but I'm saying not with all the family, but with close family, we should do that.

Women in both focus groups discussed at great length their efforts to avoid HIV-related stigma, mentioning having to be dishonest with family or persons in their social and faith networks to avoid being stigmatized by family and their community. Latinas discussed naming other diseases they or their partners had to avoid HIV disclosure (e.g., cancer). Important to the discussion was past experiences with discrimination related to living with HIV and being singled out with questions about how they were infected; for married women this was a particularly difficult point, navigating both their partner's HIV status as well as their own. Men did not specifically mention masking their HIV infection by telling friends and family they had another disease. One male participant stated, "Almost all of my neighbors know I have AIDS; to me, it doesn't matter, it doesn't matter to me what people say." The same participant however did admit that the stigma related to having HIV was a problem and concern for many other people: "It depends on the person . . . but yes there are a lot of people it [stigma] affects . . ."

Focus group participants also mentioned they often avoided discussion of HIV because they were tired of sharing their experiences with others and having to field more questions. However, apart from one participant's general concern about maintaining the confidential nature of HIV-related medical appointments, focus group participants did not otherwise mention concern about being seen at an HIV medical clinic and were enthusiastically in favor of having clinical trials sites closer to where they live.

Communication/language

Provider discussion of communication and language issues centered on the desire for improved access to bilingual staff and interpreters to facilitate enrollment of Latino patients with limited English language proficiency into clinical trials. Some providers expressed frustration with having a Spanish-speaking Latino patient, who was eligible for a study, but lacked access to an interpreter and having to ask the patient to wait. Some providers who did not speak Spanish were either learning or expressed interest in opportunities to improve Spanish-language skills.

Focus group participants talked about challenges to effective communication with health care providers as well as experiences that optimized communication. Although the importance of learning English was generally acknowledged, both men and women's groups expressed their preference communicating in Spanish during their medical appointments. Participants noted as well that although they may grasp working knowledge of English, their exposure to English medical terminology may be limited. In both male and female groups, language was also raised in the context of having trust in one's provider, and that a good relationship with the provider included ability to communicate in Spanish. Language was viewed by some as a

mediator of satisfactory clinical encounters, including availability of interpreter and patients expressed appreciation of clinician efforts to learn Spanish. As one patient expressed: "My doctor is learning Spanish and I love that . . ."

For some participants, limited English proficiency (speaking and reading) was a barrier to clinical trials participation, and one female participant stated this remained a barrier even when she offered to bring someone who could interpret during appointments, she stated:

> For example, I wanted to enroll into a neuropathy study that interests me a great deal because I have neuropathy, and they told me: "you know what, um, but you need to be proficient in English." I say: "what if I bring an interpreter?. . ." [provider response]: "No, you have to speak it."

Language was not reported by men as a specific barrier to clinical trials, but the importance of having access to interpreters was very important to both male and female focus group participants. One male focus group participant described having had a highly satisfactory interaction with a clinician through an interpreter on a telephone; the interaction included a conversation about sensitive topics whereby the patient felt that a telephone interpreter was less obtrusive to effective communication than having an interpreter physically in the consultation.

Patients felt that communication with providers was compromised when providers stereotyped them and felt that their relationship with the provider was undermined when clinicians made assumptions that the patient did not feel were accurate. The issue of cross-cultural communication also emerged with reference to diet. One male focus group participant described the following comments made by his physician: "Because you Mexicans are accustomed to eating a lot of fats . . . it's that your metabolism [of Mexicans] . . . since young children you eat many fats, then it is not like the Americans who eat a little less fat." A similar sentiment was expressed by a female participant who felt that she was unable to communicate effectively with her provider that she was eating healthfully although she was experiencing weight gain.

Cross-Cultural Issues

Providers mentioned the health belief of *fatalismo* [fatalism], or the idea that all things happen by fate or are destined to happen in relation to participation in clinical trials. According to one of the providers:

> There is an element of fatalism sometimes in the Latino community about HIV. That now I have it, I'm going to die soon, and if they want me in a study that means that I really am going to die soon.

Another cultural consideration providers noted about their Latino patients is a deep respect some have for the physician. One provider reflected: "[There is] more of a dependence on provider recommendation . . . [Latinos] see [the] doctor as an authority figure . . . may feel some pressure to comply and participate." Another provider mentioned: "[Latinos] are more likely to do what the doctor recommends . . . or want to participate [in clinical trials] to keep their doctor happy." Male and female focus group participant reflections on culture included awareness of differences in communication styles and stereotyping of non-Latinos, as one Latino focus group participant stated:

> We Latinos are accustomed to having people be a little warmer . . . "how are you? . . . how has it been going?" . . . even if it is a quick chat of two minutes. . . . the culture, the Germans, the Saxons, it is true, the culture is naturally colder, not because they are bad people or anything like that.

A second male focus group participant indicated a positive experience with care he received in the United States from physicians from Tijuana: "They understand us. They know our culture, our problems." Discussion ensued on the patient's responsibility to learn about the provider's culture and one male participant recommended that U.S. providers learn about the health care delivery system in Mexico to better understand how Mexican immigrants in the United States experience care delivery in their country of origin.

U.S.-Mexico Border Issues

Providers were aware of their Latino patients' strong ties to Mexico, including residence or having family in Tijuana. Awareness included knowledge of long wait times to cross the border and patient ability to make appointments on time. Border and immigration-related concerns and patient experiences also included co-occurrence with HIV stigma:

> The ones that live in Mexico. . . . the rest of the medical system doesn't know of their diagnosis, they live in a constant state of fear that they might get sick and they might need emergency treatment, there they would be thrown in a hospital where they might have relatives, nurses or people that know them around them, they don't want to trust them over there with their diagnosis, and unfortunately that creates an issue because physicians and nurses there deal with patients that are HIV-positive without knowing that they're treating HIV. And, of course, that skews their intervention and biases their diagnostic ability.

Male and female focus group participants discussed many instances of how the U.S.-Mexico border and immigration policies impact their daily lives. Latino men discussed differential access to HIV care and medication

depending on one's ability to cross the border, and efforts to donate unused medication to HIV-positive persons living in Tijuana. Women also discussed this circumstance, adding that there was an anxiety for them when they were crossing back from Tijuana to San Diego. Women expressed fear that U.S. border patrol agents may ask what their personal medications are for, since current U.S. policy indicates that non-U.S. citizens living with HIV may be denied entry into the United States or denied U.S. visas (National Immigration Project, 2004). Women also discussed how reliance on public transportation and concern over border patrol "sweeps" on public transportation would influence their decision to participate in a clinical trial. This consideration of transportation as a barrier to care is unique to U.S. immigrants who hold certain types of visas or who are undocumented in the United States. Women also expressed keen awareness of the implications of deportation on their ability to access HIV care, indicating concern about a lack of knowledge about the types and location of HIV medical services in Tijuana. Deportation was also mentioned as a concern among women because it separates families and potential sources of support for persons living with HIV.

DISCUSSION

Our study has several important implications for Latino participation in clinical trials and access to HIV care that provide a deeper understanding of how HIV-related stigma, communication and language, and other related cross-cultural issues and the border region impact the lives of Mexican-origin immigrants living with HIV. With some important modifications to fit our border context, the behavioral model of health services utilization adapted for this study served well as an explanatory framework for participation in clinical trials (Figure 1). Model components such as health behavior (participation in clinical trials) and outcomes (patient satisfaction with the clinical encounter) indeed appear to be influenced by the environment (U.S.-Mexico border and access to HIV care in binational context); population characteristics/predisposing characteristics (e.g., patient language, immigration status) and enabling resources (e.g., patient-provider relationship, including trust and patient ability to understand what is being said during their appointments). Our findings indicate that participation in clinical trials in this population may be influenced by cross-cultural issues that span all components of the model. We also note that resolution of environmental barriers such as moving clinical trials centers closer to communities may not necessarily improve participation if patients or their families are concerned about HIV-related stigma associated with being seen at a health care facility for HIV, including clinical trials center.

Across the four focus groups there was general agreement with provider observations and in many cases, participants expanded in great length on

these observations, engaging in a lively dialogue and expressing their experiences and additional views on HIV-related coping strategies, including failed coping strategies. Patient discussions also offer insights on stereotyping; feeling stereotyped and how patients may stereotype non-Latinos, both of which enrich understandings of how patients may respond to different clinical encounters. Focus group discussions also revealed patient sensitivity to issues surrounding fear of deportation, raised specifically during discussion of transportation-related barriers to care. This finding may serve to improve provider communication with their Latino patients who rely on public transportation.

Our findings extend those of previous studies that have quantified barriers such as lack of information about clinical trials; lack of transportation; limited clinic hours; concern over being part of an experiment; and fear of adverse events from treatment (Stone et al., 1997; Zúñiga et al., 2008; Travieso, 2003). In the current study, HIV care providers articulated several instances of how HIV-related stigma directly impacted Latino patient participation in clinical trials, particularly when patients' families are either not aware of the person's HIV status, or are aware but want to protect the patient from HIV-related stigma and may discourage patient participation in a clinical trial. The role of family appears to have a potential duality in the context of clinical trials, where families who serve as a source of social support and protectors of persons living with HIV may in some cases not support participation when HIV-related stigma is a concern. The nature of HIV stigma and how it permeates the lives of Latino patient study participants provided a deeper understanding of the patient context in which care decisions, including clinical trials participation, are made. Our work indicates that HIV medical care providers are attuned to the impact of stigma on the lives of their patients, but further study is needed to raise awareness of how HIV-related stigma may play a direct role in clinical trials participation. Gender-based differences in the impact of HIV-related stigma and coping mechanisms are also important to explore. For example, women in our focus groups mentioned coping with HIV-related stigma by telling friends and/or family members that they had cancer, rather than HIV. Male focus group participants did not identify this as a coping strategy.

Both patients and providers underscored the impact of HIV-related stigma in immigrant patients who currently live in or frequently visit Mexico. Concerns about patient lack of disclosure to other health care providers in Mexico or fear of their HIV status being disclosed if care were received in Tijuana were raised by providers and not patients. However, wherever care is received, both patients and providers mentioned concern about being recognized at an HIV care facility. In contrast to other studies that identified provider language-mediated barriers to clinical trials participation (King et al., 2007; Stone et al., 1998), our study indicated a genuine earnestness on the part of some providers to accommodate for patient language needs.

Providers were aware of the barriers that limited English proficiency could place on patient ability to participate in clinical trials and provided recommendations on how to reduce these barriers. Patient resourcefulness to bring their own interpreter, however, was not necessarily a bridge for this barrier when clinical trials materials were available in English only.

Our finding on the role of patient-provider racial or ethnic concordance offers partial support to the observation of Sohler and colleagues (Sohler, Fitzpatrick, Lindsay, Anastos, & Cunningham, 2007), that patient-provider ethnic or racial concordance was not associated with trust in provider, that is, patients tended to trust their providers regardless of whether they were of the same race/ethnicity or not. Patients in our study were aware that culturally-effective clinical communication is enhanced when receiving care from clinicians who are of Mexican-origin and familiar with Latino culture, however they were particularly appreciative of efforts made by their non-Latino providers to learn Spanish.

We observed several instances of the seemingly paradoxical nature of improving inclusivity of Latino populations into HIV clinical research studies and HIV care provision in a border context. Paradoxical responses were found for clinical trials locations; the role of family in supporting clinical trials participation; and delivery of culturally-effective care (Zúñiga et al., 2006). Although providers and patients indicated enthusiastic endorsement of having clinical trials recruitment and care centers closer to where Latino communities reside, stigma, manifested as concern over being seen at a clinical trials site or clinic exclusively for persons living with HIV, was expressed during interviews with providers as a clear barrier to clinical trials participation.

Prior recommendations to reduce barriers to HIV clinical trials participation for traditionally underserved communities include improving patient satisfaction with the quality of the patient-provider relationship and improving physician referrals to clinical trials (Cargill & Stone, 2005). Based on our study findings, opportunities to move HIV clinical trial centers closer to communities may address logistical problems for many Latinos living with HIV. However, this will necessitate thoughtful consideration of how stigma can be mitigated, with the essential need for feedback from community members themselves. Community member perspectives on research, the research institution's reputation in the community, as well as the relationship between researchers and the target community are all important considerations for successful recruitment into research studies (Sullivan et al., 2001). Concern over immigration issues necessitates that clinicians who serve immigrant communities also consider this as a potential barrier to care and clinical trials access for their patients. Provider opportunities to mitigate this concern may include becoming informed about immigrant patient rights (National Immigration Project, 2004); being sensitive to the potential for

immigration-specific duress in immigrant populations (e.g., concern about taking public transportation to clinical trials site for fear of encountering immigration authorities); and reassuring patients that their relationship with providers will not be compromised through a violation of trust.

Because our populations were drawn from care centers affiliated with a university research center, our findings may not be generalizable to other providers and Latino subgroups or nonborder dwelling populations, or populations who have had less experience with clinical trials. Although study researchers made an effort to recruit persons living with HIV who had and had not participated in clinical trials, it was apparent, particularly in the men's groups, that most participants had some experience with and knowledge about clinical trials due to receiving care from providers affiliated with the academic medical center and perhaps also due to length of time living with HIV. Nevertheless, future study is needed to understand the relative importance of major barriers in Latino populations. We also wish to acknowledge potential bias in focus group study questions. For example, questions specific to documentation status as a barrier to care could have elicited biased responses. We found, however, that as a whole, our study measure elicited frank participant discussion of sensitive issues such as stress of crossing the border with HIV medications or fear of deportation which enriched the depth of understanding of their perceived barriers to clinical trials participation and care. Finally, our small sample size may have missed important issues that larger studies may have uncovered with patients and HIV clinicians. The qualitative nature of this work, however, provides us with an in-depth understanding of barriers to clinical trials that informs future interventions to improve clinical trials representation.

CONCLUSIONS

Understanding barriers to participation in clinical trials is fundamentally inseparable from barriers to HIV-related care faced by Latino populations overall. Efforts to decrease disparities in clinical trials participation among Latino populations will include many, if not all, of the same strategies to improve patient engagement into care. This study attempts to fill an important gap in our understanding of low Latino recruitment into clinical trials, and is worthy of attention in future patient-level or provider-level interventions to promote clinical trials participation. Efforts must be made to improve consciousness among HIV clinical trials clinicians and staff of the multiple barriers potentially faced by their Latino patients, including the profound impact of HIV stigma and limited English proficiency on clinical interactions and activities. That immigrants of Mexican origin comprise a large proportion of persons living with HIV/AIDS in California makes imperative the inclusion of

deportation anxiety and U.S. immigration policies in discussions of improving access to HIV care, including participation in clinical trials.
