Romano and Stafford[2] analyzed 2 ambulatory care databases to examine the association between the use of the electronic health record (EHR)—with or without decision support tools—and clinical quality measures. Decision support tools are reminders to order medications or screening tests recommended by practice guidelines. The study found virtually no difference in 20 quality indicators among visits with no EHR, with an EHR, and with EHR plus decision support.

Commenting on the article by Romano and Stafford, McDonald and Abhyankar [3] suggest that for computerization to improve quality, EHRs need to include clinical decision tools. However, even without decision tools, an EHR combined with a clinical registry can be used to improve clinical care. The EHR-registry component can be used to generate a list of all patients in a medical practice with particular conditions (eg, diabetes mellitus), along with accompanying data (eg, hemoglobin A_{1c} [HbA_{1c}] levels). This information enables practices to identify patients who are overdue for needed interventions (eg, ocular examinations) or who have not achieved consistent disease control (eg, elevated HbA_{1c} levels). Also, registries can generate lists of patients who are overdue for preventive care (eg, mammograms).

How do these 3 articles assist us in understanding the building blocks of transformed primary care, which include the EHR, patient registry, and team-based care? The study by Romano and Stafford and the response by McDonald and Abhyankar demonstrate that the EHR is necessary but not sufficient for improved quality of care. Decision support reminders failed to improve quality of care because physicians must implement the actions that reminders prompt them to perform, for which physicians often do not have adequate time. Treating a typical panel

Safe Opioid Prescribing: A Long Way to Go

Jane M. Liebschutz, MD MPH and Daniel P. Alford, MD MPH

Clinical Addiction Research and Education Unit, Section of General Internal Medicine, Department of Medicine, Boston University School of Medicine, Boston Medical Center, Boston, MA, USA.

J Gen Intern Med 26(9):951–2
DOI: 10.1007/s11606-011-1797-3

Chronic pain is one of the most common reasons why patients visit a physician; yet, physicians are poorly trained to manage it. Despite centuries-long therapeutic use of opioids for pain, they fell out of favor for most of the 20th century in the US. However, in the 1980s, medical literature began to support the practice of prescribing opioids for chronic non-cancer pain.[1] Opioid prescribing then escalated over the past two decades,[2] despite lack of strong evidence supporting this practice.[3] Although it started as an antidote to under-treatment of pain, increased opioid prescribing has paralleled increases in opioid misuse including overdoses, diversion and addiction.[4,5]. Over the last decade, the medical and public health communities have begun to address this problem by cautioning that all patients prescribed opioids carry some degree of risk for opioid misuse. Recent clinical guidelines based on expert consensus now endorse universal assessment for opioid misuse risk and monitoring for subsequent potential harm.[6–8] The guidelines suggest that patients at "high risk" for misuse should be identified through individual patient risk factors, such as an existing diagnosis of substance use disorder (SUD), mental health problems, history of legal problems and younger age. Treating chronic pain with opioids should include monitoring for harm including urine drug testing to detect any illicit substance use and whether the prescribed opioid is being taken , frequent prescriber visits, pill counts to evaluate adherence with opioid dosing and to minimize diversion, use of state prescription drug monitoring program data, when available, and addressing aberrant opioid taking behaviors[9,10] such as patients requests for early refills. More intensive monitoring is recommended for those with more risk factors. When necessary, physicians should also refer patients to adjunctive mental health or addiction treatment specialists for co-management, when such services are available.

Few data guide the questions on quantity and frequency of monitoring to identify harm or misuse of opioid analgesics for chronic pain. The guidelines suggest conducting urine drug testing every three to six months for low-risk stable patients, and as often as weekly for high-risk patients.[8] In this journal, Starrels[11] and Morasco[12] use administrative data to examine adherence rates to minimal guideline-based care for patients in two different settings: primary care practices within the University of Pennsylvania Health System and Veterans Affairs Health Centers in the Pacific Northwest. Both authors show that although patients with the identified risk factor of SUD are monitored 2–3 times more closely with urine drug testing than patients without identified SUD, only a minority of these high risk patients are being tested. Morasco and colleagues found that even with the infrequent testing, a substantial portion of patients tested had illicit substances in the urine, including 1 in 20 patients without SUD and 1 in 7 patients with SUD. Furthermore, data from Starrels and colleagues suggest that patients with identified SUD received more frequent early prescriptions on a monthly basis including 1 out of 4 receiving multiple early refills over the duration of time receiving chronic opioids (mean 1.9 years).

Why are monitoring rates in these two systems of care so much lower than that suggested by clinical guidelines? Is it lack of familiarity with recent guidelines, or reluctance to institute time-intensive clinical practices that lack a sufficient evidence base? We believe that several factors may contribute to non-adherence to guidelines. There is a well known lack of formal pain and addiction curricula in medical schools, residencies and in continuing medical education.[13,14] In response to these gaps in medical education, federal agencies have started investing in prescriber education. In 2007 the National Institute on Drug Abuse (NIDA) partnered with eight US medical schools to develop innovative drug abuse and addiction curriculum resources.[15] Recently the FDA met with members of the pharmaceutical industry to outline new requirements for manufacturers of certain opioid analgesics to develop Risk Evaluation and Mitigation Strategies (REMS) that will require physician education.[16] As an additional sign of increased attention, in fiscal year 2010, the National Institutes of Health designated research on prescription drug abuse one of its 220 research topic funding priorities, at which time $36 million was expended in this area.

Even if the rate of monitoring using urine drug testing can be increased, it is not clear that monitoring alone can improve clinical care and thus decrease the rate of opioid misuse.[17] For example, near-universal implementation of a visual analog pain scale in the VA health system nationally was not associated with improvement in clinical care for pain.[18] Clinical care improvement requires education about interpretation of the assessment or monitoring tests, as well as effective communication skills in talking to patients about concerns about opioid misuse. Urine drug testing in particular is quite complex, and requires knowledge of the opioid chemical derivative (e.g. synthetic, semi-synthetic or naturally occurring) and potential metabolites, the duration of detection of the opioid and time of last ingested dose, and the type of assay performed (liquid chromatography vs. immunoassay) and positive cut-offs used by the lab.[19] Any unexpected result requires appropriate inquiry with the patient to help interpret the findings and place them into context. Furthermore, incorrect interpretation of urine drug testing may result in a

Published online July 7, 2011

patient being inappropriately discontinued from useful therapy and may lead to a subsequent rift in trust between patient and physician.

Physicians' attitudes toward opioid prescribing vary widely, ranging from no prescribing at all to very liberal prescribing.[20,21] There are geographic variations in both prescribing and abuse of prescription opioid analgesics.[22,23] Thus, the increasing prevalence of misuse of and addiction to prescription opioid analgesics attributable to physician prescription appears to be the result of a perfect storm: inconsistent and inadequate physician education, lack of sufficient evidence of efficacy and safety of opioid analgesia for chronic pain, and lack of adherence to guideline-based risk assessment and monitoring.

A multifaceted approach to improve opioid prescribing efficacy and safety is urgently needed. Such an approach must start with clinical policies to monitor all patients, while basing the intensity of monitoring on the individual patient's opioid misuse risk. It will need to include systems approaches, such as use of the electronic health record (EHR) to track a patient's adherence to guideline-based treatment plans. Using automated systems, point of care clinical decision support tools and statewide prescription drug monitoring program data may not only lessen the burden on physicians but may provide higher quality care.[22] It is critical that primary care physicians collaborate with colleagues in behavioral health, pharmacy, toxicology and specialty addiction and pain medicine to share knowledge and consultation on prescribing, monitoring and treatment plans if a patient is developing problems (e.g., addiction). This necessary collaboration may be facilitated in the setting of patient-centered medical homes. Additionally, patients need education on the limitations of opioid analgesics, appreciation of the risks associated with opioids (e.g., overdose) and ways to mitigate any risks (e.g. no increases in opioid dose in between visits). Research must be conducted in real world clinical settings where a multifaceted systems approach is examined for effectiveness in improving both individual and population-based outcomes.

Proton Pump Inhibitor Discontinuation in Long-Term Care

Amy Linsky, MD, MSc,[*†] *John A. Hermos, MD,*[*‡] *Elizabeth V. Lawler, DSc,*[‡§] *and James L. Rudolph, MD, SM*[‖§]

OBJECTIVES: To determine factors associated with proton pump inhibitor (PPI) discontinuation in long-term care.

DESIGN: Retrospective cohort analysis.

SETTING: Veterans Affairs (VA) long-term care facilities.

PARTICIPANTS: Veterans admitted for nonhospice care in 2005 with a length of stay of 7 days or more who were prescribed a PPI within 7 days of admission (N = 10,371).

MEASUREMENTS: Prescribed medications and comorbidities were determined from VA pharmacy and administrative databases and functional status from Minimum Data Set records. Associations between participant characteristics and PPI discontinuation were determined using Cox proportional hazard ratios (HRs), censoring at death, discharge, or 180 days after admission.

RESULTS: Participants were predominantly male (97%) and had a median age of 73 (interquartile range 60–81). There were 2,749 (27%) PPI discontinuations; 43% of these occurred within 28 days of admission. Hospitalizations (HR = 1.22, 95% confidence interval (CI) = 1.01–1.46), preadmission PPI use (HR = 1.35, 95% CI = 1.16–1.56), and lowest functional status (HR = 1.22, 95% CI = 1.03–1.45) were associated with early PPI discontinuation in adjusted models. Participants with gastric acid–related disease (HR = 0.53, 95% CI 0.46–0.61), diabetes mellitus (HR = 0.82, 95% CI 0.72–0.94), and those who were prescribed six or more medications (6–7 medications, HR = 0.78, 95% CI = 0.66–0.92; 8–10 medications, HR = 0.64, 95% CI = 0.54–0.76; ≥11 medications 0.51, 95% CI = 0.42–0.62) were less likely to have early discontinuation. No PPI discontinuer had PPIs resumed during the study, and few (9%) had histamine-2 receptor antagonist substitutions.

CONCLUSION: Although there may be clinical uncertainty regarding PPI discontinuation, more than one-quarter of participants prescribed a PPI upon admission to long-term care had it discontinued within 180 days. Targeting individuals prescribed PPIs for medication appropriateness review may reduce prescribing of potentially nonindicated medications. **J Am Geriatr Soc 59:1658–1664, 2011.**

Key words: long-term care; polypharmacy; proton pump inhibitors; prescriptions

Proton pump inhibitors (PPIs), a class of medications frequently prescribed to residents of long-term care facilities, are used to suppress production of gastric acid. In the short term, PPIs are highly effective for treating gastric acid–related diseases such as gastroesophageal reflux, esophagitis, and gastric and duodenal ulcers. Although there are critical indications for long-term use (e.g., Barrett's esophagus), chronic use is often not indicated.[1] PPI use without clear indication is common in people in hospitals,[2,3] and regardless of appropriateness of inpatient use, these individuals are then frequently discharged with a PPI prescription.[4] Although generally considered safe, recent observational studies have associated PPIs with risks of community-acquired and hospital-acquired pneumonia, *Clostridium difficile* infection, and osteoporotic fractures.[5–9] The associated morbidity of PPIs combined with the fragility of the long-term care population suggests that overuse of this medication class may disproportionately negatively affect these individuals.

Discontinuation of unnecessary or ineffective medications is challenging in long-term care settings, where residents take an average of seven to eight medications daily[10] and are at higher risk than older community-dwelling adults for adverse drug events and other medication-related complications.[11,12] However, the transition to a long-term care facility provides an opportunity to review and change prescribed medications under supervised conditions.[13] Considering the importance of these transitional periods and the fact that residents in long-term care are at high risk

0002-8614/11/$15.00

for adverse drug events,[14] the objectives of this study were to characterize the discontinuation of PPIs for residents newly admitted to Veterans Affairs (VA) long-term care facilities, identify factors independently associated with PPI discontinuation, and determine whether histamine$_2$ receptor antagonist (H_2RA) initiation for continued gastric acid suppression accompanied PPI discontinuation. It was hypothesized that discontinuation would occur early in the admission, that a greater number of total medications would be associated with PPI discontinuation, and that few residents would have a substitution of medication class from PPIs to H_2RAs. To accomplish these objectives, a retrospective epidemiological study of residents admitted to VA long-term care facilities was conducted using administrative, pharmacy, and Minimum Data Set (MDS) data.

METHODS

Study Setting and Data Sources

National VA administrative databases linked with MDS records were used to evaluate PPI prescribing in VA long-term care facilities. The MDS is a standardized assessment of nursing home residents that documents demographic information, functional status in terms of activities of daily living, and healthcare system use.[15] The Veterans Health Administration mandates completion upon admission and discharge and approximately every 3 months during any long-term care admission for which federal money is received. The VA Decision Support System (DSS) and National Patient Care Database (NPCD) files contain information on admission and discharge dates, age, sex, medical comorbidities, and pharmacy dispensing records.

Analyses were conducted at the Massachusetts Veterans Epidemiology Research and Information Center, VA Cooperative Studies Coordinating Center, VA Boston Healthcare System. The institutional review board of the VA Boston Healthcare System approved the study.

Study Population

Ten thousand eight hundred thirty-eight veterans newly admitted to a VA long-term care facility in 2005 and meeting the following criteria were identified: a completed admission MDS assessment, an admission for neither hospice nor respite care, and a prescription for a PPI within 7 days of admission. Only the first admission in 2005 per resident was selected, and 1 calendar year was chosen to minimize potential chronological trends in PPI prescribing. The study population was restricted to 10,624 individuals with a matching admission date in the VA Extended Care files of the NPCD, and then 234 individuals with a length of stay less than 7 days were excluded to allow for adequate opportunity to discontinue medications; 19 individuals without a complete functional assessment were further excluded, creating a cohort of 10,371 residents in 129 long-term care facilities analyzed in this study. Length of stay was determined according to discharge date, with a maximum follow-up of 180 days. Discharge status included discharge home, transfer to other facilities, and death. These facilities were renamed Community Living Centers in 2008 but will be referred to herein by the broader descriptive term long-term care facilities.

PPI Exposure

In the VA, long-term care residents have medications dispensed using procedures similar to those used for patients who are hospitalized. Residents are not permitted to take their own outpatient or over-the-counter medications, medications are individually bar-coded for tracking, and nurses dispense all medications. From DSS data, all days during which PPIs were dispensed to patients were determined, and the last day of PPI use was calculated by adding the days supplied to the final date dispensed.

Baseline PPI Exposure

Residents were designated as baseline users if there was any dispensing of oral PPIs in the first 7 days of the long-term care admission. This window allowed providers time for patient evaluation, medication reconciliation, and order entry. Day 7 of admission, the end of the defined enrollment period, was then set as the first day of use for the observation period.

PPI Duration

Duration of use was calculated as the number of days from Day 7 until the date of last PPI use because of discontinuation or censoring. For residents whose PPI was discontinued before Day 7, their duration was calculated by counting the days between the first date of PPI dispensing in the long-term care facility and the last day of PPI use. All measured durations of PPI use were continuous because no participant had intervening periods without PPI prescriptions.

PPI Discontinuation

If the calculated last day of PPI use was before discharge from the long-term care facility, then the participant was designated as a discontinuer. If the last day of use was at or extended beyond discharge or 180 days, the participant was designated as a continuer. No discontinuer had a subsequent reinitiation of PPI during the study admission.

Prior PPI Exposure

PPI use in the 30 days before long-term care admission was determined from VA DSS inpatient and outpatient pharmacy records. If participants had a PPI prescription with a calculated end date at or within 30 days before long-term care admission, or if they had acute care inpatient dispensing during that time, they were considered to be preadmission PPI users. Those without such documented PPI dispensing were classified as nonusers during this preadmission period. It was determined a priori that PPI exposure that ceased more than 30 days before long-term care admission probably had no remaining physiological effect.[16]

Other Medication Exposure

Histamine-2 Receptor Antagonist Use

Histamine-2 receptor antagonists (H_2RAs) have indications similar to those of PPIs, but they are neither as potent nor typically as long acting in their suppressive effect on gastric acid secretion. Because H_2RAs may be used alternatively to, or less commonly concurrently with, PPIs for gastric acid suppression, VA pharmacy records were queried for H_2RA prescriptions for the 10,371 study participants to determine whether they had a substitution in class of acid-suppressing

medication as opposed to a simple discontinuation. If participants had a H_2RA prescription within the first 7 days of long-term care admission, they were classified as baseline H_2RA users (n = 533). For those not prescribed baseline H_2RAs (n = 9,838), whether and when it was initiated during their admission was determined. In this way, six subgroups were created based on combinations of PPI use (discontinuation vs continuation) and H_2RA use (baseline vs initiation vs no use). For the subgroup comprising participants with PPI discontinuation and H_2RA initiation (a substitution of gastric acid–suppressing therapy), it was determined when, relative to PPI discontinuation, the H_2RA initiation occurred (>1 week before, ≤1 week before, ≤1 week after, >1 week after).

Medication Use Other Than Gastric Acid Suppressants

The number and type of medications that individuals take typically reflect medical and psychiatric comorbidities.[17] The number of distinct oral, intravenous, and topical medications, excluding PPIs and H_2RAs, was counted. The count could include medications prescribed on an as-needed basis if they were dispensed on the date of interest because the count reflects pharmacy dispensing and not computer order entry. Because Day 7 of admission was the first day of the analysis period, the number of medications on that day was categorized into quartiles for use in regression analyses.

Because the concurrent use of specific medications may serve as an indication for continuation of PPIs, the prevalence of use on Day 7 of aspirin, antiplatelet agents other than aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and systemic glucocorticoids was determined. Aspirin was further separated into low dose (81 mg) and other dosing for presumed differences in potential gastric irritation.

Other Variables

Participant Demographics and Medical Conditions

Age at admission and sex were obtained from administrative databases. Medical comorbidities diagnosed in the year before admission or during the study window were also recorded. Specific comorbidities and their *International Classification of Diseases, Ninth Revision, Clinical Modification* (ICD-9-CM) codes are as follows: gastric acid–related disorders (including diseases of the esophagus (530), gastric ulcer (531), duodenal ulcer (532), and gastritis and duodenitis (535)), dementia (290), diabetes mellitus (250), essential hypertension (401), chronic obstructive pulmonary disease (490–496), arthritis (711–715), chronic liver disease and cirrhosis (571), and chronic kidney disease (585–586).

Functional Status

Functional status indicators have been shown to predict mortality and have been associated with the presence of unnecessary medications.[18,19] From admission MDS records, individual performances on seven distinct activities of daily living (ADLs; dressing, personal hygiene, toilet use, locomotion on unit, transfer, bed mobility, and eating) were summed to create a composite score, the ADL Long Form.[20]

Performance on each ADL ranged from 0 (independent) to 4 (total dependence). If the activity had not occurred in the prior 7 days, the participant was considered to have total dependence for that activity and scored accordingly. Composite scores range from 0 to 28 and were categorized into quartiles for use in further analyses. There are no consensus recommendations for the analytic use of the ADL Long Form.

Hospitalizations

MDS admission assessments document the number of hospitalizations to VA Medical Centers or community facilities that occurred in the 90 days before long-term care admission. Hospitalizations were categorized as none, one, or two or more.

Analyses

Participant Characteristics

Participant age was quantified using median and interquartile range (IQR) and participant sex, medical comorbidities, preadmission PPI use, and specific medication exposures using prevalence. The medication count on admission Day 7 and the composite ADL score were each categorized into quartiles.

PPI Discontinuation and Factors Associated with PPI Discontinuation

The unadjusted prevalence of PPI discontinuation during the study was calculated. Actuarial methods were then used to derive unadjusted survival curves demonstrating the time to discontinuation to account for the discrete opportunities for discontinuation. This analysis also yielded the hazards of discontinuation throughout the study.

Characteristics which were associated with time to discontinuation were determined using Cox proportional hazard regressions. Separate models were run for individual comorbidities, medication count quartiles, specific medication exposures, ADL quartiles, hospitalizations, preadmission PPI use, baseline H_2RA use, age, and sex. Variables with moderate significance ($P<.10$) and variables with clinical relevance (age, sex, dementia) were entered into a multivariable model, using backward selection based on statistical significance to reach a final model. Sensitivity analyses compared the effect of modeling each of the four gastric acid–related disease categories separately with the effect of modeling them as a combined variable.

The proportional hazards assumption was tested by including interaction terms between each variable and the natural log of time. Because the assumption was violated for several variables, and given the nature of the hazard plot, piecewise analyses identified factors associated with discontinuation within the first 28 days of admission (21 days of PPI duration) and those associated with discontinuation after Day 28.

Patterns of PPI and H_2RA Prescribing

The prevalence of baseline H_2RA use, H_2RA initiation, and no H_2RA exposure were each determined for PPI discontinuers and continuers. For participants with PPI discontinuation and H_2RA initiation (a substitution), the proportion of participants who had H_2RAs started at various times before and after PPI discontinuation was calculated.

All analyses were conducted using SAS version 9.1 (SAS Institute, Inc., Cary, NC). Unless otherwise specified, alpha = 0.05.

RESULTS

The study population of 10,371 VA long-term care residents with an admission in 2005 and PPI prescription dispensed within the first 7 days of admission was predominantly male (97%) and had a median age of 73 (IQR 60–81) (Table 1). In this group of baseline PPI users, there was a high prevalence of comorbid conditions, including 46% with one or more ICD-9-CM–documented gastric acid–related diseases, most of which were gastroesophageal reflux or reflux esophagitis (n = 4,027, 39%). The majority (67%) had a record of a PPI prescription in the 30 days before admission. Nearly two in three participants had at least one hospitalization in the 90 days before admission. The median number of medications on admission Day 7, not including PPIs and H_2RAs, was 7 (IQR 5–10). Nearly one in three residents had exposure to low-dose (n = 1,989, 19%) or other dose (n = 1,185, 11%) aspirin, and an additional 902 residents (9%) had exposure to other antiplatelet agents. The median score for the summative seven-item ADL Long Form was 8 (IQR 2–15), suggesting moderate to severe functional impairment.

Table 1. Population Baseline Characteristics of Veterans Affairs Long-Term Care Patients Receiving a Proton Pump Inhibitor (PPI) within 7 Days of Admission (N = 10,371)

Characteristic	Value
Age, median (IQR)	73 (60–81)
Male, n (%)	10,043 (96.8)
Comorbidities (365 days before admission), n (%)

IQR = interquartile range.

PPI Discontinuation and Factors Associated with PPI Discontinuation

Slightly more than one in four participants had their PPI prescription discontinued before the end of the study period (n = 2,749, 27%). PPI discontinuation was more likely early in the observation period, with many of the discontinuations occurring in the first 28 days (n = 1,173, 43% of discontinuations). This is demonstrated in the survival curve and associated hazard rate curve (Figure 1A and B).

In unadjusted Cox proportional hazard models, factors found to be statistically significant predictors of PPI discontinuation were two or more hospitalizations in the 90 days before admission to the long-term care facility, preadmission PPI use, and being in the lowest quartile of functional status (Table 2). Factors associated with lower hazard of PPI discontinuation were six or more medications on admission Day 7; exposure to low-dose aspirin or antiplatelet agents on admission Day 7; and diagnoses of gastric acid-related disease, diabetes mellitus, chronic obstructive pulmonary disease, and hypertension.

In piecewise, adjusted analyses stratified according to time, factors associated with PPI discontinuation before Day 28 of admission (early) were hospitalization, preadmission PPI use, and worse physical function (Table 2). Gastric acid–related disease, diabetes mellitus, and six or more medications were associated with a lower hazard of PPI discontinuation before Day 28 of admission. At or after 28 days (late), only two or more hospitalizations before admission was associated with greater hazard of PPI discontinuation, whereas gastric acid–related disease remained associated with lower hazard.

Sensitivity analyses including discrete gastric acid diagnoses found estimates of association with PPI discontinuation similar to analyses with a combined variable. The hazard ratios for early discontinuation ranged from 0.45 to 0.77, compared with 0.53 for the combined variable, whereas those for late discontinuation ranged from 0.75 to 0.86, compared with 0.80 for the combined variable.

Patterns of PPI and H_2RA Prescribing

In participants with eventual PPI discontinuation (n = 2,749), 2,328 (85%) had no H_2RA exposure during the study period, 179 (6%) received an H_2RA at baseline, and 242 (9%) had an H_2RA initiated during the study window. Of these 242 H_2RA initiators, most had this medication first prescribed within 7 days before PPI

The start of analysis is Day 7 of admission to long-term care.

discontinuation (n = 104, 43%) or more than 1 week before discontinuation (n = 71, 29%) (Figure 2).

DISCUSSION

This study describes PPI discontinuation and factors associated with discontinuation. Of residents admitted to VA long-term care facilities with PPI prescriptions, 26.5% had that medication discontinued, more than 40% of which occurred within the first 4 weeks of admission. Factors predictive of early discontinuation included a hospitalization in the 90 days before admission, preadmission PPI use, and greater functional impairment. Consistent with indication-based prescribing, participants with gastric acid–related disease were less likely to have PPIs discontinued during the observation window, as were those with diabetes mellitus. PPI discontinuation did not result in subsequent resumption and infrequently led to H_2RA initiation, suggesting that these individuals were able to be managed without significant clinical consequences. Given the frequency with which people are prescribed PPIs without documented indication, these data suggest that many may be able to have this potent gastric acid suppressant safely withdrawn from their medication regimens.

These rates of PPI use and discontinuation are consistent with those from other studies that illustrate overuse of PPIs[21,22] but add to current knowledge by identifying timing of and factors associated with PPI discontinuation. Although there are no benchmark standards for PPI discontinuation, one study found that 27% of community-dwelling individuals receiving long-term PPI therapy were able to withdraw without resuming use for at least 1 year.[23] Long-term care residents may have different requirements for PPI use than acute care inpatients or community-dwelling older adults, although one study found that 61% of participants were prescribed a PPI on transfer to a skilled nursing facility and that only half of these had a diagnosis indicating appropriate use.[24] This is consistent with the finding that only 46% of the study population had documented gastric acid–related disease. Finally, by using a large national database and incorporating time to discontinuation, it was possible to demonstrate that discontinuation more often occurred early in the admission and may reflect active attention to treatment plans during transitions in care.

Because one concern related to medication appropriateness is a balance between time to benefit and expected lifespan, many individuals near the end of life are on medications from which they are unlikely to derive benefit. This study found that participants with worse functional status were more likely to have their PPI discontinued, which may indicate that these frailer, sicker individuals were seen as appropriate candidates for medication review and discontinuation of nonessential prescriptions. Such individuals in this study may also be more likely to have unnecessary medications as part of their regimen and thus have more opportunities for discontinuation.[19] Contrary to the hypothesis, individuals with six or more total medications were less likely to have a PPI discontinued. Because such individuals are at higher risk for adverse drug events, they are a prime population to target for better medication prescribing. Careful review of all medications and elimination of those without current clinical indication could lead to fewer unintended consequences and lower associated healthcare costs.

This study benefited from a large, national sample encompassing extended care admissions from all VA long-term care facilities and the integrated medical record of the VA healthcare system, which enables a cohesive view of a resident's comorbidities, healthcare usage, and medication regimen before and during admission. The demographics of the VA population (largely older men) may limit generalizability to other populations. The standardized medication administration protocols with barcode tracking captures accurate long-term care medication use. Although it was possible to capture dispensing accurately, the lack of data on preadmission use of non-VA prescribed formulations and no specific measure of indication for PPI initiation, continuation, or discontinuation limited this study. Although this is important to determine the appropriateness of PPI use, it was possible to include documented comorbidities and exposure to specific medications of interest, which may serve as a proxy for indication. Potential misclassification in administrative databases limits this.

‡ Aspirin 81 mg, aspirin other dose, and antiplatelet agents are mutually exclusive.

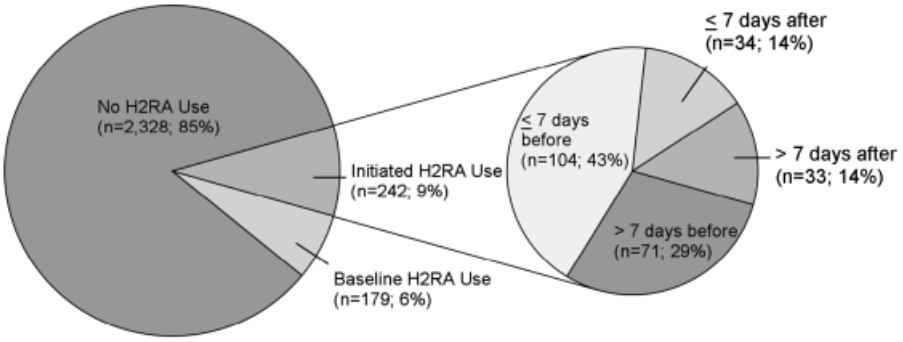

Figure 2. Patterns of histamine-2 receptor antagonist (H_2RA) use in individuals with proton pump inhibitor (PPI) discontinuation. The pie chart (left) shows the proportion of individuals with PPI discontinuation who had no H_2RA prescriptions, had baseline prescriptions, or initiated prescriptions. Few individuals with PPI prescriptions had H_2RA prescriptions during the study. For the subgroup with H_2RA initiation, the pie chart (right) illustrates the timing of the H_2RA initiation referent to the day of PPI discontinuation.

By incorporating data from the MDS, it was possible to assess resident functional status, an important predictor of morbidity and healthcare utilization.[15] Finally, this study included participant characteristics that may be associated with prescribing patterns but was unable to account for potential variation in pharmacist involvement or prescriber characteristics.

PPIs have been demonstrated to be effective for several conditions but are frequently initiated and perpetuated in chronically ill individuals without clear indication. The presence of multiple chronic conditions can lead to development of complicated medication regimens, which in turn may reduce of the ability of providers to isolate prescriptions that are no longer necessary. Therefore, clinical focus on functionally impaired individuals prescribed many medications would be appropriate for targeted medication review, including evaluation of dose, duration, and indication. Given the potential for associated negative consequences, individuals not meeting prescribing indications could reasonably have a trial of PPI withdrawal, despite apparent tolerance of the medication without overt adverse drug events. Individuals transitioning between healthcare settings provide an important opportunity to review medications and discontinue those without indication. Future work will better define which individuals will most benefit from these interventions.

In summary, although there is no current consensus or guideline regarding PPI discontinuation, it was possible to show that more than one-quarter of individuals prescribed a PPI upon admission to long-term care had it discontinued within 180 days. These findings suggest that opportunities exist in long-term facilities to evaluate and reduce prescribing of medications that may be noncritical or inappropriate. Once barriers to medication discontinuation, and to what extent they can be attributed to individual, provider, or system factors, are recognized, interventions can be implemented to improve appropriate prescribing to older adults, with the ultimate goal of reducing adverse health outcomes and associated healthcare costs due to overmedication.

Lifestyle behaviors in Massachusetts adult cancer survivors

Amy Linsky · Joshua Nyambose · Tracy A. Battaglia

Received: 30 September 2010 / Accepted: 23 November 2010 / Published online: 5 December 2010

Abstract
Introduction Adoption of healthy lifestyles in cancer survivors has potential to reduce subsequent adverse health. We sought to determine the prevalence of tobacco use, alcohol use, and physical inactivity among cancer survivors overall and site-specific survivors.
Methods We performed a cross-sectional analysis of the Massachusetts Behavioral Risk Factor Surveillance System, 2006–2008, and identified 1,670 survivors and 18,197 controls. Specific cancer sites included prostate, colorectal, female breast, and gynecologic (cervical, ovarian, uterine). Covariates included age, gender, race/ethnicity, education, income, marital status, health insurance, and physical and mental health. Gender stratified logistic regression models associated survivorship with each health behavior.
Results 4.9% of men and 7.7% of women reported a cancer history. In adjusted regression models, male survivors were similar to gender matched controls, while female survivors had comparable tobacco and alcohol use but had more physical inactivity than controls (OR 1.5; 95% CI, 1.2–1.8). By site, breast cancer survivors were more likely to be physically inactive (OR 1.5; 95% CI, 1.1–2.0) and gynecologic cancer survivors were more likely to report current tobacco use (OR 1.8; 95% CI, 1.2–2.8).
Conclusions and Implications for Cancer Survivors Specific subgroups of cancer survivors are more likely to engage in unhealthy behaviors. Accurate assessment of who may derive the most benefit will aid public health programs to effectively target limited resources.

Background

With continued improvements in detection and treatment, more Americans are surviving a diagnosis of cancer. Defining a survivor as someone with any history of a cancer diagnosis, regardless of time since diagnosis, there were nearly 12 million American survivors in 2007 [1]. These survivors are at risk for recurrence, secondary cancers, and other medical problems, including cardiovascular disease and diabetes [2].

Risk for subsequent health problems may result from cancer treatments, genetics, or lifestyle behaviors [3]. Estimates indicate that one third of cancer deaths are related to tobacco and another third are due to physical inactivity and dietary habits [4]. While a cancer diagnosis is conceptualized as a "teachable moment," behavior change made post-diagnosis is often not maintained [3]. As such, tertiary prevention via adoption and maintenance of healthy behaviors and avoidance of unhealthy habits has potential

to reduce adverse health consequences and improve quality of life for survivors [3, 5].

Studies of national survey data suggest that, as a group, cancer survivors have similar lifestyles as those without a cancer history [6–8]; however, certain survivors are at increased risk for unhealthy behaviors. Younger survivors are more often current smokers [6, 7], yet concurrently are more physically active [6]. Meanwhile, prostate cancer survivors have a higher prevalence of moderate-to-heavy alcohol use [8].

Prior studies have conflicting findings regarding unhealthy behaviors in cancer survivors, in part due to differences in methodology and unmeasured confounders, such as physical and mental health status. Furthermore, regional variation may be obscured with national level analyses. Since many public health interventions are organized at the state level, detailing survivors' behaviors within an individual state may better direct limited resources and public health planning. Therefore, we sought to determine the prevalence of unhealthy lifestyle behaviors of Massachusetts cancer survivors by conducting a cross sectional analysis using data from the Behavioral Risk Factor Surveillance System (BRFSS). Because patient characteristics associated with specific cancer sites differ, we also assessed whether survivors of specific cancers were more or less likely to engage in unhealthy lifestyles.

Methods

Data source

The BRFSS is an annual state-based cross-sectional telephone survey of adults ≥18 years, established and coordinated by the Centers for Disease Control and Prevention (CDC) [9]. A range of information is collected, including health conditions, alcohol and drug use, sexual behaviors, and environmental exposures. Massachusetts added cancer survivorship questions to the BRFSS Survey in 2006 to track behaviors of survivors.

Participants

There were 20,900 Massachusetts residents who were asked "Have you ever been diagnosed with any type of cancer?" in 2006–2008. The 18,197 respondents who reported no history of cancer comprise the non-cancer controls. The 2,339 subjects who responded affirmatively were then asked to name the cancer site (up to three). Individuals who refused or did not know cancer history or cancer site were excluded. We further removed those who did not report age and gender, reported non-melanoma skin cancer only, or had inconsistent gender/cancer combinations, yielding 1,670 cancer survivors in our study.

Cancer survivors were further classified by primary site of cancer. We focused specifically on the sites with the highest frequencies of responses: female breast, gynecologic, prostate, and colorectal (CRC). Gynecologic survivors were those who answered that they were diagnosed as having cervical, uterine, or ovarian cancer—a single combined answer option in the BRFSS. Respondents with other cancer sites or a history of multiple cancers formed separate subgroups of "Single—other" and "Multiple," respectively.

Demographics and covariates

Self-reported information was obtained for age, race, ethnicity, education, employment status, marital status, health insurance, and physical and mental health status. Race and ethnicity were recoded into white non-Hispanic vs. other. We dichotomized education, marital status, and health insurance. Employment status had three levels (employed, unemployed, retired).

Physical health was assessed using the question "For how many days during the past 30 days was your physical health not good?" We categorized responses into ≥14 day vs. <14 days, which corresponds with physical activity levels [10]. Mental health was assessed by asking "For how many days during the past 30 days was your mental health not good?" Frequent Mental Distress was considered present if the subject reported ≥14 days, consistent with CDC standards and other studies [11, 12].

Behavioral outcomes

Tobacco use Smoking behavior was measured using combinations of current and former cigarette use. "Current smokers" reported ≥100 lifetime cigarettes and current use. "Former smokers" reported ≥100 lifetime cigarettes without current use. Subjects with <100 lifetime cigarettes were classified as "Never smokers." All analyses assessing former tobacco use excluded never smokers since they could not become either a former or current smoker.

Alcohol use Heavy alcohol use was defined as an average intake in the past 30 days of 60 drinks for a man and 30 drinks for a woman, consistent with general recommendations in the absence of universal guidelines for alcohol consumption [4].

Physical inactivity Respondents were asked "During the past month...did you participate in any physical activities such as running, calisthenics, golf, gardening or walking for

exercise?" If they answered negatively, they were designated physically inactive.

Statistical analyses

To account for the complex sample survey design, all analyses were weighted to reflect the probability of selection of a telephone number, the number of adults in a household, and differences in participation by gender and age to provide Massachusetts state-level estimates. All sample sizes reported are unweighted and all percentages are weighted. Due to the imbalance in opportunity for men and women to be included in the study population (two female cancers, one male cancer, one gender neutral cancer) all analyses were stratified by gender. Within this stratification, analyses were conducted on survivors as a group and by subgroups of specific cancer sites.

We used descriptive statistics and chi-square tests to examine demographics and differences in categorical baseline characteristics. Differences in age were tested with *t*-tests. We assessed for colinearity of characteristics with non-parametric methods.

We determined both unadjusted prevalence and then age adjusted prevalence of each behavioral outcome. Adjusted rates were calculated using the direct method to the year 2000 Census Massachusetts population for each behavioral outcome for cancer survivors overall and site-specific survivors. Age adjusted logistic regression models determined the odds of each outcome for survivors and site-specific survivors compared to controls. We then modeled each behavior adjusting for age, race/ethnicity, education, and physical and mental health status, as these factors have potential to impact the adoption of health behaviors. Missing data were excluded from analysis.

Statistical significance was set at alpha=0.05. All analyses were performed using version 9.2 of SAS software (SAS Institute Inc, Cary, North Carolina). This study was approved by the Institutional Review Boards of the MA Department of Public Health and Boston University Medical Center.

Results

Population characteristics

Cancer survivors

Among the unweighted study sample of 19,867 respondents, there were more women than men (64% vs. 36%). In gender stratified samples, the weighted prevalence of having any cancer history was 4.9% for men and 7.7% for women (Table 1). Compared to same gender controls, survivors of any cancer were older, more likely to be white non-Hispanic, not be currently employed, have health insurance and report more poor physical health days (Table 2). There were no differences in poor mental health days for men or women. Among women, cancer survivors were less likely to have any college education.

Site-specific survivors (data not shown)

Among men, prostate cancer survivors (n=244) and CRC survivors (n=52) were older than controls (mean age 72 vs. 66 vs. 44 years, respectively). They were more likely to be white non-Hispanic, not be currently employed, and report more poor physical health days.

Among women, breast cancer survivors (n=479) and CRC survivors (n=72) were oldest (mean age 65 and 70 years, respectively) compared to gynecologic cancer survivors (n=275) and controls (51 and 46 years, respectively). Gynecologic survivors had the lowest prevalence of any college education. Compared to the breast and CRC survivors, they had the highest prevalence of ≥14 days poor physical health. Although not statistically significant, gynecologic survivors were more likely to have Frequent Mental Distress (14%).

Table 1 Gender stratified Massachusetts cancer survivor distribution, 2006–2008

	Men (n=6,709) n (%±SE)	Women (n=11,488) n (%±SE)
No history of cancer	6,709 (95.1±0.3)	11,488 (92.3±0.3)
Any cancer	516 (4.9±0.3)	1,154 (7.7±0.3)
Specific cancers		
Colorectal	52 (0.5±0.1)	72 (0.5±0.1)
Prostate	244 (2.2±0.2)	–
Breast	–	479 (3.1±0.2)
Gynecologic[a]	–	275 (2.1±0.2)
Single other site	188 (1.9±0.2)	264 (1.8±0.2)
Multiple sites	32 (0.3±0.1)	64 (0.3±0.1)

All percentages are weighted. Totals may not equal 100% due to rounding.

Prevalence of health behaviors

Cancer survivors

There was no difference in the age adjusted prevalence of heavy alcohol use or physical inactivity for male survivors compared to controls, but survivors were more likely to report former smoking (45% vs. 29%) and less likely to report never smoking (31% vs. 53%) (Table 3). Likewise, female cancer survivors were similar to controls in heavy alcohol use and physical inactivity, but they were more likely to report current smoking (24% vs. 16%) or former smoking (39% vs. 25%) and less likely to report never smoking (42% vs. 60%).

Site-specific survivors (data not shown)

Small sample size for site-specific male survivors precluded age adjusting, but in unadjusted analyses, men with a history of prostate cancer or CRC had comparable heavy alcohol use and physical inactivity as controls. In age adusted analyses of women survivors of breast and

gynecologic cancers, there were no differences from controls in heavy alcohol use or physical inactivity. Gynecologic survivors had more current smoking than controls (32% vs. 16%) and breast cancer survivors reported more former smoking than controls (43% vs. 25%).

Adjusted odds of health behaviors

Cancer survivors

In multivariable models, male survivors were no more likely to have heavy alcohol use, current or former tobacco use, or be physically inactive than controls (Table 4). Female survivors had similar alcohol and tobacco use as controls, but had greater odds of being physically inactive [Odds Ratio (OR) 1.5; 95% CI, 1.2–1.8].

Site-specific survivors

Separate multivariable models for male survivors of CRC or prostate cancer found no differences from controls for any unhealthy behavior (Table 4). Models for female CRC survivors also did not detect any statistically significant differences from controls. However, breast cancer survivors continued to have greater physically inactivity (OR 1.5; 95% CI, 1.1–2.0), while gynecologic cancer survivors had higher odds of current smoking (OR 1.8; 95% CI, 1.2–2.8).

Discussion

We illustrate unhealthy behaviors of cancer survivors residing in Massachusetts. Specifically, after adjusting for physical and mental health, female survivors, especially of breast cancer, were more likely to be physically inactive. Gynecologic cancer survivors were more likely to currently smoke, even after controlling for physical and mental health status. Given the known benefits of tobacco cessation and physical activity, these results highlight specific survivor subgroups to target interventions aimed at reducing health risks.

An elevated rate of former smoking among survivors overall is similar to others' findings and may reflect successful secondary prevention [7, 13]. Concurrently, the higher odds of current smoking in gynecologic cancer survivors (which includes cervical cancer) is consistent with previously reported cervical cancer survivors' behavior [6–8] and warrants further attention. We expanded on this association by controlling for mental health since higher rates of depression are seen in cervical cancer survivors [14], and depression is associated with tobacco use [15]. We also adjusted for race to account for the higher proportion of poor health behaviors in minority survivors compared to white survivors [16]. Finally, our findings may be related to the fact that tobacco increases host susceptibility to human papilloma virus [17].

Table 4 Adjusted odds of health behaviors

Abbreviations: *CI* Confidence Interval, *CRC* Colorectal, *Gyn* Gynecologic.

[a] Gynecologic cancer includes cervical, uterine, and ovarian.

In evaluating physical inactivity, we used a relatively low threshold compared to other studies that required minimum exertion or duration. Even still, in adjusted analyses, female survivors were more likely to be physically inactive. When analyzed by cancer site, breast cancer survivors were significantly more inactive than controls. This contrasts to others' findings where after adjustment survivors were no different from controls [7], or even more likely to be active [8].

Different definitions of physical activity may explain these discrepancies or there may be uncontrolled confounding. Both poor physical health and depressive symptoms have been associated with lower physical activity in breast cancer survivors [18]. Grimmett et al. did adjust for the presence of arthritis [13], but other comorbidities have physical limitations. We controlled for self-perceived physical health, which has been associated with physical activity restriction [10].

Limitations

Our findings should be interpreted in the context of the following limitations. The BRFSS interviews non-institutionalized individuals with land telephones and results may not generalize to institutionalized populations or those with only cellular telephones. All cancer history is self-reported and subject to inaccuracy, but previous research has demonstrated high quality of cancer reporting via the BRFSS [19]. Data on cancer stage and treatments are unknown, but it is unclear how each would affect the impact a cancer diagnosis has on behavior change. Given the observational nature of the study we can only assess association, not causation. The small sample sizes for subgroups of specific cancers, especially colorectal and prostate, may have been underpowered to show an association. However, this does not detract from those results which were statistically significant. We are limited by lack of data on temporality, including pre-diagnosis behaviors and time since diagnosis. Behaviors pre-diagnosis can predict post-diagnosis habits [5], and we cannot determine behavioral changes due to a cancer diagnosis. Additionally, behavioral changes may occur proximal to the diagnosis, but not be sustained with time [18]. Finally, the BRFSS options for cancer site combined cervical, uterine, and ovarian cancers into one response choice of gynecologic cancer, precluding further cancer type stratification. The relatively younger age of the gynecologic cancer survivors, along with the presence of a screening test and better survival, may indicate a higher proportion are cervical cancer survivors, but this needs to be addressed in future studies.

Implications for cancer survivors

This study provides guidance to clinicians and public health professionals for targeted interventions to improve

healthy behaviors in cancer survivors. Recognizing patterns on the state level enables the appropriate public health agencies to direct funds and programming resources to those most in need. This is highlighted by the fact that MA has similar, but not identical, findings of cancer incidence and health behaviors as compared to a national sample [20]. Age adjusted invasive cancer incidence and mortality in MA is greater than the national rate. Further, MA state level estimates of heavy drinking for men and women are higher than national prevalence estimates, while smoking rates and physical inactivity are lower. As individual states may have different behavior profiles for survivors, programs can be suitably tailored. Perhaps most striking in our study is the high rate of current tobacco use among gynecologic survivors. Unlike age, genetics, and other immutable factors, smoking is modifiable. Its numerous associations with risk for cancer and other medical conditions make it a prime target of intervention. This subgroup is younger and investments in their health may have more time to show health and economic returns.

Greater physical inactivity in breast cancer survivors also raises concern for subsequent adverse health. Vigorous exercise is associated with lower all-cause mortality in cancer survivors [21]. Engagement in physical activity has been shown to benefit breast cancer survivors, improving health outcomes and health related quality of life [22, 23]. Even with a liberal definition of physical activity, we found that breast cancer survivors had more inactivity. These survivors, who continue to grow in number, may need additional resources targeted to increasing their activity levels.

Welcomed improvements in diagnosis and treatment will also lead to a larger population of cancer survivors, with attendant increased risk for other cancers and medical conditions. Successful secondary and tertiary prevention to promote tobacco cessation and adoption of physical activity may mitigate some of these risks. With accurate assessment of populations who may derive the most benefit from interventions, public health programs can most effectively direct limited resources. Ongoing research is warranted to determine the most effective means to initiate and maintain adoption of healthy lifestyle behaviors.

Patient-Provider Language Concordance and Colorectal Cancer Screening

Amy Linsky, MD, MSc[1], Nathalie McIntosh, MSc[2], Howard Cabral, PhD[3], and Lewis E. Kazis, ScD[4]

[1]General Internal Medicine, Boston Medical Center, Boston, MA, USA; [2]Department of Health Policy and Management, Boston University School of Public Health, Boston, MA, USA; [3]Biostatistics, Boston University, Boston, MA, USA; [4]Center for the Assessment of Pharmaceutical Practices (CAPP)/Department of Health Policy and Management, Boston University School of Public Health, Boston, MA, USA.

BACKGROUND AND OBJECTIVE: Patient-provider language barriers may play a role in health-care disparities, including obtaining colorectal cancer (CRC) screening. Professional interpreters and language-concordant providers may mitigate these disparities.

DESIGN, SUBJECTS, AND MAIN MEASURES: We performed a retrospective cohort study of individuals age 50 years and older who were categorized as English-Concordant (spoke English at home, n=21,594); Other Language-Concordant (did not speak English at home but someone at their provider's office spoke their language, n=1,463); or Other Language-Discordant (did not speak English at home and no one at their provider's spoke their language, n=240). Multivariate logistic regression assessed the association of language concordance with colorectal cancer screening.

KEY RESULTS: Compared to English speakers, non-English speakers had lower use of colorectal cancer screening (30.7% vs 50.8%; OR, 0.63; 95% CI, 0.51–0.76). Compared to the English-Concordant group, the Language-Discordant group had similar screening (adjusted OR, 0.84; 95% CI, 0.58–1.21), while the Language-Concordant group had lower screening (adjusted OR, 0.57; 95% CI, 0.46–0.71).

CONCLUSIONS: Rates of CRC screening are lower in individuals who do not speak English at home compared to those who do. However, the Language-Discordant cohort had similar rates to those with English concordance, while the Language-Concordant cohort had lower rates of CRC screening. This may be due to unmeasured differences among the cohorts in patient, provider, and health care system characteristics. These results suggest that providers should especially promote the importance of CRC screening to non-English speaking patients, but that language barriers do not fully account for CRC screening rate disparities in these populations.

BACKGROUND

The United States has tremendous ethnic and linguistic diversity. According to the 2005–2007 American Community Survey, minorities comprise 26% of the population, and nearly 20% of Americans speak a language other than English at home. By 2050, it is projected that minorities will make up about half of the US population, with a similar increase in individuals speaking a language other than English at home.[1] Compared to white non-Hispanics, minorities use fewer preventive services, including colorectal cancer (CRC) screening.[2] Language plays a role in these health-care disparities.[3, 4] Language barriers may undermine medical communication, lead to inaccurate diagnosis, and contribute to poorer management or treatment adherence.[5]

Of individuals who do not speak English at home, roughly 44% speak English "less than well."[1] Patient-provider communication problems may be common for individuals who have limited English proficiency (LEP).[1,2,6] Compared to those with English proficiency, LEP patients are more likely to have difficulty understanding medical explanations,[7] getting information,[8] and have worse management of care.[9] LEP patients are less likely to have preventive[10] or primary care services,[11] access to care,[12] or be satisfied with provider communication.[13] Access to, and the quality of, care for LEP patients can be improved by using professional interpreters or language-concordant providers.[4]

Colorectal cancer screening is recommended in the routine care of older patients in the US and may be compromised because of language barriers. CRC is the third most prevalent cancer in the US.[2] Although many minorities have lower rates of CRC compared to white non-Hispanics, they tend to be diagnosed at a later stage of disease and have higher mortality rates.[2] The US Preventive Services Task Force recommends colonoscopy every 10 years in adults aged 50–75 years. Other recommendations include flexible sigmoidoscopy every 5 years or home-based fecal occult blood test (FOBT) every year.[14] It is estimated that 60% of CRC deaths could be prevented if all persons age 50 years and older were screened.[15]

Current rates of CRC screening are less than 60%, with lower rates in minorities.[16] Language appears to be a significant factor.[17] Compared to white non-Hispanics, Spanish-speaking Hispanics were 43% less likely to receive CRC screening.[18] Communication problems when discussing cancer screening are also documented with Vietnamese-Americans.[19] Furthermore, there is evidence that fewer

providers discuss CRC screening with non-English speaking patients[20] even when translators are available.[21]

OBJECTIVE

Lack of physician recommendation is often the primary reason patients are not current with guidelines.[19] Discussion of screening for CRC is complicated and time consuming, and may be omitted or abbreviated when there are language barriers.[22] A recent study showed that patients who spoke Spanish at home were less likely to receive CRC screening compared to patients who spoke English at home, even after controlling for English proficiency and patient characteristics.[23] However, that study did not take into account whether someone at the provider's office spoke the patient's preferred language. The purpose of our study is to assess the association of language concordance with CRC screening rates in patients who do not speak English at home compared to rates in those who do.

DESIGN AND SUBJECTS

We analyzed data from the Medical Expenditures Panel Survey (MEPS), a nationally representative survey of non-institutionalized US civilians with 2 years of longitudinal follow-up. We used the Consolidated Household and Medical Conditions files from the Household Component Survey and the Self-Administered Questionnaire. We merged 2002, 2004 and 2006 data, choosing alternate years to ensure distinct respondents, creating a sample of 107,720 subjects. Individuals with a self-reported history of colon or rectal cancer (*International Classification of Disease 9-CM* codes 153, 154) and those less than 50 years were excluded, as were individuals who did not have complete responses for all variables of interest. Individuals greater than 75 years were included given lack of consensus on an upper age limit for screening. Our final study sample was 23,297 subjects, representing 222 million individuals.

MAIN MEASURES

To create cohorts of patient-provider language concordance, we combined responses to the questions "What language is spoken in your home most of the time?" and "Does someone at your provider's speak the language you prefer or provide translator services?" If English was spoken at home, the subject was categorized as *English-Concordant*. If English was not spoken at home and someone at the provider's spoke the respondent's preferred language or offered translation services, the subject was categorized as *Other Language-Concordant*. Subjects who reported not speaking English at home and denied that someone at their provider's spoke their preferred language or offered translation services formed the third cohort, *Other Language-Discordant* (Fig. 1).

We assessed CRC screening using self-reported rates of FOBT and endoscopy. Given that patients may not have FOBT exactly within 12 months, we considered tests performed within 2 years prior to the date of MEPS survey completion to be current with recommendations. In MEPS data, responses for sigmoidoscopy and colonoscopy were combined into a single variable with time frame choices either within or greater than 5 years of the survey date. Therefore, if an individual had FOBT within 2 years or endoscopy within 5 years, they were classified as being current with CRC screening.

Covariates included: self-reported race/ethnicity, age, education, marital status, family income, employment status, time since last check-up, and health insurance status. Race and ethnicity were combined into a variable with five categories: white non-Hispanic, black, Hispanic, Asian, and other. Age had three categories: age 50–<65 years, 65–<75 years, and age 75–85 years (this category may include subjects >85 years as

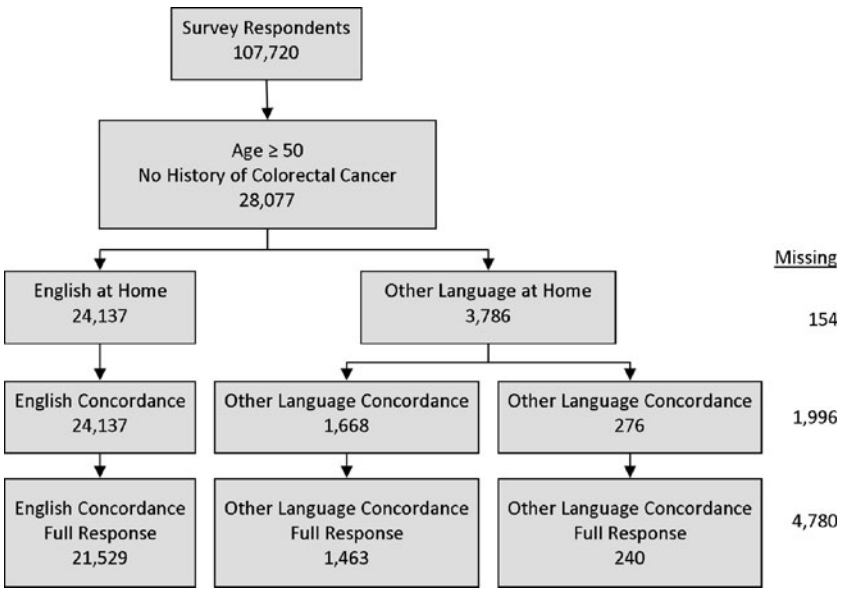

Figure 1. Sample cohorts.

MEPS top coded ages at 85). Education had four categories: no degree, high school or equivalent, some college or greater, or other. Marital status had two categories: married or not married. Total family income had four categories defined by the federal poverty line (FPL): poor/near-poor (<125% FPL), low income (125–<200% FPL), middle income (200–<400% FPL), and high income (≥400% FPL). Employment status had two categories: employed or unemployed. Time since the last checkup had three categories: within 2 years, greater than 2 years, and never. Health insurance status had three categories: any private insurance, public insurance only, and no insurance.

Co-morbidities are often considered when recommending CRC screening; however, these indices are not included in MEPS. As a proxy, the Physical Component Score (PCS) and Mental Component Score (MCS) of the 12 Item Short Form Health Survey (SF-12) were used. These scores have been well validated and are standardized with a mean of 50 for the general population.[24] Scores were converted into two categories: scores less than the sample median ("low" PCS/MCS) and those greater than or equal to the median ("high" PCS/MCS). Sample PCS and MCS medians were 47 and 54, respectively. Of note, Medicare coverage of endoscopy for average-risk adults began in 2001, so year of survey was also included. We included US region to account for regional variations. The following provider-level variables were also included: provider race, ethnicity, and sex; and provider type and specialty.

Analysis

To account for the complex sample design, survey statistical procedures were used. Weighted prevalence and standard error (SE) estimates were calculated for independent variables using MEPS survey weights, and χ^2 tests assessed for differences between cohorts. Variables with proportion of missing responses greater than 65% (provider characteristics) were eliminated. For the remaining variables, individuals with complete data were compared to those with missing data to assess generalizability. All subsequent analyses were done on samples with complete data for all variables retained (n= 23,297).

Bivariate odds ratios (ORs) and 95% confidence intervals (CIs) were used to evaluate the associations between each independent variable and receipt of CRC screening. Variables were independently assessed for confounding or effect modification of language concordance. Those yielding a ≥10% change in the magnitude of effect were considered as potential confounders.

We used multivariate logistic regression to determine the association of language concordance with CRC screening. We included in the model those variables determined *a priori* to be potentially associated with screening (sex, age, time since last checkup, marital status, employment status, year, region), as well as variables found to be confounders (race/ethnicity, education, family income, and health insurance status) or effect modifiers (PCS).

Sensitivity Analyses

We evaluated our definitions of both the primary explanatory variable and outcome variables. Patient language was re-defined by comfort level speaking English using the question "Are you comfortable conversing in English?" Individuals with LEP (those who responded "No") were then grouped by whether someone at their provider's spoke their preferred language or offered translation services. In this way, three cohorts based on English proficiency were created: English-proficient, LEP-Concordant and LEP-Discordant. A simple logistic regression using these re-defined cohorts was compared to that using the original cohorts based on language spoken at home. In addition, receipt of CRC screening was re-defined in several ways. We assessed receipt of FOBT alone, endoscopy alone, endoscopy ever, and any screen ever.

All prevalence, odds ratio, and variance estimates are presented from weighted analyses unless otherwise specified. Statistical significance was set at α=0.05. All analyses were conducted with SAS (version 9.2, SAS Institute Inc., Cary, NC). This study was granted exempt status by the Boston University Institutional Review Board.

KEY RESULTS

The final study sample of 23,297 represents 222 million individuals age 50 years or older with no history of CRC. The vast majority of respondents spoke English at home (96%). Overall, most were white non-Hispanic (81.1%), had at least a high school education (75.5%), were married (61.8%), were aged 50–64 years (57.8%), were female (54.7%), and were employed (51.3%). Few were uninsured (6.1%).

The English-Concordant cohort was predominantly white non-Hispanic (83.7%), more likely to have a high school education, and to have high income and private insurance (Table 1). The Other Language-Concordant cohort had the highest prevalence of Hispanics (60.9%), was the least educated, and most likely to be poor, have public health insurance, and be from the west. The Other Language-Discordant cohort had the highest percentage of Asians (29.4%) and those 75-85 years (29.6%), and was most likely to be unemployed or uninsured. The three cohorts were similar regarding sex, marital status, and time since last checkup. Given the large sample size, the cohorts were statistically different for all covariates except marital status (p=0.13).

The prevalence of CRC screening was greatest in the English-Concordant group, followed by the Other Language-Discordant group, and then the Other Language-Concordant group (50.8% vs 37.9% vs 28.9%, respectively). Compared to the English-Concordant cohort, the unadjusted odds of being current with CRC screening for Other Language-Concordant patients was 0.40 (95% CI, 0.33–0.47) and for Other Language-Discordant patients was 0.59 (95% CI, 0.42–0.84) (Table 2).

After adjusting for confounding, demographic and socioeconomic variables, the odds of being current with CRC screening for those who did not speak English at home was lower compared to those who did (30.7% vs 50.8%, respectively; OR, 0.63; 95% CI, 0.51–0.76).

When looking at patient-provider language concordance determined by language spoken at home and if someone at the provider's spoke the patient's preferred language, the adjusted odds of being current with CRC screening was lower for those in the Other Language-Concordant cohort compared to those in the English-Concordant cohort (OR, 0.57; 95% CI,

0.46–0.71). The Other Language-Discordant cohort did not statistically differ from the English-Concordant cohort (OR, 0.84; 95% CI, 0.58–1.21) (Table 2).

Sensitivity Analyses

Defining language concordance using English proficiency rather than language spoken at home did not change the patterns of association with CRC screening (LEP-Discordant: OR, 0.41; 95% CI, 0.20–0.83; LEP-Concordant: OR, 0.27; 95% CI, 0.19–0.37, referent to English-proficient). Furthermore, using different definitions of CRC screening (e.g., FOBT only, endoscopy only, endoscopy ever, and any screen ever) also yielded similar patterns of association, with lower rates of CRC screening in individuals who did not speak English at home compared to those who did, and higher rates of CRC screening in the Other Language-Discordant cohort compared to the Other Language-Concordant cohort (data not shown).

CONCLUSIONS

We found that individuals who do not speak English at home are less likely to be adherent with CRC screening compared to those who do. This is consistent with other reports.[3,10,23] However, in our adjusted model, we found that the Other Language-Discordant cohort is as likely as the English-Concordant cohort to be adherent to CRC screening guidelines, while the Other Language-Concordant cohort is less likely to be adherent. This was unexpected. We hypothesized that the Other Language-Concordant cohort would experience better

communication with their providers compared to the Other Language-Discordant cohort, thereby leading to higher CRC screening rates.

These findings might be due to differences between the Other Language-Concordant and Other Language-Discordant cohorts. Compared to the Other Language-Concordant group, the Other Language-Discordant respondents were less likely to be Hispanic (42% vs 61%) and more likely to be white non-Hispanic (23% vs 14%). They were also more likely to have attended college (19% vs 12%) and have a high income (27% vs 17%). Income and education are predictors of preventive health-care use;[25] however, these variables were controlled for in our model.

The discrepancy in CRC screening between the Other Language-Concordant and Other Language-Discordant groups may also be related to other unmeasured differences between the two groups. For example, provider cultural competence[7,13,26,27] and better quality of communication between patients and providers[4,22] are associated with higher CRC screening rates. Similarly, rates are higher with greater patient acculturation[28] and health literacy.[9,27,29] While these variables have been shown to be associated with CRC screening rates, we were unable to measure and include them in our study.

There are additional limitations to this study. It is possible that individuals who do not speak English at home speak English well enough to communicate adequately but answered that someone at their provider's office did not speak their language. These individuals would be misclassified as Other Language-Discordant. As a result, our cohorts may not have appropriately captured patient-provider language barriers. Some suggest that LEP is a better measure of language barriers.[4] To address this, alternatively defined cohorts based on comfort speaking English were used. Results in an unadjusted model were similar to those based on language spoken at home. Therefore, regardless of how we defined language concordance, our results suggest that individuals who are 'other language-concordant' with their providers have lower adherence to CRC screening.

In addition, our definition of being adherent to CRC screening guidelines is conservative and may misclassify some as non-adherent. To address this, multivariate models substituting adherence to current CRC guidelines with other CRC screening outcomes were analyzed. Results showed similar findings; individuals in the Other Language-Discordant groups had higher rates for each of the CRC testing outcomes compared to individuals in the Other-Language Concordant group. Furthermore, we could not identify if FOBT or endoscopy was done for diagnostic purposes due to symptoms or in individuals with higher risk, such as those with family history of CRC, which could overestimate CRC screening rates. We did not control for patient co-morbidities, which may influence the appropriateness of screening. As a proxy for co-morbidities, however, we included physical summary health status scores (PCS) in our multivariate model.[30]

Similar to prior studies, our results suggest that speaking a language other than English at home is associated with lower CRC screening. In addition, in our adjusted model we found that individuals who do not speak English at home and do not have anyone at their provider's who speaks their preferred language had CRC screening rates comparable to English speakers, while those who do not speak English at home and

have someone at their provider's who speaks their preferred language, had lower rates. These findings may be related to unmeasured differences between the two cohorts, including patient characteristics, provider cultural competence, patient acculturation, the quality of patient-provider communication, and the level of patient health literacy. Our results suggest that providers should especially promote the importance of CRC screening to non-English speaking patients, but that patient-provider language barriers do not fully account for lower CRC screening in patients who do not speak English at home.

Abstract To discuss and share knowledge around advances in the care of patients with thrombotic disorders, the Third International Symposium of Thrombosis and Anticoagulation was held in São Paulo, Brazil, from October 14–16, 2010. This scientific program was developed by clinicians for clinicians, and was promoted by four major clinical research institutes: the Brazilian Clinical Research Institute, the Duke Clinical Research Institute of the Duke University School of Medicine, the Canadian VIGOUR Centre, and the Uppsala Clinical Research Center. Comprising 3 days of academic presentations and open discussion, the symposium had as its primary goal to educate, motivate, and inspire internists, cardiologists,

The Third International Symposium of Thrombosis and Anticoagulation (ISTA) was sponsored by unrestricted grants from Alexium, AstraZeneca, Boehringer Ingelheim, Bristol-Myers Squibb, CSL Behring, Daiichi Sankyo, Leo Pharma, and Sanofi-aventis. The symposium was organized by Meeting Eventos, and the chairmen of the meeting thank Cecilia Jahnel, Fernanda Prestes, and Daniela Rodrigues for all of their assistance in organizing the event.

Introduction

Importance of thrombosis

Venous and arterial thrombosis remains the most frequent cause of death in western countries. Cardiovascular disease, including heart attack and stroke, accounts for more than 50% of deaths (http://www.cdc.gov/nchs/fastats/deaths.htm). Additionally, the presence of thromboembolism is an adverse prognostic indicator in patients with cancer, which is the second most common cause of death. As a result, there is great interest in the development of novel anticoagulant agents designed to reduce the risk of first or recurrent thrombotic event while minimizing the risk of bleeding. Arterial thrombosis is generally due to platelet activation occurring at sites of vascular injury in high-flow and high-sheer vessels. Generally, antiplatelet agents are preferred for primary or secondary prevention of arterial thrombosis because they inhibit platelet activation induced by platelet binding at sites of vascular injury and mediated by von Willebrand factor. Recent interest has focused on the development of new and more potent antiplatelet agents with special characteristics including rapid on- and off-set of action, shorter half-lives, and more potent inhibition of specific self-surface receptors including the thrombin receptor.

Venous thrombosis is generally thought to be due to activation of soluble coagulation proteins in low-flow areas of the venous system. There are some parallels in the left atrium of patients with atrial fibrillation (AF), suggesting that treatments that are effective for prevention of venous thrombosis will also be effective for prevention of systemic embolization in patients with AF. Traditional agents for prevention and treatment of venous thrombosis include heparins, low-molecular-weight heparins (LMWH), pentasaccharides, and a variety of parenteral anticoagulants used infrequently in specific circumstances such as patients with heparin-induced thrombocytopenia. Long-term therapy has traditionally been provided by warfarin administered to achieve an international normalized ratio (INR) of 2.0–3.0. The limitations of warfarin—including drug and food interactions, variability within and between patients in dosing requirements, a narrow therapeutic window, and the need for frequent INR monitoring—have led to the development of novel agents that lack some or all of these characteristics. Dabigatran and rivaroxaban are two agents that have been approved for several indications. Dabigatran recently was approved in Canada and the United States for prevention of systemic embolization in patients with AF. These agents, if proven safe in phase IV studies, offer significant advantages over warfarin for prevention of systemic embolization. They are also the subject of studies for secondary prevention of venous thrombosis. In this setting, efficacy of both agents is comparable to warfarin.

Intensification of antithrombotic therapy has a cost. There is clear evidence that bleeding rates increase as patients are treated with more aggressive antithrombotic regimens. Thus, when compared with warfarin alone, bleeding risks increase in patients treated with aspirin and warfarin, and further increase in patients treated with so-called "triple therapy." Risks of bleeding will undoubtedly be even higher in patients who are treated with "quadruple therapy," as novel antiplatelet and antithrombotic agents are brought to market.

There is also evidence that a therapeutic effect can be achieved at lower doses of antithrombotic medications than are currently employed for many indications. Thus, prophylactic doses of pentasaccharide are as effective as therapeutic doses of enoxaparin for prevention of thrombotic and other vascular complications in patients with unstable coronary syndromes. At prophylactic doses, fondaparinux produces less bleeding than enoxaparin, suggesting it may be a preferred agent for treatment in this setting. The pentasaccharide study highlights current thoughts suggesting that "de-intensification" should be considered in selected patients because currently available antithrombotics may maintain their "therapeutic effect" at levels that are associated with a lower rate of "toxicity," predominantly bleeding.

In summary, cardiovascular disease remains a leading cause of death. Significant resources have been invested in the design and evaluation of novel antithrombotic agents, which are now being evaluated for prevention of both first and recurrent thrombotic events in high-risk patients. Demonstration that intensification of anticoagulation is associated with enhanced bleeding risk has led to studies that attempt to de-intensify antithrombotic therapy. Novel agents offer the hope of simplicity of treatment with reduced toxicity; however, their safety must be proven in large patient groups.

ISTA

To discuss and share knowledge around advances in the care of patients with thrombotic disorders, the Third International Symposium of Thrombosis and Anticoagulation (ISTA) was held in São Paulo, Brazil, from October

14–16, 2010. This scientific program was developed by clinicians for clinicians, and was promoted by four major clinical research institutes: the Brazilian Clinical Research Institute (BCRI), the Duke Clinical Research Institute (DCRI) of the Duke University School of Medicine, the Canadian VIGOUR Centre (CVC), and the Uppsala Clinical Research Center (UCR). It was also supported by the Brazilian Societies of Internal Medicine, Cardiology, Intervention Cardiology, Heart Failure, Nephrology, Intensive Care Medicine, Hematology, Oncology, and Vascular Surgery, by the Latin American Group of Thrombosis and Hemostasis, and by the Anticoagulation Forum from the United States. The chairmen of the meeting were Dr. Renato D. Lopes and Dr. Richard C. Becker, both from Duke University School of Medicine and the Duke Clinical Research Institute, and Dr. David Garcia from the University of New Mexico.

Comprising 3 days of academic presentations and open discussion, the symposium had as its primary goal to educate, motivate, and inspire internists, cardiologists, hematologists, and health care providers by convening national and international visionaries, thought-leaders, and dedicated clinician-scientists to review the scientific evidence in the area of thrombosis. The following is a summary of the symposium proceedings.

Platelet biology

Platelet biology and an advanced understanding of fundamental concepts governing the behavior of platelets, both in terms of pathologic thrombotic events and the support of normal hemostasis, comprise a vital part of identifying targets for drug development and achieving optimal patient care. There are four constructs or functional themes of importance: platelet aggregation, platelet support of coagulation, platelet support of vascular integrity, and platelet support of vascular repair.

The initiation of coagulation is characterized by the assembly of coagulation proteins on tissue factor-bearing cells. This is followed by thrombin generation and, if of sufficient quantity to cause platelet activation, platelet aggregation, assembly of coagulation proteins, and a "burst" of thrombin generation with subsequent clot propagation.

Platelet activation and aggregation occurring at a site of vessel wall injury is characterized by three distinct populations of platelets. The first population is characterized by expression of ligand receptors, which in turn facilitate platelet aggregation. The second is characterized by the expression of phosphatidylserine with support coagulation protein assembly and thrombin generation. The third consists of a population of platelets with predominantly paracrine effects that are required for the important stage of vessel wall healing. This latter population of platelets has been underappreciated in considering the potential effects of long-term, robust platelet inhibition with pharmacological therapy.

Several recent observations shed new light on the important interface between platelets and coagulation protein activation within the developing thrombus. Specifically, the release of platelet polyphosphates has been shown to activate factors XI and XII, facilitating thrombin generation. More recent information also highlights the role of polyphosphates, factor XI, and factor XII as triggers of thrombosis that are not required for normal hemostasis. These observations will likely prompt increasing interest in new targets with the theoretical potential to uncouple thrombosis and hemostasis.

The importance of platelets in both a reparative capacity and as facilitators of inflammation highlights their pleotropic capabilities. Despite being anuclear cells, megakaryocytes within the bone marrow respond to a variety of signals, potentially being reprogrammed in the presence of specific conditions. In addition, the recognition that activated human platelets splice pre-mRNA into mature transcripts supports a highly dynamic capability. Whether platelet antagonists can influence either programming at the level of the megakaryocyte or peripheral circulation splicing of pre-mRNA will require further investigation. It is becoming increasingly clear that platelets no longer can be viewed as passive bystanders to vascular events and systemic conditions.

Measures of platelet function

For the last several decades, measurement of platelet function has been used primarily for diagnosis of intrinsic deficiencies of platelet hemostatic capacity. However, more recent work has focused on platelet function testing as a pharmacodynamic measure of response to platelet-directed therapy. In the treatment of atherothrombosis, inhibition of platelet activation and aggregation plays a central role in attenuating thrombus formation and propagation. Such antagonism of the atherothrombotic process is vital for secondary prevention in patients with acute coronary syndromes (ACS) and after percutaneous coronary intervention (PCI).

Two antiplatelet medications used commonly in these populations are aspirin and clopidogrel. Platelet function testing has documented substantial variability in the pharmacodynamic response to both medications; however, the prevalence and clinical impact of this variability remain largely unknown.

Several methods for assessing platelet responsiveness to clopidogrel or aspirin are available. Light-transmission aggregometry (LTA) is the historical "gold standard" for evaluation of the pharmacodynamic response to platelet-directed medications. The major disadvantages are: (1) increased processing time per sample because of the need to generate platelet rich plasma, and (2) increased inter-operator variability. The vasodilator-activated phosphoprotein (VASP) test measures the intracellular platelet response to medications inhibiting the platelet $P2Y_{12}$ receptor. Like LTA, it is a time-consuming, laboratory-based test that is technically demanding.

Newer point-of-care whole blood aggregation tests are now available. Of these, the VerifyNow® (Accumetric, Inc., San, Diego, CA) and Multiplate® (Verum Diagnostica, Munich, Germany) tests have undergone extensive clinical validation. In the Do Platelet Function Assays Predict Clinical Outcomes in Clopidogrel Pretreated Patients Undergoing Elective PCI (POPULAR) study comparing the predictive value of different platelet function tests for thrombotic and bleeding outcomes following elective PCI, the VerifyNow test demonstrated a c-statistic comparable to LTA in its ability to discriminate future thrombotic outcomes. Similarly, the Multiplate test performed well in a large German multicenter study investigating the relationship between its adenosine diphosphate (ADP) test and thrombotic outcomes after PCI.

However, the ability of existing platelet function tests to predict bleeding outcomes is more limited. To date, the association between platelet function measurements and future bleeding outcomes has been equivocal—this remains a key limitation of platelet function testing. Another key limitation of currently available platelet function tests is their inability to reliably report on the composite effect of multiple antiplatelet agents acting via different pathways. A further unresolved question is the ability of a platelet function testing-guided strategy to improve clinical outcomes. Although the recently completed Gauging Responsiveness with a VerifyNow Assay—Impact on Thrombosis and Safety (GRAVITAS) trial did not demonstrate an improvement in clinical outcomes with double-dose clopidogrel in patients with clopidogrel hypo-responsiveness identified using the VerifyNow system, other ongoing trials employing more potent $P2Y_{12}$ inhibitors will provide greater clarity on the clinical utility of platelet function testing.

Proton-pump inhibitor (PPI)–clopidogrel interactions: reality or myth?

In patients with ACS, current clinical practice guidelines recommend the use of dual antiplatelet therapy with aspirin and $P2Y_{12}$ inhibition. Aspirin, particularly at higher doses, leads not only to platelet inhibition by the effect on thromboxane A2 but also to effects on the gastric mucosa through the inhibition of prostacyclin. This results in an increased risk of peptic ulcer and gastric bleeding. Addition of clopidogrel to aspirin further increases the risk of adverse gastric bleeding events. To reduce this risk, treatment with proton-pump inhibitors (PPI) is routinely used in patients with previous peptic ulcer and often in patients with risk factors for gastric bleeding such as acute care. In fact, both clopidogrel and PPIs are among the most frequently prescribed pharmacological agents worldwide.

The most important mechanism for a poor response to clopidogrel is variable generation of the active metabolite. Approximately 85% of a clopidogrel dose is hydrolysed by esterases to an inactive metabolite. The remaining clopidogrel is available to be converted to the active metabolite in a process requiring two sequential cytochrome P450 (CYP)-dependent steps with CYP2C19 in both steps. A genetically determined reduced function allele of CYP2C19 slows clopidogrel metabolism, which leads to lower levels of the clopidogrel active metabolite and a lower pharmacodynamic platelet inhibitory effect.

Because some PPIs are known to be strong inhibitors of CYP2C19 activity, it is reasonable to believe that PPI may reduce the clinical response to clopidogrel. Controversy remains over whether this treatment interaction is clinically meaningful.

In November 2009, the U.S. Food and Drug Administration (FDA) issued a warning that concomitant use of omeprazole and clopidogrel should be avoided and that other drugs that reduce stomach acid do not interfere with the anti-clotting activity of clopidogrel. The European Medicines Agency (EMEA) extended the warning to discourage concomitant use of all PPIs unless absolutely necessary. These recommendations were based on pharmacokinetic/pharmacodynamic and observational studies. Well-performed studies have shown that the mean plasma concentration of the clopidogrel active metabolite is lower in patients treated with omeprazole in combination with clopidogrel than in patients treated with clopidogrel alone, also with a 600-mg loading and 150-mg maintenance dose. Pharmacodynamic studies have confirmed the reduction of platelet reactivity.

Whether treatment with PPIs affects cardiovascular outcome in patients receiving clopidogrel has been unclear. Several small observational studies showed a significant association between PPI use and cardiovascular risk, whereas propensity-matched studies and substudies of large randomized trials such as the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction (TRITON-TIMI) 38 and the Platelet

Inhibition and Patient Outcomes (PLATO) study revealed no association. A recently performed meta-analysis including 159,138 patients from 25 studies found an association of PPIs with reduction in gastric bleeding events and a higher risk of stent thrombosis but no association with the risk of death. One randomized trial, the Clopidogrel and the Optimization of Gastrointestinal Events Trial (COGENT), studied the effect of omeprazole versus placebo in patients treated with dual antiplatelet therapy. Although the trial was stopped prematurely for financial reasons, 3,637 patients were enrolled. The trial showed a 66% relative reduction in gastrointestinal events but no effect of omeprazole on cardiovascular events.

In summary, the totality of data suggests that a pharmacokinetic and pharmacogenetic clopidogrel–PPI interaction via CYP2C19 is real but that concomitant use of PPIs has minimal or no clinical consequence in low–medium-risk patients on long-term treatment. A small but clinically meaningful interaction with PPI in ACS patients at high ischemic risk in the acute settings cannot be excluded. Treatment with other potent $P2Y_{12}$ receptor inhibitors, such as prasugrel and ticagrelor, is not associated with an interaction with PPIs and could be considered in patients at high risk for ischemic events. In patients at risk for peptic ulcer, treatment with effective gastric protection, including PPIs, should not be withheld.

New antiplatelet agents under development

Current management of ACS includes risk stratification by clinical findings and the use of electrocardiographic and biochemical markers. It is recommended that all patients with an established diagnosis of ACS receive immediate antithrombotic treatment with dual platelet inhibition (aspirin and a $P2Y_{12}$ inhibitor) plus intravenous or subcutaneous anticoagulation. In addition, patients should also receive beta-blockers, statins, and, frequently, angiotensin-converting enzyme (ACE) inhibitors. The majority of patients hospitalized for ACS are rapidly admitted to a catheterization laboratory for identification of the culprit lesion, followed by balloon dilatation and stenting if feasible. At discharge, it is generally recommended that patients receive long-term secondary prevention with a combination of aspirin, beta-blockers, statins, ACE inhibitors, and $P2Y_{12}$ inhibitors for at least 1 year. However, despite these measures, there is still a 10% risk of death, reinfarction, or stroke during the year following discharge. The magnitude of this risk varies among patient populations, with the highest risk in older patients and those with diabetes mellitus, previous myocardial infarction (MI), cardiac or renal dysfunction, manifestations of atherosclerotic disease, or multi-vessel coronary artery disease (CAD). If current therapeutic approaches for ACS are to be improved, greater focus will be needed on these high-risk groups.

New therapies currently under development aim to prevent further progression of thrombosis and atherosclerosis and to correct underlying metabolic disturbances (e.g., diabetes and dyslipidemia). The primary challenge in preventing and managing ACS, both now and in the future, will be to tailor treatments for each patient, taking into consideration patient characteristics, comorbidities, underlying short- and long-term risk factors, and expected individual responses to different medications. These ambitions will likely place a substantial burden on global health care resources and may ultimately require prioritization among several treatment alternatives.

Platelet inhibition has been a mainstay in the prevention of MI and death in patients with ACS for approximately 20 years. Aspirin therapy yields consistent inhibition of platelet thromboxane A_2 release. However, inhibiting this pathway only modestly attenuates platelet activation without any influence on ADP-induced platelet activation. Aspirin treatment reduces the relative risk of MI and death by 30–50% compared with placebo in patients with ACS. However, aspirin alone has no convincing effect on prevention of stent thrombosis. Therefore, other pathways need to be inhibited in the highly prothrombotic environment of ACS. The $P2Y_{12}$ receptor plays a major role in the ADP-mediated amplification of platelet response regardless of the stimulus. Clopidogrel and prasugrel are thienopyridine pro-drugs acting on this receptor by almost identical active metabolites that irreversibly bind to the receptor. Slow and variable active metabolite generation leads to clopidogrel having a slow onset of action and wide inter-individual variability in pharmacodynamic response. However, as shown in the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial, compared with aspirin alone, clopidogrel provided a relative 20% reduction in death, MI, or stroke at a median of 9 months of treatment. Despite variability in platelet responsiveness, the Clopidogrel Optimal Loading Dose Usage to Reduce Recurrent Events/Optimal Antiplatelet Strategy for Interventions (CURRENT/OASIS) 7 trial—a 2×2 factorial randomized comparison of standard-dose (300 mg load/75 mg daily) versus higher-dose (600 mg load/150 mg daily for 6 days, then 75 mg daily) clopidogrel and lower-dose (75–81 mg) versus higher-dose (325 mg) aspirin treatment—failed to show superiority for the higher-dose clopidogrel regimen. However, in a subgroup analysis of PCI-treated patients, there was a substantial reduction in stent thrombosis in patients treated with the higher-dose clopidogrel regimen.

Generation of the active metabolite of prasugrel is more efficient than for clopidogrel, resulting in more rapid onset

of action, more pronounced platelet inhibition, and no clinically important variability in response. In the setting of these pharmacokinetic and pharmacodynamic features, prasugrel treatment resulted in a 20% reduction in death, MI, or stroke and a halving of the risk of stent thrombosis compared with clopidogrel in the TRITON-TIMI 38 trial of patients undergoing a planned PCI procedure. However, both the addition of clopidogrel to aspirin and the use of prasugrel instead of clopidogrel were associated with significant increases in major bleeding in CURE and TRITON-TIMI 38, respectively.

Ticagrelor, the first reversibly binding oral $P2Y_{12}$ receptor antagonist, does not require metabolic activation, has a rapid onset of action, and can disassociate from the receptor, permitting restoration of platelet function without the need for production of new platelets. In pharmacodynamic studies, ticagrelor demonstrated greater, more rapid, and more consistent ADP-induced platelet inhibition compared with clopidogrel and more rapid offset of action following cessation of therapy. In the PLATO study, 18,624 patients with ACS were randomized within 24 h after symptom onset to ticagrelor versus clopidogrel. The results showed a 16% relative reduction of the composite of cardiovascular death, MI, or stroke, a 22% reduction in total mortality, and a 33% reduction in definite stent thrombosis. Ticagrelor was not associated with an increase in overall bleeding, but, during long-term treatment, there was more non-procedural bleeding with ticagrelor.

Currently, elinogrel, a reversibly binding competitive $P2Y_{12}$ receptor antagonist for both intravenous and oral administration, is under evaluation. In a recently presented phase II trial (Novel Intravenous and Oral P2Y12 Inhibitor in Non-Urgent PCI [INNOVATE-PCI]), elinogrel was associated with a slight dose-related increase in total bleeding without a clear signal for reduction in ischemic events compared with clopidogrel.

Other targets for platelet inhibition are also under investigation (e.g., the protease-activated receptor 1 [PAR-1]). Preclinical and phase II studies suggest that consistent and high levels of PAR-1 inhibition may have a beneficial antithrombotic effect with minimal increase in bleeding. Phase III studies of the selective PAR-1 inhibitor, vorapaxar, are currently underway, both in ACS and chronic CAD.

In conclusion, several new alternatives providing more rapid and consistent platelet inhibition than clopidogrel are currently being explored for routine treatment of patients with ACS. These new treatments seem to provide additional benefits to the patients without unacceptable increases in the risk of bleeding if used appropriately. Within the next few years, even more treatment alternatives might be available to further improve outcomes of the large patient population with ACS.

Novel parenteral anticoagulants

Despite its limitations, unfractionated heparin (UFH) remains a commonly used parenteral anticoagulant in clinical practice. The major limitations of UFH include an unpredictable pharmacodynamic response, associated off-target effects, and the need for pharmacodynamic monitoring. Lack of pharmacologic specificity is another limitation. As such, the scientific community has moved toward using novel anticoagulants that target singular proteases within the coagulation system.

Bivalirudin, a direct thrombin inhibitor with a short circulating half-life, has recently shown good clinical efficacy with less bleeding compared with either UFH or LMWH. The synthetic pentasaccharide, fondaparinux, is a specific, indirect inhibitor of factor Xa. Despite, the convenience of a once-a-day subcutaneous injection for the management of patients with ACS, the need for supplemental UFH during transition to the catheterization laboratory limits its wider adoption in clinical practice. Concerns also remain over the propensity for equipment-associated thrombosis, as well as the absence of a reliable antidote to reverse its anticoagulant effect. Another factor Xa inhibitor, otamixaban, has demonstrated early safety as a parenteral anticoagulant in the catheterization laboratory; in the phase II Otamixaban in Comparison to Heparin in Subjects Undergoing Non-Urgent Percutaneous Coronary Intervention (SEPIA-PCI) trial, equipment-associated thrombosis occurred at a similar rate in both otamixaban and UFH-treated patients.

In response to existing limitations of approved parenteral anticoagulants, REG1 was designed to achieve rapid inhibition of factor IXa with active, antidote-mediated reversibility. This drug-antidote construct is now undergoing late phase II testing in patients with ACS.

Vitamin K antagonists

The vitamin K antagonists (VKAs) have been the only anticoagulants available for oral use since their first administration to a patient more than 50 years ago. The mechanism of action of this drug class is complex; they achieve their anticoagulant effect by inducing the synthesis of dysfunctional forms of factors II, VII, IX, and X. The target of VKAs is the enzyme vitamin K epoxide reductase (VKOR). Single nucleotide polymorphisms in the gene that codes for this enzyme (as well as single-nucleotide polymorphisms [SNPs] in the genes that encode CYP2C9) can render the patient more (or, in some cases, less) sensitive to warfarin; thus, common genetic variations, along with factors such as sex, age, and weight, lead to significant (and sometimes unpredictable) inter-individual variability in the

dose required to achieve the targeted anticoagulant effect. Even patients whose dose has been determined through titration and adjustment can experience clinically relevant sudden changes in their anticoagulant effect because of interactions with diet (mostly due to variation in vitamin K intake) or other medications (especially drugs that interact with the cytochrome P450 system). These features, along with the narrow therapeutic index, slow onset, and long pharmacodynamic half-life characteristic of VKAs, have created challenges for clinicians and patients alike.

Despite the undesirable attributes of VKAs, they have proven to be extremely effective in the prevention of AF-related stroke, recurrent venous thromboembolism (VTE), and other unwanted clinical events. Recently, the inconvenience of VKAs has been reduced by the opportunity for patient self-testing, but self-testing does not necessarily make VKAs safer or more effective than they are in the context of a dedicated system of anticoagulation management. Indeed, the safety of VKAs has improved with the advent of dedicated anticoagulation management services and the application of evidence-based strategies to reverse the VKA anticoagulant effect in bleeding patients. Going forward, it is likely that VKA use will decrease, but not disappear, once new oral anticoagulant agents become available.

ACS with ST-segment elevation: guidelines perspective on antithrombotic therapy

Many anticoagulants and antiplatelet agents are now available for the treatment of ACS patients. In patients with ST-segment elevation MI (STEMI) undergoing primary PCI, clopidogrel and UFH or bivalirudin (a direct antithrombin agent) are the most frequently used agents. For patients treated with lytic therapy, UFH, enoxaparin, and fondaparinux (with streptokinase only) are used as anticoagulant co-therapy. Clopidogrel is also given routinely with lytic agents to patients under age 75 years. No reliable data are available in patients aged >75 years.

Clopidogrel is widely used as an adjunctive therapy for primary PCI and has also been shown to be beneficial in patients treated with fibrinolytic therapy (Clopidogrel as Adjunctive Reperfusion Therapy [CLARITY] study; Clopidogrel and Metoprolol in Myocardial Infarction Trial [COMMIT/CCS-2]). However, its limitations—particularly slow onset of action, variability in response, and irreversible binding to the P2Y12 receptor—create challenges for STEMI care. Prasugrel, approved for use in Europe in 2009 and in the U.S. in 2009, is a third-generation thienopyridine and has a similar mechanism of action to clopidogrel but superior pharmacokinetic characteristics. The greater efficacy of prasugrel over clopidogrel in the TRITON-TIMI 38 trial was particularly evident in patients with STEMI, all of whom underwent primary PCI. However, prasugrel was associated with an increased risk of major bleeding, although in the STEMI population, there was no increase in life-threatening bleeding compared with clopidogrel.

Several novel antiplatelet therapies are currently in clinical development or have only recently been approved. The PLATO study demonstrated that ticagrelor reduced the incidence of death, MI, or stroke by 16% and of cardiovascular death by 22% compared with clopidogrel in STEMI patients. With ticagrelor, there was an increased risk of non-coronary artery bypass graft (CABG) bleeding complications. Also, cangrelor is an intravenous, fast, direct-acting, and reversible $P2Y_{12}$ inhibitor. No significant differences with clopidogrel could be demonstrated in ACS patients in the Cangrelor versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition (CHAMPION) PCI trial.

It is likely that prasugrel and ticagrelor will be recommended in the guidelines for STEMI patients undergoing primary PCI. Because these agents have not been tested prospectively with lytic agents, clopidogrel will remain the recommended ADP antagonist with lytic therapy.

Obviously, there is no role for new oral anticoagulants such as rivaroxaban and apixaban in the acute reperfusion phase of STEMI. Whether these agents may prevent recurrent ischemic events afterwards is unknown.

Antithrombotic therapy in ACS with non-ST-segment elevation

There are three antithrombotic agents to choose from: enoxaparin, fondaparinux, and bivalirudin. All have been shown to be superior to UFH. However, there are a number of considerations in choosing an antithrombotic agent for non-ST-segment elevation ACS. These include ischemic risk, bleeding risk, whether an invasive or conservative strategy will be employed, time to catheterization (<12 h vs. >12 h), whether drugs will be switched, whether the patient is aged <75 or ≥75 years, and the patient's renal function.

Major bleeding is strongly associated with subsequent mortality and ischemic events and, many believe, is at least as important as reinfarction. Most bleeding complications are iatrogenic, attributable to femoral artery access for PCI, and related to the use of potent antiplatelet and antithrombin medications. The incidence of bleeding is affected by the choice of anticoagulant and overdosing.

Enoxaparin has been shown in trials of over 22,000 patients to reduce death and MI by 20% and to have similar outcomes as compared with UFH when a conservative strategy is employed, but its use is associated with a modest increase in bleeding when an invasive strategy is employed.

There is also a large clinical experience for bivalirudin in non-ST-segment elevation ACS. Over 20,000 patients have been randomized in trials showing that major bleeding is reduced by about 50% with no increase in ischemia compared with UFH.

Crossover of antithrombotics

The patients in the Superior Yield of the New Strategy of Enoxaparin, Revascularization, and Glycoprotein IIb/IIIa Inhibitors (SYNERGY) trial who crossed over between UFH and enoxaparin had an increase in bleeding complications. Crossover occurred at various times through the study period, at times in response to clinical or clinician perception. In a secondary analysis from this study, results indicated a significant association between crossover from enoxaparin to UFH and TIMI bleeding but not in the other direction, and no crossover association was found in death or MI.

Switching from UFH or enoxaparin to bivalirudin in the Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial was not associated with an increased risk for ischemic events. Furthermore, switching to bivalirudin provided patients with a 50% reduction in bleeding.

Fondaparinux is an indirect factor Xa inhibitor tested against enoxaparin in the Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS)-5 trial. The ischemia rate was similar to UFH, but severe bleeding complications were significantly reduced with fondaparinux, and long-term mortality and stroke rates were also reduced. Because of a higher rate of catheter thrombosis when fondaparinux alone is used, UFH (85 μ/kg) should be added for patients undergoing PCI.

If there is a very high risk of ischemia, bivalirudin is recommended, or UFH with a IIb/IIIa antagonist added if there is angiographic thrombosis or poor TIMI flow. If there is a low-to-high risk of ischemia, all four agents (fondaparinux, LMWH, UFH, and bivalirudin) are good choices. Bivalirudin is an attractive option if there is an increased risk of bleeding and an early invasive strategy is planned. Fondaparinux is a good option if a conservative strategy is planned.

A number of different anticoagulant strategies can be appropriately selected based on individual risk stratification for ischemia and bleeding.

Biomarkers of thrombosis: where do we stand in 2010?

From a clinical perspective, biomarkers serve three main purposes: to diagnose or exclude a disease diagnosis; to provide information about prognosis or to risk stratify; and, most elusively, to guide treatment decisions. Pulmonary embolism (PE) and acute MI are two acute thrombotic disease entities, often presenting with similar symptoms, for which clinically useful biomarkers of thrombosis have evolved across each of these three domains.

Pulmonary embolism is first classified as high or intermediate/low risk based on hemodynamic and respiratory status. For those who are stable (i.e., intermediate/low risk), the biomarker, D-dimer, is used to exclude the diagnosis of PE and to guide further imaging and/or treatment. Given its exquisite sensitivity, despite low specificity, its negative predictive value is very high, such that further work-up with imaging or treatment is not necessary if the D-dimer concentration is low.

Troponin remains the gold standard for establishing a diagnosis of MI in the setting of clinical symptoms of ischemia. Troponin assays are more sensitive and more specific for myocardial injury than creatine kinase (CK)-MB. However, the increasing clinical availability of high-sensitivity troponin assays that can detect circulating troponin at levels well below the 99th percentile of a normal reference population and can also achieve 10% coefficient of variation (CV) at the 99th percentile is challenging the diagnostic utility of troponin testing for diagnosis of MI. However, the increased sensitivity of these assays is offset by reduced clinical specificity, resulting in low positive predictive value. For example, up to 70% of patients with heart failure, which often co-exists with coronary disease, may present with elevated troponin by high-sensitivity assays. The parameters for diagnostic use of these assays are still being discussed. However, these assays may be particularly useful in early diagnosis/triage in the emergency room, where elevations above the 99th percentile in MI patients are detectable much earlier than with standard assays. Given these challenges, heightened awareness of the relationship of pre-test probability with the occurrence of false-positive (and false-negative) diagnoses will be needed.

In the meantime, systematic efforts to increase the accuracy of physicians' clinical assessments of risk in patients with suspected ACS must be undertaken. In a study from the Canadian ACS 2 Registry, despite the availability of the 12-lead electrocardiogram (ECG) and results of assays for markers of myocardial necrosis, there was little relationship between physician-estimated risk category and that determined from available risk scores, with wide variability in these risk scores within the physician-estimated category. A better alignment between physician-estimated risk and systematically determined risk is critical as this study also showed that physicians, overall, treat patients whom they judge as being at higher risk more aggressively with both coronary procedures and medications.

Even with a systematic approach to risk stratification, novel or existing biomarkers may be useful in refining prognosis or guiding treatment selection. Many biomarkers of thrombosis and inflammation have been identified, but rarely have studies considered more than a few biomarkers simultaneously, and few have made the translation from biomarker of risk to biomarker for stratified application of treatments. Troponin testing is the cardiovascular biomarker that best exemplifies this feature. In studies mostly done with older assays, troponin identified high-risk populations that were most likely to benefit from glycoprotein (GP) IIb/IIIa inhibitors, LMWH, and a strategy of early angiography in patients presenting with non-ST-segment elevation ACS. Whether this will be true as high-sensitivity troponin assays become available, particularly for levels below the 99th percentile of current assays, remains to be seen.

The role of high-sensitivity C-reactive protein (hsCRP) in guiding therapy with statins recently has come under scrutiny. Although the Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) showed that patients with normal low-density lipoprotein cholesterol (LDL-C) who had an hsCRP level > 2 mg/dl benefitted from treatment with rosuvastatin, there was no arm with similar LDL-C levels but hsCRP < 2 mg/dl. Thus, this trial cannot be used to argue that hsCRP should be used to guide statin treatment in primary prevention patients. Additionally, a recent cost-effectiveness analysis suggested that, assuming long-term safety of statins, availability of low-cost generic agents, and similar efficacy of statins in low-to-intermediate risk patients, treating men with statins without screening hsCRP would be cost-effective down to 50 years. At 70 years, using hsCRP to guide therapy would be cost-effective in both men and women; in both men and women, the lower bounds of age for primary prevention without hsCRP guidance rose with increasing numbers of cardiovascular risk factors.

As an example of the increasing interface of genetics with clinical care, there has been much interest in the use of genetic testing for the CYP2C19 mutation to guide clopidogrel therapy. However, despite associations of the mutation with outcome and demonstrated pharmacodynamic and pharmacokinetic variability with clopidogrel treatment according to carrier status, studies to date have not demonstrated that testing for this genetic mutation is useful in guiding treatment. A large randomized clinical trial, GRAVITAS, evaluated whether tailored clopidogrel dosing according to phenotypic platelet responsiveness measured prior to discharge after drug-eluting stent implantation would reduce thrombotic complications of stent implantation. Its results were presented at the 2010 Scientific Sessions of the American Heart Association (AHA) in Chicago and showed no benefit on cardiovascular outcomes or stent thrombosis with a double dose of clopidogrel in patients receiving drug-eluting stents with high residual platelet activity on the regular clopidogrel dose. These results are not yet published.

Thus, in 2010, it is increasingly evident that global risk assessment is needed to help clinicians align treatment with diagnosis and risk. Biomarkers play an important role in this process. However, rapid advances in assay technology and the increasing availability of new biomarkers generated from genomic discovery and applications of genetic testing create challenges that must be considered. Novel biomarkers must be systematic and rigorously evaluated, and their practical clinical utility must be demonstrated before they become part of a routine risk assessment strategy.

Measuring quality in ACS: where does antithrombotic therapy fit?

Quality of care has been defined as the "degree to which health care services increase the likelihood of desired health outcomes and are consistent with current professional knowledge." Simply put, this asks: Are we doing the right things (practicing evidence-based care); are we doing the right things right (delivering this care in a safe, skilled manner); and are our patients better off for it (are their outcomes improved)? When viewed in this manner, contemporary treatment of patients with ACS is challenged. Studies have consistently demonstrated an under-utilization of evidence-based therapies, as well as failure to provide such care in a safe and timely fashion. And while care is improving over time, consistent gaps remain. For example, 2010 data from the ACTION Registry®-Get With the Guidelines (GWTG)™ found that between 15 and 20% of eligible ACS patients fail to receive dual antiplatelet therapy acutely and at hospital discharge.

The standard application of evidence-based therapies, however, neglects to consider that these treatments ideally should be "personalized" for the individual patient. Antithrombotic therapies in ACS care effectively prevent recurrent ischemic events or, alternatively, cause iatrogenic bleeding. The balance between the benefits and risks is influenced by three domains. The first domain relates to features of the drug itself, including drug absorption, activation, potency, clearance, and interaction with other drugs. Patient factors represent a second domain influencing safety and efficacy of antithrombotic therapies in ACS, including such factors as patient age, sex, renal function, and presence of diabetes. These clinical features influence the baseline odds for recurrent ischemic events but also can affect the safety of antithrombotic therapy, either through

changing the drug's pharmacokinetic and dynamic properties or increasing the patient's underlying disposition to bleed (i.e., peptic ulcer disease).

Provider and system factors also influence the quality of care and subsequent outcomes in ACS. Studies have found that a number of patients in the United States receive the wrong dose of antithrombotic therapies. Combined, up to 20% of all bleeds in the United States are estimated to be caused by excessive antithrombotic therapies. The reasons for excessive drug dosing often relate to a failure to individualize dose based on body weight, age, or renal function.

While there are challenges to the effective and safe use of antithrombotic therapies in ACS, the world is changing, and efforts to improve the quality of ACS care delivered around the world abound. In particular, giving clinicians feedback on their care practices relative to those of their peers has been shown consistently to improve ACS quality of care. Moving forward, this follow-up and feedback regarding ACS practices must extend to consider longitudinal care and outcomes. For example, studies have consistently demonstrated that patients who discontinue dual antiplatelet therapy early after receiving a stent are at high risk for subsequent cardiac events. Importantly, patient compliance appears modifiable via patient education. Those who understand the reasons for their medications and the need for continued use have higher rates of compliance.

In the future, both providers and patients will have increasing access to electronic tools to facilitate better ACS care. These include electronic order entry systems that will support wiser drug choices and prevent medical errors related to drug dosing. We will also see the evolution of community systems of care that will encourage appropriate triage of ACS patients to support more timely ACS care. Finally, we will see the evolution of patient health records that will support a new collaborative model of care between patients and their caregivers.

Antiphospholipid syndrome

Antiphospholipid syndrome is widely recognized but incompletely understood. There are five areas worthy of consideration: pathophysiology, epidemiology, clinical manifestations, diagnosis, and management. The pathophysiology of antiphospholipid syndrome involves production of IgG antibodies against beta 2-glycoprotein I on the surface of vascular endothelial cells. The antibodies cause expression of adhesion molecules and up-regulation of tissue factor production. In addition, they produce up-regulation of tissue factor within monocytes, expression of GP IIb/IIIa receptors on platelets, and increased thromboxane A2 synthesis. The interaction of antibodies with coagulation regulatory proteins such as activated protein C in combination with complement activation and inflammation establishes a highly prothrombotic state. The available evidence suggests that an existing thrombophilia in antiphospholipid syndrome can be exaggerated acutely as part of a putative "second hit" phenomenon following trauma, infection, and other conditions in which a prothrombotic environment rapidly develops.

Antiphospholipid antibodies are detected in 20% of patients with an ischemic stroke before age 50 years, 20% of patients with VTE, 10–15% of women with recurring miscarriages, and 20% of women with a diagnosis of preeclampsia. The most common clinical manifestations of antiphospholipid syndrome, occurring in >20% of individuals, include VTE, thrombocytopenia, miscarriage or fetal loss, ischemic stroke or transient ischemic attack, migraine headache, and livedo reticularis. Less common clinical manifestations, occurring in 10–20% of individuals, include heart valve abnormalities, hemolytic anemia, and accelerated CAD. Unusual clinical manifestations, occurring in <10% of individuals, include seizures, vascular dementia, retinal artery or vein thrombosis, pulmonary hypertension, skin ulcers with digital gangrene, osteonecrosis, renal insufficiency, and mesenteric ischemia.

The diagnosis of antiphospholipid syndrome is supported by clinical criteria, including vascular thrombosis involving one or more episodes of arterial, venous, or small-vessel thrombosis in any tissue or organ. Thrombosis should be present without substantial evidence of inflammation within the vessel wall. A diagnosis of antiphospholipid syndrome in the context of pregnancy is supported by at least one of the following criteria: one or more unexplained deaths of a morphologically healthy fetus at or beyond the 10th week of gestation; one or more premature births of a morphologically healthy new born before the 34th week of gestation either because of eclampsia or severe preeclampsia; or at least three unexplained consecutive spontaneous abortions before the 10th week of gestation, with anatomical or chromosomal abnormalities having been excluded.

The laboratory diagnosis of antiphospholipid syndrome includes the following: detection of a lupus anticoagulant on two or more occasions at least 12 weeks apart; anticardiolipin antibody of IgG or IgM subtype, or both in serum or plasma, present in medium or high titers on at least two or more occasions at least 12 weeks apart measured with a standardized ELISA; or anti-beta 2 GP1 antibody of IgG or IgM subtype, or both in serum or plasma, at medium or high titers on at least two or more occasions at least 12 weeks apart.

The management of patients with antiphospholipid syndrome includes a strategy of primary prophylaxis,

where patients with systemic lupus erythematosus and a circulating lupus anticoagulant or persistently positive anticardiolipin antibody titer would receive hydroxychloroquine either alone or in combination with low-dose aspirin. Patients with obstetric antiphospholipid syndrome are traditionally treated with low-dose aspirin, while asymptomatic carriers of antiphospholipid antibodies do not typically require therapy. However, it is important to emphasize that all patients with antiphospholipid antibodies likely benefit from strict control of vascular risk factors and should receive adequate thromboprophylaxis in high-risk situations such as surgery, the post-partum period, and during prolonged periods of immobilization. Management of patients with antiphospholipid syndrome without previous thrombosis but recurring early (pre-embryonic or embryonic) miscarriages should include either low-dose aspirin alone or in combination with either UFH or LMWH. Patients with antiphospholipid syndrome without previous thrombosis but with prior fetal death at more than 10 weeks gestation or early delivery (<34 weeks gestation) due to severe preeclampsia or placental insufficiency should be treated with UFH or LMWH throughout pregnancy.

Secondary prophylaxis of patients with antiphospholipid syndrome and prior thrombosis typically includes indefinite anticoagulation with warfarin, titrated to a target INR of 2.5 (range 2.0–3.0). There is a suggestion that patients with a prior arterial thrombotic event should be targeted to a higher INR (3.5; range 3.0–4.0) or warfarin titrated to a target INR of 2.5 plus low-dose aspirin. The latter two strategies have also been used for patients with recurring events despite warfarin anticoagulation.

The potential use of newer-generation anticoagulants, such as oral direct factor Xa or direct thrombin inhibitors, will require further evaluation.

Venous thromboembolism prophylaxis in surgical patients

Venous thromboembolism is the most preventable cause of morbidity and mortality in postoperative settings; it is the second most common medical complication, the third most common source of excess health care resource utilization, and the third most common cause of mortality in postoperative patients. Accordingly, pulmonary embolism is the most common yet preventable cause of death.

Proximal vein VTE presents the highest risk for PE: 50% asymptomatic or ''silent'' PE and 25% of distal vein VTE will extend to proximal veins within 1 week of presentation. Most postoperative cases of VTE are clinically silent: 2–30% of in-hospital postoperative deaths are attributable to PE.

Over 30 million operations are performed annually in the United States, and the incidence of postoperative VTE without prophylaxis is 10–20% for low-risk and up to 80% in high-risk patients. The rates of fatal PE in the highest-risk patients range from 0.5 to 30%, with length of hospital stay of 5.4 days, excess mortality of 6.6%, and costs reaching $25,000 more than compared with controls.

There were approximately 38 million discharges in the United States in 2006: 7 million were surgical inpatients. According to American College of Chest Physicians (ACCP) Antithrombotic and Thrombolytic Guidelines risk categories, 44% of these patients were at low risk for VTE; 15, 24, and 17% were at moderate, high, and very high risk, respectively. Risk assessment strategy and systematic computerized electronic alerts should be a combined objective to increase the use of VTE prophylaxis and to reduce the rates of symptomatic VTE among hospitalized patients.

For prevention of this common problem, new evidence is available to support novel anticoagulant therapy.

Rivaroxaban

Evidence for this oral, direct factor Xa inhibitor for thromboprophylaxis was presented in the results from the Regulation of Coagulation in Orthopedic Surgery to Prevent Deep Venous Thrombosis and Pulmonary Embolism (RECORD) 1, 2, 3, and 4 trials (Table 1). The RECORD 1 trial was designed to evaluate oral rivaroxaban compared with subcutaneous enoxaparin for extended thromboprophylaxis after total hip arthroplasty. The primary outcome was total VTE: any deep vein thrombosis (DVT), non-fatal PE, and all-cause mortality at 36 days (range 30–42); secondary outcomes included major VTE: proximal DVT, non-fatal PE, and VTE-related death. DVT included any, proximal, distal, and symptomatic VTE.

In the RECORD 2 trial, extended thromboprophylaxis with oral rivaroxaban versus short-term subcutaneous enoxaparin following total hip replacement was evaluated. The main study question was whether extended-duration prophylaxis was superior to short-duration prophylaxis. In summary, RECORD 2 showed that extended-duration prophylaxis was superior to short-duration prophylaxis and that rivaroxaban provided an effective option for such a strategy and had a good safety profile.

Finally, RECORD 3 and 4 evaluated thromboprophylaxis after total knee arthroplasty and found that rivaroxaban (10 mg once a day for 10–14 days), given in a fixed, once-daily dose regimen without coagulation monitoring, was superior to enoxaparin (40 mg once a day for 10–14 days) in preventing venous thrombosis with similar rates of bleeding.

Table 1 Main efficacy outcomes of the RECORD trials

Trial	Setting	Enoxaparin regimen	Rivaroxaban regimen	DVT/PE/death (%)	RRR (%)	Symptomatic VTE (%)	RRR (%)
RECORD 1, $n = 4{,}541$	Hip arthroplasty	40 mg qd, 35 d	10 mg qd, 35 d	3.7 vs. 1.1	70	0.5 vs. 0.3	NS
RECORD 2, $n = 2{,}509$	Hip arthroplasty	40 mg qd, 10–14 d	10 mg qd, 31–39 d	9.3 vs. 2.0	79	1.2 vs. 0.2	80
RECORD 3, $n = 2{,}531$	Knee arthroplasty	40 mg qd, 10–14 d	10 mg qd, 10–14 d	18.9 vs. 9.6	49	2.0 vs. 0.7	66
RECORD 4, $n = 3{,}148$	Knee arthroplasty	30 mg bid, 10–14 d	10 mg qd, 10–14 d	10.1 vs. 6.9	32	1.2 vs. 0.7	NS

Bid twice daily; *d* days; *NS* not significant; *qd* daily; *RRR* relative risk reduction

Apixaban

Apixaban, an oral, direct factor Xa inhibitor, was evaluated for DVT prophylaxis after total knee replacement in a phase II dose-ranging study. Aggregated apixaban doses resulted in a 21% ($P < 0.02$) reduction in VTE and all-cause death compared with enoxaparin and a 53% ($P < 0.01$) reduction compared with warfarin. Major bleeding event rates were low (0–3.3%) and comparable across all apixaban arms and the enoxaparin and warfarin groups. Similar results were shown in a dose-ranging trial for the treatment of DVT.

The phase III, randomized, double-blind Apixaban Dose Orally versus Anticoagulation with Enoxaparin (ADVANCE)-1 trial compared the efficacy and safety of 2.5 mg oral apixaban twice daily to subcutaneous 30 mg enoxaparin for the prevention of VTE after total knee replacement in 3195 patients. The primary outcome rates in each arm were similar (8.99% vs. 8.85%). The predetermined non-inferiority end point was not met, but event rates were comparable, and there was less clinically relevant bleeding in the apixaban arm. There was no difference between the two groups in serious adverse events.

The Apixaban Dose Orally versus Anticoagulation with Enoxaparin (ADVANCE)-2 trial compared apixaban (2.5 mg orally twice daily) with enoxaparin (40 mg subcutaneously daily) for preventing VTE after total knee replacement. The primary efficacy outcome (all VTE) occurred in 15.1% of patients in the apixaban group and 24.4% in the enoxaparin group. A nonsignificant trend toward less clinically relevant bleeding also favored apixaban (3.5 vs. 4.8%, $P = 0.09$).

The Apixaban Dose Orally versus Anticoagulation with Enoxaparin (ADVANCE)-3 trial evaluated the efficacy and safety of oral, twice-daily apixaban 2.5 mg compared with subcutaneous enoxaparin 40 mg once daily in patients undergoing elective total hip replacement surgery. In this study, the primary efficacy end point occurred in 1.4% of patients in the apixaban group and 3.9% of patients in the enoxaparin group, demonstrating a statistically significant relative risk reduction for apixaban of 64% ($P < 0.001$ for non-inferiority and superiority). The safety outcome of major bleeding occurred in 0.8% of patients who received apixaban and in 0.7% of patients who received enoxaparin ($P = 0.54$). There was no difference between the two groups in serious adverse events.

Dabigatran

In patients undergoing total hip replacement who were enrolled in the Dabigatran Etexilate Compared with Enoxaparin in Prevention of VTE Following Total Hip Arthroplasty (RE-NOVATE) trial, both doses of the oral direct thrombin inhibitor, dabigatran etexilate, given for a median of 33 days were as effective as enoxaparin for the prevention of VTE, with a similar safety profile. Furthermore, dabigatran etexilate proved to be non-inferior to enoxaparin, when administered for the same duration, for reducing the risk of total VTE and all-cause mortality after total hip replacement. In patients undergoing total knee replacement who were enrolled in the Thromboembolism Prevention after Knee Surgery (RE-MODEL) trial, both doses of the oral direct thrombin inhibitor dabigatran etexilate, given for 6–10 days, were as effective as enoxaparin for the prevention of VTE, with a similar safety profile. Dabigatran etexilate proved to be non-inferior to enoxaparin (40 mg daily started the night before surgery) for the prevention of VTE after total knee replacement.

Should patients with cancer receive primary VTE prophylaxis?

Patients with cancer are at high risk for VTE, which is the cause of death in many patients with advanced malignancy. The risk for developing VTE is highest during the first 3 months after diagnosis and depends on many factors, including the use (and type) of chemotherapy as well as the

site and stage of the neoplasm. Recent randomized trials have confirmed the hypothesis that anticoagulants, especially when administered in therapeutic doses, can reduce the risk of VTE in at-risk cancer patients. Unfortunately, the absolute risk reductions achieved in several of the trials reported to date have been small and do not justify the hazards and costs associated with a strategy of routine prophylaxis in all patients. For example, the Prophylaxis of Thromboembolic Events in Cancer Patients Receiving Chemotherapy (PROTECHT) study enrolled 1,150 patients with advanced lung, breast, or colon cancer (all were receiving chemotherapy) and randomly assigned them to either nadroparin (prophylactic dose) or placebo. Although the proportion of patients experiencing the primary end point was lower in the treatment group (2.1 vs. 3.9%, $P = 0.033$), this small risk difference has not resulted in the adoption of primary prevention strategies for these populations. The PROTECHT results indicate that 55 patients would have to be treated with LMWH for 1 year to prevent one thromboembolic event.

At least two trials that have recruited patients with pancreatic cancer receiving gemcitabine (and that compared therapeutic-dose LMWH to placebo) have demonstrated more dramatic risk reductions for VTE but did not clearly show a survival advantage and have yet to be published in full manuscript form. Several groups have now validated the risk prediction model of Khorana et al.—a scoring system that has demonstrated that the risk of developing VTE increases with a number of factors, such as elevated white blood cell or platelet count, increased body mass index, or decreased hemoglobin. However, the absolute VTE risk level at which practicing oncologists and their patients should consider primary prevention remains unclear and may change if/when oral anticoagulants are shown to be effective for this purpose. At this time, the National Cancer Center Network guidelines do not recommend routine use of primary VTE prophylaxis in any outpatient cancer population, except for patients with multiple myeloma who are receiving lenalidomide and dexamethasone.

Are there patients with PE who can be treated out of hospital?

Pulmonary embolism is a common condition affecting more than 1.5 million Americans yearly. It is a serious disease that accounts for 10% of all in-hospital deaths and is a major contributing factor in another 10% of deaths. Despite these elevated death rates, PE might be a more benign condition when associated with a lower thrombus burden. In this case, mortality is extremely low, and patients might be considered for outpatient therapy. Therefore, risk stratification is of utmost importance when considering therapy in PE.

Several risk stratification scores have been developed and include variables such as age, clinical status at hospital admission (heart rate, blood pressure, and respiratory rate), presence of cancer, and hypoxemia ($SatO_2 < 90\%$). The commonly used Geneva risk score demonstrates good discrimination for the prediction of death, major bleeding, and recurrent VTE at 3 months. Patients stratified as low risk (80% of total) have a 2.2% event rate, whereas high-risk patients have increased risk of complications (26%). Another famous score called PESI (Pulmonary Embolism Severity Index) performs similarly for the prediction of the same end points. More recently, echocardiographic data and biomarker measurements, such as cardiac troponins (cTnT and cTnI) and brain natriuretic peptide (BNP), have been included in these scores. Biomarkers predict death and other complications following PE with an odds ratio as high as 17.9 according to some studies. They also improve discrimination beyond clinical and echocardiographic variables. In conclusion, patients admitted with PE are at different risk. Currently available risk stratification scores help predict complications and enable the choice of the most suitable therapy for each patient. A study from the Netherlands presented as a late-breaking session at the American Society of Hematology annual meeting in December of 2010 indicates that out-of-hospital therapy may be reasonable in selected patients with PE.

Approaches for patients with venous thrombosis in unusual sites

The vast majority of proven episodes of DVT occur in the deep veins of the legs. When they occur in the proximal veins, embolization may travel to the lungs, producing PE. DVT and PE are often described as VTE and comprise a leading cause of hospital-acquired morbidity and mortality.

Venous thrombosis may occur in any vein. Recently, the frequency of DVT in non-leg veins has increased dramatically due to the increased sensitivity of our radiologic investigations. For example, improved resolution of abdominal ultrasonography and contrast-enhanced computed tomography (CT) scanning has led to a rapid increase in the frequency of detection of splanchnic venous thrombosis, oftentimes occurring in patients with minimal or no referable symptoms who are undergoing evaluation for unrelated medical indications. Cerebral vein thrombosis is a potentially devastating form of thromboembolism that is optimally detected with magnetic resonance venography or direct angiography. Again, due to the increasing availability and resolution of these modalities, the frequency of detection of these thrombi is increasing. Finally, DVT may

occur in other vascular sites such as the renal veins, pelvic veins, pulmonary veins, and in varicose veins located in any vascular distribution.

Thrombophilia testing is widely available and grossly overused. However, there appears to be a particular predilection for patients with selected forms of thrombophilia to develop thrombosis in unusual sites. For example, patients with paroxysmal nocturnal hemoglobinuria (PNH) appear to be particularly prone to develop Budd-Chiari syndrome, while patients with the JAK-2 mutation appear prone to splanchnic vein thrombosis. A recent systematic review demonstrated that almost one third of patients presenting with splanchnic venous thrombosis had the JAK-2 mutation, with many patients having a normal complete blood cell count. The JAK-2 mutation (although recently discovered) has traditionally been identified as being characteristic of myeloproliferative disorders. The mechanism by which this mutation predisposes a patient to splanchnic venous thrombosis is unknown. Both the lupus anticoagulant and anticardiolipin antibody are frequently detected in patients presenting with unusual forms of thrombosis, particularly at young ages. Detection of antiphospholipid antibodies, including both lupus anticoagulant and anticardiolipin antibody, is important because most experts would recommend extended-duration therapy with an oral anticoagulant in patients with these antibodies. There are no specific therapies for the JAK-2 mutation, and patients appear to be treated effectively with oral anticoagulants. Patients with PNH may be resistant to warfarin administered to a traditional INR between 2 and 3; recent studies have suggested a high rate of "warfarin failure." Eculizumab is a recently approved medication that blocks the terminal complement components and thus reduces hemolysis in patients with PNH. Indirect evidence suggests that this medication may also ameliorate the thrombotic complications of this disorder.

More common thrombophilias, such as the prothrombin gene mutation, appear to be particularly common in patients with cerebral vein thrombosis.

Ovarian vein and other pelvic vein thrombosis appear to be particularly common in the peripartum period. Renal vein thrombosis is particularly common in patients with renal cell carcinoma and may be more common in patients with nephrotic syndrome. DVT of the upper extremity is particularly common in the setting of indwelling central venous catheters and in athletes, presumably because of impingement on the veins leaving the arm during vigorous exercise.

Patients with unusual site thrombosis appear to respond to anticoagulation, with similar recurrence rates as patients with PE or thrombosis in the deep veins of the leg. Thus, a rapid-acting parenteral anticoagulant should be administered initially and overlapped with an oral VKA. This therapy may need to be modified as a result of studies of novel agents that may or may not require the initial course of parental anticoagulants.

There is no evidence as to how patients with "asymptomatic" clots should be treated. Most experts would treat patients with thrombi discovered in the setting of cancer or other high-risk situations. If there is reasonable evidence of prior thrombosis, then it may be reasonable to not anticoagulate. Patients who appear to be at high risk of complications, however, probably should be anticoagulated using a rapid-acting, parenteral anticoagulant overlapped with an oral VKA.

The duration of therapeutic anticoagulation has not been studied in these patients. Most experts extend anticoagulation because of a perception that recurrent disease could be associated with catastrophic complications. However, there is reasonable evidence that anticoagulants can be safely discontinued in selected patients, particularly in those with cerebral vein thrombosis.

In summary, DVT may occur in any vein. Thrombophilias appear to be particularly common in patients with unusual site thrombosis. Recent attention has focused on the JAK-2 mutation and PNH as causes of splanchnic and hepatic vein thrombosis, respectively. Anticoagulant therapy is indicated for all symptomatic patients. Optimal therapy of patients with screening-detected clots is unknown. In general, anticoagulant therapy is extended in patients with unusual site thrombosis due to the potentially catastrophic implications of recurrence.

Debate: VTE prophylaxis should be the default position for hospitalized medical patients—for/against

Thromboprophylaxis: the case against

There is no question that selected patients admitted to the hospital with medical disorders are at high risk of DVT and PE, oftentimes described as VTE. However, recommendations for the use of VTE prophylaxis have tended to err on the side of suggesting prophylaxis for most patients, despite a singular lack of evidence to support this recommendation. The ACCP guidelines recommend strongly that anticoagulant prophylaxis be provided to patients identified at high risk of VTE. Such patients include those with an extended duration of immobilization, congestive heart failure, serious thrombophilias, or those with more than one risk factor.

The case that VTE prophylaxis is not required in all patients is made simply. Patients with active bleeding or those perceived to be at very high risk of bleeding should not receive pharmacologic prophylaxis, thus establishing that there is a small but important subgroup of patients in whom prophylaxis is contraindicated. The bigger question

is whether VTE prophylaxis should be provided to low-to-moderate-risk patients.

Prophylaxis may be mechanical or pharmacologic. Mechanical prophylaxis can be active or passive. Passive mechanical prophylaxis, most commonly manifest as graduated compression stockings (GCS), are probably effective for the prevention of VTE but are significantly expensive when routinely used across a hospital and may be associated with transmission of infection. Intermittent pneumatic compression devices are probably more effective than passive compression devices, but they are expensive and are generally poorly used in hospitalized patients. Furthermore, reuse of intermittent compression device bladders may be associated with infectious diseases such as methicillin-resistant *Staphylococcus aureus*. There is no high-quality evidence by which to gauge the effectiveness of intermittent pneumatic compression devices in medically ill patients.

Pharmacologic prophylaxis generally consists of heparin or LMWH administered twice or three times daily. There is clear evidence that, in high-risk patients, pharmacologic prophylaxis reduces the risk of symptomatic DVT, PE, and fatal PE. However, there have been no studies demonstrating the effectiveness of these agents in the low-to-moderate-risk patient.

Irrespective of the indication, there is clear evidence that anticoagulants administered at prophylactic doses increase the risk of major bleeding. Major bleeding is expensive to treat and may be fatal in rare cases.

Modeling of the impact of prophylaxis provision on low-to-moderate-risk patients suggests that the risk of PE and fatal PE is low and very low, respectively. Although it is logical to assume that pharmacologic prophylaxis would further reduce the risk of thrombosis, there is also little doubt that prophylaxis would increase the risk of major and fatal bleeding. Rough modeling suggests, in fact, that, in low-risk patients, provision of prophylaxis would actually cause more fatal bleeding episodes than it prevented through reduced risk of PE. Additionally, the routine use of prophylaxis increases direct drug acquisition costs and dramatically increases the costs associated with the management of bleeding complications.

Based on the lack of evidence of efficacy, indirect but highly suggestive evidence of toxicity, a likely adverse cost-effectiveness profile, and the possibility that prophylaxis delivered to low-to-moderate-risk patients may actually increase the risk of death, it is clear that it is inappropriate to recommend VTE prophylaxis uniformly for medical patients.

Thromboprophylaxis: the case for

Pulmonary embolism is among the leading causes of death among patients hospitalized for acute medical illness. Although effective mechanical and pharmacologic modalities are available to reduce the risk of PE and DVT, clinicians often do not employ VTE prevention strategies for at-risk patients admitted with nonsurgical illnesses. The reasons for this underutilization of effective prophylaxis are not known with certainty; however, there are probably many factors involved. First, the physician caring for a patient with acute medical illness can easily be distracted by many other demands for his/her attention; VTE prevention can easily be forgotten. Second, a validated, user-friendly scheme by which medical patients can be stratified according to VTE risk does not exist. In light of the potential for "sensory overload" among inpatient physicians and the lack of an easy-to-use risk assessment model, it is unreasonable to expect health care providers reliably to prescribe prophylaxis against VTE to at-risk patients.

Cost is not a reason to oppose the routine use of VTE prevention strategies among medical patients. UFH and graduated compression stockings are relatively inexpensive, and there is high-quality evidence that both will reduce the risk of symptomatic DVT and PE. The absolute risk of major bleeding is not substantially increased by the use of low-dose anticoagulants (e.g., LMWH, fondaparinux, UFH) in this population. In other words, because of low baseline risk of bleeding in this population, it is likely that well over 100 patients would have to be treated with low-dose anticoagulants (versus nothing) to cause one additional major hemorrhage. While it would certainly be reasonable to withhold anticoagulants from a patient at high risk for bleeding (e.g., a cancer patient with profound thrombocytopenia), the "default" position should be to provide VTE prophylaxis to all medical patients because: 1) even patients at high risk for bleeding can benefit from mechanical interventions, and 2) for the vast majority of patients at "average" risk for bleeding, the trade-off will favor low-dose anticoagulants.

Triple therapy: patients with CAD and AF

Patients with cardiovascular disease may have several concomitant indications for antithrombotic therapy including ACS, DVT and PE, mechanical valves, AF, and coronary stent implantation. Overlapping indications for antithrombotic therapy may lead to the need for "triple therapy," defined here as aspirin, clopidogrel, and oral anticoagulation.

As the population ages, more patients will have both ACS and AF; accordingly triple therapy may be used more frequently. Prior studies have shown that, with more antithrombotic therapy, risk of bleeding increases. Many antiplatelet and anticoagulant drugs are part of the foundation for treatment of ACS and AF, making the decision

about the right combination of these agents challenging. However, limited evidence is available to guide therapeutic decision-making about triple therapy. Registry information, subgroup analyses from clinical trials, and overviews of single-center experiences have been published, but no randomized trials evaluating different strategies of triple therapy have been completed.

Multiple guidelines and consensus statements from national societies provide recommendations for clinicians concerning the use of triple therapy. A simple flow diagram can be used by physicians to guide decisions about the need for dual antiplatelet therapy or triple therapy based on the assessment of patient bleeding and stroke risk. Five additional factors should be considered: 1) use of the lowest dose of antiplatelet therapy; 2) use of bare metal stents versus drug-eluting stents to minimize the duration of antiplatelet therapy; 3) optimal INR within a range of 2.0–2.5; 4) gastric protection with PPIs; and 5) minimization of the duration of triple therapy. It is also important to re-evaluate regularly the need for triple therapy. The risk of stent thrombosis will decrease over time, whereas bleeding risk will remain constant.

Two ongoing randomized clinical trials will evaluate the role of triple therapy: the What Is the Optimal Antiplatelet and Anticoagulant Therapy in Patients with Oral Anticoagulation and Coronary Stenting (WOEST) study of $\sim$ 500 patients post-stenting randomized to triple therapy versus dual therapy (clopidogrel and an oral anticoagulant) and the Intracoronary Stenting and Antithrombotic Regimen: Testing of a Six-Week Versus a Six-Month Clopidogrel Treatment Regimen in Patients With Concomitant Aspirin and Oral Anticoagulant Therapy Following Drug-Eluting Stenting (ISAR-Triple) trial of $\sim$600 patients post-drug-eluting stent implantation randomized to triple therapy for 6 weeks versus triple therapy for 6 months.

Several new antiplatelet and anticoagulant agents are also being studied for ACS and AF, including the PAR-1 inhibitors in the Thrombin Receptor Antagonist for Clinical Events Reduction (TRACER) and TRA-2P programs; factor Xa inhibitors in the Anti-Xa Therapy to Lower Cardiovascular Events in Addition to Aspirin with or without Thienopyridine Therapy in Subjects with Acute Coronary Syndrome-Thrombolysis In Myocardial Infarction 46 (ATLAS ACS-TIMI 46) and the Apixaban for Prevention of Acute Ischemic Events (APPRAISE)-2 ACS trials; and factor Xa inhibitors in the Global Study to Assess the Safety and Effectiveness of DU-176b versus Standard Practice of Dosing with Warfarin in Patients with Atrial Fibrillation (ENGAGE AF-TIMI 48), Apixaban for the Prevention of Stroke in Subjects with Atrial Fibrillation (ARISTOTLE), and the Efficacy and Safety Study of Rivaroxaban with Warfarin for the Prevention of Stroke and Non-Central Nervous System Systemic Embolism in Patients with Non-Valvular Atrial Fibrillation (ROCKET AF) trials. The future will be interesting. Triple therapy may actually be redefined in the future with new $P2Y_{12}$ inhibitors such as prasugrel and ticagrelor, oral factor Xa inhibitors, and antithrombin agents. Indeed, warfarin may become obsolete in patients with ACS and AF. In addition, triple therapy may be replaced by "quadruple therapy" with aspirin, the $P2Y_{12}$ inhibition, PAR-1 inhibition, and oral anticoagulants.

Measuring quality in atrial fibrillation

Atrial fibrillation is a major health concern as assessed by almost any metric. Over 3 million U.S. citizens have AF, a number that is expected to nearly double by the year 2050. Patients with either paroxysmal or persistent AF have three-to-five-fold increased risk for stroke, and AF accounts for up to 75,000 strokes per year (15% of all U.S. strokes). Furthermore, those with AF have significantly higher mortality and lower quality of life than those without.

Treatment of AF is complex but centers on two major goals: reducing patients' embolic risk and controlling their symptoms. Oral anticoagulant therapies (e.g., VKAs like warfarin) are extremely effective in reducing patients' risk for stroke. However, the use of warfarin is complex and concomitantly can increase patients' risk for bleeding events. Thus, warfarin use is reserved for those with at least moderate stroke risk.

Current American College of Cardiology/American Heart Association (ACC/AHA) AF performance indicators include assessing the thromboembolic risk (CHADS score), initiating warfarin in those with moderate or high risk, and then closely monitoring warfarin therapy to ensure that patients are in a narrow therapeutic range. Opportunities for improvement on each of these performance metrics abound. Depending on the study, only about 30–60% of eligible AF patients in community practice actually receive warfarin therapy. Those at highest risk, as assessed by the CHADS score, are paradoxically less likely to receive warfarin therapy. And even when instituted, time-in-therapeutic range (TTR)—an important indicator of warfarin's safety and effectiveness—ranges from 30 to 60% in community case series. Newer agents, such as the oral direct thrombin and factor Xa inhibitors, represent a major leap forward for antithrombotic therapy for AF. These new drug classes offer easier patient management without constant drug monitoring. Furthermore, relative to warfarin, these new drugs are being demonstrated to have similar or improved thrombotic protection and significantly better safety profiles.

The second goal of AF management is to control patient symptoms and improve quality of life. Rhythm control of AF, either with anti-arrhythmic drugs or with AF ablation procedures, can restore sinus rhythm in many patients with AF. However, studies to date in mildly symptomatic patient subgroups have had difficulty showing that restoration of sinus rhythm necessarily improves quality of life or reduces stroke risks; further research is needed.

New anticoagulants for stroke prevention in atrial fibrillation

Warfarin is effective for stroke prevention in AF but has limitations because of variability in response and an increased risk of bleeding. The most feared complication of warfarin is intracranial bleeding. The efficacy and safety of warfarin is related to the TTR, which is an INR of 2.0–3.0; there is an increased risk of stroke and death at INR < 2 and of bleeding at INR > 3. However, the risk of bleeding, including intracranial bleeding, is present also in patients within the target range. This limits the indication for warfarin to patients with an intermediate-to-high risk of stroke (i.e., with a $CHADS_2$ risk score above 1) to maintain the net clinical benefit.

Therefore, development of new oral anticoagulants aims to demonstrate that they are at least as effective as warfarin and with better safety, allowing use in lower-risk populations. The new alternatives provide more specific inhibition of the coagulation cascade (i.e., by inhibition of thrombin [dabigatran] or factor Xa [apixaban, rivaroxaban, edoxaban, betrixaban]). Currently, the final results from prospective trials comparing these new treatment alternatives to warfarin in patients with AF and an increased risk of stroke are available for dabigatran from the pivotal Randomized Evaluation of Long-term Anticoagulant Therapy Warfarin Compared with Dabigatran (RE-LY) trial performed with a PROBE design. However, prospective double-blind trials comparing apixaban and rivaroxaban, respectively, with warfarin in similar populations have been presented or will be presented within the next year.

The ROCKET AF trial was presented at the AHA Scientific Sessions in November 2010. This study was a prospective, randomized, double-blind, double dummy, parallel-group, multicenter, event-driven non-inferiority study comparing the safety and efficacy of dose-adjusted warfarin with rivaroxaban 20 mg once daily. The primary efficacy end point for non-inferiority in ROCKET AF was the composite of stroke (ischemic and hemorrhagic) and non-central nervous system systemic embolism. The rate of primary outcome per 100 patient-years was 2.12 in the rivaroxaban arm compared with 2.42 in the warfarin arm ($P = 0.117$ for superiority, $P < 0.001$ for non-inferiority). Rivaroxaban also had a slightly better mortality profile: 582 deaths versus 632 in the warfarin group, but the difference was not statistically significant. In a per-protocol analysis, rivaroxaban was superior to warfarin with a primary outcome rate of 1.71 per 100 patient-years versus 2.16 ($P = 0.018$ for superiority and $P < 0.001$ for non-inferiority). Importantly, patients treated with rivaroxaban had fewer intracranial hemorrhages (0.49 vs. 0.74%, $P = 0.019$), fewer critical organ bleeds (0.82 vs. 1.18%, $P = 0.007$) and lower bleeding-related deaths (0.24 vs. 0.48%, $P = 0.003$) than those on warfarin. Rivaroxaban was well tolerated in the study, and rates of discontinuation due to adverse events were similar to those seen for patients on warfarin. One major criticism of the study was the poor INR control compared with previous AF trials. Among warfarin patients, the median time spent within therapeutic range was just 57.8%; they were above therapeutic range 11.9% of the time and below range 19.7% of the time. The results of the study are not published yet.

The RE-LY trial randomized 18,113 patients with AF in 951 sites to blinded fixed doses of dabigatran 110 mg or dabigatran 150 mg twice daily versus unblinded warfarin dose adjusted to INR 2.0–3.0. Median follow-up was 2 years. Rates of the primary outcome were 1.70% per year on warfarin versus 1.55% per year on dabigatran 110 mg (P non-inferiority < 0.001) and 1.11% per year on dabigatran 150 mg (P superiority < 0.001). Rates of major hemorrhage were 3.46% per year on warfarin versus 2.74% per year on dabigatran 110 mg ($P = 0.002$) and 3.22% per year on dabigatran 150 mg ($P = 0.32$). Rates of hemorrhagic stroke were 0.38% per year on warfarin versus 0.12% per year on dabigatran 110 mg ($P < 0.001$) and 0.10% per year on dabigatran 150 mg ($P < 0.001$). Mortality rates were 4.13% per year on warfarin versus 3.74% per year on dabigatran 110 mg ($P < 0.12$) and 3.63% per year on dabigatran 150 mg ($P < 0.047$).

Continued analyses of the RE-LY database have investigated the relative effects of dabigatran in relation to the average time in therapeutic range (cTTR) in each center's warfarin population and to $CHADS_2$ score. The quartiles of cTTR for the warfarin patients were <57, 57–65, 65–73, and >73%. There were no significant interactions with cTTR concerning the superiority of dabigatran 150 mg or the non-inferiority of dabigatran 110 mg versus warfarin for prevention of stroke and systemic embolism and both doses' superiority concerning intracranial bleeding. With dabigatran 150 mg, there was less major bleeding and lower but similar bleeding at higher quartiles of cTTR, while the rates of major bleeding were lower with dabigatran 110 mg irrespective of cTTR. Total mortality was lower with both dabigatran doses at lower cTTR levels and similar at higher cTTR levels.

In the RE-LY trial, around one third of patients had $CHADS_2$ scores 0–1, 2, or 3–6. Increasing $CHADS_2$ scores were associated with increased risks for stroke, bleeding, and mortality, with consistent benefits of dabigatran across all $CHADS_2$ risk groups above 0. Also, patients with the highest risk for new events (i.e., those with previous stroke) had consistent benefits with dabigatran versus warfarin.

Recently, the Apixaban versus Acetylsalicylic Acid to Prevent Strokes (AVERROES) trial compared the factor Xa inhibitor, apixaban (5 mg b.i.d.), with aspirin (80–325 mg/day) for stroke prevention in patients with AF who were unsuitable for oral anticoagulation. The trial was prematurely terminated because apixaban was found superior to aspirin in prevention of the primary end point of stroke and systemic embolism: there was a 54% reduction ($P < 0.001$) at a mean follow-up of 1.1 years. There was no significant difference in major bleeding or any other major safety end point. Apixaban was better tolerated than aspirin, with fewer discontinuations of apixaban compared with aspirin (RR 0.88, 95% CI 0.78–1.00, $P = 0.04$).

In summary, for patients with AF, direct thrombin inhibition with dabigatran provides an attractive alternative to warfarin therapy that preserves or improves on the reduction in stroke and systemic embolism achievable with warfarin with similar to lower rates of major hemorrhage. Factor Xa inhibition with apixaban offers a superior alternative to aspirin for stroke prevention in AF patients who are not candidates for warfarin, with even better tolerance than aspirin. The role of rivaroxaban or apixaban in treatment of warfarin-eligible patients awaits peer-reviewed data from ongoing or recently completed studies. Therefore, there is great hope that soon several new treatment alternatives will be available for stroke prevention in AF that should improve both patient outcomes and quality of life.

The relative importance of stroke and bleeding risk in patients with AF: a case-based approach

You are seeing a new patient in clinic. She is an 82-year-old female with hypertension, diastolic heart failure, and non-valvular AF. She has no idea how long she has been in AF, and she reports no change in her symptoms. Her heart rate is irregular, 85 beats per minute, and her blood pressure is 130/80 mmHg. She asks, "Should I start warfarin?" Initially, this seems like a relatively easy question; however, the decision to start a patient on life-long anticoagulation requires a careful assessment of benefits and risks of anticoagulation and consideration of how this information should be used for an individual patient.

Evidence-based medicine, as described by David Sackett, is the process of combining quantitative evidence about medical practice with expert physician judgment to ensure each individual patient the best medical care with reproducible high quality. To provide evidence-based thromboembolism prophylaxis in patients with AF, one has to carefully consider the benefits of thromboembolism prophylaxis (primarily a reduction in the risk of thromboembolic stroke) and the risks of thromboembolism prophylaxis (primarily an increase in the risk of bleeding). These population-based benefits and risks then need to be applied to the individual patient.

The absolute risk of stroke in patients with AF is less related to the burden of AF and more related to patient comorbidities. A number of risk scores have been developed. The most common is the $CHADS_2$ score, which assigns one point for heart failure, hypertension, age $>$ 75 years, and diabetes, and two points for prior stroke. The risk of stroke increases with increasing $CHADS_2$ score, from roughly 2% per year for $CHADS_2$ scores of 0–1 to over 15% per year for $CHADS_2$ scores of over 6. A newer score, the CHADS-VASC, includes points for female sex, vascular disease, and age between 65 and 75 years, and assigns two points for age $>$ 75 years. The CHADS-VASC score better stratifies risk in patients with a $CHADS_2$ score of 0. Our patient has a $CHADS_2$ score of 3 and a CHADS-VASC score of 4. Based on this, her annual risk of stroke is 6–8%. She says, "I'm old and understand I have a risk of stroke, but should I take warfarin?"

There are two additional important factors that have to be incorporated when considering the potential benefits of warfarin for this patient. The first is just how bad a stroke is likely to be and the second is whether warfarin will be effective at reducing the risk of stroke. The definition of stroke used in most of the clinical trials of thromboembolism prophylaxis in patients with AF is non-traumatic, focal neurologic deficit lasting at least 24 h. Thus, some strokes are devastating, while others result in no long-term deficit. However, strokes in patients with AF tend to be severe, with more than two-thirds resulting in death or permanent disability. Also important is that warfarin is highly effective at reducing strokes in patients with AF. Treatment with warfarin results in a roughly two-thirds reduction in stroke. Therefore, our patient has a more than 4% risk per year of a disabling stroke, and her risk of stroke could be reduced to roughly 2% with warfarin.

Warfarin, a potent anticoagulant, has bleeding as its major side effect. Warfarin is most effective in patients who maintain an INR between 2 and 3. With an INR below 2, the risk of stroke promptly increases. With an INR above 3, the risk of bleeding increases. However, even with reasonably good INR control, patients taking warfarin have a roughly 2% annual risk of major bleeding. The risk factors for bleeding substantially overlap with the risk factors for stroke. The recently developed

HAS-BLED score assigns one point each for hypertension, abnormal renal function, abnormal liver function, prior stroke, a history of bleeding, poor INR control, age > 65 years, and drug and alcohol use. The risk of bleeding ranges from 1% with a HAS-BLED score of 0 to more than 15% with a HAS-BLED score of 5. Our patient has a HAS-BLED score of 2 or more; thus, an annual risk of major bleeding on warfarin of 3% or more. She asks, "How bad is major bleeding?"

Like stroke, it is important to consider the range of major bleeding. The definition of major bleeding in most clinical trials of thromboembolism prophylaxis in patients with AF is that of the International Society of Thrombosis and Hemostasis (ISTH). ISTH major bleeding includes fatal bleeding, symptomatic intracranial, intra-articular, intra-spinal, pericardial, intraocular, retroperitoneal, or intramuscular bleeding with compartment syndrome, or bleeding resulting in a fall in hemoglobin of at least 2 g/dl or leading to transfusion of two or more units of red blood cells. In the recently reported RE-LY trial, the rate of major bleeding with warfarin was 3.6%, while the rate of the most devastating intracranial bleeding was only 0.7%. These were in contrast to a stroke rate of 1.6%. Intracranial bleeding is consistently associated with much worse outcomes than other types of major bleeding. When one considers a "net clinical benefit" that includes reduction in stroke and increase in only intracranial bleeding, those patients with a $CHADS_2$ score of 2 or more have a significant benefit with warfarin. This includes our patient above who, with a $CHADS_2$ score of 3, would be expected to have a net benefit of roughly 2% per year with warfarin. Now that we have covered the major efficacy and safety issues with warfarin, our patient asks, "Are there are any other downsides to warfarin?"

Warfarin, although one of the most effective drugs available to prevent devastating consequences of atrial fibrillation, also has significant downsides beyond bleeding. Warfarin has a host of dietary and drug interactions and requires at least monthly INR monitoring; many patients are plagued by significant INR variability requiring frequent dose changes. Finally, and perhaps most importantly, the dietary and drug interactions and the need for frequent monitoring create a constant worry on both the part of the patient and his or her physician. It is for these reasons that warfarin isn't used in close to half of patients with AF, including many of those who are at the highest risk of stroke. Fortunately, for all patients with AF, there are a host of alternatives to warfarin, including factor X and factor II (thrombin) inhibitors that are in development. Some of these may offer better efficacy and/or safety than warfarin, but all are likely to result in less worry; thus, hopefully, we will see more use of effective thromboembolism prophylaxis in patients with AF. Based on this discussion, our patient has decided to start warfarin as thromboembolism prophylaxis, at least until one of these alternative anticoagulants is available.

The anticoagulation of STEMI patients not eligible for reperfusion

In clinical practice, approximately 30% of patients with STEMI will not receive reperfusion therapy, either by primary PCI or lytics, because of delayed presentation, increased risk of bleeding, or patient-related factors. Systemic anticoagulants have been tested in this setting as a way to reduce the occurrence of adverse events, including mortality and re-infarction. A limited number of contemporary trials are available to guide clinical decision-making; however, there is no clear consensus on the use of systemic anticoagulation in this setting.

In a post-hoc analysis of the Thrombolysis in Myocardial Infarction (TIMI) 11B and Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q wave Coronary Events (ESSENCE) trials, of the 7081 patients initially identified as having non-STEMI, 252 were subsequently found to have Q-wave MI. When treated with enoxaparin instead of UFH, these patients had 28% less death, MI, and recurrent angina at 30 days ($P = 0.04$). These results prompted the Treatment of Enoxaparin and Tirofiban in Acute Myocardial Infarction (TETAMI) trial, which, to this day, remains the only prospective randomized controlled trial specifically testing anticoagulation strategies in STEMI patients not eligible for early reperfusion therapy. TETAMI compared the efficacy and safety of enoxaparin versus UFH and eptifibatide versus placebo in a factorial design. In this context, enoxaparin and UFH were equivalent in terms death, re-infarction, or recurrent angina at 30 days (15.7 vs. 17.3%, respectively; OR = 0.89, 95% CI 0.66–1.21, P = NS). Tirofiban was not superior to placebo to improve outcome and tended to increase the rate of major bleeding.

In a more contemporary setting, the randomized double-blind OASIS-6 trial compared fondaparinux with UFH or placebo in STEMI patients, some of whom who were not eligible to receive reperfusion. In this subgroup, fondaparinux was better than either UFH or placebo at reducing the occurrence of death or MI at 30 days (12.2 vs. 15.1%, $P = 0.04$). Interestingly, the rate of major bleeding among patients treated with fondaparinux was similar to controls (hazards ratio = 0.84, 95% CI 0.47–1.50, $P = 0.55$).

Despite our best efforts, a significant proportion of patients do not receive reperfusion therapy. In 2010, we don't know with certainty that anticoagulation is superior to no anticoagulation in patients with STEMI not eligible for reperfusion.

Antiplatelet therapy in patients undergoing CABG surgery: what should we do?

Antiplatelet therapy significantly reduces mortality in ACS. However, a problem is posed when patients on antiplatelet therapy require cardiac surgery, as this represents a recognized risk for increased surgical blood loss. Formerly, aspirin was suspended for 5 days before surgery; in recent years, this approach has not been routinely followed. In fact, some centers introduce aspirin before surgery, especially when an off-pump technique is employed. The same practice of introducing aspirin before surgery does not occur with clopidogrel, which is most widely used in ACS after drug-eluting stent implantation and before primary PCI for MI. Clopidogrel is administered in emergency rooms when ACS is suspected, even before a definitive diagnosis is made. It permanently blocks platelets, and its effect only diminishes after the natural platelet replacement, which takes 5–7 days in a normal subject. CABG surgery should be avoided during this period, but this is not strictly observed in practice, nor is it clear the magnitude of the contribution of clopidogrel to surgical bleeding. Short-acting and reversible antiplatelet drugs, such as ticagrelor (oral) and cangrelor (intravenous), are being introduced, but they are not yet in general clinical practice. Abciximab, a humanized monoclonal antibody to the platelet GP IIb/IIIa receptor, irreversibly binds the receptor, has a more intensive antiplatelet effect, and should be avoided before surgery. However, the small-molecule GP IIb/IIIa inhibitors (eptifibatide and tirofiban) reversibly bind the receptor, have short half-lives, and have not been shown to increase CABG-related bleeding.

Most guidelines and practicing cardiac surgical centers recommend stopping clopidogrel administration for 5 days before elective surgery. In one multicenter analysis, exposure to clopidogrel within 5 days before CABG was associated with a 9.8-fold increase in need for reoperation ($P < 0.01$). However, other analyses have found weaker or no relationship with reoperation. In urgent situations, the risk of MI or its extension must be balanced against the risk of surgical bleeding, increased morbidity, and possible mortality. Intravenous UFH, on the other hand, could be safely and efficaciously introduced instead of clopidogrel in emergency situations, until a coronary artery anatomical diagnosis is obtained and a decision for PCI or CABG is made. One strategy commonly used is to not administer clopidogrel or prasugrel until the anatomy is known in STEMI patients. However, in NSTE ACS patients, the overall rate of CABG is only 10–15%, and there are no effective methods to predict at presentation who those individuals will be. Thus, the ischemic benefits of early treatment in this situation may outweigh the downsides of delay to CABG if it is ultimately indicated.

In the unstable patient with severe proximal coronary artery lesions, when surgery must be performed in the presence of clopidogrel, some adjuvant measures for better hemostasis may be considered, though few data are available for their effectiveness. These include careful surgical evaluation, the use of prophylactic antithrombotic agents, such as epsilon-aminocaproic acid or tranexamic acid (not aprotinin), during and after the procedure, and platelet infusion.

Statistical issues in the design and analysis of clinical research

As new drugs and devices are developed, questions arise as to the efficacy and safety of these treatments overall and relative to other available treatments, as well as to which patient populations would benefit most from the new therapy. The ideal situation for answering these questions would be to treat the entire population of eligible patients and observe all responses. But it is usually impossible to treat and evaluate every possible patient. Instead, we study the use of the therapy in a sample of the population. Based on the results observed in the sample, we make inferences about what we would expect to see if we could have applied the treatment to the entire population.

Multiple aspects of research determine the level of confidence one can have that the results observed in the sample are real and not just an anomaly of that sample or experiment. The number of patients studied must be large enough to provide adequate power to detect a significant difference. The patients studied should be generalizable to the population of interest. The allocation of treatment to the patients must be in a random fashion to ensure no biases are introduced during the selection process. The blinding of treatment is another important step in eliminating bias. When possible, the treating physician, the patient, and all others involved in the study should be blinded to the treatment that the patient is receiving.

All aspects of the study should be clearly specified and well-defined. When possible, the actual end point of interest should be studied rather than a surrogate end point. For the end point, the definition should be explicitly described, thus allowing for reproducibility in future studies. The protocol should state upfront whether the results will be based on the enrolling physician's determination, independent core laboratory results, or an independent adjudication committee determination of the end point. The timing of the end point should be based on clinical relevance. With long-term outcomes, the short-term results are also known. But the treatment may only affect outcomes acutely, so results may become diluted after an extended period of time.

Randomization of the treatment of interest is not always possible. There are situations in which randomization would be unethical and/or impossible to implement. In these cases, we must instead study series of patients and use special statistical tools to account for biases. These include adjusting for confounders or for the propensity to receive one treatment versus another. If the modeling process can fully adjust for all of the factors that are associated with receiving the treatment and with the outcome of interest, then one can make causal inferences. However, this situation is seldom possible.

With multiple treatments for the same condition, the growing increase of genetic markers, globalization of clinical trials, and many changes in research over the past few years, the analytic issues have become increasingly complex. Statistical expertise is needed to ensure high-quality, accurate results. A greater understanding of the underlying statistical issues in clinical research is needed for the non-statistician, who must critically review and incorporate this ever-growing wealth of clinical information.

Globalization of clinical research

Cardiovascular disease accounts for at least 30% of deaths worldwide (16.6 million people estimated in 2002). Notably, the majority of these individuals are in the low- and middle-income brackets, reaffirming that this is not only a disease of the rich. Projections by Beaglehole and Bonita indicate a growing cardiovascular burden across all income groups such that it is estimated that over three quarters of all deaths will occur secondary to chronic non-communicable disease by the year 2030. Of these non-communicable diseases, cardiovascular disease will be the most dominant. The socioeconomic determinants of this trend provide a compelling impetus to invest in research on health policy and integration of health systems that will enhance the application of available knowledge and close the treatment gaps that exist.

Remarkably, the cost of care bears little relationship to life expectancy: in this regard, the average per capita expenditure across a wide spectrum of countries is $2986 with an average life expectancy of approximately 79 years. At the extremes, Mexico spends slightly more than $800 and the United States in excess of $7000 per capita, yet both have below-average life expectancies indicating the complexity of this relationship. Notably, the Scandinavian countries, Canada, Switzerland, Australia, and France expend more than the median amounts but also have life expectancies in excess of the average.

The Treatment and Outcomes of Acute Coronary Syndromes in India (CREATE) registry offers insight into some of the challenges facing global cardiovascular research. It highlights the relatively young age at which MI occurs, the still dominant incidence of STEMI versus non-STEMI, with mortality from STEMI in excess of 8%. Remarkably, there is a delay from symptom onset to hospitalization of approximately 5 h for STEMI patients and an additional delay from hospitalization to fibrinolysis of nearly 1 h. The large majority of patients are transported to hospital by taxi or private vehicle, but as many as a third use public transportation and only a minority have access to ambulance transportation. As communicated by Prabhakaran, several factors impair research progress in India, including an entrenched bureaucracy, a lack of interdisciplinary and transdisciplinary research, resistance to change across all levels, substantial mobility and instability of the trained workforce, and the dominance of commercial contract research organizations (CROs) with a profit mandate.

On a broader global scale, perverse economic incentives exist in the provision of health care, and there remain huge disparities in access to high-quality health care. Moreover, the chasm between what we know versus how we integrate knowledge, coupled with fear of liability and a sometimes unreasonable quest for diagnostic certainty, contribute to inefficiencies. The treatment-risk paradox is pervasive, and too many dollars are spent on marginal gains or the so-called "flat portion" of the cost–benefit curve.

It is reassuring that there appears to be a renewed understanding of the importance of global academic collaboration based on several factors, including information technology and its transformation of the world into a global village. Moreover, there is a commonality of health-related issues and increasing concern about the costs of health care, which are driving an effort to acquire the best metrics for demonstration of return on investment in health care costs. An increasing number of questions regarding comparative efficacy that require head-to-head evaluations ensures no lack of meaningful projects to undertake. As mortality declines and life expectancy increases in a number of countries, new emphasis on better metrics to assess quality of life has emerged. Striking a balance between the content of care and elements associated with human behavior that contribute to the epidemics of obesity and diabetes remains a major challenge. In this regard, better understanding of the future of personalized medicine and genomics versus broad population approaches is mandatory. An important caveat for research in the developing world relates to statements by both the World Health Organization and the World Medical Organization affirming that, when conducting research in developing countries, it is necessary to ensure that the results of the research will be applicable to those populations in whom it is conducted so that they can benefit from the results.

As one surveys the global treatment gap, it is sobering to contemplate that <10% of global health research is devoted to diseases comprising 90% of the global disease burden. Indeed, a third of the world's population receives only 2% of global health resources, and only 5% of health research is devoted to prevention resources versus 95% dedicated to treatment. Daar et al. highlight six key challenges in tackling chronic non-communicable disease: (1) raising public awareness; (2) enhancing economic, legal, and environmental policies; (3) modifying risk factors; (4) engaging businesses and community; (5) mitigating health impacts of poverty and urbanization; and (6) reorienting health systems.

The VIGOUR Group is well prepared to execute its mission of enhancing worldwide cardiovascular health by the creation, implementation, and evaluation of novel strategies developed through global collaboration. Shared perspectives among group members relate to a strong social conscience and recognition of partnership within a global village. Not only is there an appreciation of the profound unmet needs that exist but also of the mismatch between resources on health expenditures versus key unanswered research questions. In a recent publication by Califf et al. from the VIGOUR Group, four key issues were identified: (1) the lack of definitive evidence to guide care, (2) disease heterogeneity, (3) inadequate funding, and (4) paucity of new leadership. To foster global academic collaboration, infrastructure at all health professional levels is needed, fiscal transparency and stability of academic research organizations (AROs) are required, and the right balance must be struck between individual versus group rewards for achievement. There is a compelling need to develop new leaders and define an appropriate career path for those engaging in these efforts. Each of these issues is associated with opportunities and strategies that will help to drive the cycle of quality on a global basis.

Role of AROs

Conducting high-quality global clinical research is increasingly challenging. The world is "flattening" (Thomas L. Freidman) due to a variety of forces including advances in information technology that allow efficient sharing of data across the globe. However, multiple impediments remain for efficient clinical trial conduct.

Most AROs have three key priorities: (1) patient care, (2) education, and (3) research. These priorities are often reflected in mission statements such as those from the Duke Clinical Research Institute (DCRI), the Brazilian Clinical Research Institute (BCRI), the Canadian VIGOUR Centre (CVC), and the Uppsala Clinical Research Center (UCR). The typical ARO will encompass a variety of research initiatives, including clinical trials, registries, health economics, quality-of-life projects, methodological research, core laboratories, and education. These programs are supported by a framework of coordinating center services. By contrast, missions of commercial CROs are different and typically reflect a goal of maximizing returns or providing efficient services. In a simplistic view, an ARO performs research, and a commercial CRO performs research services.

The United States and many parts of the world are experiencing a shortage of clinical trial investigators and coordinators. Financial pressures and the demands of clinical practice both are central issues of concern, along with growing complexities involving contracts and regulations, lack of training, and less infrastructure to support site-based research at many institutions. Efforts are needed to better understand local site challenges and to respond to those challenges. The Clinical Trials Network, which is part of the National Institutes of Health Roadmap (www.ctnbestpractices.org), provides site investigators with opportunities to learn and network in support of their daily activities.

Cardiovascular disease is and likely will remain the number one cause of death in the world; thus, identifying new and promising therapies is critical. Large clinical outcomes trials will remain the standard for assessing the benefits and safety of new agents, and, as such, clinical trials to evaluate novel therapies will remain large in size and require a global effort. Global clinical research driven by collaboration will be essential to complete these large trials quickly and efficiently. Relationships such as those that have been established between the DCRI and BCRI in Sao Paulo, Brazil, will help create the foundation and infrastructure for performing quality clinical research in the future. Several key priorities for AROs include: (1) creating a culture of excellence and partnership; (2) evaluating novel, efficient, and less costly trial designs and operations; (3) promoting evidence-based medicine and evidence-based trial operations; and (4) developing a sustainable clinical research community through focused support of site investigators. The future has challenges but also exciting opportunities.

Warfarin and acetaminophen interaction: a summary of the evidence and biologic plausibility

Renato D. Lopes,[1] John D. Horowitz,[2] David A. Garcia,[3] Mark A. Crowther,[4] and Elaine M. Hylek[5]

[1]Duke Clinical Research Institute, Duke University Medical Center, Durham, NC; [2]University of Adelaide, Queen Elizabeth Hospital, Adelaide, Australia; [3]Department of Medicine, University of New Mexico Health Sciences Center, Albuquerque, NM; [4]Department of Medicine, McMaster University, Hamilton, ON; and [5]Department of Medicine, Research Unit, Section of General Internal Medicine, Boston University School of Medicine, Boston, MA

Case presentation

Ms TS is a 66-year-old woman who receives warfarin for prevention of systemic embolization in the setting of hypertension, diabetes, and atrial fibrillation. She had a transient ischemic attack about 4 years ago when she was receiving aspirin. Her INR control was excellent; however, over the past few months it has become erratic, and her average dose required to maintain an INR of 2.0 to 3.0 appears to have decreased. She has had back pain over this same period and has been taking acetaminophen at doses as large as 650 mg four times daily, with her dose varying based on her symptoms. You recall a potential interaction and wonder if (1) her acetaminophen use is contributing to her loss of INR control, and (2) does this interaction place her at increased risk of warfarin-related complications?

Warfarin has remained the most commonly prescribed vitamin K antagonist (VKA) since its introduction into clinical practice approximately 60 years ago. VKAs exert their effect by inhibiting the cyclic replenishment of reduced vitamin K, an obligate cofactor in the γ-carboxylation of the biologically inactive procoagulant factors II, VII, IX, and X, as well as the anticoagulant factors protein C, protein S, and protein Z.[1] The resultant anticoagulant effect is measured by the international normalized ratio (INR), which for most indications is targeted between 2.0 and 3.0. Thromboembolism, major hemorrhage, and death have all been strongly linked to the proportion of time spent in this therapeutic range.[2,3] Despite its efficacy in preventing and treating thromboembolic disease, warfarin has several limitations that challenge its effectiveness in clinical practice, including a narrow therapeutic index, variable dose-response, and importantly the potential for important interactions with numerous commonly used medications.[4]

Reports of an interaction between warfarin and acetaminophen first appeared in the literature in 1968.[5] Acetaminophen is part of the class of drugs known as "aniline analgesics"; it is the only such drug still in use today.[6] Acetaminophen is used worldwide as an analgesic and antipyretic. Because aspirin and other nonsteroidal anti-inflammatory drugs inhibit platelet function and can cause injury to the gastric mucosa, acetaminophen is the analgesic of choice for patients receiving oral anticoagulant therapy. Establishing the validity of this interaction is critically important as acetaminophen is currently the recommended first-line therapy for pain control in older adults, the group at highest risk of hemorrhage and concomitant use of VKAs.[7] The objectives of this focused review are to summarize the observational and randomized data investigating this interaction, to provide insights into possible biologic mechanisms, and to suggest clinical practice recommendations for patients receiving both VKAs and acetaminophen.

Observational data

Early case reports demonstrated a temporal increase in the INR among persons taking warfarin after acetaminophen exposure, suggesting an interaction.[8,9] Subsequent observational studies investigated the relationships between acetaminophen and INR and acetaminophen and hemorrhage among persons prescribed warfarin. In a case-control study, 93 consecutive patients with an INR greater than 6 were compared with 196 randomly selected control patients with an INR in the range of 1.7 to 3.3. Participants were interviewed within 24 hours of the INR measurement, and pertinent exposures within the previous 7 days were recorded. Acetaminophen was independently associated in a dose-dependent fashion with an INR greater than 6.0. For persons taking acetaminophen 9.1 g/week or more, the odds of an INR greater than 6.0 were increased 10-fold. This dose-response relationship persisted after controlling for other factors known to potentiate warfarin.[10]

Another case-control study enrolled 53 patients with an INR greater than 4.5 and 106 control patients with an in-range INR. Amiodarone (9.4% vs 0%, $P < .004$), acetaminophen (18.9% vs 0.9%, $P < .001$), tramadol (5.6% vs 0%, $P < .04$), ofloxacine (11.3% vs 1.9%, $P < .001$), and lactulose (11.3% vs 0%, $P < .001$) were associated with INR elevation. Other factors included fever, malnutrition, dehydration, and acute diarrhea.[11] Bleeding complications occurred in 19.2% of cases versus 3.9% of the controls.

Shalansky et al prospectively studied 171 warfarin-treated patients to assess the risk of bleeding and elevated INR associated with the use of complementary and alternative medicines.[12] Patients kept a diary of selected exposures for 16 weeks. Pharmacy, laboratory, and medical records were subsequently queried for evidence of bleeding or elevations in INR. Acetaminophen was associated with increased risk of bleeding (OR = 1.42; 95% confidence interval [CI], 1.05-1.90) and INR elevation, although the latter did not achieve statistical significance (OR = 1.76; 95% CI, 0.85-3.63, $P = .13$).[12] Warfarin use of less than 3 months' duration was the only statistically significant risk factor identified for increased INR.

In a retrospective study of a postmortem toxicology database, Launiainen et al[13] reported an association of combination therapy with fatal hemorrhage. Of the 328 patients who were taking warfarin at the time of death, a potentially interacting drug was present in one-third, and acetaminophen was the most common (50%). Concomitant use of acetaminophen and warfarin was associated with a 4.6 and 2.7 times higher risk of fatal bleeding than either acetaminophen or warfarin alone, respectively.[13]

Submitted August 3, 2011; accepted August 30, 2011. Prepublished online as *Blood* First Edition paper, September 12, 2011; DOI 10.1182/blood-2011-08-335612.

Table 1. Randomized evaluations of the impact of acetaminophen on the pharmacodynamics of warfarin

Study, period	Study size	Acetaminophen dose	Study outcome
Antlitz,[16] 1968	20	650 mg vs placebo for 2 doses	No significant difference in prothrombin times between acetaminophen and placebo during the 48-hour period after 2 doses of study drug.
Mahé,[17] 2004	11	4 g/d vs placebo for 14 d	The mean observed INR was significantly increased after 4 days in the acetaminophen group. The mean maximum INR observed was 3.47 in the acetaminophen arm and 2.61 in the placebo arm ($P = .001$). The mean maximum increase in the INR was 1.04 (acetaminophen group) versus 0.20 (placebo group; $P = .003$).
Mahé,[18] 2006	20	4 g/d vs placebo for 14 d	The mean maximum INR observed was 3.45 in the acetaminophen arm and 2.66 in the placebo arm ($P = .03$). The mean maximum increase in the INR was 1.20 (acetaminophen group) versus 0.37 (placebo group; $P < .001$). Significant reductions in the vitamin K-dependent clotting factors II, VII, IX, and X accompanied the increase in INR.
Parra,[19] 2007	36	2 g/d, 4 g/d; vs placebo for 4 wk	At week 2, the 2 g/d group had significantly higher INR compared with placebo ($P = .01$). At weeks 1, 2, and 3, the 4 g/d group had significantly higher INR than placebo ($P = .04$, $P = .01$, and $P = .01$, respectively).
Zhang,[20] 2011	45	2 g/d, 3 g/d; vs placebo for 10 d	The mean INR increase was 0.70, 0.67, and 0.14 in the 2 g/d group, 3 g/d group, and in the placebo group, respectively ($P = .01$). Factor VII levels were lower in the acetaminophen groups compared with placebo, but not levels of factors II and V.

INR indicates international normalized ratio.

No association between acetaminophen and INR was found in a retrospective study of 54 persons prescribed nonwarfarin VKAs, acenocoumarol, or phenprocoumon. However, 9 patients in the acetaminophen group required a reduction in coumarin dose after acetaminophen exposure compared with one in the control group, which may have blunted any increase in the INR.[14]

Observational studies investigating the interaction between acetaminophen and warfarin are limited in their ability to ascertain duration, dose, and cumulative dose of acetaminophen given the nonprescription or "over-the-counter" status of acetaminophen. The temporal relationship between acetaminophen exposure and INR elevation mandates standardized INR measurement at baseline and at prespecified intervals among persons already stabilized on warfarin. These limitations and the concern for residual confounding mandate a randomized assessment.

Intervention and randomized data

To investigate an observed increase in INR after a course of acetaminophen, a 74-year-old man was rechallenged with acetaminophen 1 g 4 times per day for 3 consecutive days. On rechallenge, the INR increased from 2.4 to 6.3, factor VII activity decreased from 29.4% to 15.5%, and there was no significant change in warfarin plasma concentration (1.54 μg/mL vs 1.34 μg/mL). These findings argued against a pharmacokinetic basis for the interaction and, instead, suggested a pharmacodynamic mechanism for the elevation in INR.[15]

Five randomized trials have been performed to evaluate the effect of acetaminophen on INR in patients treated with warfarin (Table 1). Four of the 5 studies were positive. The one negative study, published in 1969, randomized 20 patients with stable prothrombin times to 2 doses of acetaminophen 650 mg or matching placebo given at 8 am and 12 noon. Prothrombin times were measured at 8 am, 10 am, 12 noon, 2 pm, and 4 pm on the day of study drug administration, and at 8 am on the following 2 days. This study found no significant difference in prothrombin times between acetaminophen and placebo during the 48-hour period after study drug administration. This study demonstrated either no effect or no measurable effect of low-dose acetaminophen given for a very short duration.[16]

In 2004, Mahé et al randomized 11 stable warfarin patients to 4 grams per day of acetaminophen or placebo for 14 days.[18] This was a prospective, double-blind, placebo-controlled trial. The mean observed INR was significantly increased after 4 days and throughout the study period in the acetaminophen group, whereas no differences were observed in the placebo group ($P = .001$, Table 1).[17] In a follow-up study 2 years later, the authors conducted a double-blind, placebo-controlled, randomized, crossover study in 20 patients with stable INR. Participants were randomized to receive placebo or acetaminophen 1 g 4 times daily for 14 days. INR and clotting factor activities were measured before the first drug administration and then on days 2, 4, 7, 9, 11, and 14. The authors demonstrated that the mean INR rose rapidly after the start of acetaminophen and was significantly increased after 1 week of acetaminophen intake compared with placebo ($P = .0002$). Significant reductions in the vitamin K-dependent clotting factors II, VII, IX, and X accompanied this increase in INR.[18]

In 2007, Parra et al performed another randomized, double-blind, placebo-controlled trial testing the effect of different doses of acetaminophen versus placebo on INR in patients stabilized on warfarin.[19] Patients received acetaminophen 2 g/day (n = 12) or 4 g/day (n = 12) or matching placebo 4 times/day (n = 12) for 4 weeks. More than 50% of the patients receiving acetaminophen exceeded the upper limit of the therapeutic INR range compared with 17% in the placebo group. At week 4, no differences were observed in alanine aminotransferase and aspartate aminotransferase between either of the acetaminophen groups or placebo. Patients receiving 4 g/day had significantly higher alanine aminotransferase at week 2 compared with placebo, suggesting a modest and temporary hepatic effect associated with the higher dose of acetaminophen. In more than 80% of the patients who developed an elevated INR and did not have their dose adjusted, the INR returned to normal when acetaminophen was stopped.[19]

Finally and more recently, the largest trial to date randomized 45 patients to one of 3 arms: acetaminophen 2 g/day, acetaminophen 3 g/day, and placebo for 10 consecutive days. Both doses of acetaminophen were associated with an increase in INR compared with placebo. The maximum INR increase was independently associated with a decrease in factor II ($P < .001$) and factor VII ($P < .001$) activities with an increase in acetaminophen plasma concentrations ($P < .001$).[20]

Biologic plausibility and mechanistic insights

A number of investigators have performed carefully designed experiments to evaluate the possibility that acetaminophen and/or its metabolites affect warfarin pharmacokinetics. Given that warfarin is a racemic mixture of R- and S-enantiomers with substantially differing pharmacokinetics and potency, these investigations have examined both enantiomers and have been adequately powered to exclude any major interactions. Given the lack of evidence for a pharmacokinetic interaction, a pharmacodynamic mechanism was hypothesized.[21] The concept that acetaminophen might interact with warfarin by potentiating its inhibition of components of the vitamin K cycle was initially raised by Thijssen et al.[22] These investigators drew attention to the recent finding that acetaminophen overdose had been associated with elevation of INR and diminution of vitamin K-dependent factors VII and IX levels (and not factor VIIIc) in the absence of other indices of acetaminophen-induced hepatotoxicity as evidence that acetaminophen and/or its metabolites might inhibit vitamin K function.[23]

These investigators therefore evaluated the effects of acetaminophen and its metabolite N-acetyl-p-benzoquinone-imine (NAPQ1) on the activity of 2 key enzymes of the vitamin K cycle, vitamin K-dependent carboxylase and vitamin K-epoxide reductase (VKOR), in washed microsomal preparations. Acetaminophen did not affect activities of either enzyme. However, NAPQI oxidized vitamin K-hydroquinone (KH2), the "active" form of the vitamin. In addition, NAPQI directly inhibited vitamin K-dependent carboxylation. Furthermore, VKOR activity was inhibited by NAPQI. Therefore, NAPQI disrupted the vitamin K cycle, potentially at 3 sites. Although the potency of NAPQI as an inhibitor at any one point of the cycle appeared limited, the interactions are important as they may be synergistic and dependent on localized intracellular increases in concentrations of NAPQI under certain circumstances.

Implications of variable production of NAPQI with therapeutic acetaminophen ingestion

The production of NAPQI as a toxic metabolite of acetaminophen has received considerable scientific attention in the context of acetaminophen overdose. NAPQI production reflects largely or entirely metabolism of acetaminophen by cytochrome P4502E1 (CYP2E1) with substantially increased generation of CYP2E1 occurring during overdose.[24-26] Furthermore, there is considerable evidence that NAPQI depletes tissue sulfhydryls, including glutathione, and is covalently protein-bound.[27]

A number of metabolic pathways for acetaminophen have been delineated, including conjugation with glucuronic acid and subsequent elimination of the nontoxic conjugate. NAPQI generation, catalyzed by CYP2E1 in the presence of nicotinamide adenine dinucleotide phosphate (NADPH), does not inevitably lead to its accumulation, given that NAPQI can be rapidly cleared by conjugation with glutathione. The potential for NAPQI accumulation and toxicity therefore results from induction of CYP2E1 and/or depletion of glutathione. It is important to emphasize that variable generation of NAPQI reflects not only tissue acetaminophen concentrate but also induction of CYP2E1. Acetaminophen itself increases expression of CYP2E1, and this may occur with subtoxic doses of acetaminophen.[28,29] Other factors that may potentially induce CYP2E1 include ethanol and diabetes mellitus/hyperglycemia.[30,31] Other sources of variability in CYP2E1 activity include the Dra I polymorphism of the CYP2E1 gene, which may potentiate activity of CYP2E1 in response to inducing agents, and the inhibitory effect of nitric oxide (Figure 1).[31,32]

The effects of NAPQI in inactivating vitamin K-dependent γ-carboxylase and VKOR are not its only enzymatic interactions. NAPQI may also inhibit components of the mitochondrial electron transport chain.[33] However, detailed evaluation of the full extent of direct toxic effects of NAPQI has been limited to date.

Potential downstream effectors of CYP2E1 activation/NAPQI production by acetaminophen

The potential ramifications of CYP2E1 activation and NAPQI production on the vitamin K cycle are extensive and include: (1) inactivation of VKOR via oxidation of essential cysteine moieties, (2) impairment of reductive reactivation of VKOR, and (3) impairment of VKOR-supported activation of vitamin K γ-carboxylase. It is probable that, although the extent of CYP2E1 activation is critical to impairment of the vitamin K cycle in the presence of acetaminophen, NAPQI is not the

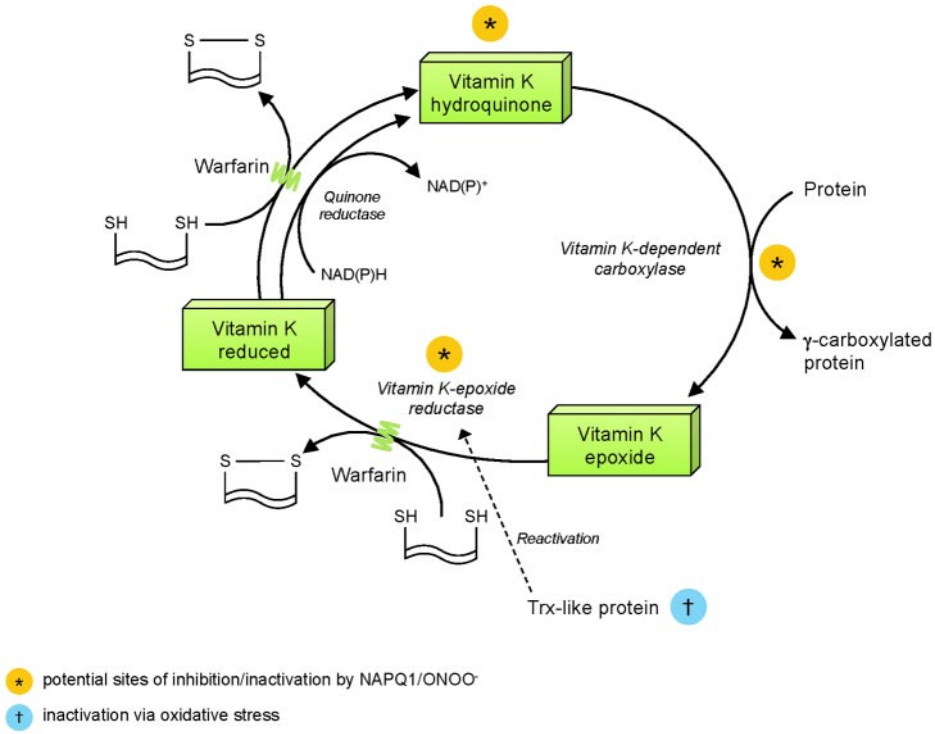

Figure 2. Points of potential disruption of vitamin K cycle and potentiation of warfarin effect by NAPQ1 and ONOO⁻. NAD(P)H indicates reduced nicotinamide adenine dinucleotide phosphate; NAD(P)⁺, oxidized nicotinamide adenine dinucleotide phosphate; ONOO⁻, peroxynitrite; and SH, sulfhydryl group.

only effector of the extensive oxidative changes that underlie this impairment. One such potential effector is peroxynitrite, a reactive species produced via the reaction of superoxide anion with nitric oxide. There is an extensive literature suggesting that peroxynitrite modulates the development of acetaminophen hepatotoxicity.[34] Release of reactive oxygen species via CYP2E1 activation has been shown to deplete sulfhydryl sources, such as reduced glutathione in mitochondria and endoplasmic reticulum.[30] Similarly, there is some evidence that scavenging of peroxynitrite may limit the cytotoxic effects of acetaminophen.[35]

The impact of CYP2E1 up-regulation is also potentially modified in other ways. The role of nitric oxide is particularly complex, as nitric oxide is both involved in peroxynitrite formation as well as, apparently, via its activation of soluble guanylate cyclase, able to limit CYP2E1-related toxicity by limiting its expression.[31,36] There is also considerable evidence that the transcription factor Nrf2, which controls antioxidant defense in part via increased glutathione synthesis, limits CYP2E1 toxicity.[37]

The activity of VKOR, vital to the integrity of the vitamin K cycle, is physiologically inhibited by oxidation of key cysteine moieties.[38,39] Thus, any form of oxidative stress, via NAPQI, peroxynitrite, or both, could inactivate VKOR, as originally demonstrated by Thijssen et al.[22] Indeed, depletion of glutathione and other sulfhydryl molecules is a common modality of peroxynitrite toxicity. Equally important is the susceptibility of VKOR reactivation to oxidative stress. Although the molecules reactivating VKOR have not been identified conclusively, there is considerable evidence that they are thioredoxin-like.[39] As activity of thioredoxin is itself impaired in the presence of oxidative stress and/or via its physiologic antagonist thioredoxin-interacting protein, it seems likely, although as yet unexplored, that this represents a further site of the acetaminophen-vitamin K interaction. It has also recently been demonstrated that thioredoxin activity drives the role of VKOR in supporting vitamin K-dependent γ-carboxylation.[39] Furthermore, the activity of vitamin K-dependent carboxylase is inhibited by oxidation of sulfhydryl groups, although these lie outside the catalytic site of the molecule.[40] Therefore, the observations of Thijssen et al[22] may reflect interplay of CYP2E1 activation, NAPQI and peroxynitrite production, and thioredoxin inactivation, as outlined in Figure 2.

General recommendations

The requisite features of causality exist for a warfarin/acetaminophen interaction: temporal relationship, measurable effect with dechallenge and rechallenge, dose-response, exclusion or accounting of other possible etiologic factors, and biologic plausibility. The strength of our clinical practice recommendations is low because, although the evidence of an important warfarin/acetaminophen interaction that results in INR variation is strong, there are no prospective management studies to indicate that the recommendations we make would reduce patient-important events, such as major bleeding or thrombosis.

In warfarin-treated patients who will use more than or equal to 2 g/day of acetaminophen for at least 3 consecutive days, we suggest that the INR should be tested 3 to 5 days after the first acetaminophen dose (grade 2C). In warfarin-treated patients with otherwise unexplained INR variability, acetaminophen use should be considered as a possible contributing factor (grade 2C).

On a wider scale, acetaminophen may disrupt, not only the production of the vitamin K-dependent proteins of the coagulation cascade, but all vitamin K-dependent proteins, such as those that normally function as inhibitors of calcification and modulate signal transduction and cell growth. Evaluation of long-term effects of acetaminophen ingestion with these changes in mind seems appropriate.

Patient Report

A 16-year-old adolescent male presented to his primary care physician with a low-grade fever and symptoms consistent with an upper respiratory tract infection. Over the next 3 months, he received 2 courses of azithromycin and albuterol. His cough never resolved, and he developed worsening dyspnea on exertion. He was finally admitted to an outside hospital, where a chest X ray revealed bilateral pleural effusions and an enlarged heart. Pleural and pericardial effusions were confirmed on CT.

His dyspnea on exertion and radiological findings prompted the placement of bilateral chest tubes followed by mechanical ventilation for 5 days. After an echocardiogram, a pericardiocentesis without concurrent cardiac catheterization drained 127 mL of fluid. No active bacterial, fungal, or viral infections were found. He was also treated with stress-dose steroids. He was transferred to Johns Hopkins Hospital with massive pleural fluid output of 3 to 5 L per day.

His past medical history was significant for ADHD, gastroesophageal reflux disease, milk protein allergy, and allergic colitis as an infant. He had been diagnosed with constitutional growth delay with, his height and weight were below the fifth percentile. His family history and social history were unremarkable.

On physical exam, he appeared fatigued and had an increased work of breathing. His respiratory rate was 23 breaths per minute with a room air oxygen saturation of 100%. His heart rate was 125 bpm, with a normal blood pressure. The lower lung breath sounds were decreased bilaterally. Jugular venous distention was not visible. He had a quiet precordium with a normal heart exam but for tachycardia. His abdomen was distended and demonstrated shifting dullness. He had no lower-extremity or sacral edema.

Pleural fluid studies revealed a pleural fluid-to-serum LDH (Lactate dehydrogenase) ratio of less than 0.6, fulfilling Light's criteria characteristic of transudate.[1] LDH was 124 U/L, less than two thirds the upper limit of normal. The pleural fluid-to-serum protein level was just greater than 0.5 at the outside hospital but was less than 0.5 at Johns Hopkins. Laboratory studies at the outside hospital and at Johns Hopkins were remarkable for a negative infectious disease workup and no signs of rheumatological disease or oncological disease. His liver function tests were abnormal on admission (Table 1).

An ECG, an echocardiogram, a thoracic and abdominal CT, and an abdominal ultrasound revealed a low-voltage QRS, a small pericardial effusion, bilateral areas of consolidation in the left and right lower lobes, large amounts of ascites, and patent hepatic vasculature with normal liver echotexture. A trial of stress-dose steroids did not improve his symptoms as 3 to 5 L/d of pleural fluid continued to drain from his chest tubes daily.

A follow-up echocardiogram 1 week later revealed impaired diastolic dysfunction, which led to a right and left heart catheterization with pressures consistent with constrictive pericarditis. A retrospective review of the first echocardiogram showed an increased diastolic inflow velocity E' by tissue Doppler and a diastolic septal bounce consistent with diastolic dysfunction and constrictive pericarditis. A right and left heart catheterization showed elevated end-diastolic pressures.

The diagnosis was effusive-constrictive pericarditis

Hospital Course

An uncomplicated pericardiotomy was performed. The procedure revealed chronically inflamed, fibrotic, and thickened parietal and visceral pericardial layers bridged by synechiae. Once the thick peel of visceral pericardium was incised, the freed right ventricle immediately bulged. At the end of the pericardiectomy, only the parietal pericardium on the diaphragmatic surface and posterior to the phrenic nerves was left. The patient's cardiac index as well as the central venous, pulmonary artery, and wedge pressures improved (Table 2). Pathological testing ruled

out an infectious etiology of the pericarditis. Both chest tubes were removed successfully 12 days later. The patient returned to his premorbid state 3 months after surgery.

Commentary

We describe a 16-year-old adolescent who presented with extensive third-space effusions and dramatic chest tube output attributable to effusive-constrictive pericarditis. Constrictive pericarditis is characterized by the persistence of elevated right atrial pressures after removal of pericardial fluid.[2] It is rare in children[3] and adults[4] and can remain unsuspected until autopsy. In our patient, pericarditis of unknown etiology developed chronically. In the absence of neoplastic processes, most cases of pericarditis are idiopathic in adults.[5]

The inflammatory pericardial effusion and the constriction as a result of diseased pericardium led to an impaired myocardial relaxation and diastolic dysfunction. The poor filling capability resulted in a decreased cardiac output with compensatory tachycardia. As a consequence of this gradual process, heart failure led to ascites, massive pleural effusions, and congestive hepatopathy.

Although it is a rare entity, of effusive-constrictive pericarditis since a visceral pericardiectomy is indicated, which is much more complex than a parietal pericardiectomy. However, drainage of the pericardial fluid or removal of only the parietal pericardium is ineffective when a visceral pericardial constriction is present.[2]

The diagnostic accuracy of conventional flow Doppler is poor in the case of constrictive processes.[4] Tissue Doppler imaging (TDI) is a novel, noninvasive technique for the assessment of cardiac function by myocardial tissue velocity and deformation rather than blood flow.[6] In contrast to flow Doppler, it allows us to distinguish constrictive physiology caused by pericardial pathology from restrictive physiology of diseased myocardium. Constrictive physiology impairing ventricular relaxation results in higher TDI e' waves at the septal in comparison to the lateral mitral ring respiratory septal motion shift as well. Current guidelines recommend TDI studies to diagnose diastolic dysfunction.[6] In our case, the detection of diastolic dysfunction by TDI ultimately led to the correct diagnosis of constrictive pericarditis.

The diagnosis of this treatable disease will be delayed if one fails to consider that a constrictive process can present concurrently with a tense effusion. Effusive-constrictive pericarditis should be included in the differential diagnosis of breathlessness in constellation with pleural effusions, pericardial effusions, and/or ascites, and should be investigated by TDI. Right- and left-cardiac catheterization during pericardiocentesis is still the diagnostic gold standard. However, characteristic TDI wave patterns can identify constrictive physiology and could render purely diagnostic cardiac catheterization redundant.

After pericardiocentesis, intrapericardial pressures decrease in patients with effusive-constrictive pericarditis, but their right atrial and right- and left-ventricular end-diastolic pressures remain elevated, although slightly reduced. This is known as dip-plateau morphology.

Conclusion

The clinical manifestations of effusive-constrictive pericarditis may be extracardial. Transudative pleural effusions should prompt an evaluation for cardiac diastolic dysfunction among other entities. For the detection of diastolic function, TDI can be an invaluable, noninvasive diagnostic tool and can distinguish restrictive

patterns from constrictive ones. Finally, effusive-constrictive pericarditis is an elusive diagnosis if pericardiocentesis occurs without concurrent heart catheterization. Consider effusive-constrictive pericarditis in patients without symptom resolution after pericardiocentesis.

(*Received 24 June 2010; final version received 29 November 2010*)

The 2004 terror attack on a school in Beslan, North Caucasus, with more than 1300 children and their families taken hostage and 334 people killed, ended after extreme violence. Following the disaster, many survivors with blast ear injuries developed complications because no microsurgery services were available in the region. Here, we present our strategies in North Ossetia to strengthen subspecialty surgical care in a region of instable security conditions.

Disaster modifies disease burden in an environment of conflict-related health-care limitations. We built on available secondary care and partnered international with local stakeholders to reach and treat victims of a humanitarian disaster. A strategy of mutual commitment resulted in treatment of all consenting Beslan victims with blast trauma sequelae and of non disaster-related patients.

Credible, sustained partnerships and needs assessments beyond the immediate phases after a disaster are essential to facilitate a meaningful transition from humanitarian aid to capacity building exceeding existing insufficient standards. Psychosocial impacts of disaster might constitute a barrier to care and need to be assessed when responding to the burden of surgical disease in conflict or post-conflict settings. Involving local citizen groups in the planning process can be useful to identify and access vulnerable populations. Integration of our strategy into broader efforts might strengthen the local health system through management and leadership.

Keywords: burden of surgical disease; post-conflict; capacity building; North Caucasus; Beslan

Background

The North Caucasus remains a region of frequent human rights violations and resurging violence from armed opposition groups (Lunze 2009). The recent conflict over South Ossetia and ongoing attacks from militant groups in Chechnya, Ingushetia and Dagestan illustrate its political instability. Most non-governmental organisations (NGOs) have withdrawn due to security concerns. Health systems in the region, economically most disadvantaged within the Russian Federation, are weakened from past conflicts; while they provide primary care, they lack the capacity for specialised services.

On 1 September 2004, a group of terrorists attacked a school in Beslan, a small town with a population of 30,000, situated in the Republic of North Ossetia-Alania

(an autonomous republic that is a part of the Russian Federation and neighbours Chechnya). In Russia, 1 September is traditionally the first day of school after summer vacation, when pupils together with their families gather in schools to celebrate. At the Beslan school, the terrorist group took more than 1300 children and their families hostage. After 3 days of what is now considered one of the worst massacres on a civilian population in Europe in recent history (Moscardino *et al*. 2010), Russian security forces stormed the building and ended the siege with the use of heavy artillery. The incident left 334 victims dead and many more injured. During the final storm, indoor bomb explosions in the gymnasium caused blast injuries in numerous survivors. Among survivors, traumatic ear defects are the most common blast injury (DePalma *et al*. 2005), which are amenable to relatively straightforward treatment but require subspecialty management (Wolf *et al*. 2009).

In peripheral regions of the Russian Federation, patients requiring services beyond local capacity are referred to central institutions following a quota system which provides a limited number of grants for specialized services (WHO 2005). While initially complex traumatic injuries resulting from the Beslan terror act had been addressed in North Ossetian hospitals or at major centres elsewhere within the Russian Federation (Schreeb *et al*. 2004), several years later many victims had still not received comprehensive medical care beyond the acute immediate response. Traumatic blast ear defects resulting from bomb explosions need to be assessed promptly after the incident. Delays in treatment are associated with further damages (Wolf *et al*. 2009), which may require extensive microsurgical reconstruction and expertise typically found only at major developed medical centres.

Two years after the disaster, clinicians at the Vladikavkaz Children's Hospital in the capital of North Ossetia-Alania observed an increased burden of post-traumatic middle ear injury. Tympanic lesions left untreated caused different pathological reactions in the mucosal and bony structures of the middle ear, requiring extensive microsurgical reconstruction procedures to limit destructive processes. In some cases middle ear prostheses were needed in order to guarantee an effective conduction of acoustic waves in the tympanon, to attempt an improvement in hearing or to prevent further hearing loss. No surgical capacity was available in or near North Ossetia to perform the necessary microsurgery for these patients.

Following an appeal from the Vladikavkaz Children's Hospital directed at the last author of this article, who trained there, she procured an ear-nose-throat (ENT) operation microscope and shipped it to Vladikavkaz Children's Hospital. Due to lack of local surgical subspecialty expertise, this was insufficient to meet the Beslan victims' needs. Health facilities in North Ossetia are outdated and poorly equipped. Personnel are skilled in general surgical services, but lack training and dedicated equipment for microsurgical procedures; and available services are poorly coordinated due to insufficiencies in management and leadership in the health sector.

Methods

The two authors initially arranged for consultation and treatment in Germany for patients from the Caucasus region with complex middle ear injuries. However, this approach soon proved unaffordable and unsustainable due to high transport and medical care costs. Most importantly, treatment abroad did not address the unavailability of microsurgical services in the North Caucasus. The two authors

therefore partnered with two ENT surgeons skilled in otologic operation techniques (Professor Thomas Eichhorn, Cottbus, and Dr Christian Offergeld, Freiburg; both in Germany), the Vladikavkaz Children's Hospital, the North Ossetian Ministry of Health, and local citizen groups in order to reassess the situation 2 years after the terror act and to formulate the following objectives, plans and strategies:

(1) Partner local government authorities, hospital faculty and staff and academic institutions as well as citizen groups, to identify and address the immediate need for surgical ENT treatment for Beslan victims and to offer them comprehensive treatment.
(2) Explore management and leadership challenges that led to the current gap.
(3) Create capacity by appropriately equipping and training surgeons from the region in microsurgical techniques with the long-term goal to establish comprehensive subspecialty services in the region.

Building on available structures, from the initial phase on, tasks such as strategic and administrative procedures, access to patients, patient care and follow-up activities were equally shared between international and local health professionals. This common approach allowed for clarifying goals and expectations, and identified opportunities for management and leadership improvement. It also helped ease procedural hurdles such as necessary formalities, accreditations and required permits, and allowed us to operate freely in a highly politicised environment where security concerns limit the operability of many organisations. In order to assess the local context from a supply and demand perspective, we conducted an assessment of local resources, infrastructure and surgical needs. Medical faculty and citizen groups in North Ossetia delivered the necessary data.

Results

While dedicated operation room capacity including anesthesia and basic surgical supplies existed and surgical care is established in North Ossetia, there was an almost complete lack of supplies and equipment for specialised surgery and microsurgery (see Table 1). Following the determination and coordination of available resources in

Table 1. Available and needed resources for specialised surgery at the Children's Hospital Vladikavkaz, North Ossetia-Alania.

Available resources	Local needs
Anesthesia machines and gas supplies	Operation microscope (with observer tube for teaching purposes), sterile covers and replacement lamps
Sterilising equipment	Electrocouter with ground plates and cables
Surgical gowns, caps, masks, gloves and drapes	Complete sets of dedicated instruments for ENT microsurgery
Elastic bandages, swabs and dressings	Microsurgical scalpel blades
Normal saline and Ringer's solutions	Absorbable haemostatic sponges
Needles, syringes	Dedicated suture material
Catecholamines	Dedicated drainage catheters
Antibiotics	
Disinfectants	

North Ossetia, we procured further specialised supplies and equipment for microsurgery to complement existing material. To incorporate best surgical practices into local care, one of the ENT specialists (Professor Thomas Eichhorn) at his institution in Germany trained a North Ossetian surgeon (Dr Zemfira Tsorieva) in microsurgical skills, who became competent to identify suitable patients, coordinated paediatric and adult surgical as well as anaesthesiologic services available in North Ossetia and ensured follow-up of patients in the post-operative phase.

Victims were identified and characterised using data from medical faculty and citizen groups in North Ossetia, as well as international academic and WHO sources (Schreeb *et al*. 2004). This assessment of specialised surgical needs yielded 19 patients with complex ear pathologies (see Table 2). Since many victims were mentally traumatised (Parfitt 2004), we consulted with the victims' representatives and human rights groups to assist medical staff at the Children's Hospital Vladikavkaz in accessing eligible patients. As a result, 10 identified victims were evaluated for surgical interventions by locally trained staff, who also obtained written informed consent from 14 eligible patients (six of whom were victims of the Beslan disaster), provided preoperative care and planned for operation room capacities.

We were confronted with four victims for whom surgical treatment was indicated but who refused treatments for psychosocial reasons, consistent with similar accounts from citizen groups. We were unable to further characterise the psychosocial burden and mental disease among the Beslan victims or to quantify the number of victims who declined treatment for those reasons.

The Children's Hospital Vladikavkaz provided operation room management, anesthesia staff and equipment as well as nursing staff for both adult and paediatric patients. Our team, including international volunteers and local surgeons, performed and documented, in total, 15 comprehensive microsurgical operations mainly for complex middle ear pathologies, including one additional non-elective emergency procedure, without intra- or post-operative complications (see Table 3). During the operations, local adult and paediatric surgeons from the area were instructed in microsurgery techniques.

All patients received care at no cost to them and without informal payments. During our activities in North Ossetia, we operated unhindered, with support from the North Ossetian health minister and assisted by one of his staff members. Two German journalists video-documented our activities and reported on the reactions of the local population without restrictions.

Table 2. Needs assessment of patient recruitment for specialised otological care after the Beslan disaster.

	Number
Hostages held at school in Beslan	1355
Hostages killed	334
Victims hospitalised	661
Victims requiring intensive care	110
Victims initially identified with post-traumatic ear disease	140
Victims identified with post-traumatic chronic middle ear otitis after two years	19
Victims identified with indication for specialised surgery	6

Table 3. Patient characteristics, diagnoses and interventions at the Children's Hospital Vladikavkaz, North Ossetia-Alania.

Patient characteristics	
Median age (range)	15 years (1.5 months–44 years)
Gender	5 females
	10 males
Diagnoses	10 cases of post-traumatic tympanic perforation
	Four cases of chronic otitis media
	One case of acute mastoiditis
Interventions	Thirteen tympanoplasties (including six with reconstruction of ossicular chain, two with adenotomy, one with ossicular prosthesis, and one with ossicular prosthesis and mastoidectomy)
	One tympanic tube insertion
	One emergency mastoidectomy

Management and leadership opportunities were identified as the need for improvement in coordination of health services and their availability to vulnerable populations; for mobilisation of current human resource potential by training existing faculty and junior health professionals; as well as for extension of microsurgery capacities to other surgical specialties (e.g., ophthalmology) and outreach to neighbouring post-conflict regions, such as South Ossetia, Chechnya and Ingushetia.

Discussion

This partnership to address the burden of surgical disease in the North Caucasus region resulted from an act of violence and a humanitarian disaster. In conflict and post-conflict situations, the most vulnerable populations are most difficult to reach. Partnering international volunteers with a variety of local stakeholders and involving citizen groups, such as victims' representatives and human rights organisations, lent credibility to reaching out to victims of the Beslan disaster and treating all eligible consenting individuals with sequelae of blast injuries resulting from insufficient subspecialty services. Key stakeholders were the health ministry, which oversees all health-care related activities, and the medical academy, which bundles all medical training and postgraduate medical education.

Local clinicians instructed during this collaboration continue to provide subspecialty patient care and train other providers in peripheral facilities. Most importantly – based on process evaluations and clinical outcomes – they will shape future training activities, as effective capacity building in the surgical specialties will require a strong commitment to education (Lancet Editorial 2010). Thus, the conjoint strategy started to address the local burden of surgical disease by strengthening subspecialty services for the region. Adequate, sustainable secondary level care, not only in acute emergency responses but also in longer-term post-conflict contexts and adapted to local needs, is fundamental for effective health systems, but often overlooked (Campbell and Doull 2010).

Our concerted approach, built on outdated but existing structures of secondary care, involved local resources from the beginning. Middle-income countries such

as those in the former Soviet Union or South America offer particular opportunities to address surgical burden beyond general surgery. Unlike in most low-income countries, where appropriate anesthesia services are severely limited (Hodges *et al*. 2007), we could rely on effective anesthesia capacity in North Ossetia.

Our needs assessment found poor infrastructure, inadequate equipment and supplies, and health professionals – albeit sufficient in number – who were inadequately trained. These factors represent typical barriers to appropriate and effective delivery of surgical services (Spiegel and Gosselin 2007). Our findings are consistent with systematic surveys suggesting that strengthening of infrastructure, supplies and procedures in low- and midle-income countries is urgently needed (Kushner *et al*. 2010). Substandard facilities threaten patients' outcomes (Lancet Editorial 2010), and effective, safe surgery is no luxury for midle-income countries: although this has not yet been studied for subspeciality services, there is increasing evidence that the cost-effectiveness ratio of surgical services might compare favourably with selected primary health interventions (Debas *et al*. 2006).

An evaluation conducted immediately after the Beslan disaster concluded that early post-trauma emergency care for victims was appropriately handled by local and national health resources, whereas international assistance – that unlike in other emergencies the authorities of the Russian Federation had requested – was deemed excessive, inappropriate and largely ignoring local needs (Schreeb *et al*. 2004). Our own assessment years after the disaster found a disease burden which was the result of insufficient subspecialty services.

We therefore advocate for periodical, reliable data collection beyond the short- and mid-term phases after a disaster, particularly once international attention and media coverage have faded, to reveal how both needs and available resources develop over time and in changing political environments, and to facilitate a meaningful transition from necessary humanitarian aid to appropriate partnerships for development.

Rather than reflecting the mere availability of services, meaningful needs assessments have to distinguish whether conflicts increase or modify disease burden, and whether they limit the availability of or access to health services (Lunze 2009, Kushner *et al*. 2010). We believe that the Beslan disaster led not only to an increase in the disease burden as we describe it, but also to impaired victims' care seeking for mental health reasons.

During the terror act in Beslan, victims had to endure extreme violence for several days under inhumane conditions. The resulting psychological trauma is considered a quaternary pattern of injury (Wolf *et al*. 2009). Although national and international organisations responded early to mental trauma with psychosocial counselling and rehabilitation (Parfitt 2004, UNICEF 2004), we suspect post-traumatic stress disorder to substantially impair victims access to treatment even years after the trauma. However, our planning focused on the delivery of surgical care rather than addressing potential barriers to accessing this care. Investigating and addressing mental health effects of terrorism and violence is immensely difficult in the complex and chaotic setting during and after disasters (North and Pfefferbaum 2002). Although it would have been relevant, we did not have the capacity nor did we attempt to measure to what extent psychosocial impacts and mental trauma affected patients' access to elective, subspecialised surgical services.

On the basis of our needs assessment, we had planned operations for 19 identified patients with ear complications. In fact, only a minority of six Beslan victims

consented to an operation. The majority of patients were operated on for advanced pathologies less commonly encountered in effective health systems, which were not conflict-related. Even assuming that some families raised sufficient funds to access care elsewhere, we believe that a number of disaster victims did not reach our services due to psychosocial barriers. We consider the negative impact of terror on survivors' mental health, mediated even after years by daily stressors of a post-conflict society with ongoing violence (Miller and Rasmussen 2010), to have impaired our recruitment of this vulnerable patient population for surgical treatment.

Several studies investigating mental health in Beslan victims confirmed our anecdotal observations that the terror attack persistently impaired the psychological well-being of victims as well as of their families and caregivers (Scrimin *et al*. 2006, Moscardino *et al*. 2008). Regardless of being directly or indirectly exposed, the disaster influenced the reorganisation of family life and the disruption of community ties (Moscardino *et al*. 2010). Cultural values and gender differences factor into victims' coping strategies and are inherently complex in this society, where deeply rooted traditions shape everyday life (Moscardino *et al*. 2007).

Therefore, assessment of mental health effects, neglected during our own planning, should be part of programming efforts when responding to the burden of surgical disease, particularly in conflict or post-conflict settings. This could be done in collaboration with groups or organisations with expertise in post-conflict psychosocial health who have an established relation with the population. Involving human rights groups in the planning process, albeit a delicate step, can assist in identifying and accessing these populations, to which international organisations have less access, for security and various other reasons.

Limitations

Adequate funding is a crucial requirement to transition the response to the global burden of surgical disease from – in many cases – helpful short-term volunteer surgical missions to sustainable and more meaningful efforts (Farmer and Kim 2008, Farmer 2010). Given the current working conditions for NGOs in the Russian Federation, in spite of uniting a whole variety of stakeholders, we deliberately chose to act as members of civil society and not as an organisation, in order to safeguard our own security and minimise risks for the organisations we worked with. This has severely limited our ability to seek funding, which is difficult to obtain for a region with a volatile security situation and travel restrictions for foreign personnel.

More long-term efforts than our interventions are required to ensure ongoing appropriate surgical care delivery at international standards. To achieve proficiency in specialised techniques such as otologic operations usually takes several years of postgraduate training at a dedicated institution. While this is hardly feasible in a middle-income country, training health personnel abroad carries the risk of brain drain through those who are not willing or able to return to their home country.

Conclusions

We identified a number of strategies that we believe might be helpful when planning capacity building for surgical care in post-conflict settings:

(1) Building on available secondary care in midle-income countries can address the post-conflict burden of surgical disease beyond general surgery.
(2) Partnering international with local stakeholders, including citizen groups, can create credible partnerships to access vulnerable populations in politicised environments.
(3) Needs assessments beyond the short- and mid-term phases after a disaster are essential to facilitate a meaningful transition from humanitarian aid to partnerships for development.
(4) Psychosocial impacts might affect both needs and care seeking and should be assessed as part of a comprehensive approach when responding to the burden of surgical disease in conflict or post-conflict settings.
(5) Health-care delivery planning will have to accommodate a case mix that will not only include conflict-related burdens, but also advanced and natural course pathologies resulting from health systems insufficiencies.

Given how rapidly post-conflict situations change, these strategies will have to be adapted over time and place to given – and changing – needs, political and security circumstances. Short-term surgical missions focusing on a limited range of pathologies have a recognised value and have made substantial contributions to many of the disadvantaged in this world (Farmer and Kim 2008). In a public health framework, humanitarian operations and skills training have been considered selective preventive interventions of political violence at the level of society at large (De Jong 2010). However, sustainable change requires sustained investments of time and resources beyond an initially vertical mission and critical analysis, in order to create the conditions that incentivise current health professionals to continue working in and developing their professional environment. We see a true value of our strategies in the ongoing commitment to our partnership, which now aims at integrating the important pillar of high-quality surgical care delivery into broader efforts of strengthening the local health system through management and leadership.

Using highly variable warfarin dosing to identify patients at risk for adverse events

Lyndonna Marrast[1], Mary Evans[1], Al Ozonoff[2], Lori E Henault[1] and Adam J Rose[3,1*]

Abstract

Background: Patients who receive highly variable doses of warfarin may be at risk for poor anticoagulation control and adverse events. However, we lack a system to identify patients with the highest dose variability. Our objectives were to develop a scoring system to identify patients with high dose variability, and to validate this new measure by demonstrating that patients so identified have poor anticoagulation control and higher rates of adverse events (criterion validity).

Methods: We used a database of over 4, 000 patients who received oral anticoagulation in community practice between 2000-2002. We reviewed the charts of 168 patients with large warfarin dose variation and agreed on 18 risk factor definitions for high dose variability. We identified 109 patients with the highest dose variability (cases), as measured by coefficient of variation (CoV, SD/mean). We matched each case to two controls with low dose variability. Then, we examined all 327 charts, blinded to case/control status, to identify the presence or absence of the 18 risk factors for dose variability. We performed a multivariable analysis to identify independent predictors of high CoV. We also compared anticoagulation control, as measured by percent time in therapeutic range (TTR), and rates of adverse events between groups.

Results: CoV corresponded with other measures of anticoagulation control. TTR was 53% among cases and 79% among controls ($p < 0.001$). CoV also predicted adverse events. Six cases experienced a major hemorrhage versus 1 control ($p < 0.001$) and 3 cases had a thromboembolic event versus 0 control patients ($p = 0.04$). Independent predictors of high dose variability included hospitalization (OR = 21.3), decreased oral intake (OR = 12.2), use of systemic steroids (OR = 6.1), acetaminophen (OR = 4.0) and antibiotics (OR = 2.7; $p < 0.05$ for all).

Conclusion: CoV can be used to identify patients at risk for poor anticoagulation control and adverse events. This new measure has the potential to identify patients at high risk before they suffer adverse events.

Keywords: anticoagulants, dose variability, medication therapy management, risk factors, warfarin.

Background

Warfarin is the standard anticoagulation treatment for atrial fibrillation, venous thromboembolism (VTE), and mechanical heart valves [1-4]. Close monitoring of the International Normalized Ratio (INR) is required due to the drug's very narrow therapeutic window. Many factors can affect INR levels [1,5,6]. Values must be kept within range to reduce the risk of hemorrhage [7,8] and the risk of developing thromboembolism [9]. Previous studies have shown that patients experiencing better anticoagulation control have fewer such adverse events [10-14].

Assessment of adequate anticoagulation control has traditionally been determined by examining INR values themselves, through summary statistics such as percent time in therapeutic range (TTR) [15] or INR variability [16,17]. Several studies have explored the patient-level predictors of control as measured by TTR [10,18,19]. However, there is reason to believe that variability in warfarin doses could also serve to identify patients who are experiencing poorly controlled anticoagulation, thus placing them at risk for adverse events.

We therefore used a large, nationally representative database of community-based oral anticoagulation care

to address three related questions. First, we sought to develop a measure of warfarin dose variability that could be used to describe a population and identify patients with highly variable doses over time. Second, we sought to internally validate this new dose variability score as a measure of anticoagulation control using criterion validity. That is, we sought to demonstrate that patients identified as having high dose variability have worse anticoagulation control as measured by TTR and are at higher risk for adverse events than patients with less variability. Finally, through chart review, we sought to identify patient-level predictors of high dose variability. Our overarching goal was to develop a score that could be used to identify patients at high risk for complications.

Methods

Database

The Anticoagulation Consortium to Improve Outcomes Nationally (ACTION) study was a large prospective cohort study designed to assess the management of warfarin in community practice within the US [19-21]. A total of 101 participating sites in 31 states recruited 6761 patients receiving long-term oral anticoagulation. All sites used a freely-available software package called CoumaCare for tasks such as patient tracking and recording clinical data. In the database, clinicians updated patient's weekly warfarin dose at each visit. Because the present study relied upon chart reviews, we limited this study to the 47 sites of care that recorded complete notes for at least 90% of INR values. Excluded sites recorded notes only when the INR was not therapeutic. Therefore, this study was limited to 4489 patients.

Enrollment in ACTION occurred between April 2000 and February 2002. Patients were eligible to participate if they were 18 years or older and able to provide informed consent. All data were collected and their completeness rigorously ensured by McKesson HBOC, an independent data management organization. Missing data fields and data entry errors were resolved directly with the sites by the data coordinating center on a weekly basis before the data were transmitted to study investigators. The study protocol was approved by the Western Institutional Review Board of Olympia, WA, and by local review boards where they existed.

Patients were eligible for inclusion in the present study if they had an INR target range of 2-3. Indications for anticoagulation were grouped as follows: atrial fibrillation, venous thromboembolism, valvular heart disease/prosthetic heart valve, and all others. The database included demographics (age, gender, and race) and several comorbid conditions (coronary artery disease, congestive heart failure, hypertension, diabetes) as recorded by the patients' clinicians. Weekly dose of warfarin was recorded for all patients in the database, and was updated by clinicians at each visit. We used these weekly doses to assess the stability of warfarin dose over time for each patient, as will be explained below.

Chart Reviews

We performed two separate chart reviews, in our efforts to create a score that describes patients with high warfarin dose variability. The first review was implicit; it was performed by chart reviewers without relying upon pre-established definitions. Three physician examiners (LM, ME, and AJR) independently reviewed the charts of 168 patients who had a 2-fold or greater difference between the lowest and highest weekly warfarin dose (e.g. 14 mg/week versus 28 mg/week). The concept behind the review was to remain open to the possibilities of factors that may be present in the database rather than rely solely upon preconceived ideas. Next, the reviewers met and compiled a list of 18 variables believed to have played the greatest role in the dose variability. They reached a consensus regarding a standard definition for each variable in the chart review instrument (Table 1).

We found that the criterion used to identify patients with high dose variability (i.e. twofold or greater dose range) did not capture the dose variability we had in mind. Specifically, the method identified a relatively large proportion of patients with one or two outlier doses but otherwise stable dosing. Not all of the patients identified by this score seemed to be experiencing the highly variable anticoagulation control that we were trying to capture. We therefore decided to use the coefficient of variation (CoV) to characterize warfarin dose variability. CoV is defined as the standard deviation of the weekly warfarin dose divided by the mean weekly warfarin dose.

We labeled all patients with CoV greater than 0.2 as patients with high dose variation ("cases"). There were 123 such patients, representing 2.7% of the dataset. Patients with CoV below 0.05 (1019 patients, representing 23% of the dataset) were eligible to be controls. Each case was matched to 2 controls within the same site of care. Charts were excluded if: 1) there were no controls available to match the case patients or 2) the patient was new to warfarin (less than 1 month experience as of study entry). A total of 14 cases and 12 potential controls were removed for these reasons, leaving 109 cases and 218 controls.

The reviewers then independently reviewed charts to identify the 18 variables defined in the chart review instrument. This second review was explicit in that it relied upon the variable definitions described in the instrument. During this second chart review, reviewers were blinded to whether the patient was a case or a control patient. If a factor was present at any time, we recorded this indicator as "1" (present) versus "0" (not present). Each reviewer abstracted one-third of the charts. Fifty of the charts were

Table 1 Chart Review Instrument

	Variable	Definition
1	Diet	Any mention of "greens", specific foods high in vitamin K, and dietary content of vitamin K. DOES NOT INCLUDE statements that the vitamin K content of the diet is unchanged.
2	Dietary Supplements	Any mention of multivitamins, Ensure, Boost, Slimfast, etc. as they relate to vitamin K intake. DOES NOT INCLUDE simply listing a multivitamin in the medication list.
3	Adherence	Any mention of problems with adherence to pill-taking, including unauthorized self-adjustment of doses and memory issues. DOES NOT INCLUDE dose confusion after a hospital stay and DOES NOT INCLUDE aspects of adherence (diet, lab follow up, etc.) beyond pill-taking.
4	Hospital or Nursing Home Stay	Any mention of a hospital or nursing home stay EXCEPT for CHF (because that has its own variable - see below)
5	Nausea and Vomiting	Any mention
6	Decreased PO Intake or Decreased Appetite	Any mention
7	Diarrhea	Any mention
8	Decompensated CHF	Any mention of fluid overload, fluid retention, edema, pulmonary edema. Any titration of lasix doses, trending of weight regarding fluid status, use of metolazone (i.e. zaroxolyn), or any obvious CHF regimen. Any hospital admissions for fluid overload.
9	Alcohol	Any mention of alcohol except "denies." Exception - one serving per day or less does not count
10	Amiodarone	Any mention of amiodarone or its brand names "pacerone" or "cordarone."
11	Acetaminophen	Any mention of acetaminophen, products containing acetaminophen. Includes the abbreviation "APAP."
12	NSAIDS/COX-2 Inhibitors	Any mention at all, including mention in the medication list.
13	Procedures	Any mention of a procedure in conjunction with a dose reduction or a "hold" of warfarin - even if the procedure is ultimately cancelled.
14	Cancer	Any mention of cancer, with or without specific therapies such as chemotherapy, radiation, etc. DOES NOT INCLUDE a mere history of cancer.
15	Missed Appointments	Any recorded missed appointments - unless due to hospitalization (which is a different variable).
16	Systemic Corticosteroids	Any mention. DOES NOT INCLUDE joint injections, skin creams, etc.
17	Alternative Medications	Any mention - including but not limited to saw palmetto, St. John's Wort, Echinacea, Coenzyme Q10, etc.
18	Antibacterial Antibiotics	Any mention - must be systemic therapy, not local (such as skin creams, etc.)

For all items, one mention is sufficient to mark the item "yes." Mark a "1" if present, or a "0" if absent.

reviewed by all three reviewers to assess inter-rater agreement.

Adverse Events

Ischemic stroke/systemic arterial embolism, VTE and major hemorrhage were the adverse outcomes of interest. We defined major hemorrhage according to the definition of the International Society of Thrombosis and Haemostasis: a fatal event, an event requiring hospitalization with transfusion of at least two units of packed red blood cells, or bleeding involving a critical anatomical site such as the cranium or the retroperitoneum [22]. All patient progress notes were individually reviewed for evidence of adverse events; events were validated directly with the sites by McKesson.

Statistical Analyses

Kappa (κ) statistics were computed to assess inter-rater reliability for the second chart review. To assess significance of effects when comparing categorical variables with the matched design, we used Monte Carlo permutation methods with 10, 000 iterations to compute empirical p-values. Case-control status within each "cluster" of matched observations was randomly permuted 10, 000 times, with a test statistic (e.g., Pearson's chi-square statistic) calculated upon each iteration. This was used as a reference distribution, under the null hypothesis of no association with case status, to compute the empirical p-value. Groups were compared on continuous variables using a generalized linear model to account for correlation between each case and its matched controls. We used conditional logistic regression models to determine the factors that independently predict case status while controlling for patient level covariates (i.e. age, gender, race, co-morbid conditions). Analyses were performed using SAS, version 9.1 (SAS Corporation) and R, version 2.8 (R Foundation).

Results

Baseline Characteristics

There were 109 cases with high dose variability and 218 site-matched controls with low dose variability (Table 2). The mean coefficient of variation (CoV) of the cases was 0.24 and the mean for the controls was 0.02 ($p < 0.001$). The two groups were similar in demographics: most participants were white (89% of cases and 94% of controls) and many were 75 years of age or older (50% of cases and 42% of controls). Forty-five percent of cases were female, compared to 32% of controls ($p = 0.02$). Atrial fibrillation

Table 2 Baseline patient characteristics compared between cases (n = 109) and controls (n = 218)

Demographics	Cases (%)	Controls (%)	P-value
Age 75 or Older	50	42	0.20*
Female	45	32	0.02*
Nonwhite Race	11	6	0.10*
Hypertension	48	47	0.99*
Diabetes	21	21	0.99*

*Comparison via Monte Carlo simulation

†Comparison via Generalized Estimating Equations (GEE)

was the indication for anticoagulation in 67% and 58% of the cases and controls, respectively. Among the 69 patients with "other" indications for anticoagulation, 27 were anticoagulated for stroke, transient ischemic attack, or cerebrovascular disease; 22 were anticoagulated for congestive heart failure; 13 were anticoagulated for coronary artery disease; 4 were anticoagulated for hypercoagulability; and 3 were anticoagulated for other reasons. Co-morbidities such as hypertension, diabetes, and coronary artery disease were similar between groups.

Validation of Coefficient of Variation as a Measure of Risk

CoV corresponded well with other measures of anticoagulation control and risk for adverse events. The 109 case patients had a mean TTR of 53%, compared to 79% for the 218 control patients ($p < 0.001$). Cases had a higher rate of adverse events. Six case patients experienced major hemorrhage, compared to only 1 control patient ($p < 0.001$). Three case patients had thromboembolic events (2 embolic strokes and 1 pulmonary embolism), compared to 0 control patients ($p = 0.04$).

Predictors of Dose Variability

We assessed predictors of dose variability using chart review. The 3 reviewers achieved a very good rate of inter-rater reliability (three-way $\kappa = 0.76$). In the unadjusted analysis (Table 3), most of the risk factors we examined were associated with case status. Particularly strong associations were seen with amiodarone (12 cases vs. no controls, $p < 0.001$) and a diagnosis of cancer (8 cases vs. 1 control, $p < 0.001$). When present, these variables were highly indicative of high CoV.

After adjustment for covariates (Table 4), variables independently associated with large dose variation included hospital/nursing home stay (OR = 21.3), decreased oral intake (OR = 12.2), use of systemic steroids (OR = 6.1), use of acetaminophen (OR = 4.0), and use of antibiotics (OR = 2.7). Effect size of amiodarone and cancer could not be calculated because there were too few controls with these variables. The presence of these variables precluded model convergence; therefore, these variables were omitted from the model.

Table 3 Proportion of cases and controls with risk factors for extreme dose variability (unadjusted results).

Risk Factors	Cases (n = 109)	Controls (n = 218)	p-value*
Acetaminophen	**33 (30%)**	**30 (14%)**	**< 0.001**
Adherence	**48 (44%)**	**67 (31%)**	**0.01**
Alcohol	9 (8%)	16 (7%)	0.99
Alternative Medication	11 (10%)	10 (5%)	0.08
Amiodarone	**12 (11%)**	**0 (0%)**	**< 0.001**
Antibiotic Use	**47 (43%)**	**44 (20%)**	**< 0.001**
Cancer	**8 (7%)**	**1 (0%)**	**< 0.001**
CHF (Decompensated)	**14 (13%)**	**7 (3%)**	**0.001**
Decreased Oral Intake	**21 (19%)**	**8 (4%)**	**< 0.001**
Diarrhea	**15 (14%)**	**10 (5%)**	**0.003**
Dietary Supplement	8 (7%)	6 (3%)	0.06
Dietary Vitamin K	40 (37%)	73 (34%)	0.61
Hospitalizations/Nursing Home	**47 (43%)**	**12 (6%)**	**< 0.001**
Missed Appointments	12 (11%)	22 (10%)	0.99
Nausea/Vomiting	**10 (9%)**	**5 (2%)**	**0.01**
NSAID Use	**19 (17%)**	**18 (8%)**	**0.02**
Procedures	28 (26%)	41 (19%)	0.21
Systemic Steroids	**12 (11%)**	**9 (4%)**	**0.03**

All variables were obtained by chart review and all are yes/no variables.
Boldface variables are significant at the 0.05 level.

Discussion

In this study, we have describe a new measure to identify patients at risk for adverse outcomes of anticoagulation care, have shown that the measure is correlated with INR control and adverse events, and have examined patient-level predictors of being in this high-risk group. The characteristics independently predictive of large weekly variation in warfarin dose were hospitalization/nursing home stay, decreased oral intake, use of systemic steroids, acetaminophen, and antibiotics. In addition, the use of amiodarone and a diagnosis of cancer were almost certainly risk factors for high CoV, though we could not estimate an effect size.

This study suggests that CoV could be an important tool for identifying patients at high risk for poorly controlled anticoagulation therapy and adverse events. Patients identified as high-risk might be referred for case management, adherence training, more intensive follow-up, or indeed reconsideration of whether this particular patient is a good candidate for warfarin. The utility of

Table 4 Multivariate analysis of risk factors for extreme warfarin variability

Chart Review Variables	Odds Ratio (95% CI)	p-value
Acetaminophen	**4.0 (1.33 to 6.30)**	**0.01**
Adherence	2.0 (0.87 to 4.65)	0.10
Alcohol	2.5 (0.65 to 10.00)	0.18
Alternative Medication	2.0 (0.38 to 9.63)	0.44
Amiodarone	*	*
Antibiotic Use	**2.7 (1.11 to 6.33)**	**0.03**
Cancer	*	*
CHF (Decompensated)	2.0 (0.34 to 11.58)	0.44
Decreased Oral Intake	**12.2 (2.25 to 65.68)**	**0.004**
Diarrhea	2.8 (0.51 to 15.67)	0.23
Dietary Supplement	1.0 (0.12 to 7.90)	0.98

Hospitalizations/Nursing Home	**21.3 (6.21 to 73.14)**	**< 0.001**
Missed Appointments	1.6 (0.51 to 5.15)	0.42
Nausea/Vomiting	4.4 (0.70 to 27.91)	0.11
NSAID Use	1.3 (0.36 to 4.72)	0.69
Procedures	1.4 (0.59 to 3.36)	0.44
Systemic Steroids	**6.1 (1.10 to 34.20)**	**0.04**

Variables are adjusted for all other variables in the table, as well as for age, gender, race, and comorbid conditions (not shown).

* These variables were not estimable in the multivariate model, because too few control patients had these characteristics. Therefore, these variables were omitted from the model.

such an approach for preventing adverse events could be examined in a prospective study. Anticoagulation control (as measured by TTR) could also be used to prospectively identify patients at high risk for adverse events. Our study did not directly compare the ability of these two measures (TTR vs. dose CoV) to identify patients at highest risk for adverse events; this would also be a suitable topic for future study. We suspect that, in many care settings, there is no effort to prospectively identify patients at high risk of adverse events. If the utility of this approach can be established, it may be more widely employed.

An ideal next step to further this research would be to use CoV to identify patients at high risk for poor outcomes in the context of a quasi-experimental design. At some sites of care, patients with extremely high CoV might be referred for case management, adherence training, more intensive follow-up, or indeed reconsideration of whether this particular patient is a good candidate for warfarin. At other sites of care, CoV would be noted, but not acted upon. The outcomes for patients with high CoV (TTR and hopefully clinical outcomes) would be compared, and the effectiveness and cost-effectiveness of the intervention assessed.

Hospitalization had the strongest association with unstable anticoagulation control of any variable in our multivariate analysis. Being hospitalized can contribute to variable dosing for several reasons. When patients are hospitalized, warfarin therapy is often interrupted, and patients may receive parenteral anticoagulation or no anticoagulation at all. Hospitalization also involves large changes in the patient's lifestyle and diet. Returning home, the patient attempts to re-establish usual habits while often restarting warfarin therapy at the previous dose. Unsurprisingly, this combination of circumstances produces out-of-range INR values. Hospitalization is also a general marker of illness severity, which can predict poorer anticoagulation control both before and after hospitalization. Previous studies have also examined the event of a hospitalization as a time-dependent inducer of variable anticoagulation control [23].

Several studies have shown an association with warfarin and acetaminophen [24,25]. Hylek et al. [26] described acetaminophen as an underrecognized source of INR elevation. Her study which included a case-control prospective design assessed patients with high INR values (> 6.0). Acetaminophen was noted as a risk factor that was documented only as case studies in the literature previously. One study examined the prevalence of adverse warfarin-drug combinations in a post-mortem toxicology database. Acetaminophen accounted for more than half of the warfarin drug interactions. In that study, there were more deaths with the combination of acetaminophen and warfarin than with either drug alone [27]. Despite these data, discordant findings showing lack of an association with acetaminophen and warfarin potentiation have been reported [28-30]. The present study reinforces the theory that the use of acetaminophen can contribute to poor anticoagulation control.

Several other studies have described factors associated with anticoagulation control [31-33]. One study, similar to ours, examined factors that contribute to unstable control and found no association with dietary habits or the presence of comorbid conditions. Instead, they found greater instability among patients working full-time, among those with inadequate understanding of oral anticoagulation therapy, and among those with CYP2c9*3 variants [31]. Other studies have examined factors associated with extremely stable control. Witt et al. [32,33] performed 2 studies looking at patients that spent 100% of the time in therapeutic range. Both studies found that older age, lack of co-morbidities and a standard INR target range (i.e. 2-3) were associated with stable control.

There are several strengths to our study. We used a large, nationally representative database of patients receiving warfarin in community-based practice. Our three chart reviewers achieved a very good rate of inter-rater reliability. Finally, this database (ACTION) contains weekly warfarin doses for all patients. These data are usually not available, since warfarin is often prescribed

"use as directed" and so dose changes cannot be reliably abstracted. This is a unique feature of this database, without which we could not have performed this study.

Despite this our study has some limitations. First, this study did not address the question of whether high dose variability is a cause or a consequence of poor anticoagulation control, although we would suspect that it is predominantly a consequence of it. Nevertheless, this study does demonstrate that dose variability is both measurable and related to important clinical outcomes, regardless of its causal relationship with anticoagulation control. As such, it might be used to identify patients at elevated risk for adverse events. Second, this study was limited to risk factors for high CoV that were clearly documented in the clinical notes; however, some risk factors may have been present, but poorly recognized or poorly documented. Our results with regard to risk factors for high CoV should be regarded as exploratory, particularly where a risk factor was shown not to predict high CoV, because an absence of documentation is not conclusive proof that something did not occur. Third, we emphasize that we have only subjected our new scoring system to internal validation, i.e. within the same dataset. A higher level of validation would be attained by demonstrating its utility in a separate dataset. Fourth, the confidence intervals identified in our multivariable analysis of patient-level risk factors for high dose variability are quite large. Therefore, the true magnitude of these effects is not precisely known. A final limitation is that this study evaluates patients with a target INR range of 2-3 and at least 1 month of experience with warfarin; our study results may not apply to patients who are new to warfarin or those with other target ranges.

Conclusions

In this study, we have derived and internally validated a new measure to identify patients at high risk for poor anticoagulation control in clinical practice, namely the coefficient of variation of weekly warfarin doses. This measure identifies patients at high risk for poor anticoagulation control and adverse events. Future studies should explore the use of this measure to identify patients for intervention before they have experienced an adverse event.

Information Need

Education level, not health literacy, associated with information needs for patients with cancer

ABSTRACT

Objective: Cancer patients receiving adjuvant therapy encounter increasingly complex situations and decisions with each new procedure and therapy. To make informed decisions about care, they need to be able to access, process, and understand information. Individuals with limited health literacy may not be able to obtain or understand important information about their cancer and treatment. The rate of low health literacy has been shown to be higher among African Americans than among non-Hispanic Whites. This study examined the associations between race, health literacy, and self-reported needs for information about disease, diagnostic tests, treatments, physical care, and psychosocial resources.
Methods: Measures assessing information needs were administered to 138 newly diagnosed cancer patients. Demographics were assessed by survey and health literacy was assessed with two commonly used measures: the Rapid Estimate Adult Literacy in Medicine (REALM) and the Short Test of Health Literacy in Adults (STOFHLA).
Results: Study findings indicate that educational attainment, rather than health literacy, is a significant predictor of information needs.
Conclusion: Overcoming barriers to information needs may be less dependent on literacy considerations and more dependent on issues that divide across levels of educational attainment.
Practice implications: Oncologists and hospital staff should be attentive to the fact that many patients require additional assistance to meet their information needs.

1. Introduction

For patients with limited health literacy, understanding and communicating cancer treatment options, goals, and preferences is particularly challenging [1]. The Institute of Medicine (IOM) defines health literacy as "the degree to which individuals have the capacity to obtain, process and understand basic health information and services needed to make appropriate health decisions" [2]. Up to 98 million Americans struggle to function within the health care system due to limited health literacy [3], making this a significant problem in the delivery of care to the nation's cancer population.

There is compelling evidence that individuals with limited health literacy have worse outcomes, including lower treatment adherence, more frequent hospitalizations, and higher mortality than those with adequate health literacy [4–10]. The definitions and conceptual models of health literacy continue to evolve from initial writings which emphasized reading and math [2,11] to current views that incorporate a broader range of attributes (e.g., listening, communicating, using information) and is well described in a commentary by Berkman et al. [12]. We do know that limited education, low socioeconomic status, and minority race are risk factors for both limited health literacy and worse cancer outcomes [3,4] and may be important mechanisms of disparities in healthcare outcomes for patients with cancer.

Patients are called upon to be increasingly responsible for self-care at the same time that medical care becomes more complex and technical. Studies with breast cancer patients have shown that expressed needs for information about disease and treatment are very high, particularly at the beginning of treatments [13,14]. Since breast cancer is an illness primarily affecting women, we needed to

doi:10.1016/j.pec.2011.03.022

explore other cancer populations. Research indicates that information seeking is associated with better psychosocial outcomes, such as satisfaction with coping, decisions, and treatment as well as improved physical function [15–17]. Patients with lower income and education, and those who are minorities [6], have been shown to ask fewer questions and have greater difficulty effectively communicating preferences [18,19]. This, in turn, negatively affects shared decision making between patients and providers [1,2]. Race and ethnicity also appear to influence information preferences [20] and perceptions of met/unmet information needs [21]. For example, more African Americans than Caucasians request information about psychosocial support (e.g., support groups, family support) from the NCI Cancer Information Service call center [22,23]. African-Americans also tend to receive less information from and communicate less with physicians [19,24,25].

In addition to well-documented disparities that affect access to cancer therapy and survival [26,27], there are disparities in accessibility to and utilization of pertinent cancer care information [18]. Often the individuals most in need of interventions are those that are the hardest to reach or have the least resources. Overall, ethnic minorities and low-income populations have less access than the general population to relevant information necessary to navigate the health care system and obtain optimal care [28]. In order to develop effective information interventions, it is essential to understand what information patients need.

The purpose of the study was to examine and measure the associations between race, health literacy, and self-reported needs for information about disease, diagnostic tests, treatments, physical care, and psychosocial resources. Based on the literature, we expected that African American participants would score lower on health literacy measures [3] and would have more information needs than non-Hispanic White participants [20,29,30]. We hypothesized that patients with lower health literacy would have greater information needs than those with higher health literacy and that health literacy would mediate the impact of race on information needs.

2. Methods

2.1. Participants

Patients eligible to participate in this observational study were newly diagnosed African American and non-Hispanic White adults with solid tumor cancers Stages II–IV and who would be receiving treatment. Patients with stages 0–I cancer were excluded as they may not undergo further treatment and therefore may have fewer and different information needs compared to patients diagnosed at later stages.

2.2. Recruitment procedures

Potential participants were identified through the Virginia Commonwealth University (VCU) Massey Cancer Center's electronic record system and oncologist referral. Patient enrollment included those treated at both the academic campus as well as a community hospital satellite setting. Study staff contacted potential participants' oncologists and requested permission to discuss the study with individual patients. If the oncologist approved, the patient was contacted in-person during a clinic visit or by letter with an opt-out telephone number. People who did not opt-out, received a follow-up phone call to further explain the study and answer any questions.

During the first meeting with patients interested in the study, the consent form was reviewed and written informed consent was obtained for those who agreed to participate. After consent was obtained, study staff administered the questionnaire and participants were paid $25 upon survey completion. This study was approved by the Virginia Commonwealth University Institutional Review Board.

2.3. Measures

2.3.1. Sociodemographics

The questionnaire included sociodemographics, two validated measures of health literacy, and a validated measure of information needs. The sociodemographic variables assessed included: gender, age, race, marital status, educational attainment, total household income in the previous year, cancer type, cancer stage, and insurance status.

2.3.2. Health literacy

Health Literacy assessment was conducted with two commonly used measures. The first, the Rapid Estimate of Adult Literacy in Medicine (REALM) [31], is a 3-min health word pronunciation test. The REALM consists of a list of 66 words printed on a sheet, beginning with common words and becoming progressively more difficult. Participants are asked to read the list aloud and the research assistant judges if words are pronounced correctly. The REALM gives estimates of four levels of proficiency: 3rd grade and below (0–18), 4th to 6th grade (19–44), 7th to 8th grade (45–60), and high school or above (61–66). The REALM has been highly correlated with the Short Test of Functional Health Literacy in Adults (STOFHLA) (0.80), the Test of Functional Health Literacy in Adults (TOFHLA) (0.84), The Wide Range Achievement Test-Revised (WRAT-R) (0.88), Slosson Oral Reading Test-Revised (SORT-R) (0.96), and Peabody Individual Achievement Test-Revised (PIAT-R) (0.97). The REALM test–retest consistency is high at 0.97 [31].

The second measure, The Short Test of Health Literacy in Adults (STOFHLA) [32–34] is a timed paper and pen test, consisting of 36 reading and four numeracy questions. The test assesses reading ability by providing health-related passages with words missing in a modified Cloze format. Respondents choose the correct answer out of four possible choices for each blank. The test assesses numeracy by providing prescription vials and hospital forms. Respondents calculate numeric answers. The reading section (72 points) and the numeracy section (28 points) are summed for the total STOFHLA score, ranging from 0 to 100. The score then is distributed between three health literacy levels: adequate (67–100), marginal (56–66) and inadequate (0–55). Internal consistency is high (Cronbach's alpha 0.98) and has concurrent validity with the long version of TOFHLA ($r = 0.91$) and the REALM [32]. An additional approach to improve sensitivity of the STOFHLA measure was developed by Wolf et al. [35] which divides the raw scores into seven categories. In this study we used both traditional scoring as well as the Wolf Categories.

2.3.3. Information needs

The Toronto Informational Needs Questionnaire (TINQ) was developed to identify information needs of women with breast cancer and tested with 114 women during adjuvant therapy for breast cancer [13,14]. It was adapted for this study by eliminating the four breast cancer specific questions and retaining the remaining 45 questions related to all cancers. Higher scores represent higher information needs. Internal consistency is good between 0.85 and 0.90 for subscales and $\alpha = 0.94$ for the total questionnaire. Participants are asked to rate the importance of possible areas of informational needs on a five point Likert Scale ranging from 1 (not at all important) to 5 (extremely important). They are asked to report their need for information specifically as of the time of survey administration. There are five subscales for

the TINQ. The disease subscale (score range 8–40) is about the disease, expected disease progression, and prognosis. The subscale for diagnostic tests (score range 7–35) addresses purpose, method, and side effects of tests. The treatment subscale (score range 16–80) is related to reasons for, administration of, and reactions to treatment. The physical subscale (score range 6–30) regards self-care. The psychosocial subscale (score range 8–40) addresses emotional and psychological needs for both patient and family. Five questions were added about tangible information needs issues (e.g., "transportation to the cancer center" and "where to find money to pay medical bills"). These tangible information needs questions were generated from findings of focus groups conducted by the investigators [20,36] and pilot tested with 107 African American and White female cancer patients. The TINQ and the tangible information needs questions are scored separately, with the total TINQ score ranging from 45 to 225 and the tangible score ranging from 5 to 25. With the exception of the REALM and STOFHLA, all measures were administered verbally by research staff.

2.3.4. Statistical analysis

Analyses were conducted using PASW 17.0 [37]. Descriptive statistics and bivariate correlations were examined.

Separate regression equations were created to examine the relationship between race, age, gender, cancer type, and cancer stage for the following dependent variables: each information needs subscale (disease, diagnostic tests, treatment, physical, psychosocial and tangible) and total information needs. As health literacy was an independent variable of specific interest, we employed a multistep modeling approach in which health literacy and education were introduced sequentially to distinguish the potentially different effects of these two factors. As such, the next set of equations added a measure of health literacy to test the relationship between health literacy and each of the information needs dependent variables. After examining the relationship between sociodemographics, health literacy, and information needs, we explored the role of education in these relationships by adding education (dummy coded) to each regression equation. As the REALM and STOFHLA measure different health literacy skills and as the traditional STOFHLA and the Wolf STOFHLA categories emphasize different categorical distributions, all models that include health literacy were evaluated three times (i.e., using the REALM, STOFHLA, or the Wolf STOFHLA Categories) to evaluate stability of our findings across different measures of health literacy [35]. Race (dummy coded), age, gender, cancer type, and cancer stage (dummy coded) were included as covariates in each model described above.

3. Results

3.1. Participant characteristics

Participants (N = 138) included 62 (45%) African American and 76 (55%) non-Hispanic White patients with cancer (Table 1). The mean age was 54.7 (SD 11.8) with 62% female and 38% male. Over half the sample had completed education above high school while 25% had attained a high school diploma or General Education Diploma (GED) and 23% had less than high school. Fifty three percent of participants had income less than $30,000 per year with 19% having less than $10,000 per year. While about half of the sample reported being either unemployed (30%) or on disability (22%), most reported having some type of health insurance (75%). Cancer types included gastrointestinal (24%), breast (23%), lung (26%), lymphoma (18%), and other cancer (9%). Stages of cancer included II (35%), III (38%) and IV (27%).

Thirty five percent of the African American sample reported having less than a high school education and 34% reported making less than $10,000 per year. In comparison, 12% of the White sample reported having less than a high school education and 6% reported making less than $10,000 per year.

3.2. Health literacy

Fully 86% of participants were found to have Adequate HL on the STOFHLA, while 62% scored at the high school level on the REALM, and 57% scored in the highest level (Category 7) of the Wolf categories. African Americans were more likely to have limited health literacy than Whites, as measured by the REALM (24% vs. 3%, $p < .01$) and the STOFHLA (23% vs. 1%, $p < .01$). Few participants with high school or higher educational attainment scored 6th grade or below on the REALM (3%) or had inadequate or marginal health literacy on the STOFHLA (1.4%) as shown in Table 2.

3.3. Information needs

Information needs were high in all categories (Table 3), with a total mean of 193.3 (SD = 31.7, range 61–225) and an average of 4.3 (Confidence Interval (CI) 95%) out of a possible 5 on the Likert scale. Participants reported the greatest need for information about disease (average 4.6, CI 95%) and the least need for psychosocial information (average 3.7, CI 95%).

Range	10–25	5–25	5–25	

3.4. Bivariate analyses

In the bivariate analyses for information needs (Table 4), lower education significantly correlated with higher information needs in all TINQ subscales, total TINQ, and tangible information. Similarly, African American race was significantly correlated with higher information needs, with the exception of the Disease subscale. The REALM and STOFHLA were significantly correlated with TINQ Psychosocial subscale, TINQ total, and tangible information needs. The Wolf categories were only significantly correlated with TINQ Psychosocial subscale and tangible information needs.

3.5. Regression models

In the set of regression equations separately examining the influence of adding the health literacy measures as predictors of the various information needs, African American race significantly correlated with greater information needs with the exception of TINQ treatment subscale. Gender, age, cancer type, and cancer stage (sociodemographics) were not significant. The health literacy measures were not related to any of the information needs variables. Table 5 shows these results for the STOFHLA; results for the REALM and the Wolf version of STOFHLA scoring are all consistent with these findings and are not shown.

Addition of education to the prediction models reveals that education is associated with each domain of information needs; specifically, a lower level of educational attainment was associated with higher information needs. For example, in the final model, controlling for sociodemographics, health literacy and adjusting for education, we would predict that someone with ≤H.S. education would have a score of 204.3 on the Info Needs Total as compared to a score of 183.8 for someone with HS or more.

The magnitude for the TINQ differences comparing those with less than a H.S. Diploma versus those with more than a H.S. Diploma/GED were statistically significant (i.e., $p < .5$) for the total TINQ as well as for each subscale as seen in Table 4. We computed the effect sizes for low education (≤H.S. degree) as compared to higher education (>H.S. degree) for information needs and the results were as follows: Information needs Disease subscale, Cohen's d = .60, effect size .29; Information needs Tests

Table 4
Bivariate correlations for the Toronto Informational Needs Questionnaire (TINQ), race, health literacy, and education.

[a] Model 1 includes race and cancer stage (data shown) as well as age, gender, and cancer type (data not shown as these variables were not significant in any model).
[b] Model 2 includes all of Model 1 as well as a health literacy measure. Data for STOFHLA models shown. Results for the REALM and Wolf STOFHLA Categories were consistent with these findings and are not reported.
[c] Model 3 includes all of Model 2 as well as education. Results for the REALM and Wolf STOFHLA Categories were consistent with these findings and are not reported.
* Significant at the .05 level (2-tailed).
** Significant at the .01 level (2-tailed).

subscale, Cohen's $d = .60$, effect size .29; Information needs Treatment subscale, Cohen's $d = .53$, effect size .26; Information needs Physical subscale, Cohen's $d = .58$, effect size .28; Information needs Psychosocial subscale, Cohen's $d = .70$, effect size .33; Total TINQ, Cohen's $d = .69$, effect size .33; Tangible information needs, Cohen's $d = 1.01$, effect size .45. There were no meaningful differences for participants with less than a H.S. diploma compared with those who had achieved a Diploma/GED. With the addition of education to the models, none of the measures of health literacy were associated with any domain of information needs. African American race was significantly associated with greater tangible information needs (Cohen's $d = .75$, effect size .35). Stage II cancer was significantly associated with greater information needs in the TINQ Disease, Tests, and Treatment subscales, and the total TINQ, although the effect size was small (<.12) for each subscale.

4. Discussion

4.1. Discussion

Contrary to our hypothesis, health literacy was not significantly associated with information needs, while educational attainment was significantly associated with information needs. That is, people with a low level of educational attainment reported a higher need for cancer care information than people who had completed a higher level of education. Specifically, people who had not completed secondary education had more information needs than those who attained some college or post graduate education. If a higher level of information needs was found to be associated with both limited health literacy and limited education, there would be relatively strong evidence that simplifying educational materials and providing support for patient education is warranted as a means to fulfill patient's self-assessed information needs. As we did not observe such a finding, alternative conceptualizations need to be considered.

There may be several reasons why we observe discordant findings for education and health literacy. First, although these two constructs are related to each other, they measure different phenomenon. Completed education is not always a predictor of either literacy or health literacy [38,39]. Those with limited formal education may have attained higher skills than a grade level would indicate. In addition, educational systems vary and completion of a particular grade level does not ensure equivalent skills across individuals [38,39]. Finally, the meaning of education level may vary by race and actual education (vs. grade completion) may not

be reflected accurately in standard demographic classifications. For example, after the federal ruling in 1955 to end segregation in schools, the Virginia General Assembly cut off state funds from integrated schools and ultimately closed entire school systems in 1958. Some schools were closed for a year, others (like Prince Edward County) were closed until 1964. Over 13,000 students were without school for at least one semester [40]. While public schools were closed for everyone, education remained accessible for the wealthier classes through state funded tuition vouchers to segregated private schools [41]. It is difficult to ascertain the specific effects this has had on those "lost classes" of the late fifties, but what is certain is that the heaviest burden was left on blacks and lower class whites.

Second, while we used the most common health literacy measurement tools used in the medical literature, the REALM is a word pronunciation test and the STOFHLA is a test of prose literacy and numeracy. Other domains of health literacy not evaluated by these measures (i.e., verbal literacy, information finding skills, and navigation) may be more likely connected to information needs for cancer patients. In addition, the measures do not assess other constructs relevant to information needs that may be linked to educational attainment (e.g., self-efficacy, resource rich environments, social status, or other phenomena related to staying in school). It is not clear how lower educational level leads to higher information needs. Additional phenomena – beyond actual literacy skills, such as differing attitudes or expectations, greater social capital, or more resources may be available to individuals whose education level is greater than H.S. than those with a H.S. education or less.

Although there has been a fair amount of work done on health literacy, there are few studies on the role of health literacy in information needs, particularly in cancer [42,43]. It is important to note that the information needs assessment is subjective, i.e., people with higher educational attainment may believe that they have sufficient knowledge about cancer care. They may actually have the knowledge, having accessed information prior to the interview through the Internet, reading pamphlets, or talking with other people. Alternatively, they may not have the knowledge; a false sense of confidence may lead to their low TINQ scores. This could occur because people can be unaware of their information needs or may not be willing to say they need information. Possibly, people with higher education are generally more confident about being able to access information, even if they have not faced the challenges of their current circumstances.

The highest reported need for information was in the disease domain (average 4.6, CI 95%). This domain includes questions about whether cancer will come back, how cancer acts in the body, ways the disease will affect the patient over time, and what caused the cancer. It makes sense that these are critical issues for newly diagnosed patients as they adjust to their diagnosis. Presumably need for information related to disease will decrease over time, once patients have received and processed this information. Information about tests, treatments, and physical self-care may be more easily obtained and understood because they tend to be concrete and finite. For example, once a patient has received a particular test, there would be little need for additional information unless scheduled for a different one.

Two of the greatest differences in information needs by level of education were discovered on the tangible and psychosocial information subscales. These questions relate to issues outside immediate medical concerns. For example, tangible information questions include needing information about transportation to the cancer center and ways to obtain help paying bills. Because lower education was associated with lesser income it is likely that these types of questions were more relevant to individuals who may need additional financial support than to those with adequate means. The psychosocial questions include items about counseling for the patient and family members and finding support groups. Participants with greater education and income were more likely to have health insurance that cover these services and might not need information provided through the cancer center. It may also be more culturally or socially acceptable to participate in therapy or support groups for individuals with greater means than for those with lesser means. Additionally they may have more resources available than do individuals with limited education and income, thus decreasing the need for this information.

As we had posited, African American participants scored lower on the health literacy measures and had some differences in information needs from White participants. In the first set of regression models, African American race was significantly associated with greater information needs. However, when these data are controlled for health literacy and education the difference between races no longer is significant, with the exception of tangible information needs. Generally African Americans in our patient population tend to have lower socioeconomic status than Whites and frequently reside in the city rather than suburbs. This may account for greater tangible information needs related to paying bills and obtaining transportation to their appointments.

Stage of cancer was not significantly associated with information needs until the final step of the regression model, and the effect size was weak. In this sample, patients with Stage II cancers had greater information needs than those with Stage III or IV cancers. Patients with Stage II cancers have more complex choices for curative treatment than those with Stage IV cancers have for palliative treatment, and presumably would require more information to best understand available options. Treatments for Stage III cancers may at times resemble that for Stage II or Stage IV cancers, which may explain the small differences between groups. With a larger sample, important differences between cancer stage may be identified.

4.2. Strengths and limitations

First, this study collected self-report data that we did not attempt to validate by other means. Self report questionnaires are frequently used in behavioral studies and are considered reliable. In this study, the questionnaires were verbally administered by trained interviewers, which has been shown to reveal more detailed and accurate information than written surveys [44].

Second, the study was conducted at a single cancer center. More than half of the sample had limited income (<$30,000/year) and nearly half had a high school education or less so the results may not be generalizable to other populations. However, many teaching hospitals and academic centers serve a similar patient population. The fact that participants primarily were from an underserved and less educated population makes the findings that educational attainment was a greater predictor of information needs than health literacy particularly relevant.

Third, our sample size does not afford adequate power to discern subgroup analyses, such as cancer type, with confidence. The role of cancer stage also needs to be further explored. The sample size is however adequate to judge the main comparison about health literacy and education. In addition, the analyses remained stable across multiple models and analytic approaches.

The majority of the participants scored adequate on the health literacy measures, raising the question of whether the measures lack the sensitivity to identify a more complete construct of health literacy. Although the measures we used are the ones most commonly used in health literacy research they do not comprehensively cover the broader constructs of health literacy [45,46]. Future work to develop measurement tools that capture other dimensions of health literacy could be informative. Non-Hispanic

White participants were more likely than African American participants to have more than a high school education and to have adequate health literacy however when race was removed from the equation the findings did not change.

This study showed that there was some variation between health literacy scores on the STOFHLA (86% adequate health literacy) and the REALM (62% high school level). These findings are consistent with other studies [6,46–48] and described in a systematic review by Paasche-Orlow et al. [6]. Comparison between studies must take into account different ways that researchers categorize "marginal," "inadequate," and "limited" or "low" health literacy.

Finally, findings reported here were from cross-sectional data. As part of an ongoing longitudinal study, continued observation of this cohort with data collection at Time 2 (4 months) and Time 3 (8 months) will provide the opportunity to see how information needs change over time.

4.3. Conclusions

Study findings indicate that educational attainment, rather than health literacy, is a significant predictor of information needs. Although research has demonstrated the benefits of improving the readability of written materials for individuals with limited literacy, overcoming barriers to information needs may be less dependent on literacy considerations and more dependent on issues that divide across levels of educational attainment. More work is needed to understand the attributes that higher education confers and the relevance of those attributes to cancer care information needs. Documentation of education on intake assessment forms may be useful.

Ultimately, there likely will be many barriers to cancer patient's information needs. Identifying these barriers may help with design of systems to promote patient education and fulfillment of educational needs. The current work shows that health literacy, as typically measured in the medical literature, was not an important barrier for the patients in our cohort. Low educational attainment was the sole factor identified; further research is needed to learn how to translate this observation into specific guidance for clinicians. In the meantime, using "Universal Precautions" to ensure patient's comprehension is the most appropriate approach [7].

4.4. Practice implications

Oncologists and hospital staff should be attentive to the fact that many patients may require additional assistance to meet their information needs. Providers should assume that all patients have ongoing information needs until proven otherwise. Providers cannot rely on patients' requests for information but should evaluate and confirm comprehension [49]. Indeed, the absence of questions should be considered a warning sign! More frequent conversations with a patient can help reinforce health concepts and promote a common understanding of the treatment plan. Providers should assume the burden of communication, checking whether they have been clear rather than whether the patient "understands" [50]. Finally, when available, patient navigators, medical librarians, and volunteers can assist both provider and patient by helping to gather and discuss complex information with patients and their support network.

Acknowledgements

This project was funded by the American Cancer Society MRSGT-08-143-01-CPPB.

Disclosure: The first author is a co-investigator on an NIH funded R01 to develop a new health literacy measure for cancer patients.

I confirm all patient/personal identifiers have been removed or disguised so the patient/person(s) described are not identifiable and cannot be identified through the details of the story.

We thank all the many oncologists, nurses and staff who helped us with recruitment and supported the study, Amy Sullivan, EdD for commenting on an earlier draft of this article and Clara Cline for her research on education and desegregation in Virginia.

Public Health, Medicine, and Dentistry as Partners in Community Health: A Pioneering Initiative in Interprofessional, Practice-Based Education

Lois McCloskey, DrPH, MPH; Rebecca Condon, MPH; Christopher W. Shanahan, MD, MPH; James Wolff, MD, MPH, MAT; Corinna Culler, DrPH, RDH; Richard Kalish, MD, MPH, MS

Context: As public health challenges grow more complex, the call for professional education to be interprofessional, collaborative, and grounded in real world practice has intensified. **Objective:** In this article, we describe the development, implementation, and results of one pioneering course at Boston University that aims to prepare public health, medical, and dental students for their combined roles in community health settings. **Setting and Participants**: The Schools of Public Health, Medicine, and Dental Medicine jointly offered the course in partnership with 3 community organizations. Participants include MPH, MD, and DMD candidates. **Intervention:** The course design integrates the use of "The Challenge Model" (created by Management Sciences for Health) with training in public health consultation techniques (eg, community-based participatory research, logic models, monitoring and evaluation). Teams of 6 to 8 medical and public health students collaborate with managers and staff of a community health center to address 1 organizational challenge and recommend a sustainability plan. **Results:** Postcourse evaluations revealed that a cross-disciplinary, practice-based education model is feasible and can meet students' learning objectives and exceed expectations of community partners. We overcame formidable obstacles related to the "silo'ed" nature of academic institutions and the competing priorities within overburdened community organizations. We found that sustained project implementation was attained at some but not all sites, yet all sites highly valued the perspective and contribution of student teams. **Conclusion:** Dynamic and replicable, this practice-based education model is adaptable to professional schools whose work intersects in the real world and calls for collaborative leadership.

KEY WORDS: campus-community partnerships, collaborative leadership, community health, competency-based education, dental education, health professions education reform, interprofessional education, medical education, practice-based education, public health education, team-based education

As the public health challenges facing our nation and world grow more complex and inequities more intractable, the call for major reforms in health professional education grows more urgent. In their groundbreaking report, the 2010 *Lancet Commission on the Education of Health Professionals for the 21st Century* points to problems that keep today's curricula for

Goldman School of Dental Medicine, Boston University, Boston, Massachusetts.

The authors thank their community partners for generous support and participation. These include Boston Healthcare for the Homeless Project; Codman Square Community Health Center, Greater Roslindale Medical and Dental Center, South Boston Community Health Center, and South End Community Health Center. In addition, they thank Deans R. Meenan, K. Antman, and J. Hutter from the Boston University Schools of Public Health, Medicine, and Dental Medicine, respectively, for their support of the pioneering initiative, and Leigh Sweet, MD, MPH, for her contribution to the original course design and its promotion. They acknowledge the Maternal and Child Health Bureau Public Health Training Grant (2 T76 MC000017-15) and the Community Health Unit/General Internal Medicine Section/Department of Internal Medicine at the School of Medicine, both of which provided funds to support the participation of organizational partners.

J Public Health Management Practice, 2011, 17(4), 298–307

the health professions fragmented and outdated, and graduates, ill-equipped. Chief among the problems are: "the mismatch of competencies to patient and population needs, poor teamwork, narrow technical focus without broader contextual understanding, and weak leadership."[1(1923)] The commission declares a vision and strategy for the education of health care professionals that is multiprofessional, global in outlook, and systems-oriented.[1]

A rich history of education reform precedes the work of the commission. One hundred years ago, the 1910 Flexner Report launched what is deemed the "first generation" of reform, focused on science-based professionalism in medical education.[2] Similar reports followed in nursing[3] and dentistry[4]; and in 1915, the forward-looking Welch-Rose Report argued the need for collaborative public health and medical practice, and created a blueprint for public health and "preventive medicine" education for the century.[5] The "second generation" of reforms, as noted by the *Lancet Commission*, came in the wake of World War II. Government invested heavily in academic health centers, with strengthened research, education, patient care (medicine), and population services (public health). Instructional innovations were focused on problem-based learning and efforts and interdisciplinary integration.[1]

The commission's far-reaching recommendations reflect a culmination of a "third generation" of calls for innovation across all professions—calls for interprofessional and practice-based education,[6-19] academic-community partnerships,[17,20-24] competency-based instruction,[25-35] team-based learning,[36] and leadership development.[9,29,37] Perhaps most important in launching this generation of reform was the 1988 landmark Institute of Medicine Report, *"The Future of Public Health."*[8] As Fineberg and colleagues observed, "the single most influential recommendation of the Institute of Medicine report (was) its insistence that professional education be grounded in "real world" public health."[38(240)] The report spawned myriad funded educational collaborations between medicine and public health, many of them in community settings.[10-12]

However, serious institutional barriers to realizing these lofty reform goals have been well documented[1,15,24,39]—among them, "hyperspecialization and rigid tribalism"[1(1944)] within professions. Nonetheless, the goals are repeatedly declared central to equipping a health workforce to meet the demands of a culturally diverse and aging population, the burden of chronic illness, intransigent health disparities, and increasingly complex health systems.[1,7,9,15,16]

In this article, we describe a pioneering initiative at Boston University that seeks to go beyond traditional, silo'ed, and institution-bound curricula and demonstrate the feasibility and value of instruction that is multi- and interprofessional; practice-, team-, and competency-based, carried out in community settings. "Leading Community Health Initiatives: Public Health, Medicine and Dentistry as Partners" is a 1-semester 4-credit course offered jointly by the Boston University School of Public Health (BUSPH), Boston University School of Medicine (BUSM), and Boston University School of Dental Medicine (BUSDM), co-taught by faculty from each school, and codriven by the needs of community partners and academic learning objectives. It is the first known course of its kind to be reported in the literature. We have offered and evaluated the course twice, first with the BUSPH and BUSM (fall 2009), and then with the addition of BUSDM (fall 2010). We present here our methods (course development, design, and evaluation), results (evaluation findings), lessons learned, and implications for expansion and replication.

Methods

Setting

Boston University Medical campus is home to 3 professional schools (BUSM, BUSDM, and BUSPH) and Boston Medical Center, the largest safety net hospital in New England. Boston Medical Center is also affiliated with 15 community health centers throughout Boston, serving more than a quarter million people annually. All 3 schools have a strong focus on community health practice. Despite these strengths, the course described here is the first multischool offering and the first in each school to prepare students for interprofessional, team-based practice in the context of community partnerships.

Course development

The course was created as a result of student activism. In the spring of 2008, 2 students—1 from medicine and 1 from public health—participated in a weekend-long leadership development workshop for medical and public health students taught by a BUSPH faculty member. Inspired by collaborative educational experience and what they learned about leadership, the 2 students first met with the deans of education at both schools, and then garnered the support of faculty. They encountered both enthusiasm and resistance. Administrators were concerned about where tuition dollars would go, as no infrastructure or precedent existed for sharing tuition dollars in the context of a single course. Faculty members were concerned about workload and teaching credit. Ultimately, 4 faculty members (2 BUSM, 2 BUSPH) signed on because the course fit their

professional goals and commitments. Both sets of administrators saw the pedagogic and long-term institutional value of the initiative and created the necessary administrative mechanisms. The course is the first to be "double coded" with a separate designation for each school. As a result, tuition dollars and faculty teaching credit flow to the students' home school and department.

The course was reviewed by the curriculum committees of BUSM and BUSPH; both enthusiastically approved it and raised one caution—assure ways to advance the projects beyond the semester's end (eg, student internships, plans, or both for sustainability). These administrative, financial, and curricular supports, which entailed out-of-the-ordinary upfront costs to each school, particularly in faculty time), made it possible for us to launch the course and test its feasibility, value, and sustainability.

Course Design and Implementation

Course goals and learning objectives

The course serves 3 broad goals common to all 3 participating fields and schools: (1) to increase and promote collaboration between medicine, public health, and dentistry; (2) to strengthen partnerships with community organizations in nearby neighborhoods; and (3) to prepare health care professionals to be self-reflective and collaborative team members and leaders, able to affect change in health systems and in the health of communities. The key learning objectives of the course address interdisciplinary/crosscutting competencies within the framework of the Association of Schools of Public Health[28] (leadership, diversity and culture, communication, and systems thinking). These align with key overarching principles of the American Association of Medical Colleges[26]; competencies defined by the Accreditation Council of Graduate Medical Education[27] (practice-based learning and improvement, interpersonal and communication skills, and systems-based practice); and competencies of the American Dental Education Association (ADEA) (health promotion and disease prevention, community involvement, professional growth and development; see Table 1).[34]

Teaching approach and techniques

The course is based on a collaborative team model and uses student-centered, practice-based learning methods, with limited didactic teaching. At the heart of our instruction is the question posed to each student: "How can I, as an emerging physician, dentist, or public health care professional, work with my interprofessional team and community partners to address an organizational challenge that will contribute to improvements in community health?" As such, self and team reflection are critical components of learning.

The course is divided into 4 overlapping units: (1) key themes: complements and tensions across the 3 professions; community partnerships; self-reflective team building and leadership; (2) tools for community health project management and consultation (see later); (3) field work at community sites; and (4) presentations, reflections, and wrap up.

Teams are composed of 6 to 8 students and each is partnered with a community site and preceptor. Each faculty member guides the work of one team and serves as liaison to the respective site. With 4 faculty members, the course can accommodate up to 32 students. We assign students to groups on the basis of student choice and interprofessional balance. In its first year, 27 students enrolled, including 22 in public health and 5 in medicine; and in the second year, 32 enrolled, with 23 in public health, 4 in medicine, and 6 in dentistry. Clinicians among the public health students helped balance the public health/clinical presence in each group. The relatively low number of medical students relates not to lack of interest, but schedule constraints—heavy course load in the first year and a 12-week elective schedule in the fourth year that does not perfectly map onto the 15-week semester at BUSPH.

The 5 community partner sites include 4 federally qualified community health centers and 1 community-based organization dedicated to homeless families (see Table 2). The sites were selected based on: (1) faculty's preexisting relationships with the organization and senior staff; (2) capacity of key staff to precept teams (at least 2 hours per week on average) and engage other staff as needed; (3) identification of a health- or systems-related "problem area" that is a priority of the organization and is feasible to address in a 12-week period. Faculty members meet with site preceptors several months before the course begins to an issue and prepare them for their role. Each is paid an honorarium of $ 1500.

Course elements

To achieve its learning objectives, the course combines tools for leadership development, community health project management, and self-reflection, summarized below:

- **The Challenge Model**—a tool created by *Management Sciences for Health*[40,41] to provide a systematic way for teams to experience the direct impact of leadership practices on achievement of results. It guides students through an iterative process of creating a

TABLE 1 ● Course Learning Objectives and Associated ASPH Competencies for MPH[28]

Learning Objectives[a]	Methods	ASPH Competencies
Increase capacity for collaborative leadership	Self- and team reflection Completion of Challenge Model Hands-on project management Collaboration on team project and presentations	Leadership[b] Develop strategies to motivate and collaborate Leadership Use collaborative methods for achieving organizational and community health goals
Increase capacity engage and partner with diverse community organizations and residents	Community-based participatory research framework and interviewing techniques Conduct meetings, interviews, and focus groups Develop and manage project in partnership Plan for project sustainability	Diversity and Culture[c] Use basic concepts and skills involved in community engagement
Increase ability to present results of collaborative projects to diverse stakeholders	Oral presentation to partner site stakeholders, faculty, and peers Consultant report	Communication and Informatics[d] Demonstrate effective written and oral skills for diverse audiences

shared vision, defining a measurable result, scanning the environment, analyzing stakeholder interests, identifying opportunities and obstacles, and articulating a challenge to be met. The team selects priority actions and indicators to monitor their completion. The process requires collaboration with each other and the partner site to assure that the measurable result is feasible in a 15-week period and meaningful to the organization.

- **Logic Model and Data Monitoring and Evaluation Plan**[42]—a conceptual framework that illustrates a project's resources (designated as inputs)

TABLE 2 ● Community Site Partners

Codman Square Community Health Center

Codman Square Community Health Center is located in the heart of Dorchester, one of Boston's poorest and most vulnerable neighborhoods, and is noted for its integration of personal health care with community redevelopment, including a neighborhood gym and school. The population of Dorchester is an ethnically diverse mix of African Americans, European Americans, Caribbean Americans, Latinos, and East and Southeast Asian Americans.

Greater Roslindale Medical and Dental Center

Greater Roslindale Medical and Dental Center services span the full range of primary care and ancillary social services allowing patients to access a comprehensive set of services in one location. Its staff is fluent in Spanish, English, Albanian, and Greek and serves the ethnically diverse, middle- and low-income families primarily from the Roslindale, Hyde Park, and West Roxbury neighborhoods of Boston.

Boston Health Care for the Homeless Project

Boston Health Care for the Homeless Project has provided or assured access to high quality health care for all homeless men, women, and children in the greater Boston area for 25 years. In 2010, the Boston health care for the homeless project served more than 11 000 patients. Most of their clients stay in the emergency shelter system, eat in soup kitchens, or visit drop-in centers. The Boston health care for the homeless project also serves unsheltered homeless people as well as those who were formerly homeless and live in transitional or permanent housing.

South Boston Community Health Center

In addition to a full array of medical services and specialty clinics (eg, diabetes, sports medicine, HIV), South Boston Community Health Center offers a food pantry, interpreter services, financial counseling and a cutting edge, assets-based youth development program, the Institute for a Healthier Community. South Boston Community Health Center serves residents of South Boston, a community in which almost 25% of families live in poverty. Although largely white historically, increasing numbers of Latino and African Americans live in South Boston and are served by South Boston Community Health Center.

South End Community Health Center

South End Community Health Center provides a full range of primary care, mental health, dental, eye care, and women, infants and children services to over 15 000 registered patients. South End Community Health Center is recognized for its outstanding preventive care strategies and its cultural and linguistic accessibility and its deep community roots (53% of the staff is hired from the community, with a Board with high representation of community residents). South End Community Health Center is the largest provider of care for the Latino community in the greater Boston area.

and expected results (designated as outputs) in the short and longer term. A Logic Model depicts assumptions about how a project will influence the factors that underlie the challenge being addressed. Elements of a Logic Model are then linked to a data-monitoring plan for process and outcome evaluation.

- **Community-based participatory research framework**—"a collaborative research approach that is designed to ensure structures for participation by communities affected by the issue being studied, representatives of organizations, and researchers in all aspects of the process to improve health and well-being through taking action, including social change."[43] **Community-based participatory research framework** prompts students to grapple with the personal and ethical challenges inherent in working as academics in racially and culturally diverse community settings. We also train students to use specific tools of **community-based participatory research framework**, such as in-depth interviewing; each develops a semi-structured interview format for use in their stakeholder analysis.
- **E-portfolios and peer reviews:** The original tool we used to facilitate individual reflection and peer review within teams, the *Team Learning Assistant*[44]*;* proved to be too laborious. We replaced it with the use of electronic portfolios.[45] Each student creates an individual electronic portfolio to store their responses to assigned and self-generated reflection questions on his or her learning and professional development. In addition, each team member assesses their own and their teammates' strengths and challenges as a team player and collaborative leader.

Assignments, assessment, and team products

Each team has 4 assignments related to the site project: (1) completed "challenge model" and "logic model"; (2) final presentation to stakeholders at the partner site (rehearsed in class); (3) consultation report that summarizes the process, findings, and products, and makes recommendations for implementation and sustainability; and (4) a team electronic portfolio that visually presents the project and contains all team products. Faculty members provide feedback collectively. Students receive team grades for these 4 assignments and individual grades for class participation and reflections. Table 3 portrays each team's challenge and final products by site for both years.

Evaluation Methods

We used 3 methods to conduct a postcourse evaluation to assess satisfaction and impacts of the course: (1) BUSPH online anonymous course evaluation, including quantitative ratings on course elements and instructors, overall course ratings, and open-ended questions about strengths and limitations; (2) a specially designed online survey for medical and dental students; and (3) interviews with 1 or 2 site preceptors/staff members at each site after project completion. The interviews were conducted by phone and lasted for 15 to 20 minutes, in 2009 by a member of the instructional team 6 months after the semester ended, and in 2010, by a research assistant 6 weeks out. The interviews elicited the perspective of community partners on 3 levels: its impact on the organization, the products created, and the processes by which work was accomplished.[17] Finally, we asked respondents to recommend course improvements and rate their willingness to participate in the future. The Boston Medical Center institutional review board reviewed the evaluation plan and granted an exemption.

Evaluation Results

Student perspectives

Overall, the students highly valued the practice- and team-based model of learning and offered excellent suggestions about how to realize its benefits more fully. Each year approximately 60% of the students completed the online course evaluation. In both years, respondents rated the course highly (4.2 of 5.00 in 2009 and 4.4 in 2010) and the large majority (over 90%) said they would "definitely" or "probably" recommend the course to a friend. Among the specific components assessed, "working with other students was valuable" and "the course connected material to other disciplines" were given the highest rating. Elements related to pacing and workload received lower ratings. Responses to open-ended questions further shed light on the strengths and limitations of the course from student perspective. The 3 most valued aspects repeatedly mentioned were: (1) working closely with a community health organization and stakeholders; (2) being able to solve real life problems; and (3) working on a team with students from other schools, even though it was not easy. One 2009 student stated, "The greatest value was the real-life experience of working with an organization and its stakeholders, and also working in a team, as this is likely to be the case at many points in my career." In 2010, a student put it this way: "Finally-an MPH course that lets us use our skills in the field! So important for our future experiences and jobs. . .I have never learned so much in 15 weeks as I did in this course." Another elaborated, "Giving students the opportunity to take a problem and figure out a solution themselves. We rarely get that much decision-making power in school." Other

TABLE 3 ● Products Recommendations by Community Partner Site

Community Partner Site	Team Challenge	Products & Recommendations
Boston	2009	2009
Healthcare for the Homeless	Incomplete acquisition of immunization data from homeless children	Revised patient consent form Improved data collection tool Feedback loop
	2010	2010
	Low smoking cessation rates among adult clients	Team of smoking cessation champions Organizational-wide culture change recommendations Revised patient flow model
Codman Square Health Center (Team 1)	2009	2009
	Low enrollment rates of pregnant women in the Start Initiative, an infant mortality reduction project	Informational brochure and poster Updated refusal survey Recommendations to expand use of incentives, align data systems and tailor enrollment pitch of the Healthy Start Initiative to diverse groups
Codman Square Health Center (Team 2)	2009	2009
	Low knowledge of Human immunodeficiency virus and compliance with treatment among diverse immigrant patients	Patient educational tool Healthy living card
Greater Roslindale Medical and Dental Center	2009	2009
	Increasing rates of obesity in patients of all ages in Roslindale	Template for "Roslindale Right Bites" brochure and restaurant pitch script Recruitment of participating restaurants with window logo and specific "Right Bites" menus
South Boston Community Health Center	2010	2010
	Food insecurity and lack of affordable healthy food options	Youth-designed photo-voice exhibit on food availability and choices Youth-run game table at South Boston "Community Day" Initiation of community cookbook
South End Community Health Center (Team 1)	2010	2010
	Poor pediatric asthma management	"Childhood Asthma Clinic" membership card and brochure Enhanced workflow map Handbook of community resources Recommendations to enhance patient adherence
South End Community Health Center (Team 2)	2010	2010
	High prevalence of early childhood dental caries	Piloted, standardized protocol for applying fluoride varnish to children under the age of 5 years On-site training for pilot week Reference binders with educational materials for parents Referral cards for dental clinic

strengths frequently noted include the following: "the interactions on our team between medical and public health students," "multiple instructors," and "receiving constant feedback from the professors."

The limitations most frequently noted were: transportation difficulties to sites far from campus (2009 only) and the pacing of the course. In both years, even after significant revisions in 2010, students expressed frustration that they did not "get to the field" sooner and recommended condensing the first unit concerning the themes, defining the challenge and selecting a measurable result.

Over the 2 years, half of the medical and dental students responded to the separate evaluation survey. All but one "agreed" or "strongly agreed" that the course better prepared them to work as a community health professional. As one dental student stated, "I gained a deeper understanding of the current relationship between dentistry and public health, and gained skills to improve it as a practicing dentist." Like their public

health peers, clinical students most valued the immersion into an organization's inner-workings. One medical student expressed it this way: "I think the biggest impact on me was the sense of how organization and implementation of change in a health care setting is accomplished." In both years, students noted that a more equal distribution of students across professions would enhance the course.

Site partner' perspectives

In interviews with 12 site partners, all conveyed high satisfaction with the process and results. They consistently commented on students' professionalism and work quality. When asked to rate the value of the team's presentation and report, all respondents assigned a "4" or "5." When asked to name the most valued aspects, the large majority cited the fresh, focused, outside perspective. In 2009, one nurse manager stated, "We had not taken the time to look at our problem from an organizational point of view and we had not analyzed our data." In 2010, one preceptor noted, "their presence was able to catapult the issue higher on the organizational radar." Speaking from her position as director of public health, one respondent took a different angle, "Students brought analytic and critical thinking to the staff. In community health centers staff work hard and it felt like a treat to create space to introspect and think strategically about their work. It was validating and affirming, and brought their work into focus." Our partners also valued information collected from stakeholders never before included, such as patients, restaurant owners, and even providers "down the hall."

When asked about challenges, preceptors repeatedly noted the difficulty of defining a specific project and doing so early in the process. Informed by our experience in 2009, we defined projects more clearly and pitched them at the right level in 2010; yet like students, the preceptors recommended an earlier start on fieldwork. Some also noted the challenges of large team size.

The impact and sustainability of the projects were mixed in 2009 and uniformly positive in 2010. A few examples convey the factors that facilitated higher versus lower impact and sustained effort. In 2009, the challenge selected by the Boston Health Care for the Homeless team was narrowly focused and addressed a "systems issue" (see Table 3). The team created a "feedback loop" that engaged parents in documenting their child's immunizations. The loop has been used successfully for over 1 year. A project at Greater Roslindale Health Center involved student's recruitment of restaurant owners to participate in the "Right Bites" program to encourage healthy menu options. Although deemed by the heath center staff as "beyond expectations," "Right Bites" has not been implemented because of the absence of resources for ongoing work beyond the health center's walls.

In 2010, all projects were considered highly successful and are being sustained (see Table 3). At South Boston Health Center, students were able to launch a new project within an existing youth empowerment organization; and the center has the staff to continue the work. In the preceptor's words, "It sparked a whole new interest in nutrition. When BU came in, it made us realize we need to continue this work. . .and I loved the idea of the kids working with really dynamic (graduate) students. It was an inspiration to them." Likewise, at South End Health Center, one team created a comprehensive plan to address adult obesity and "marketed it" successfully to the staff; and another effectively demonstrated the feasibility of adding oral health prevention activities to primary care visits by bridging the gap between dental and pediatric clinics. As one preceptor said, "Because of (what) they did, the peds department has started using topical fluoride in kids when they go for check ups!"

All interviewees rated their willingness to participate in future years as "very high." Their recommendations for improvements reinforce those of students: (1) carefully define projects at the outset to allow a rapid start; (2) assure a staff person with adequate time and authority to invest in the process; (3) build in a check-in 3 to 6 months postcourse; and (4) involve students in the advancement of projects through ongoing practice. Boston University School of Medicine has since awarded small grant funding to students on 2 teams to support project evaluation and further implementation.

Discussion

The education of community health professionals is in need of reform. Lofty ideals of interprofessional, practice- and team-based, and community-engaged training have received policy attention for decades. In practice, however, the ideals are rarely applied. As the *Lancet Commission* urges, the time is right for innovative initiatives to apply and test these ideals in "real life" within and across universities.[1] The initiative described here is the first known course to apply the principles of reform on one campus and one community. Our modest though pioneering initiative has produced valuable lessons for others who seek imaginative ways to cut across traditional boundaries and educate health professionals for collaborative community practice.

Lesson 1: A multischool, community-partnered, practice-based course is feasible, can meet its learning objectives, and can contribute to change within community health settings

In 2 semesters, our course provided 59 students substantive first-hand experience in the challenges and rewards of working in urban community health. They experienced the highs and lows of life among mission-minded, committed community health professionals, the draw of working on complex, interesting challenges, the constraints of threatened funding cuts and tight resources, the frustrations of underfunded information systems, and the complications of sometimes highly politicized workplaces. They experienced the complexity of understanding and working with diverse collaborators and stakeholders, working across cultural, class, and racial/ethnic differences; and they discovered their own strengths and limitations as team players and leaders. All of these experiences were the focus of student reflections throughout the course.

Lesson 2: Such efforts require administrative support, careful balancing of team- and skill building and field immersion, and generous time investment of faculty and community partners

Within academia, the administrative challenges were important to tackle first. Financial incentives support a silo approach to learning and there exists no template for cross-school education. As described, we overcame these through student and faculty persuasion, and far-sighted administrators who recognized that the course serves a core mission of the 3 schools. The challenge within academia that has proved most difficult to overcome is the recruitment of medical students, largely due to time constraints.

Pedagogically, the toughest challenge is navigating the fine balance between multiple themes and objectives related to crosscutting competencies in the 3 professions (eg, leadership and team building), specific technical skills needed to plan and implement community health projects (eg, logic model building, interviewing), and the time intensity of the field project itself. Our experience suggests that the lions' share of classroom time should be spent on substantive skill building and that field time should be maximized. Competencies such as team building are best woven into field experience, not explored at length in class.

Pragmatically, the rhythm of semester-based education and the "real time" needs of projects geared to systems or behavior change are not easily melded. It is time intensive for site staff and faculty to support fieldwork of students in a telescoped time frame. We learned from interviews, however, that our partners are profoundly committed to the combined agenda of mentoring students as future leaders and getting a job done in their organization. As others have found, the dedication of community partners is a key factor for success in community-campus initiatives.[39]

Lesson 3: An interprofessional, practice-based course can have positive impacts within the partner organizations that go beyond the measurable results and educational objectives

Our evaluation data suggest that the projects most likely to lead to measurable results and sustained effort are: (1) more narrowly focused at the outset; (2) prioritized by the organization; (3) precepted by staff with adequate time to invest and authority to engage other staff; and (4) backed by the will and resources for sustained effort, even if reliant on volunteers and students. Projects with these characteristics are most likely to meet the ultimate aim of practice-based and community-partnered education: reciprocal benefit.[6,20]

We discovered that even in the context of mixed project success, community partners viewed students' contributions as positive and useful. Sites uniformly valued their fresh, outside perspectives that stimulated internal discussions and ideas. Such benefits are often attributed to the best of outside consultants. These contributions are made by students with substantial faculty guidance, and are, in the end, credited to the university.

Lesson 4: An interprofessional course is an effective venue for faculty to model the competencies of leadership we seek to inspire in future health leaders

As faculty, our close communication and collaboration with the site partners allow us to model the day-to-day workings of strong community partnerships. Likewise, the course integrity depends on our ability as a faculty team to work well together as we teach, jointly assess students, and respond to complicated team dynamics. Such team building is challenging for 4 faculty members with intensely busy schedules. Our commitment to weekly meetings or conference calls, and continual email contact, as well as our willingness to self-reflect, has proved critical to the course and team integrity.

Lesson 5: Collaborative, practice-based educational initiatives can be flexible, expandable, and replicable

In "real world" community health settings, various professions, including managers, nurses, social workers, attorneys, occupational and physical therapists all play

important roles. This course model can be expanded by the inclusion of collaborators from any one or more of these professional schools, as our addition of the BUSDM demonstrated. The addition of each profession will greatly enrich the collaborative learning and the array of projects; yet introduce logistic and pedagogic complexities. On the basis of our experience to date, these are complexities well worth taking on.

Conclusion

Emerging leaders of community health must be prepared to meet complex challenges in communities, locally and globally. As such, schools of public health, medicine, dentistry, and others with health-related missions, must assure curricula that give students first-hand immersion in organizations and experience in collaborative practice—across disciplines, sectors, and diverse cultural environments.[7,29] This pioneering initiative at Boston University, the first known of its kind to be implemented and evaluated, is ideally suited as a vehicle for building competencies in crosscutting areas, such as leadership, community engagement and systems thinking, which are shared by public health, medicine, dentistry, nursing, and other health professions.[3,4,6,16,25-28] Dynamic and replicable, the promise of the model lies in its adaptability to any set of professional schools whose work intersects in the real world and calls for collaborative, interprofessional practice, and leadership.

Section of General Internal Medicine, Department of Medicine, Boston University School of Medicine, Boston, Massachusetts, USA

We are pleased to present this special issue on Health Literacy of the *Journal of Health Communication*. This marks the second year in a row that the Journal has published a special issue on this topic, demonstrating its ongoing commitment to field of health literacy. The articles in this special issue help to nudge the field forward, illustrating some important advances and future directions, while acknowledging ongoing challenges.

As with the inaugural version, this issue presents findings from the prior year's Health Literacy Annual Research Conference (HARC) which took place in October 2010 in Washington DC. The number of abstract submissions and meeting attendees

This supplement is supported by the following: National Institute on Minority Health and Health Disparities (NIMHD; grant # 2 R13 MD003392-03); Agency for Healthcare Research and Quality (AHRQ); Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD); National Institute of Biomedical Imaging and Bioengineering (NBIB); Section of General Internal Medicine, Boston University Medical Center; OptumHealth; RTI International; and Health Literacy & Learning Program (HeLP), Northwestern University.

Address correspondence to Michael K. Paasche-Orlow, Department of Medicine, Boston University School of Medicine, 801 Massachusetts Avenue, 2nd Floor, Boston, MA 02118, USA. E-mail: Michael.PaascheOrlow@bmc.org

increased by 20% relative to the first year, reflecting the growing interest of those from diverse disciplines. The goals of HARC include: (1) professional development, (2) advancing the science of health literacy research, and (3) promotion of interdisciplinary research. We aim to create a venue that can help attract young investigators and new ideas and methods to the field. We aim to promote the discourse in this field of inquiry especially regarding core definitional issues, health disparities, and health quality. The varied nature of the research that is relevant to the problem of health literacy makes an interdisciplinary conference incredibly important; bringing such a group of researchers together provides the milieu for new admixtures, new collaborations, and further creativity. A marker of the success we are having in expanding the field towards this goal is that more than half of the presentations at HARC II represented the work of non-MD PhD investigators from a wide array of disciplines. We are hoping for continued growth for HARC III, which will take place October 17–18 in Chicago and will be held in coordination with the International Conference on Communication in Healthcare (ICCH). We hope to see you there (http://www.bumc.bu.edu/healthliteracyconference/)!

In their Commentary, Pleasant et al., describe a research agenda that includes building a new comprehensive approach to the measurement of health literacy and why this is an important task facing health literacy research and practice. Their call for linking health literacy measurement to theory relates to the Commentary by Johnson et al., which is a call to regain a focus on basic research as the basis for effective interventions. It is quite useful to read these Commentaries in concert with a review of the current status of health literacy intervention research. In fact, we include two papers that review health literacy interventions (Sheridan et al. and Allen et al.) as they represent very different approaches to the review and appraisal of the current health literacy intervention literature.

One study underway tests intervention strategies that help educate patients and improve self-care skills in the area of hypertension (Baker et al.). This is one of the few studies to use a randomized control trial study design and look at clinical outcomes. Kandula and colleagues are using an experimental approach to test the effectiveness of teaching strategies to improve patients' recall and retention of information about diabetes management. Other strategies are considered for increasing health literacy including a wellness curriculum for low-income youth (Diamond et al.) and through adult education programs (Freedman et al.).

Several authors share ongoing work in health literacy measurement and methodology (Fransen et al.), including technology-based data collection approaches (Hahn et al.) and how health literacy can affect health care interactions (Manganello et al. and Martin et al.). Rubin and colleagues look at the association between older adults' spoken interactive health literacy and health care experiences among a low-income population. This paper and the paper by Pizur-Barnekow et al. illustrate the practical challenges of measuring interactive health literacy, which is the least studied of all health literacy components. Chin et al. investigate multiple paths to health literacy by exploring the effects of selected cognitive elements in an elderly cohort for two of the most commonly used measures of literacy, while An et al. examine the comprehension of direct to consumer advertising in an elderly cohort.

This special issue examines health literacy as a risk factor for misuse of medication (Shone et al.) and the relationship between health literacy and various intermediate health outcomes including adherence to medications (Osborn et al.). Sentell et al. present the first population-based examination of the prevalence and

associations of health literacy in a Hawaiian sample. Macabasco-O'Connell and Fry-Bowers describe the knowledge and perception of health literacy among nursing professionals. Hardie et al. demonstrate the relationship between health literacy, health services utilization and cost for members of a health plan. This article along with an accompanying editorial by Rush and Paasche-Orlow promote the expansion of health literacy interventions into larger operational settings. A European perspective on how this can happen is presented by Sørensen and Brand.

The papers included in this special issue clearly represent a wide variety of methods and perspectives. Some of the variability represents logical differences that inherently emerge from the research questions; however, it appears that some of the variability represents underlying conceptual disagreements about health literacy. To a certain extent, we, as the editors of this volume, tried not to impose our views. By and large, we tried to allow authors to express themselves. Yet, the process has reinforced our view that the field could greatly benefit from clarity and consensus. Disagreements will likely persist, but they should represent the well examined views of an intellectually curious and vibrant health literacy research community.

SHORT REPORT Open Access

Use of electronic personal health record systems to encourage HIV screening: an exploratory study of patient and provider perspectives

D Keith McInnes[1,2*], Jeffrey L Solomon[1], Barbara G Bokhour[1,2], Steven M Asch[3,4], David Ross[5], Kim M Nazi[6] and Allen L Gifford[1,2,7]

Abstract

Background: When detected, HIV can be effectively treated with antiretroviral therapy. Nevertheless in the U.S. approximately 25% of those who are HIV-infected do not know it. Much remains unknown about how to increase HIV testing rates. New Internet outreach methods have the potential to increase disease awareness and screening among patients, especially as electronic personal health records (PHRs) become more widely available. In the US Department of Veterans' Affairs medical care system, 900,000 veterans have indicated an interest in receiving electronic health-related communications through the PHR. Therefore we sought to evaluate the optimal circumstances and conditions for outreach about HIV screening. In an exploratory, qualitative research study we examined patient and provider perceptions of Internet-based outreach to increase HIV screening among veterans who use the Veterans Health Administration (VHA) health care system.

Findings: We conducted two rounds of focus groups with veterans and healthcare providers at VHA medical centers. The study's first phase elicited general perceptions of an electronic outreach program to increase screening for HIV, diabetes, and high cholesterol. Using phase 1 results, outreach message texts were drafted and then presented to participants in the second phase. Analysis followed modified grounded theory.
Patients and providers indicated that electronic outreach through a PHR would provide useful information and would motivate patients to be screened for HIV. Patients believed that electronic information would be more convenient and understandable than information provided verbally. Patients saw little difference between messages about HIV versus about diabetes and cholesterol. Providers, however, felt patients would disapprove of HIV-related messages due to stigma. Providers expected increased workload from the electronic outreach, and thus suggested adding primary care resources and devising methods to smooth the flow of patients getting screened. When provided a choice between unsecured emails versus PHRs as the delivery mechanism for disease screening messages, both patients and providers preferred PHRs.

Conclusions: There is considerable potential to use PHR systems for electronic outreach and social marketing to communicate to patients about, and increase rates of, disease screening, including for HIV. Planning for direct-to-patient communications through PHRs should include providers and address provider reservations, especially about workload increases.

Background

Arguments for expanding HIV screening are compelling. When detected, HIV can be effectively treated with antiretroviral therapy (ART), which improves patient survival, helps prevent HIV transmission, and is cost effective [1-3]. Nevertheless in the U.S. approximately 25% of those who are HIV-infected do not know it [4,5]. Much remains unknown about how to increase HIV testing rates in the US.

Direct outreach to patients via the Internet is a potentially efficient means of educating patients about the importance of HIV screening. Patient electronic personal health record (PHR) systems may be a useful vehicle for such outreach [6-8]. Little is known, however, about how patients and healthcare providers would perceive use of the PHR to disseminate disease screening messages, or whether such messages would increase HIV testing, e.g. by increasing patient knowledge [9], self-efficacy [10], and activation [11]. Additionally this type of outreach could raise patient concerns about privacy of information on the Internet, especially for stigmatized conditions like HIV. Providers may have concerns that workload will increase, or that direct-to-patient outreach circumvents provider authority. While electronic outreach for health purposes is not new, it has largely been evaluated in the context of randomized trials of specific interventions [12-14], or newsletters for which consumers pro-actively register [15]. Little is known about how providers and patients within a large health care organization would perceive large-scale, unsolicited, outreach via an electronic personal health record system to encourage HIV screening.

As the largest provider of HIV care in the U.S., the Department of Veterans Affairs (VA) is well suited for evaluating different methods for increasing HIV testing. The VA already devotes considerable effort to increasing HIV screening rates [16], including clinical reminders in the electronic medical record, provider performance profiling, and reducing paperwork barriers to testing [17-19]. Still, testing rates are sub-optimal, with an estimated 20% to 50% of VA patients with documented risk factors for HIV infection having been tested [20-22]. The VA's electronic PHR, My Health*e*Vet, contains email addresses of nearly 1,000,000 veterans, most of whom (87%) report using VA health care [23]. Thus the VA is an appropriate system for implementing and evaluating large scale electronic outreach for HIV screening. The VA PHR was (and is) evolving rapidly, with new versions released approximately every 6 months (current version is 11.2). In addition, at the time of this study the VA was preparing to adopt new Centers for Disease Control and Prevention (CDC) recommendations for routine, instead of risk-based, HIV testing. Among other things this involved the elimination of the requirement to obtain written patient consent prior to testing. In the context of this rapidly changing landscape we selected methods which would quickly provide VA policy makers with preliminary patient and provider perceptions of the use of the PHR to encourage more HIV screening.

We explored patient and provider attitudes toward an electronic outreach program for HIV screening, based on a PHR platform. We conducted focus groups with patients and providers about HIV testing. We also discussed diabetes and cholesterol screening with participants to assess whether attitudes toward outreach to increase screening depended on the health condition. We explored the acceptability of messages embedded directly in personal emails versus messages posted on the PHR website. Our focus group guides were informed by the Information-Motivation-Behavioral Skills (IMB) model which has guided health promotion and chronic disease management, including HIV [24,25]. We used the model to guide broad categories of questions to include in the focus groups. Qualitative methods were used because, with such new areas of research, it is important to identify salient patient and provider perceptions and themes prior to embarking on larger scale quantitative research [26-28].

Methods

Overview

Four focus groups were conducted between September 2008 and March 2009, in two phases (Figure 1). The first phase explored HIV screening (and other disease screening) in general terms and sought participant suggestions about the content and framing of the electronic outreach messages. Results from this phase guided the investigators in drafting the content of messages. In the second phase, we presented participants the draft text of HIV, diabetes, and cholesterol screening messages in order to explore patient and provider perceptions of realistic content. It was important to compare perceptions of other chronic health conditions to HIV in order to assess whether HIV-related stigma would adversely affect acceptance of HIV screening messages. The message text was based on VA and Centers for Disease Control and Prevention (CDC) screening guidelines, as well as findings from the phase 1 focus groups. The Institutional Review Board of the Edith Nourse Rogers Memorial VA Medical Center, Bedford, MA approved the study including all recruitment methods. Study subjects completed written informed consent prior to participating.

Participants and Setting

A total of 12 patients (6 in each focus group) and 15 providers (6 in one focus group, 9 in the other)

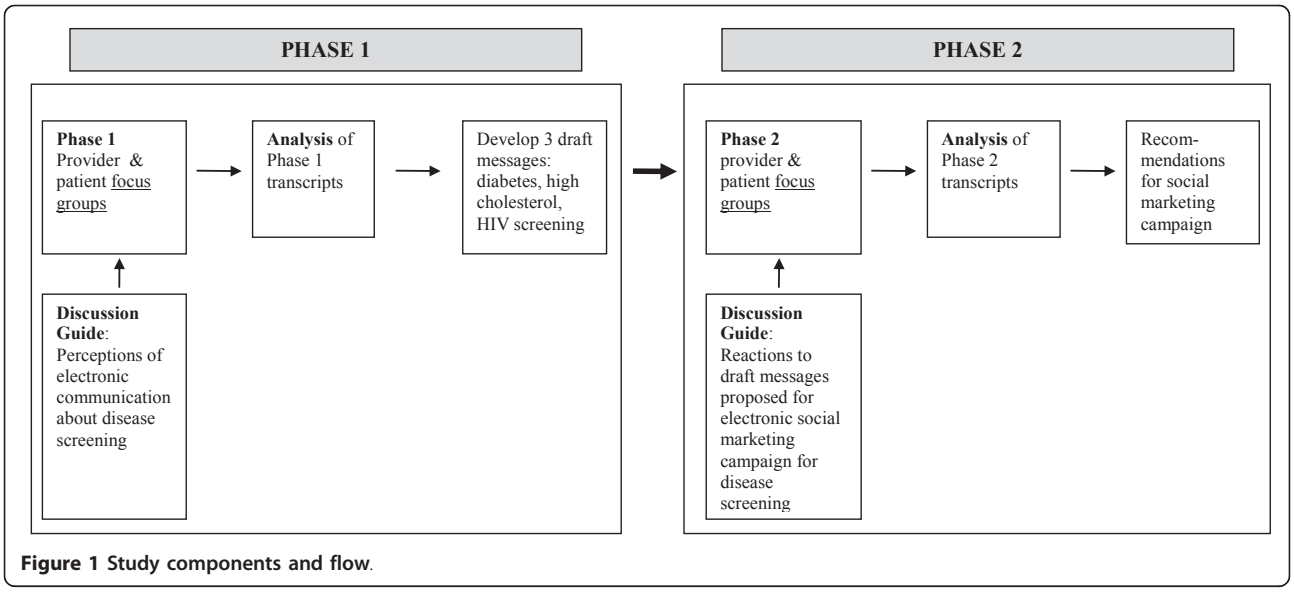

Figure 1 Study components and flow.

participated. Patients were recruited from a Boston area VA medical center. We posted recruitment fliers on walls and a "crawler" message on the televisions in the medical center waiting areas. We also approached veterans at new-patient orientation sessions and in the veterans computer center (KM and LM). Patients received $20 for their participation.

Primary care providers were recruited from another urban New England VA medical center. The invitation to providers was extended by a research team member (KM) who described the study at a primary care staff meeting. Providers were not compensated for participating.

Procedures

There were two facilitators (KM and JS) for each focus group. Following the IMB model, we developed focus group guides to explore whether the concept of electronic disease screening messages, and message content, were perceived as providing valuable information. Secondly questions assessed how likely the information was to motivate patients to seriously consider being tested, and how likely they would be to take action, i.e. ask their provider for a test (behavioral skills). More specifically, the phase 1 patient focus group guide covered experience with disease screening; sources of information about disease screening; experience with Internet and My Health*e*Vet; and, attitudes toward the proposed VA electronic outreach program to increase disease screening rates. The phase 2 patient guide elicited reactions to draft texts of messages for HIV, cholesterol, and diabetes screening (Figure 2) that might be part of the VA disease screening outreach program. Patient focus groups lasted two hours.

The phase 1 provider focus group guide elicited discussion of how providers decide to screen individual patients for diseases; provider views of patient requests for disease screening; provider perceptions of the proposed electronic outreach program; and their assessments of how patients would react to such a program. The phase 2 guide asked providers for their reactions to the same draft messages (for HIV, cholesterol, diabetes) that were shown to patients (Figure 2). They were asked how they anticipated their patients would respond, what questions their patients might ask, and what they thought patient reaction would be. Provider focus groups lasted one hour.

While the research was conducted in two phases, with separate focus group guides for each phase, the results are presented by themes, rather than phase. This is because there was considerable overlap between the focus group guides from the first and second phases. Hence the themes we uncovered emerged from all four focus groups. We have indicated after each quote which phase it came from, e.g. "Patient FG1" refers to first phase patient focus group. Because the focus group guides are lengthy (they make extensive use of probes and prompts that the focus group facilitator can use at his or her discretion) they are not included here, however they are provided for interested readers in Additional File 1: Focus group guides used for patients and providers. All focus groups were audio-taped and transcribed.

Analysis

We used an iterative process to guide the analysis and interpret data, based on grounded theory methods [29]. Immediately following each focus group the facilitators discussed their impressions of significant points that

Dear Veteran:

Did you know that the VA encourages veterans to get a variety of routine health tests, such as checking your cholesterol? Read below to see why.

Why check my cholesterol?

- Over 100 million American adults have cholesterol levels which are higher than recommended.
- Having high blood cholesterol can put you at risk for heart disease, the leading cause of death in the US.
- Adults aged 20 years or older should have their cholesterol checked every 5 years.
- If you think you may not have had a cholesterol test in the past 5 years, ask your provider at your next visit.

The good news!: Cholesterol can be lowered through diet, physical activity, weight control and medication.

Dear Veteran:

Did you know that the VA encourages veterans to get a variety of routine health tests, such as testing for diabetes? Read below to see why.

Why check for diabetes?

- About 24 million Americans have diabetes, but one quarter of these people don't know they have it, because they haven't been tested recently.
- Diabetes can cause serious health problems like heart disease, strokes, blindness, and kidney disease.
- Adults aged 45 years or older should have their blood sugar checked (the test for diabetes) at least every 3 years.
- If you have not had your blood sugar checked in the past 3 years, or if you are unsure, ask your provider at your next visit.

The good news!: If you don't have diabetes, your provider can help you keep it that way. If you do have diabetes, your provider can tell you many ways to control it.

Dear Veteran:
Did you know that the VA encourages veterans to get a variety of routine health tests, such as testing for HIV disease? Read below to see why.

Why check for HIV disease?

- Over 1 million Americans have HIV. Unfortunately a quarter of the people who have HIV don't know they have it because they have never been tested.
- Having HIV but not knowing you have it means that you could spread the virus to other people. Also, untreated HIV causes AIDS, which is a very serious disease.
- The Centers for Disease Control (CDC) recommends that all adults get tested for HIV.
- If you think you may not have been tested for HIV, or are unsure, ask your provider at your next visit.

The good news!: Most people tested for HIV don't have it. But if you do have HIV you won't lose any VA benefits, and the VA has excellent health care for HIV.

Figure 2 Text of electronic messages shown to patients and providers in focus groups.

emerged from the focus group. In addition, within a week the facilitators briefed the whole research team, summarizing the focus group content, and eliciting comments about emerging themes. Audio-recordings were transcribed verbatim by a professional transcription firm. Focus group facilitators (KM and JS) verified the transcripts and analyzed them by open coding, i.e. identifying key concepts emerging from the language used by participants, and assigning codes (descriptive phrases) to segments of text. NVivo

qualitative analysis software (QSR, Melbourne, Australia) was used to facilitate data coding and sorting. Coded text segments were reviewed by three investigators (KM, JS, and BB) to categorize codes into distinct themes. Where similar themes were identified in patient and provider transcripts, we examined similarities and differences in patient and provider perspectives. In a final phase, after developing preliminary interpretations, we searched through the data for alternative interpretations and rival conclusions.

Results

Participant Characteristics

Patients ranged in age from 48 to 71 years of age. Most were white and male. Two-thirds were Internet users (used email and/or the Internet). All had some college education. The 5 physicians and 7 primary-care nurse practitioners participating ranged in age from 46-60 years (see Table 1).

Overview of findings

Patients and providers perceived important informational and educational benefits of the proposed electronic outreach. Several providers expressed substantial privacy concerns related to the social stigma associated with HIV. Patients, for the most part, did not perceive HIV messages to be inherently more sensitive than messages about diabetes and cholesterol. Providers anticipated increased workload and made recommendations for message content in order to minimize disruption to primary care practice.

Perceived benefits for patients of screening messages in general

The more information the better

Patients and providers perceived that electronic disease screening outreach would improve patient access to useful health information, with important educational value. For providers there was a perception that it would reinforce messages they give to patients. Patients seemed interested in more information, and saw this outreach as a potentially good way to achieve this goal. Here, a patient expresses his view that too many people take their bodies and their health for granted, and that the messages proposed could help combat this complacency.

> "I think all this information would be great. Because I think how else are we going to know what to do with the only true asset we own [which] is our body. And some people spend more time getting the oil changed in their car than they do worrying about what's going on in [their bodies]." *(Patient FG2)*

Providers realized that their repeated recommendations to patients to be screened lose effectiveness. Using a new medium, i.e. the Internet, could be a useful adjunct to what providers are trying to communicate to their patients.

> "I think for established patients, this is reinforcing education. The last sentence [of the draft text shown to providers], 'Cholesterol can be lowered,' they're hearing that all the time from us. And now they're reading it, so [it's] another teaching tool." *(Provider FG2)*

Information using lay language and available when patients are ready for it

Patients could imagine scenarios in which disease screening information provided electronically would be better than verbal information from their doctor. The patient below knows there are times when other factors, in this instance substance use, interfere with his ability

Table 1 Characteristics of focus group participants

	Patient Focus Groups	Provider Focus Groups
Number	6 in group 1	6 in group 1
	6 in group 2	9 in group 2*
Gender	2 female; 10 male	8 female; 4 male
Race/Ethnicity	9 white	[Not collected]
	1 African American	
	1 Hispanic	
	1 Pacific Islander/Hawaiian	
Education/Qualifications	6 some college or college degree	7 nurse practitioners
	3 some graduate or graduate degree	5 medical doctors
	3 not provided	
Age	48 to 71 years	46 to 60 years

* There were 12 unique providers because 3 providers participated in both focus groups.

to absorb important messages from his doctor.

> "Let's say I went in from detox. [My doctor] might be saying all this stuff to me but I might be in a situation where I'm like, 'I ain't listening to all this stuff at this point now.' When my head starts to clear out [I might think] 'Okay. What did this doctor say?'" (*Patient FG2*)

An electronic message gives the patient another opportunity to receive the information, and the choice of when and how many times to read it. These messages can be carefully worded to accommodate low literacy levels, as expressed by this patient,

> "If you put [the web information] in layman's terms pretty much explaining LDL or HDL...and how you get it, [that's better than having] $20 dollar words in there." (*Patient FG2)*

Messages can motivate patients

Patients felt that electronic outreach would motivate them to be proactive about their health. Most felt the electronic messages would remind them to be screened, or at least contemplate getting screened. Here a patient finds the idea of an email about HIV screening to be non-threatening, and potentially motivating.

> "They're not telling you [you have to be tested for HIV]. They're putting it in your mind saying... "Have you ever thought about getting HIV testing?" It's non-offensive. You're not prying. But it gets you thinking. Something like that might work." (*Patient FG1*)

Below, two patients, discussing diabetes screening, conclude that outreach messages would be valuable, despite their different perceived risk for the condition. The first realizes that a common "if it's not broken, don't fix it" attitude, may prevent people from thinking about getting preventive testing.

> "As far as [an email] prompting you to go and get [a test] done, yeah there's probably people that aren't even aware that they should have them. Up until five years ago, I never thought about getting my blood sugar checked. What do I care? It's not bothering me any." *(Patient FG2)*

The second patient has a family history of diabetes that he/she might inadvertently ignore. Periodic reminders can be the extra motivation to take action and get tested.

> "My father has diabetes. My mother is borderline diabetes [sic]. I've been checked periodically through the years and I don't seem to be having it...It might slip my mind where I'm not thinking I'm going to get it...and then all of a sudden I see [the electronic message about diabetes screening] and I say, 'Maybe I ought to go and have it checked.' So it's kind of like a kick in the pants." (*Patient FG2*)

HIV content: patient acceptance, provider wariness

Our focus group questions sought to contrast electronic outreach for non-sensitive conditions (i.e. diabetes and cholesterol) with HIV, a stigmatized condition. Few patients, however, made this distinction. Patients thought electronic messages about HIV were acceptable and useful, especially if they were clearly written as public health announcements for wide distribution. One patient likened HIV information delivered electronically through the PHR to posters about HIV testing found in many VA medical center waiting rooms; while another felt that because the material was for a generic patient audience it would not raise objections:

> "I wouldn't mind [getting a message about HIV testing]; it's pasted all over the walls of the VA. I mean, I think the information is good." (*Patient FG2*)
> "None of this is laden with any personal information on yourself or anything like that...I can't see any of this being upsetting to anybody." *(Patient FG2)*

A third patient, however, speaking about messages sent to personal email addresses, was worried about possible security breaches and the stigma of being associated with HIV. He suspected that once information entered his computer it would be difficult to erase, thus allowing later users to find such messages.

> "I don't want 'You get tested for HIV' [in an email]... I've given away computers I've had to people who never had one... They can get into your mainframe, as you folks may know. They can find stuff that you left in there. I'm not taking that chance.... I'm very careful about what goes in my computer. I have a disk that I put everything on. I don't let it go on my mainframe. But some stuff goes in there. You think I want to take a chance and let HIV go in there? And they accidentally find it? Hell, no!" *(Patient FG1)*

This type of concern supports placing the disease screening messages on the PHR website, rather than delivering it directly into patient email inboxes. This sentiment is summarized by a patient in the first focus

group (referring to the PHR by its VA name, "My Health*e*Vet"):

> "I would like to see [a message in my personal email stating] "You have messages at My Health*e*Vet." That's all I want to see. Just tell me to go My Health*e*Vet website, log in and I get messages there. I'd rather see a message there than coming into [my personal email]." *(Patient FG1)*

Providers aired substantially more concerns about HIV messages than patients. Some providers felt that patients would be irresponsible with emails containing HIV-related content. The provider below, for example, described how patients easily find doctor email addresses, and could send their doctors inappropriate email. The provider expresses two issues: the risk that the patient becomes associated, in other people's minds, with a stigmatized condition, and the risk that providers get criticized from their employer for participating in inappropriate email use.

> "I see a lot of problems with this, because there are going to be some [veterans] who aren't thinking about confidentiality. And they're going to be emailing their provider, which is 'my name-dot-VA-dot-gov'; And they're going to be saying 'Oh, I got this thing on HIV. I think I should be tested.' And it's going to be out there in the Internet world, floating around. And the VA is going to get dinged - or me - for 'Oh my God, why did this person email you about this?'" *(Provider FG2)*

This provider expresses the view, correct in some instances, that regular email messages are vulnerable because they "float around" in the Internet easily opened and read by other Internet users.

Another aspect of provider resistance toward HIV-related emails was that they could create suspicions among patients that the VA is withholding information from patients:

> "And I think if you sent them an email, there are some people who might be walking in the next day, 'I got this email that told me to come in and be tested!...Why are you worried?...Why'd you send it to me? Did you send it to anybody else?'" (*Provider FG1*)

This view may reflect provider sensitivity to claims by veterans and active duty military that the US government releases too slowly important health-related information, especially for risks related to military service [30].

Finally, another provider's hesitation was that the HIV message was inappropriate because it was promoting a substantial deviation from the way providers recommended HIV testing. One provider remarked, "...this third [message] on HIV is like a bombshell," because it recommended routine HIV testing. Providers had described in the first focus group that they typically recommend HIV testing to their patients only if risk factors were present, i.e. intravenous drug use or men having sex with men. A consequence of these concerns seemed to be that providers preferred, if an outreach program were conducted, that content be posted on the PHR website, rather than transmitted via email. Patients and providers approved of a "tickler" email message to patients that would indicate there is new content on the PHR, with a hyperlink to the PHR website.

Perceived provider burden

A prominent provider concern was that electronic outreach for disease screening would lead to unmanageable workload. They anticipated the outreach would result in a substantial increase in patient phone calls, time spent explaining and clarifying the outreach program, and additional appointments.

> "If the VA is going to send out a newsletter [about disease screening],...especially if you're sending it electronically,...you're going to get this flood of phone calls the day it goes out, and probably the next week. And, if you're not prepared for that, you've got to have your telephone staff prepared. You have to have your primary care nursing staff prepared, your primary care provider staff. Because these things have this, like, volcano effect." (*Provider FG2*)

One provider suggested that the messages should contain preemptive language to discourage patients from immediately calling or visiting their provider:

> "If you maybe send out [an electronic] newsletter [to patients that says] '... your provider will be asking you for A, B, C, D, E, F, G at your annual - highlighted, underlined, in bold, different color - visit', so [the patients realize] you don't need a PSA every time you come to the walk-in." (*Provider FG1*)

These providers did not reject the electronic outreach initiative, but have suggested that to be successful, it would be wise to make advance preparations with staff and to include education of patients that indicates this is not urgent and can be handled at annual - or other regularly scheduled visits. Other providers concurred, but also reflected a feeling that PCPs are being

shouldered with increasing demands and performance measures, often without increases in resources:

> "How can I do this? I want to be doing X, Y, and Z, and you're adding another element that I'm responsible for." *(Provider FG1)*

Patients, interestingly, did not indicate they would rush to contact their providers or make appointments to see their doctors as a result of electronic messages. In fact some patients believed that if the electronic communication had links to more information it might actually save doctors time:

> "If you need more information...instead of having an hour conversation with the doctor and having the doctor teach you, you could actually go to a place on [the patient website for more information]." (*Patient FG2*)

Discussion

As health care systems adopt new information technologies it is appropriate to consider their use for public health purposes, such as disease screening. This study takes a first, exploratory step in evaluating the acceptability of outreach via an electronic PHR system by soliciting patient and provider perceptions through focus groups. We found that perceptions were, on the whole, positive. Patients and providers acknowledged educational, informational, and motivational benefits of electronic messages. Providers especially, and patients to a much smaller degree, expressed privacy concerns about messages that contained HIV content. Those concerns could be mitigated by posting patient content on the PHR website, as opposed to embedding it in personal email messages. A bigger issue for providers, however, was that this kind of outreach could lead to unacceptable increases in workload. They suggested it could be mitigated by increased primary care resources and management of patient flow so that most additional disease screening could occur during annual visits or spread more evenly over time.

Patients indicated that electronic content afforded the ability to view information when and where convenient, at appropriate reading-levels, and with web-links to multiple sources of information. Using individual email addresses, however, carries the potential risk of creating suspicions among patients that they have been contacted based on specific clinical signs of HIV, or based on HIV risk stereotypes, e.g. homosexuality or intravenous drug use. HIV-related stigma also seemed to underlie provider worries that patients would unwittingly expose themselves to stigma if they sent their doctors emails about HIV testing. Accordingly, patients and providers favored an outreach approach that delivered content impersonally, i.e. posted on the healthcare system PHR website.

Our findings support the IMB model in that both patients and providers indicated that the electronic messages were perceived as providing important information, and that they would lead to patient action in terms of inquiries about, or actual increases in, testing. The findings also highlighted to us that the health belief model (HBM) [31] could be an important addition to the IMB model in helping to understand patient and provider responses to electronic messages about disease screening. This makes sense in that the health belief model often guides health-related social marketing campaigns [32-35] that rely on perceived susceptibility to disease to motivate people to take action. Patients with high perceived susceptibility may seek information, screening, and care on their own. Others patients, however, may have consciously or unconsciously suppressed the knowledge that their family history or risky health behaviors could make them vulnerable to certain health conditions. For such patients the electronic messages serve as external cues ("cues to action" in the terminology of HBM) motivating them to take action and get tested. While the current draft messages (Figure 2) incorporate concepts of information and motivation from the IMB model, future versions could have links to skill-building material - another important IMB component. For example the HIV message could link to material about how to have a conversation with a partner about using condoms, while the diabetes message could link to simple instructions for increasing daily physical activity.

It is noteworthy that the participating patients were middle aged and older adults, most of whom were not highly experienced computer and Internet users. Nevertheless nearly all recognized advantages that such technologies provide in distributing beneficial health information, a finding supported by Pew Research Center findings that older adults are increasing their presence online [36,37].

Provider concerns that electronic communications with patients may create unmanageable workloads have been documented previously [38]. Evidence suggests, however, that patient use of PHRs, secure messaging, and similar electronic communication tools do not overwhelm providers [39,40]. There is even evidence that electronic communication reduces in-person and telephone communication [6]. We found support for this, e.g. a patient stating that accessing information from a website could replace "an hour conversation with the doctor". The above notwithstanding, we do not dismiss provider concerns about increased workloads. Primary

care providers face health system demands for better quality of care at lower costs, with resultant increased stress and loss of autonomy [41,42]. On the other hand solutions exist to even out demands on providers, for example by staggering electronic outreach messages based on patient birth dates or social security numbers.

The success of HIV screening campaigns may rest partly on patient perceptions that, in the event of a positive HIV test, they can gain access to compassionate providers and effective treatments, i.e. there is good linkage to care [43-45]. When HIV screening outreach is conducted by a health facility or system that has strong HIV care programs, it is likely the outreach will be more successful. In this regard, the VA would seem to be especially well suited to employ the kind of electronic outreach described in our study because it is a large, comprehensive health care system with specialized HIV clinics to care for veterans with HIV/AIDS. Currently approximately 23,000 veterans with HIV are in treatment in the VA [46].

This study was conducted 6 months before the VA formally adopted CDC guidelines which recommend routine HIV testing for all adults in care, regardless of risk factors [47]. This policy change eliminated written patient informed consent for HIV testing, in favor of verbal consent. Thus our findings represent patient and provider perceptions prior to implementation of the new HIV testing policy in the VA. Adherence to the CDC guidelines is far from universal even after the policy change in the VA and in other settings [48], suggesting the importance of continued outreach to patients to encourage HIV testing. In addition even in settings where the guidelines are closely adhered too, there will be patients who come for care infrequently and thus would benefit from this kind of outreach; the outreach messages might prompt them to make a visit or a phone call to discuss testing with their provider. In any case it will be important to evaluate whether patient and provider perceptions of HIV testing messages have changed in the VA and to extend the analysis to non VA sites.

As PHR systems continue to expand their capabilities, it is easy to imagine moving from occasional broad electronic outreach programs to more routine patient reminders that patients see when they open up their PHR. In the VA, for example, the PHR has recently implemented reminders for preventive care and procedures, such as diabetes care (foot and retinal exams), cancer screening, and immunizations [49]. It would not be difficult, technically, to add HIV screening to that list.

Limitations

Our study was limited to 2 patient focus groups and 2 provider focus groups conducted in one region of the U. S. Thus our findings may not be generalizable to other regions and other healthcare systems. Only 2 female patients participated (1 in each group), also limiting generalizability. Our participants were middle-aged and older, and thus probably reacted differently to some issues than would participants in their 20s and 30s who have grown up with computers. Also participant responses might have differed had they been reacting to a "live" electronic outreach program rather than a proposed one. Our use of draft text, however, which participants reviewed in the focus groups, is likely to have created a sense of concreteness and immediacy.

Conclusions

The growth in online information systems connecting healthcare organizations with their patients provides an excellent opportunity to conduct low cost and potentially high impact electronic outreach and social marketing. Our findings suggest that patients and providers endorse the use of PHRs for disease screening outreach, even for a stigmatized health condition such as HIV. For providers it is important that prior to initiating wide-scale electronic outreach forethought be given to management of patient expectations and flow. Before large scale implementation of such a program, validation from other geographic regions and with other age groups would be beneficial. If executed properly, electronic outreach campaigns through PHR systems may lead to increased screening, increased detection, and improved health.

Abstract

While decisions made according to Bayes' theorem are the academic normative standard, the theorem is rarely used explicitly in clinical practice. Yet the principles can be followed without intimidating mathematics. To do so, one can first categorise the prior-probability of the disease being tested for as very unlikely (less likely than 10%), unlikely (10–33%), uncertain (34–66%), likely (67–90%) or very likely (more likely than 90%). Usually, for disorders that are very unlikely or very likely, no further testing is needed. If the prior probability is unlikely, uncertain or likely, a test and a Bayesian-inspired update process incorporating the result can help. A positive result of a good test increases the probability of the disorder by one likelihood category (eg, from uncertain to likely) and a negative test decreases the probability by one category. If testing is needed to escape the extremes of likelihood (eg, a very unlikely but particularly dangerous condition or in the circumstance of population screening, or a very likely condition with a particularly noxious treatment), two tests may be needed to achieve. Negative results of tests with sensitivity ≥99% are sufficient to rule-out a diagnosis; positive results of tests with specificity ≥99% are sufficient to rule-in a diagnosis. This method overcomes some common heuristic errors: ignoring the base rate, probability adjustment errors and order effects. The simplicity of the method, while still adhering to the basic principles of Bayes' theorem, has the potential to increase its application in clinical practice.

Bayes' theorem[1] remains the normative standard for diagnosis, but it is often violated in clinical practice. Attempts to simplify its application with diagnostic computer programs,[2 3] nomograms,[4] rulers[5] or internet calculators[6] have not helped to increase its use. Bayes' theorem helps overcome many well-known cognitive errors in diagnosis, such as ignoring the base rate, probability adjustment errors (conservatism, anchoring and adjustment) and order effects.[7] Bayes' theorem and its underlying precepts are introduced early in medical school and medical texts, for example, Chapter 3 of 392 chapters in *Harrison's Principles of Internal Medicine*.[8] Even so, adherence to Bayes' principles is all but absent – low probability diseases are still tested for causing unneeded cost and risk, and high probability diseases are ignored when a single negative test returns.

The basic idea of Bayes' theorem for medical diagnosis is well accepted. A diagnosis is not necessarily confirmed just because a test was positive. Diagnosis is usually not a binary decision (ie, true of false) turning on a single datum, but a dynamic probabilistic assessment. The post-test probability (also called the updated probability, posterior-probability or positive-predictive value) of a diagnosis is dependent on how likely the diagnosis was before the test was done (the pretest probability, also referred to as the prevalence or prior-probability), the test result (positive or negative) and the ability of the test to discriminate between those afflicted and not afflicted with the disease (test characteristics expressed as sensitivity and specificity, or likelihood ratios). A simple formula, Bayes' theorem, combines these elements to produce the post-test probability of the disease. A positive test increases confidence in a diagnosis, but usually does not indicate certainty. Whether this confidence exceeds a treatment (or action) threshold[9] remains a decision for the clinician and patient. Likewise, a negative test decreases confidence in a diagnosis, but rarely rules it out completely. It is up to those involved to decide if further action is warranted.

What if an easy, non-mathematical method to apply these concepts were available? Could the application of Bayes' theorem find its appropriate place in clinical practice and not be relegated to academic exercises for medical students and residents? Could its benefits in clinical practice finally be realised? There is a simple, qualitative or categorical application of Bayes' theorem that might ease the application of Bayes' underlying precepts. The method is based on categorising the pretest probability and handling a small set of probabilistic categories instead of the full spectrum of continuous probabilities, thus eliminating the need for mathematical calculations. In this paper, we first introduce this qualitative method. Then we present the mathematical justification for the method and the conditions under which it holds. Finally we present some special cases that reinforce the method.

Qualitative Bayes' theorem

Bayes' theorem's concepts can be applied using qualitative methods. First one must commit to the pretest probability – how likely the diagnosis is from the start. This probability is expressed categorically – *very unlikely* (less likely than 10%), *unlikely* (between 10% and 33%), *uncertain* (between 34% and 66%), *likely* (between 67% and 90%) or *very likely* (more likely than 90%) (table 1).

If the initial assessment is *very unlikely* or *very likely*, then in most cases it is not worth further testing according to Bayes' theorem – the results would either confirm what is already near certain or it would minimally move the post-test probability in the opposite direction. Either way, the clinician would not normally take additional actions. There are at least two situations where it is still important to proceed with further testing. First, if the diagnosis is *very unlikely* but needs to be ruled out with more certainty, as in a very dangerous disease, the clinician may want to proceed with testing. For example, at what probability is the clinician willing to send a patient home in whom a diagnosis of subarachnoid haemorrhage is being considered? Similarly, if the diagnosis is *very likely*, but

Table 1 Categorical probabilities

Categorical probability	Numerical probability
Very unlikely	Less likely than 10%
Unlikely	Between 10% and 33%
Uncertain	Between 34% and 66%
Likely	Between 67% and 90%
Very likely	More likely than 90%

needs to be ruled in with more certainty, such as when the treatment is especially dangerous or noxious, further testing is indicated. For example, at what probability is the clinician willing to commit a patient with liver disease to a course of anticoagulation with warfarin for a deep venous thrombosis?

If the probability is in one of the intermediate categories, then further testing is appropriate. The clinician may order a test and then interpret the results. A positive result moves the clinician to the next more likely category. A negative result moves the clinician to the next less likely category.

For example, if the clinician is seeing a 35-year-old man in the office who presents with substernal, exertional chest pain that was relieved with rest, the patient has anginal chest pain. His pretest probability of having coronary artery disease (CAD) is *likely*, about 70%.[10] Further testing is warranted and a stress test is ordered. If the result is negative, the diagnosis of CAD is *uncertain* – not absent. If the result is positive, CAD is *very likely*. But, if the patient were a woman, her pretest probability of having CAD is *unlikely* (about 26%). Further testing is also warranted. In this circumstance, if the stress test is negative, the diagnosis of CAD is *very unlikely*. If the test is positive, CAD is *uncertain* – not definitively present.

When does the qualitative approach to applying Bayes' theorem work?

Using the above intuitive cut-offs, and tests with sensitivities and specificities between 80% and 90%, the above procedure is a good approximation to Bayes' theorem.

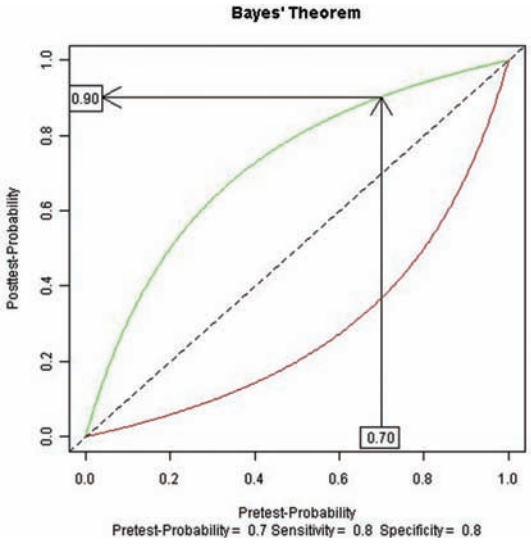

Figure 1 Graphical interpretation of Bayes' theorem.

A graphical approach to Bayes' theorem can demonstrate how the qualitative approximation works (figure 1). Here the horizontal-axis is the pretest probability, the curves represent the relationship between the pretest probability and the post-test probability for a given sensitivity and specificity (80% for each in this example, roughly corresponding to the test characteristics for a nuclear stress test) and the vertical-axis is the post-test probability. The diagonal line is usually included and represents no change in the post-test probability with the test result (ie, the test did not change the clinician's assessment of the probability). Separate curves represent a positive result (green), which increases the post-test probability (ie, is above the diagonal line), and a negative result (red), which reduces the post-test probability. To use Bayes' theorem, one starts on the horizontal-axis at the appropriate pretest probability and draws a vertical line until it intersects the appropriate curve for a positive (green) or negative test (red) result. One then draws a horizontal line to find the appropriate post-test probability on the vertical-axis. Figure 1 exemplifies this for the case above, a man with anginal chest pain and a positive stress test. One first locates 70% on the horizontal-axis, follows the arrow up until it intersects the positive result (green) curve, then follows the arrow horizontally until it intersects the vertical-axis at the post-test probability of 90%. A similar procedure is followed for a negative test, using the red line, giving a post-test probability of 37%.

In the categorical case, all the pretest probabilities between 67% and 90% (the *likely* category) need to be considered while holding the sensitivity and specificity constant at 80%. This only needs to be done for the lower (67%) and the upper limits (90%), see figure 2. For a positive test, the post-test probabilities range between 89% and 97% (arrows). To get the lower limit of post-test probability for a positive test, one follows the arrow from a pretest probability of 67% up until point A in figure 2 (where the arrow intersects the curve representing Bayes' theorem's post-test probability for a positive result), and then reads

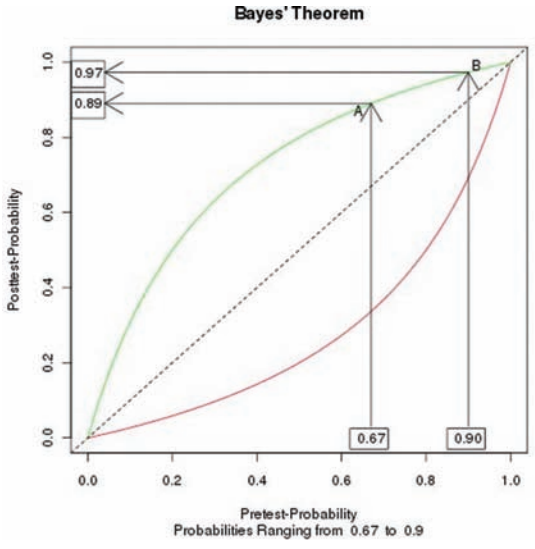

Figure 2 Graphical interpretation of Bayes' theorem for a range of pretest probabilities from 67% to 90% (*likely* category).

the post-test probability (89%) off the vertical-axis. For the upper limit of the post-test probability, one follows the arrow from a pretest probability of 90% up until point B in figure 2, and then finds the post-test probability (97%) on the vertical-axis. This gives the range of post-test probabilities for the *likely* category. For a negative result, the post-test probabilities range between 33% and 69%.

Next, expand the range of sensitivities and specificities from 80% to 90%, representing good tests. Now, instead of a (green) *curve* to represent the relationship between pretest and post-test probabilities, we have a (green) *band* (figure 3). Like before, one follows the arrow from the pretest probability until it firsts meets the band (A in figure 3) to get the lower limit of the post-test probability and until it meets the top of the band (B in figure 3) to get the upper limit of the post-test probability. For the *likely* category examined above, we can see that the post-test probabilities for a positive test now range between 89% and 99% – almost all in the *very likely* category – and for a negative test between 18% and 69% – almost all in the *uncertain or unlikely* categories. The transformation of the pretest probabilities is shown as the purple inverted 'L' in figure 3. The results for all the categories are shown in figure 4 and table 2.

The method is an approximation. It forces a Bayesian inspired analysis on the interpretation of test results and gives results consistent with Bayes' theorem. The approximation is weakest in the two cells with contradictory data (eg, *unlikely* with a *positive* test result and *likely* with a *negative* test result) as expected. The results remain a good approximation even with expanded ranges for test characteristics (sensitivity and specificity). For example, if the range of test characteristics is between 70% and 80%, probability cut-offs of <20%, 20–45%, 46–55%, 56–80% and >80% work well. Since the method is only an approximation and our estimates of pretest probabilities are also poor estimates, just using the cut-offs *likely*, *uncertain* and *unlikely* will suffice.

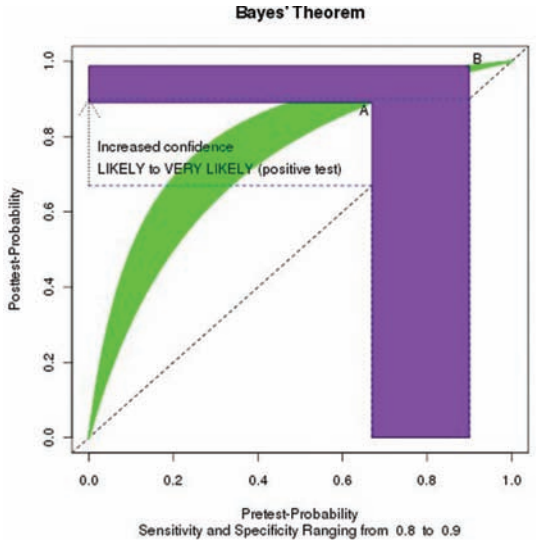

Figure 3 Graphical interpretation of Bayes' theorem for a range of pretest probabilities from 67% to 90% (*likely* category), and sensitivities and specificities ranging between 80% and 90%.

Special cases

Rule-in and rule-out tests – tests in which a single result is capable of near definitively ruling-in or ruling-out a diagnosis – are important. For example, a low brain natriuretic peptide is suitable for ruling-out systolic heart failure. Any test with sensitivity greater than 99% is sufficient to rule-out a diagnosis from even the *likely* category (SnOUT) and any test with specificity greater than 99% is sufficient to rule-in a diagnosis from even the *unlikely* category (SpIN).

In the *very* categories, since the curves are fairly flat in this region (figure 1, for example), two tests might be needed to produce a clinically significant change in the probabilities.

This method does not apply to most screening tests because the pretest probabilities are so low. The method reminds the clinician that a positive result on a screening test is usually not diagnostic, because the change in probabilities is not large enough with a single test. It will usually take two tests to go from *very unlikely* (as target conditions are in the general population) to *very likely* (the final probability a clinician is interested in before undertaking a colectomy, mastectomy or prostatectomy). For example, a 45-year-old woman has a 5-year probability of having breast cancer of about 1%.[11] The sensitivity of routine screening mammography ranges from 71% to 96% and the specificity ranges from 94% to 97%.[12] Using values of 80% for sensitivity and 96% for specificity, a positive test increases the probability to 17%. Using the qualitative categories described herein, the woman's risk of breast cancer would go from *very unlikely* to *unlikely* with the single positive screening test.

Many diseases and tests have appropriate prevalences, and sensitivities and specificities for the tests published, for example, tropinin I for myocardial infarction[13] or urine Chlamydia infection in men.[14]

Summary

In summary, here is a qualitative procedure to follow to approximate the results of a Bayesian diagnostic decision analysis.

1. What is the pretest probability of the disease being considered? Ideally this comes from an evidence-based source. If it is very *likely* (<10–20%) or *very unlikely* (>80–90%), in general, no further testing is needed.
2. One first categorises the pretest probability as *likely, uncertain* or *unlikely*.
3. If the test is positive, the post-test probability increases by one qualitative category (eg, unlikely to uncertain). If the test is negative, the post-test probability decreases by one qualitative category (eg, *unlikely to very unlikely*).
4. This process continues until the clinician is comfortable enough with the confidence in the diagnosis considering the patient's preferences, the risk of the disease and the effects of treatment.
5. Negative tests with sensitivities near 99% can almost certainly rule out a disease, since the post-test sensitivity will be *very unlikely* even if the original pretest probability was *likely*. Similarly, positive tests with

specificities near 99% can almost certainly rule in a disease.

6. If the pretest probability was *very likely* or *very unlikely*, and further testing is indicated, two tests are needed to escape the very categories. This is because the change in the probabilities is small within these categories. Two concordant results are needed to change out of the very categories.

Table 2 Pretest and post-test probabilities for a categorical version of Bayes' theorem

	Test result			
Category	**Positive**		**Negative**	
Unlikely	0.31	0.82	0.01	0.11
Uncertain	0.66	0.95	0.05	0.33
Likely	0.89	0.99	0.18	0.69

Diagnosis

ABSTRACT

The Current Opioid Misuse Measure (COMM), a self-report assessment of past-month aberrant medication-related behaviors, has been validated in specialty pain management patients. The performance characteristics of the COMM were evaluated in primary care (PC) patients with chronic pain. It was hypothesized that the COMM could identify patients with prescription drug use disorder (PDD). English-speaking adults awaiting PC visits at an urban, safety-net hospital, who had chronic pain and had received any opioid analgesic prescription in the past year, were administered the COMM. The Composite International Diagnostic Interview served as the "gold standard," using DSM-IV criteria for PDD and other substance use disorders (SUDs). A receiver operating characteristic (ROC) curve demonstrated the COMM's diagnostic test characteristics. Of the 238 participants, 27 (11%) met DSM-IV PDD criteria, whereas 17 (7%) had other SUDs, and 194 (82%) had no disorder. The mean COMM score was higher in those with PDD than among all others (ie, those with other SUDs or no disorder, mean 20.4 [SD 10.8] vs 8.4 [SD 7.5], $P < .0001$). A COMM score of $\geqslant 13$ had a sensitivity of 77% and a specificity of 77% for identifying patients with PDD. The area under the ROC curve was 0.84. For chronic pain patients prescribed opioids, the development of PDD is an undesirable complication. Among PC patients with chronic pain-prescribed prescription opioids, the COMM is a promising tool for identifying those with PDD.

1. Introduction

Multiple studies have shown dramatic increases in prescriptions for opioid analgesics for chronic non-cancer chronic pain in the United States [12,25,31]. Although more Americans use marijuana for pain relief, the number of first time abusers of prescription pain medications has recently exceeded the number of new marijuana users [1]. With the initial diagnosis and management of chronic, non-cancer pain falling largely under the domain of the primary care physician (PCP), many of these doctors report they are not adequately trained to recognize and manage patients at high-risk for, or experiencing, prescription drug use disorder (PDD) [6]. Experts in addiction and pain debate what constitutes PDD in a chronic pain population [15,30]. Although there is some consensus regarding clinical features that patients with PDD typically exhibit, no single "gold standard" exists for diagnosing PDD in primary care (PC) patients with chronic pain [2,4,5,9,29].

Current practice guidelines recommend using the Current Opioid Misuse Measure (COMM) to assess patients who are prescribed opioid therapy [7]. Developed by experts in pain and addiction, the COMM is a patient self-report assessment of past-month aberrant medication-related behaviors, defined as behaviors that are concerning for addiction or taking a medication in a way other than how it is prescribed [5,27]. Aberrant medication-related behaviors may include PDD as well as unintentional misuse, purposeful diversion, or addiction to substances other than pain medication. The COMM validation study was conducted with patients treated in specialty pain management clinics, and a score of 9 or greater was determined to be suggestive of prior 30-day prescription opioid misuse.

The diagnostic capabilities of the COMM have not been evaluated among PC patient populations. Diagnostic tests may perform differently when used in clinical settings other than those in which

they are validated. The COMM may serve as a practical means of monitoring PC patients treated with opioid therapy for the development of PDD; however, it remains to be determined whether this group of patients can be accurately assessed for PDD with this tool. Using a DSM-IV diagnosis of PDD as a gold standard, the diagnostic performance characteristics of the COMM were evaluated among a sample of PC patients with chronic pain who had received prescription opioids in the past year. The research team chose a broad sample of those at risk for PDD because the clinical challenges are not limited to those using daily current opioids. It was hypothesized that the COMM could identify participants with PDD and could distinguish them from all others. Second, as an exploratory aim, it was hypothesized that the COMM can differentiate those with PDD, some of whom may have a comorbid illicit drug disorder and/or comorbid past year alcohol dependence, from participants with a lone other substance use disorder (SUD) (ie, lone illicit drug disorder and/or past-year alcohol dependence), a prior disorder (PDD or SUD), or no disorder. A receiver operating characteristic (ROC) curve was constructed to evaluate whether the established COMM threshold score of 9 is suggestive of PDD in this patient sample.

2. Methods

2.1. Study design

This was a cross-sectional study of PC patients with chronic pain, defined as lasting for 3 months or longer, completed at the PC clinics of an urban, safety-net, academic medical center [3,18]. The study consisted of 2 parts: an interview with a trained member of the research team, and a subsequent electronic medical record review for abstraction of prescription opioid data to meet entry criteria.

2.2. Setting

Patients waiting for scheduled PC visits were recruited by trained research interviewers. Interviewers were physicians, master's degree-level professionals, college graduates, and college students who underwent 60+ hours of interview training. All participants were approached in the waiting rooms of an academic, urban, safety-net hospital primary care practice [18] Safety-net hospitals in the United States care for poor and vulnerable populations who may be uninsured or underinsured, and includes disproportionate numbers of underrepresented minorities [5].

2.3. Recruitment and enrollment

Between February 2005 and August 2006, a total of 2194 patients were approached, of whom 822 (37.4%) were eligible for the study based on explicit criteria (ie, were 18–60 years of age, spoke English, endorsed pain of at least 3 months' duration, reported use of any analgesic medication (including over-the-counter or prescription) in the prior month, and had a scheduled PC appointment). More than 75% of those eligible (620/822) agreed to participate in the study. Electronic medical record entries from 12 months before study entry were reviewed looking for documentation of an opioid prescription. Standardized chart abstraction forms were used and the electronic medical records were comprehensive. They included notes from all clinic visits, all emergency department records, all inpatient discharge summaries, phone notes, and an institutional prescription database. Patients were eligible for inclusion in this study if they had at least 1 prescription for any of the following opioids in the prior year: butorphanol/stadol; codeine/Tylenol# 2, 3, 4; fentanyl oral/Actiq; fentanyl transdermal (Duragesic); hydrocodone (Vicodin, Norco, Zydone, Maxidone, Lortab, Lorcet, Hydrocet, Co-Gesic, Anexsia); hydromorphone (Dilaudid); meperidine (Demerol); methadone (for pain, not maintenance treatment); morphine-immediate release (MSIR); morphine-extended release (MSContin); nalbuphine (Nubain); oxycodone-immediate release (Percocet, Roxicet, Endocet, Tylox, OxyIR, Roxicodone); Oxycodone-Long acting (Oxycontin); Pentazocine (Talwin); Propoxyphene (Darvon, Darvocet); levorphanol (Levo-Dromoran); and oxymorphone (Numorphan, Opana, Opana ER). Thus, the 238 patients that were prescribed an opioid pain reliever in the prior 12 months were the study sample for this analysis. Informed consent was obtained from eligible patients, and participants were compensated $10. The Boston University Medical Center Institutional Review Board approved the study.

2.4. Measures and key variables

Unless otherwise noted, all variables are obtained from subject interview.

2.5. Study terminology

For the purpose of this study, PDD will be used to describe participants who meet DSM-IV criteria for current (past year) prescription opioid abuse or dependence [2]. During the interview portion, participants were assessed using the Composite International Diagnostic Interview (CIDI) v.2.1 module on Drug Disorders [21]. Using the CIDI, PDD was defined as meeting DSM-IV criteria for current (past-year) prescription opioid abuse or dependence [21]. Criteria for abuse included social, physical, or legal consequences from use. The criteria for dependence included compulsive use, health consequences, and physical dependence (ie, tolerance or withdrawal). Physical dependence alone did not suffice to meet the diagnosis. Participants with PDD could also have comorbid other SUDs.

Other SUD will describe participants who meet DSM-IV criteria for any current (past year) illicit drug abuse or dependence and/or past year alcohol dependence [21]. These were assessed using the CIDI v.2.1 module on Drug Disorders (illicit drugs) and the CIDI-short form (CIDI-SF) for alcohol dependence [21]. Participants with PDD may also have another SUD (ie, comorbid illicit drug disorder and/ or past-year alcohol dependence), but will only be analyzed in the group labeled PDD. Prior drug disorder was defined as meeting DSM-IV criteria for prior (>12 months ago) prescription drug disorder and/or illicit drug disorder [21]. Current alcohol abuse and past alcohol use disorders were not measured using the full CIDI; instead the CIDI-SF was used to reduce respondent time burden. Nicotine dependence was not included in the variable SUD. (Fig. 1). For the main analysis, the participants with Current PDD were compared with all others, which included some with other SUDs. For the exploratory analyses, participants were assigned to one of the following groups: Current PDD, Current Other SUD (have SUD other than PDD), Prior SUD (with or without PDD), and No Lifetime Disorder.

Chronic pain has many different definitions, but experts agree that it is pain that persists for months or years [26]. For the purpose of this study, chronic pain is defined as pain of at least 3 months' duration.

2.6. COMM measure

During the interview portion of the study, each participant was administered a 40-question beta version of the Current Opioid Misuse Measure [5]. Subsequently, the COMM was narrowed down to 17 questions during its validation study [5]. The 17 questions include one newly constructed question. Specifically, question K23 from the beta version, "How often has something happened that

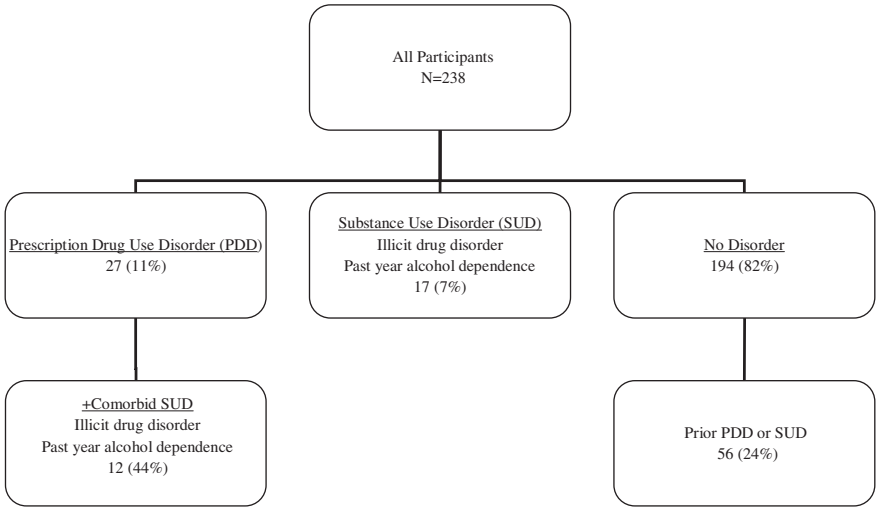

Fig. 1. Study participants and DSM-IV diagnoses.

has worried you about how you're handling your medications?" was separated into two COMM questions: COMM question 10, "How often have you been worried about how you're handling your medications?" and COMM question 11, "How often have others been worried about how you're handling your medications?" For the study presented, participants' scores were calculated based on the 16 questions present in the beta version that were retained in the final COMM questionnaire. Some of the participants' scores would have been higher had not that question been omitted.

2.7. Other variables

The following key variables were examined: (1) sociodemographic factors including age (in years), gender, race/ethnicity (African American/black, Hispanic, white, other), income ($\geqslant$\$20,000 or <\$20,000), employment (unemployed or receiving disability payments vs other), education (less than high school, high school or higher education), marital status (partnered, divorced, single), health insurance (Medicaid/Medicare vs others, including private and uninsured); (2) lifetime post-traumatic stress disorder (PTSD) diagnosis from the CIDI v. 2.1 PTSD module [21]; (3) current Major Depression from the Patient Health Questionnaire (PHQ) for Depression, a 9-item validated measure correlated with past 2-week Major Depression [17]; (4) family history of SUD (single question about first-degree relatives having alcohol or drug problems); (5) current cigarette smoking (taken from the visit closest to the interview date during the electronic medical record review) [18].

2.8. Statistical analysis

Descriptive statistics were calculated using frequencies, means, medians, and standard deviations. To describe the level of opioid medication prescription, we grouped the participants by number of equivalent pills of 5 mg oxycodone (the most common opioid medication prescription), given the plethora of different types of prescriptions, including medication, strength, dosing instructions, and number of fills (original plus any refills). Participants with PDD were compared to all others using *t* tests for continuous data and the Fisher's exact test for categorical data.

As the COMM scores were not distributed normally, all statistical analyses were conducting using both parametric and nonparametric tests of difference. To address the first hypothesis, that the COMM can identify subjects with PDD and distinguish them from all others, the *t* test and Wilcoxon rank-sum test were performed to examine COMM scores by drug disorder groups (PDD versus no disorder) [10]. Both parametric and nonparametric analysis of variance (*F* test and Kruskal–Wallis test) were used to explore the second hypothesis, that the COMM can differentiate participants with PDD from subjects with a single other SUD, a prior disorder (PDD or SUD), or no disorder. As both the parametric and nonparametric tests yielded the same statistically significant results, the mean scores are reported in this paper. Finally, a receiver operating characteristic (ROC) curve was constructed. Using this curve, it was determined whether a threshold score of 9 was suggestive of PDD in this patient sample. The data analysis for this paper was generated using SAS/STAT 9.1 statistical software (SAS Institute, Cary, NC). The Type I error level for all tests was set at 0.05.

3. Results

The demographic characteristics of all 238 participants, stratified by DSM-IV diagnosis of PDD or no PDD are presented (Table 1). Among the entire subject panel, 15% of the subjects received the equivalent of 20 tablets of 5 mg oxycodone in <2 fills, 12.6% received 21–60 tablets in $\leqslant$3 fills, 22.7% received 61–150 tablets

Table 1
Demographic characteristics of participants stratified by PDD diagnosis.

Variable	Current PDD N = 27 (11%) (%)	No PDD = 211 (89%) (%)	*P* value
Mean age (SD)	47.0 (7.9)	46.6 (8.6)	.85
Female gender	15 (56%)	118 (56%)	1.0
Race/ethnicity			
African American	19 (70%)	125 (60%)	.36
Hispanic	(11%)	1 (10%)	
White	(19%)	2 (20%)	
Other	0	21 (10%)

<12 y	9 (33%)	62 (29%)	.66
>12 y	8 (67%)	49 (71%)	
Receiving disability payments	16 (59%)	105 (50%)	.42
Lifetime PTSD	13 (48%)	73 (35%)	.20
Current depression (past 2 wk)	17 (63%)	74 (35%)	.006
Current smoking	21 (81%)	97 (47%)	.001
Current alcohol dependence or drug disorder[a]	12 (44%)	17 (8%)	<.001
Mean (SD) COMM score	20.4 (10.8)	8.4 (7.5)	<.001

[a] Other than prescription opioid.

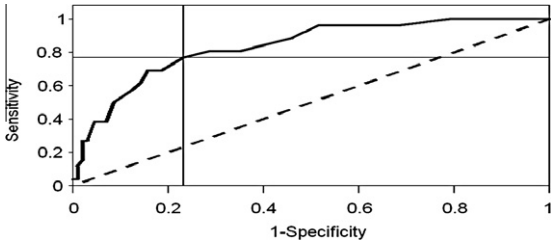

Fig. 2. Receiver operating characteristic curve. Current Opioid Misuse Measure (COMM) prediction score sensitivity and specificity estimates measured against a DSM-IV diagnosis of prescription drug use disorder (PDD). Area under the curve = 0.84 (95% confidence interval, 0.76, 0.91). Diagonal line represents chance prediction.

in ⩽3 fills, and 49.6% received >150 tablets or >3 fills of any amount (eg, 4 prescriptions of 20 tablets each). The majority of those in the last category received >6 fills. Of the participants, 11% (27/238) met DSM-IV criteria for current PDD. There were few differences among the 2 groups of subjects with respect to mean age, distribution of gender and race/ethnicity, and education level attained. The sample had a mean age in the 40s, was largely African American, and the majority had 12 or more years of education. At least 50% of those with PDD and those with no PDD were receiving disability payments, and nearly a third of each group had lifetime post-traumatic stress disorder. Consistent with other studies examining clinical risk factors for PDD [14,18,19], participants with PDD were more likely to experience current depression, to smoke, or to have past-year other drug disorder.

The mean COMM score for those subjects with current PDD, 20.4 (SD 10.8), was significantly higher than those with no current PDD, 8.4 (SD 7.5), $P < .0001$, as was the median COMM score 18.5 vs 7.5, $P < .0001$ (Table 1). Among all participants, COMM scores ranged from 0 to 45. An ROC curve of the COMM data compared to a DSM-IV diagnosis of PDD was constructed (Fig. 2). The area under the curve was 0.84 (95% confidence interval = 0.76, 0.91). Diagnostic performance characteristics across a range of possible COMM scores are presented in Table 2. In this sample, a COMM score of thirteen has the maximum sum of sensitivity and specificity, with a sensitivity of 0.77 and a specificity of 0.77, for identifying participants with DSM-IV PDD. At this value, the positive predictive value (PPV) is 0.30 and the negative predictive value (NPV) is 0.96, and the positive and negative likelihood ratios are 3.31 and 0.30, respectively. This indicates that the probability of having PDD with a positive COMM score is 30%, whereas the probability of not having PDD when the COMM is normal (ie, below the threshold value of 13) is 96% [11].

All 238 subjects were categorized according to whether they met criteria for a DSM-IV diagnosis of current PDD (11%, 27/238), current other SUD (7%, 17/238), or no disorder (82%, 194/238). Participants with no disorder were further categorized based on whether they met criteria for a prior disorder (PDD or other SUD) (24% 56/238) or had no lifetime disorder (58% 138/238) (Fig. 1). Mean COMM scores were calculated for participants with PDD, current other SUD, prior disorder (PDD or SUD), and no lifetime disorder. The mean score for those with PDD remained significantly different from all other groups, including participants with a current other SUD, whereas the other groups did not differ significantly from each other (Table 3).

Table 3
Mean COMM scores for Current PDD vs all others.

Disorder group	Mean (SD) COMM score	Median score	*P* value
Current PDD	20.4 (10.8)	18.5	<.0001
Current other SUD	13.0 (7.4)	12.0	
Prior disorder	9.1 (8.3)	6.0	
No lifetime disorder	7.6 (6.9)	6.0	

4. Discussion

Using a DSM-IV diagnosis of PDD as a gold standard, the diagnostic performance characteristics of the COMM were evaluated among a sample of PC patients with chronic pain who had received prescription opioids in the prior year. The data confirm the hypothesis that the Current Opioid Misuse Measure can distinguish those with a DSM-IV diagnosis of PDD. When compared with the findings presented in the original COMM validation study, conducted among a cohort of patients from specialty pain clinics, the diagnostic characteristics of the COMM seem different in our urban, academic PC patient sample [5]. In that original study, the threshold (cutoff) value used was 9 to detect opioid misuse as defined by a composite measure (not a diagnosis of PDD). In our data, with 2 questions different from the original, a threshold value of 13, rather than 9, maximized the sum of sensitivity and specificity for identifying patients with DSM-IV diagnosis of PDD.

A ROC curve analysis suggests a cutoff point of 13 to maximize the sensitivity and specificity of the COMM within this PC population. The area under the curve of 0.84 implies that the test is good, or moderately accurate, for identifying participants with DSM-IV PDD [13]. As in the original COMM validation study, the selected cutoff score results in greater sensitivity so that few cases of actual PDD are missed [5]. Changing the cutoff to obtain greater specificity limits the number of false-positive results [11]. Individual clinicians, based on the overall prevalence of PDD in their own patient population, may decide to choose a COMM score that maximizes either sensitivity or specificity, rather than the sum of the 2 values [11].

Results also support the exploratory hypothesis that the COMM appears to distinguish patients with PDD, some of whom may have comorbid illicit drug disorders and/or past-year alcohol dependence, from those with a single other SUD, a prior drug disorder (PDD or SUD), or no disorder. The discriminatory capacity of the COMM supports the content validity of the tool [11]. This is

Table 2
COMM Prediction Score vs DSM-IV diagnosis.

COMM score	Sensitivity	Specificity	PPV	NPV	Positive likelihood ratio	Negative likelihood ratio
7	0.961	0.484	0.196	0.989	1.866	0.079
8	0.884	0.540	0.201	0.972	1.924	0.213
9	0.846	0.595	0.215	0.967	2.094	0.258
10	0.807	0.646	0.230	0.962	2.284	0.297
11	0.802	0.681	0.25	0.964	2.538	0.282
12	0.807	0.712	0.269	0.965	2.805	0.270
13	0.769	0.767	0.303	0.962	3.311	0.300
14	0.692	0.813	0.327	0.952	3.704	0.3784
15	0.692	0.843	0.367	0.954	4.421	0.364
16	0.615	0.858	0.363	0.944	4.351	0.447
17	0.576	0.873	0.375	0.940	4.569	0.484

particularly valuable, as patients with other current SUDs or prior disorders (PDD or SUD), while being at higher risk for opioid misuse, may not be currently abusing prescription opioids. Clinicians must appropriately monitor these patients, and the COMM appears to specifically measure PDD [8,20].

The predictive value calculations demonstrate that primary care clinicians can feel fairly confident that patients (in a population with a comparable prevalence of PDD) with a COMM score of less than 13 do not have PDD. However, only 30% of patients with a COMM score of 13 or greater will have PDD. These data reflect the fact that predictive value calculations are affected by the prevalence of disease in a population [11]. Furthermore, as concluded in the original COMM validation study, this tool appears to identify some patients who are not likely to be having problems with their prescription opioids[5]; rather, some of those patients identified as positive will be false positive—ie, patients identified as misusing their medication when they are not. Clinicians are encouraged to practice caution when interpreting the COMM scores and to take into consideration other extenuating circumstances [5,23].

The cutoff COMM score obtained in this study was higher than that obtained in the first published validation study [5]. One possible explanation for this finding can be derived from the fact that a different gold standard was chosen for the current study, using the CIDI to assess for DSM-IV criteria for PDD or other SUDs, whereas the original validation study compared the 40-question beta version of the COMM to the Aberrant Drug Behavior Index [4,5,9]. The Aberrant Drug Behavior Index may measure aberrant medication related behaviors that do not meet criteria for DSM-IV PDD, but are thought by experts to be indicative of prescription opioid "misuse" or "nonmedical use"[15,24,27,30]. In addition, unlike the DSM-IV, the Aberrant Drug Behavior Index will label a patient as having PDD if they use an illicit substance, such as cocaine, while prescribed as an opiate. Using the CIDI as the gold standard permitted a comprehensive assessment of participants for a variety of substance use disorders including PDD, other SUD, and prior disorder (PDD or SUD). Performing this complete analysis focused on use of this instrument for patients at high risk for PDD who may receive opioid analgesic therapy [6,7,19,20,27]. However, primary care clinicians may consider using COMM scores with lower cutoffs as a trigger to discuss potential misuse of the medication in addition to potential PDD.

The COMM was developed as a self-administered questionnaire, and could be incorporated into standard practice for patients chronically prescribed opioids [5]. It requires less than 10 minutes and is easily scored by adding the responses. Ideal timing of the measure (eg, every month, twice yearly) and its utility in combination with treatment contracts, urine toxicology screens, pills counts and prescription monitoring will need to be studied

This study has certain limitations that require consideration. For example, the cross-sectional design does not allow for patients to be followed over time, limiting the types of inferences possible. Specifically, the COMM was only administered once to study participants, so we lack test re-test reliability. In addition, there were a small number of study participants with a DSM-IV diagnosis of current PDD. However, the overall sample size was large enough to produce unambiguous and statistically significant results in each test. These findings do support the need for larger studies in which primary care patients are followed up prospectively, and the COMM is administered repeatedly. Because geography and culture heavily influence use of prescription opioids in clinical and addiction contexts, it is not clear whether these findings are generalizable to areas outside the US or even different primary care populations within the United States.

Another aspect of the study design that should be taken into consideration is the study's reliance, relying on the electronic medical record for data regarding opioid prescriptions. Thus, it might mean that participants who received opioid prescriptions from providers outside of the medical center were excluded from the study. However, by obtaining primary prescription data, recall bias was minimized [22]. Furthermore, implementation of the COMM is oriented toward clinical practices that prescribe opioid therapy, thus providing some assurance that the appropriate patients will ultimately benefit from its use.

The study is also limited by the fact that some participants were not prescribed chronic opioids, and the data analysis did not control for the dose or duration of opioid therapy. Consequently, these results may be less relevant to patients who are prescribed chronic or high-dose opioid therapy. Current guidelines define chronic opioid therapy as "daily or near-daily use of opioids for at least 90 days" [7,16]. It is plausible that some subjects in this study demonstrated behaviors consistent with addiction due to inadequately controlled pain. The extent to which this occurred would have biased the results toward the null hypothesis. Referred to as pseudoaddiction, this preoccupation with opioids often resolves once the pain is adequately controlled [27,28]. For experts in pain and addiction, there is valid concern about patients with pseudoaddiction being inaccurately labeled as PDD [27,28].

Finally, as with any screener, there are always false positives and false negatives. As noted by Butler et al. [5], the COMM is only one source of patient information and should not be used as the sole means of determining whether opioid therapy is appropriate.

5. Conclusions

Among a sample of PC patients with chronic pain had received prescription opioids in the past year, the Current Opioid Misuse Measure (COMM) can identify patients with PDD. Overall, the COMM is a unique clinical tool that demonstrates utility for PC clinicians. Not only does it serve as a validated measure for assessing PDD, but it also provides a means of tracking these behaviors to identify patients at-risk for prescription opioid misuse.

For patients with chronic pain-prescribed opioids, the development of PDD is a serious complication. For primary care physicians treating patients with chronic pain with prescription opioids, the COMM is a promising tool for identifying patients who may have PDD and for helping to confirm that the probability for PDD is low. Future research, in which prospective studies of the COMM are conducted in a variety of PC settings is needed.

Conflict of interest statement

Older Adults' Inpatient and Emergency Department Utilization for Ambulatory-Care-Sensitive Conditions: Relationship With Alcohol Consumption

Elizabeth S. Levy Merrick, PhD, MSW[1], Dominic Hodgkin, PhD[1], Deborah W. Garnick, ScD[1], Constance M. Horgan, ScD[1], Lee Panas, MS[1], Marian Ryan, RRT, MPH, CHES[1], Frederic C. Blow, PhD[2], and Richard Saitz, MD, MPH[3,4,5]

Abstract

Objective: This study examined the relationship between drinking that exceeds guideline-recommended limits and acute-care utilization for ambulatory-care-sensitive conditions (ACSCs) by older Medicare beneficiaries. **Method:** This secondary data analysis used the 2001-2006 Medicare Current Beneficiary Survey (unweighted n = 5,570 community dwelling, past-year drinkers, 65 years and older). Self-reported alcohol consumption

(categorized as within guidelines, exceeding monthly but not daily limits, or heavy episodic) and covariates were used to predict ACSC hospitalization, emergency department visit not resulting in admission, and emergency department visit that did result in admission. **Results:** Heavy episodic drinking was significantly associated with higher likelihood of an ACSC emergency department visit not resulting in admission (adjusted odds ratio = 1.91, 95% CI: 1.11-3.30; $p < .05$). Drinking pattern was not significant for other ACSC measures. **Discussion:** Results partially support the hypothesis that excessive drinking may be related to ACSC acute-care utilization among older adults, suggesting increased risk of lower quality outpatient care.

Keywords

older adults, alcohol, ambulatory-care-sensitive conditions, health care utilization, quality of care

Introduction

Older adults frequently have unhealthy drinking patterns, ranging from risky drinking (which incurs increased risk of adverse consequences) to alcohol disorders (Saitz, 2003). Recent national prevalence estimates for adults aged 65 and older range from 9% drinking in excess of national guidelines (Merrick, Horgan, et al., 2008) to gender-specific rates of 13% and 8% with at-risk use and 14% and 3% with binge drinking (five or more drinks on same occasion in past 30 days) for men and women, respectively (Blazer & Wu, 2009). Among the problems associated with excessive drinking is the possibility of increased risk for inadequate medical care. This study investigated the relationship between excessive drinking and acute-care utilization for ambulatory-care-sensitive conditions (ACSCs).

Excessive drinking could be connected to inadequate medical care in several ways. Patients with excessive drinking may underuse routine care including primary care (Ford, Trestman, Tennen, & Allen, 2005; Girard, Partridge, Becker, & Bock, 2004; Kunz, 1997; Rice & Duncan, 1995; Rice et al., 2000), for reasons including concerns about stigma or financial barriers to care. Excessive alcohol consumption could reflect generalized self-neglect of health (Blow, Brockmann, & Barry, 2004; Hazelton, Sterns, & Chisholm, 2003). In any case, the result may be lower use of recommended services or delays in seeking care until problems are more severe. At the same time, providers sometimes have attitudinal barriers toward patients with alcohol problems (Anderson et al., 2004; Deehan, Templeton, Taylor, Drummond, &

Strang, 1998; Freidman, McCullough, Chin, & Saitz, 2000; Kaner et al., 2009), which could potentially result in differential treatment. These patients may be more difficult to treat, or scarce clinical time may be taken up with competing demands.

Although the mechanisms are not well understood, there is some evidence of lower quality medical care for persons with mental disorders, and in some cases substance use disorders specifically, in disparate clinical contexts (Clark, Weir, Ouellette, Zhang, & Baxter, 2009; Desai, Rosenheck, Druss, & Perlin, 2002; Druss, Rask, & Katon, 2008; Rathore, Wang, Druss, Masoudi, & Krumholz, 2008). Older adults who drink excessively according to various criteria are less likely to receive preventive medical care (Merrick, Hodgkin, et al., 2008; Moore et al., 2001; Ozminkowski et al., 2006).

However, acute-care utilization for ACSC has seldom been explored in relation to excessive drinking. ACSCs are conditions for which "timely and effective outpatient care can help to reduce the risks of hospitalization by either preventing the onset of an illness or condition, controlling an acute episodic illness or condition, or managing a chronic disease or condition" (Billings et al., 1993, p. 163). Congestive heart failure (CHF), diabetes, asthma, and chronic obstructive pulmonary disease (COPD) are examples of ACSCs. Measuring hospitalization for ACSCs is one approach to examining access to adequate outpatient care. Numerous ACSC indicators have been developed, including the widely used Agency for Healthcare Research and Quality (AHRQ) Prevention Quality Indicators (PQIs). These are designed to identify admissions that evidence suggests could have been avoided, at least in part, through better access to high-quality outpatient care (AHRQ, 2008). Researchers have considered which ACSC indicators are most appropriate for an older adult population (McCall, Brody, Mobley, & Subramanian, 2004). The concept and diagnosis specifications have more recently been extended to emergency department visits (Logan, Riley, & Barker, 2008; McCall et al., 2004).

The relationship between alcohol use and ACSC inpatient and emergency department utilization is important to investigate in older adults, who experience adverse health events at high rates and face special issues with alcohol. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) defines risky drinking amounts for those 65 years and older as more than seven drinks per week or more than three drinks on any single day (NIAAA, 2005). Similarly, the American Geriatrics Society defines risky drinking as, on average, no more than 1 drink per day, 7 drinks per week, or 3 drinks on heavier drinking occasions (American Geriatrics Society, 2006). Exceeding these limits is associated with interpersonal and functioning problems for

elders (Moos, Brennan, Schutte, & Moos, 2004), who have higher sensitivity and impaired ability to metabolize alcohol (Saitz, 2003). Limits may be lower or abstinence may be best for older adults who use medications that interact with alcohol or have medical problems that can be adversely affected by alcohol consumption.

Many studies have examined the occurrence and predictors of ACSC hospitalization (and, more recently, ACSC emergency department visits), but few have examined the role of alcohol consumption. Li and colleagues examined New York state hospital discharge data for adults aged 20 to 64 years (Li, Glance, Cai, & Mukamel, 2008). Inpatients with mental disorders (including substance use disorders) were significantly more likely than other admitted inpatients to have been admitted for an ACSC and also had longer average length of stay. Another study with a mixed-age inpatient sample found that binge drinking (five or more alcoholic beverages per occasion during the past 30 days) was predictive of preventable hospitalization (Arozullah et al., 2006).

Other factors found to be associated with ACSC hospitalization include health status, comorbidity, and functional limitations (Culler, Parchman, & Przybylski, 1998; Niefeld et al., 2003); income (Billings, Anderson, & Newman, 1996; Billings et al., 1993; Blustein, Hanson, & Shea, 1998); health insurance status (Weissman, Gatsonis, & Epstein, 1992; Zeng et al., 2006); mental disorders (Bynum et al., 2004; Himelhoch, Weller, Wu, Anderson, & Cooper, 2004); access to regular primary care or community health centers (Culler et al., 1998; Epstein, 2001; Falik, Needleman, Wells, & Korb, 2001); continuity of care (Gill & Mainous, 1998); and race and ethnicity (Culler et al., 1998; Friedman & Basu, 2004; Laditka, Laditka, & Mastanduno, 2003). McCall et al., using the 1999 Medicare Current Beneficiary Survey, found that prior ACSC hospitalization, comorbidity, and health status were among the significant predictors for some ACSCs among older beneficiaries (McCall et al., 2004). No variables for alcohol use or mental disorders were included. For ACSC emergency department use, barriers to primary care may contribute to higher utilization for ACSCs among Black adults and Medicaid patients (Oster & Bindman, 2003). Among older adults, emergency department and observation stay utilization increased between 1992 and 2000 for 10 of 11 ACSCs studied, including CHF, pneumonia, and cellulitis (McCall et al., 2004).

The current study aimed to help address the lack of research in this area by focusing on the relationship between self-reported alcohol consumption and ACSC acute-care utilization in a nationally representative sample of older adults. We hypothesized that drinking that exceeded guideline-recommended

limits, particularly heavy episodic drinking, would be positively related to ACSC hospitalization and emergency department use.

Method

Data and Sample

The primary data source was the Medicare Current Beneficiary Survey (MCBS) for 2001-2006. The MCBS is an ongoing survey of a representative national sample of the Medicare population by the Centers for Medicare and Medicaid Services. The sample is selected using a stratified, multistage probability design to represent the national Medicare population (Centers for Medicare and Medicaid Services, n.d.). Sample weights are provided to achieve nationally representative estimates, in this analysis for the continuously enrolled Medicare population. Beneficiaries sampled from Medicare enrollment files (or proxies) are interviewed three times a year including in-person, computer-assisted interviewing. There is a 4-year rotating panel design. Beneficiaries were randomly selected according to age strata from a nationally representative set of 107 geographic primary sampling units, with oversampling of the disabled (age <65) and those aged 65 and older. Normalized sampling weights were assigned to represent the population. The survey content includes sociodemographics, health, and functional status, and utilization. The 2001, 2003, and 2005 MCBS included items regarding alcohol consumption as well as data for covariates (detailed in the Measures section; Centers for Medicare and Medicaid Services, n.d.). Subjects' Medicare claims were linked to survey data for this analysis. We used data from 2001, 2003, and 2005 for baseline characteristics including drinking and covariates, and from 2002, 2004, and 2006 to identify hospitalization and emergency department services for ACSCs. This approach seeks to avoid reverse causality bias between ACSC use and other variables. To maximize sample size, we included beneficiaries present in the MCBS and continuously enrolled for any two consecutive years: 2001 and 2002, 2003 and 2004, or 2005 and 2006.

The analytic sample identification started with 20,482 community-dwelling beneficiaries who were 65 years or older. Of these, 13,612 were nondrinkers and another 129 were missing alcohol data and were excluded. This analysis focused on persons who reported drinking alcohol in a typical month in the past year because nondrinkers would constitute an especially heterogeneous group including lifetime abstainers and those who quit due to health problems, and these differences would be unobservable. Health maintenance organization enrollees were excluded because their claims were not available ($n = 1,171$).

Our final study sample included 5,570 persons representing a weighted *N* of 15,128,450. Bivariate comparison totals varied due to item-missing data (all <4%). The logistic regression sample consisted of 5,046 individuals.

Measures

Dependent Variables: Measures of Acute-Care Utilization for ACSCs.

The three dependent variables were binary measures of any ACSC hospitalization, ACSC emergency department visit not resulting in inpatient admission (thus not overlapping with ACSC hospitalization), and ACSC emergency department visit that did result in admission. We identified ACSCs by applying the specifications from two sources. First, following AHRQ specifications, we used all 13 relevant PQIs (excluding low birth weight): diabetes short-term complications, perforated appendix, diabetes long-term complications, COPD, hypertension, CHF, dehydration, bacterial pneumonia, urinary tract infection, angina without procedure, uncontrolled diabetes, adult asthma, and rate of lower extremity amputation among patients with diabetes (AHRQ, 2008). Second, we adopted 15 indicators identified by McCall et al. (2004) through literature review and deemed appropriate by clinical experts for application to older adults: asthma/COPD, cellulitis, CHF, dehydration, diabetes, hypertension, hypoglycemia, hypokalemia, influenza, urinary tract infection, malnutrition, perforated or bleeding ulcer, pneumonia, seizure disorder, and severe ear/nose/throat infection. The specifications were adopted from the original source and an expanded version published in a later ACSC study (Zeng et al., 2006).

There is substantial overlap between the two indicator lists. If a utilization event qualified in terms of either source, we counted it as an ACSC event. For sensitivity analysis purposes, we examined frequencies for each list of indicators separately and found that the differences were quite small in magnitude. We identified hospitalizations with an ACSC principal diagnosis. Although the PQI set was developed for application to inpatient hospitalization, we follow previous research that has extended the ACSC concept and diagnostic specifications to emergency department visits (Logan et al., 2008; McCall et al., 2004).

We identified emergency department visits based on procedure and location codes. For emergency department utilization that did not result in hospital admission, we used the visit primary diagnosis. Emergency department visits that resulted in admission were necessarily identified through the inpatient file, and the primary admitting diagnosis was attributed to the preceding emergency department visit.

Alcohol Consumption Variables. The 2001, 2003, and 2005 MCBS included three alcohol consumption items. Quantity and frequency were ascertained by asking, "Please think about a typical month in the past year. On how many days did you drink any type of alcoholic beverage? On those days that you drank alcohol, how many drinks did you have?" Heavy episodic drinking was assessed by asking, "Please think about a typical month in the past year. On how many days did you have four or more drinks in a single day?" Alcoholic beverages were described as including "liquor such as whiskey or gin, mixed drinks, wine, beer, and any other type of alcoholic beverage."

To assess unhealthy drinking in terms of consuming risky amounts of alcohol (regardless of whether alcohol consequences or disorders were present), we defined alcohol measures reflecting two parameters in the NIAAA and American Geriatrics Society guidelines (American Geriatrics Society Clinical Practice Committee, n.d.). First, to be consistent with the weekly guideline we defined *exceeding monthly limits* as more than 30 drinks per typical month. (A total of 42 respondents reporting 31 drinks per month whose responses were clearly based on a 31-day month were coded as negative as the items did not specify standardized number of days per month.) Second, we constructed a heavy episodic drinking variable indicating whether an individual reported four or more drinks in any single day during a typical month in the past year, according to either drinking quantity item.

We categorized respondents into three mutually exclusive categories: within-guidelines drinkers (not exceeding the monthly limit or the three-drink, single-day limit), drinkers who exceeded the monthly limit but not the single-day limit, and heavy episodic drinkers who exceeded the single-day drinking limit, with or without exceeding the monthly limit. For secondary analyses, we calculated a continuous measure of drinks per month, based on the quantity–frequency responses. To address nonlinearity, we included a squared term in the regressions.

Covariates. Covariates were selected that previous research found to affect health care utilization.

Sociodemographic variables. We included gender, race, Hispanic ethnicity, annual household income, age, education, marital status, region, and residence in a metropolitan area. Living arrangement was not included due to high correlation with marital status.

Health status variables. We controlled for health status by utilizing DxCG (diagnostic cost group) risk adjustment software that uses sex, age, and diagnosis codes from claims to construct a continuous measure of relative risk of health care resource use (DxCG, 2009). Compared to other illness burden indices or scales, the DxCG score contains higher specificity related to the

individual's clinical profile in projecting future health care costs and estimating an individual's care management needs (Zhao, Ash, Ellis, & Slaughter, 2002; Zhao et al., 2001). Thus, it may be used as a proxy for health status in that higher DxCG risk scores denote higher health care resource use risk and presumably poorer health (Wang et al., 2000). A value of 1 indicates the individual's predicted cost equals the population average for all persons with Medicare claims; higher values indicate higher than average predicted costs. For bivariate analyses, we created categories: no claims or claims not indicative of significant health risk (DxCG score < 0.1), claims indicative of lower than average health risk (0.1 ≤ DxCG score ≤ 1), and claims indicative of higher than average health risk (DxCG score > 1). For logistic regression models, we used the continuous measure; increasing scores indicate higher risk of health care resource use (poorer health status). We also included dichotomous variables for current smoking and for presence of a chronic disease explicitly related to ACSC indicators. We used diagnosis codes from the Centers for Medicare and Medicaid Services' Chronic Condition Data Warehouse (COPD, diabetes, CHF; Buccaneer Computer Systems and Services, 2009) and the AHRQ PQI specifications (hypertension, asthma); two outpatient claims or one inpatient claim during the baseline year were required for all but CHF in which one claim of any type was required.

We controlled for functional status using a modified Katz Index of Independence in Activities of Daily Living (ADL) variable constructed from survey data (Katz, Ford, Moskowitz, Jackson, & Jaffe, 1963; Shelkey & Wallace, 1999). Respondents were asked whether they had trouble or needed assistance with six ADLs: bathing, dressing, transferring, toileting, continence, or feeding. If no difficulty was indicated, that activity received a score of 1. The resulting variable reflects a 7-position scale (0-6) of the number of independent ADLs.

Two mental health variables were used. First, a self-reported depression variable was created. Respondents were asked, "In the past 12 months, how much of the time did you feel sad, blue, or depressed?" (all, most, some, little, or none of the time), and "In the past 12 months, have you had 2 weeks or more when you lost interest or pleasure in things that you usually cared about or enjoyed?" (yes, no). Respondents who answered "all" or "most of the time" to the first question and/or "yes" to the second question were categorized as having self-reported depression. This approximates the modified PHQ-2 validated for older adults (Li, Friedman, Conwell, & Fiscella, 2007). Second, a dichotomous variable indicating behavioral health diagnosis was constructed based on the presence of one inpatient claim or two outpatient claims with an International Classification of Diseases (ninth edition; ICD-9) mental health

or substance use disorder diagnosis, excluding alcohol disorders. We excluded alcohol diagnosis from our main models as we wanted to observe the full effect of self-reported drinking, but we included this in alternate versions. We found that although in bivariate analyses the presence of a claim with an alcohol disorder diagnosis was associated with significantly higher rates of ACSC acute-care utilization, it was not statistically significant in a multivariate context.

Access variables. We included measures on self-reported trouble getting needed care during the past 12 months, private supplemental insurance, and Medicaid coverage. We also included a measure for living in a county designated as a full-county primary care health professional shortage area according to Health Resources and Services Administration data (Health Resources and Services Administration, n.d.). In addition, we constructed variables indicating type of usual care: no particular "medical person or clinic" usually seen when respondent is sick or for advice, except for hospital emergency room or walk-in urgent care center; primary care physician (family practice, general practice, geriatrics, internal medicine); or nonprimary care physician. We constructed a variable indicating a prior-year ACSC event. Due to multicollinearity, it was not included in final models. When we tested its inclusion, this variable was positive and significant but did not affect the direction, magnitude, or significance of alcohol variables.

Statistical Analysis

Results are weighted estimates that represent the continuously enrolled, community-dwelling, non-HMO, elderly Medicare population of current drinkers. Chi-square tests were used to assess bivariate differences involving drinking categories; chi-square statistics were corrected for the survey design and converted to *F* statistics. The continuous drinks per month variable was significantly skewed, and bivariate testing accounted for skewness. We conducted logistic regression analyses to model occurrence of an ACSC hospitalization or emergency room visit as a function of alcohol consumption (drinking category) and covariates. We also constructed a continuous measure of alcohol consumption—number of drinks per month—and included in a separate set of logistic regression models. We explored the use of an instrumental variables approach to address any potential bias due to unobserved differences between drinking groups. Among several exogenous variables (e.g., Sunday ban on alcohol sales, beer tax) that have been previously used as instruments for alcohol use, none were found for this sample of older drinkers that met the assumptions required for

instrumental variables analysis (Wooldridge, 2006) and were robust to specific geographic inclusion (notably Puerto Rico).

Due to the complex sampling design, using procedures that assumed equal probability of selection would likely lead to underestimating standard errors (Cohen, 1997; Lemeshow et al., 1998). The SVY: LOGIT procedure of the statistical package STATA version 9.0 was used to more accurately determine the statistical significance of observed differences (STATA Corporation, n.d.).

Results

As shown in Table 1, the weighted sample was predominantly White (93.0%), male (55.2%), and married (65.4%). Only 16.2% were more than 80 years old. More than half had some education beyond high school. Three quarters (75.2%) reported within-guidelines alcohol consumption in a typical month in the past year. Ten percent exceeded the monthly limit only, and 14.8% reported heavy episodic drinking. Drinking patterns varied significantly by sociodemographic, health, and access variables.

Number of drinking days, drinks per drinking day, and drinks per month (weighted) varied significantly by drinking category ($p < .01$; data not shown). As noted earlier, the continuous measure of drinks per month was constructed from quantity-frequency variables, which were not harmonized with the separate heavy episodic drinking survey item. Among within-guidelines drinkers, the mean number of drinking days during a typical month was 9.1 (standard error *[SE]* 0.2) with median of 3.7, and the mean number of drinks per drinking day was 1.2 (*SE* 0.01) with median of 0.8. The mean number of drinks per month was 10.3 (*SE* 0.2) and the median was 4.8. For drinkers exceeding monthly limits only, the mean number of drinking days during a typical month was 27.7 (*SE* 0.2) with a median of 29.3, and the mean number of drinks per drinking day was 2.2 (*SE* 0.02) with a median of 2.0. The mean number of drinks per month was 59.9 (*SE* 0.6) and the median was 58.9. For heavy episodic drinkers, the mean number of drinking days was 18.7 (*SE* 0.5) with a median of 19.8, and the mean number of drinks per drinking day was 3.8 (*SE* 0.1) with a median of 3.0. The mean number of drinks per month was 67.9 (*SE* 3.7) and the median was 50.0. The mean number of days with heavy drinking was 7.3 (*SE* 0.4) with a median of 2.9.

Overall, 3.5% had an ACSC hospitalization during the year, 2.1% had an ACSC emergency department visit that did not result in inpatient admission, and 2.1% had an emergency department visit that resulted in admission (Table 2). Drinking category was not significantly related to ACSC hospitalization in bivariate analyses. Drinking category was significantly associated

Note: ACSC = Ambulatory-care-sensitive condition; ADLs = activities of daily living.
Weighted sample used; significance based on chi-square tests, corrected for survey design.
N for each bivariate comparison varied slightly due to item-missing data, <4% for all variables.
Percentages shown are for nonmissing data.
a. Values combined to avoid unweighted cell sizes < 11.
*$p < .05$. **$p < .01$. ACSC measure varies significantly by independent variable.

The most common ACSCs for hospitalization were CHF (0.9%), bacterial pneumonia (0.8%), and asthma/COPD (0.7%; data not shown). For emergency department visits that did not result in admission, urinary tract infections (0.4%), asthma/COPD (0.3%), and cellulitis (0.3%) were most common. For emergency department visits that resulted in admission, asthma/COPD (0.4%), CHF (0.4%), and bacterial pneumonia (0.4%) were most common. Although the numbers within each specific ACSC were small, thus limiting statistical power to identify significant differences by drinking pattern, there was a significant bivariate relationship between specific ACSC and drinking pattern in several cases. For example, there was a significant relationship between hypertension and drinking pattern across all types of utilization ($p < .01$), with heavy episodic drinkers having the highest utilization. Urinary tract infection and cellulitis were also significantly associated with drinking pattern ($p < .01$), with persons who exceeded monthly guidelines only showing the highest rates of emergency department visits that did not result in admission.

In the logistic regression model predicting ACSC hospitalization, drinking variables were not significant. Being over 80 years of age, African American, having higher relative health risk score, independence in 0 to 4 ADLs, and chronic disease were associated with higher likelihood of an ACSC hospitalization; living in the West region of the country was associated with lower likelihood relative to the South (Table 3). In the model predicting any ACSC emergency department visit that did not result in inpatient admission, heavy episodic drinking was significantly associated with higher likelihood (adjusted odds ratio = 1.91, 95% confidence interval: 1.11-3.30, $p < .05$). Other factors associated with greater likelihood of utilization included older age, greater relative health risk, independence in 0 to 4 ADLs, and chronic disease. Finally, in the model predicting any ACSC emergency department visit that resulted in inpatient admission, drinking variables were not significant. Greater relative health risk and independence in 0 to 4 ADLs were associated with higher likelihood of this type of utilization. Being a high school graduate (relative to having less than a high school education), annual household income of more than US$40,000 per year, and living in the Midwest or West (relative to South) were associated with lower likelihoods.

In another set of alternate logistic regression analyses using a continuous measure of drinks per month as well as a squared term to address nonlinearity, there was no significant effect on ACSC hospitalization or emergency department utilization resulting in admission (data not shown). However, for emergency department utilization that did not result in admission, there was a significant, positive relationship (odds ratio = 1.01, $p < .05$)

Discussion

Heavy episodic drinking was a predictor of ACSC emergency department use that did not result in admission, but drinking variables did not predict ACSC hospitalization or emergency department visits resulting in hospital admission. Thus, we found partial support for the hypothesis that older adults whose drinking exceeded guideline-recommended limits would be at greater risk of ACSC acute-care utilization. This is consistent with prior studies that found evidence for lower quality of medical or preventive care for persons with substance abuse problems defined in various ways (Arozullah et al., 2006; Clark et al., 2009; Desai et al., 2002; Li et al., 2008; Merrick, Horgan, et al., 2008; Ozminkowski et al., 2006) and extends this line of inquiry by finding this connection between older adults' self-reported drinking and ACSC emergency department use. As ACSC severity level for emergency department visits not resulting in admission is likely lower, our findings suggest that people with heavy episodic drinking may experience some deficiencies in access to or quality of outpatient care but in ways that do not affect the most severe outcomes. Heavy episodic drinkers may be using the emergency department for issues that should normally have been addressed earlier in primary care but are not so far advanced as to require hospitalization. Small numbers greatly inhibited our ability to examine specific ACSCs. However, we did find that for some ACSCs (notably hypertension) that can be worsened by excessive drinking utilization varied by drinking pattern with heavy episodic drinkers more likely to have ACSC utilization.

The fact that this relationship occurs only for those with heavy episodic drinking rather than those who exceed monthly limits only echoes findings from a previous study on receipt of preventive services (Merrick, Hodgkin, et al., 2008). The level of drinking represented in the group exceeding monthly limits only is not extremely high, with most respondents indicating consumption of two drinks per day most days of the month. Older adults whose drinking exceeds monthly limits only may reflect a population without current impairment affecting use of outpatient services that prevents ACSC acute-care utilization. Heavy episodic drinkers may be more likely to have alcohol disorders, compared to persons exceeding monthly guidelines only, some of whom who may be continuing to drink at levels that were acceptable for younger ages.

The alternate, exploratory analysis we conducted using drinks per month as the key explanatory variable, when we accounted for nonlinearity, yielded results similar to the results for heavy episodic drinking. Future research to

investigate the potentially complex influences of drinking pattern as well as drinking quantity in more detail would be fruitful. Future work should also investigate the causal mechanisms underlying the association we identified between episodic heavy drinking (or greater number of drinks per month) and ACSC emergency department visits not resulting in admission. Identifying the provider, patient, and system roles in barriers to care for this group will be useful.

Study limitations include possible underreporting of alcohol consumption, although self-reported alcohol consumption is in general considered to be as accurate as other drinking measures (Babor, Steinberg, Anton, & Del Boca, 2000). Relatively small sample size limited statistical power to detect small differences. As noted earlier, it is possible that unobserved differences between drinking groups could create bias, but we were unable to identify satisfactory instruments for our sample and measures. However, one main possible source of bias in this type of analysis is health status differences, and the multivariate models we used included multiple health and functional status variables, somewhat reducing risk this bias. Furthermore, we focused on past-year drinkers, avoiding the bias that could have resulted from including a large, heterogeneous group of nondrinkers, many of whom might have quit drinking due to ill health. Previous research on effects of drinking on acute-care utilization (but not ACSC specifically) that used instrumental variables found no evidence of bias in a different nationally representative sample of older adults (Balsa, Homer, Fleming, & French, 2008). Another limitation is the imprecision of the continuous drinking measures for heavy episodic drinkers in our secondary analyses. This is due to lack of harmonization across alcohol variables and lack of information on specific number of drinks consumed on heavy drinking days. We also note that the application of ACSC indicators to emergency department utilization is a more recent extension of the concept and specifications originally applied to hospitalization.

The study findings add to the understanding of the full range of risks associated with drinking that exceeds recommended guidelines for older adults. They may be useful to outpatient and emergency room providers in raising awareness of this issue, which in turn may heighten vigilance and effective interventions. This may contribute to efforts to both address alcohol issues and reduce acute-care utilization for ACSCs in older adults. The findings also provide a useful contribution in analyzing the effects of a relevant factor largely absent from the large body of research on predictors of ACSC hospitalization and emergency department utilization.

ABSTRACT

Abbreviation use is a preventable cause of medication errors. The objective of this study was to test whether computerized alerts designed to reduce medication abbreviations and embedded within an electronic progress note program could reduce these abbreviations in the non-computer-assisted handwritten notes of physicians. Fifty-nine physicians were randomized to one of three groups: a forced correction alert group; an auto-correction alert group; or a group that received no alerts. Over time, physicians in all groups significantly reduced their use of these abbreviations in their handwritten notes. Physicians exposed to the forced correction alert showed the greatest reductions in use when compared to controls (p=0.02) and the auto-correction alert group (p=0.0005). Knowledge of unapproved abbreviations was measured before and after the intervention and did not improve (p=0.81). This work demonstrates the effects that alert systems can have on physician behavior in a non-computerized environment and in the absence of knowledge.

INTRODUCTION

Medication errors are responsible for a large number of adverse drug events in patients each year, and the use of medication abbreviations accounts for a subset of these errors.[1–3] For years, professional organizations and regulatory agencies have emphasized the danger of medication abbreviations and have mandated the elimination of the most error-prone abbreviations in medical documentation.[4–7] Because the majority of abbreviation errors originate during medication prescribing,[8] strategies to reduce abbreviations have largely focused on education to modify physician documentation.[9–11] Promulgation of a 'Do Not Use' list of abbreviations created by the Institute of Safe Medication Practices, included in the National Patient Safety Goals, and endorsed by the Joint Commission[4] has served as the primary educational campaign, but there is poor compliance among hospital staff with this practice.[12]

From 2004 to 2006, 643 151 medication errors were reported to the United States Pharmacopeia MEDMARX program from 628 facilities, and 29 974 (4.7%) of these errors involved abbreviation use.[8] Eighty-one per cent of the abbreviation errors occurred during medication prescribing, and 0.3% of errors resulted in patient harm. While a direct association between abbreviations and medication errors has been established, little is known about the best ways to eliminate or reduce abbreviation use.

Medication errors, and in some settings adverse drug events, have been reduced with the adoption of computerized provider order entry (CPOE) and clinical decision support systems (CDSS).[13 14] However, despite widespread acceptance of the benefits of health information technology and national agendas to expand their use,[15 16] in 2008 only 17% of US hospitals had adopted CPOE.[17] As a result, opportunities to introduce medication abbreviations into handwritten documentation remain a source of medication errors and patient harm.

Although a direct link between abbreviations in handwritten notes and medication prescribing errors has not been established, written documentation in the form of handwritten notes and electronic entries with free text is capable of introducing abbreviations that can be misinterpreted and cause errors.[18 19] As the integration of electronic medical records expands nationally, it is important to understand how computerized alerts and clinical decision support influence the knowledge and behaviors of healthcare professionals. Given the paucity of research around electronic interventions to decrease unsafe medication abbreviation use, we conducted a randomized-controlled trial to evaluate the effects of computerized alerts designed to reduce unapproved abbreviations on the frequency of use of these abbreviations in an electronic progress note system and in the non-computer-assisted handwritten documentation of physicians.

METHODS

Study design overview

This study was conducted between July 2006 and June 2007. All internal medicine interns (N=59) at the Hospital of the University of Pennsylvania enrolled in the study at the beginning of their internship. The University of Pennsylvania Institutional Review Board approved the study and granted a waiver of written informed consent. As a condition of the Institutional Review Board approval, participating interns were told that they were part of an ongoing study to examine the effects of computerized interventions designed to reduce unapproved abbreviations but given minimal information about the study. Specific details of the study were withheld to avoid biasing the results. No sources of external funding supported this investigation.

Overview of information systems and medical records at the study site

The hospital has a CPOE system for physician orders and diagnostic test results. The inpatient

medical record is a hybrid of electronic and handwritten documentation. At the time of this study, all history and physical exams (H & Ps) were handwritten, and daily progress notes were created using a customized electronic progress note template. These templates were created within a data-storage program at the University of Pennsylvania (Medview, Microsoft ASP.NET v1.1). All clinical data including medications was entered into the computer by hand and copied forward for daily editing. Progress notes were printed daily and placed into the paper medical record where attending physicians could review and addend them by hand.

Design of the clinical decision support system

The authors of this study designed the clinical decision-support system. Alerts were integrated into the customized electronic progress note templates. The progress note application was modified with regular expression pattern-matching code on the client and server to recognize abbreviations from the Joint Commissions' 'Do Not Use' abbreviation list[4] anywhere in the text and medication lists of the notes, and to generate an alert based on the participant's study group assignment. The application tracked the number of alerts generated for each note. The 'Do Not Use' abbreviation list includes: QD, QOD, MS04, MgSO4, U, IU, trailing zeros, and naked decimal points (table 1). The abbreviation 'MS—morphine sulfate' was not included in our study because we believed that it would reduce the specificity of the alert system. 'MS' within medical record documentation is commonly used to denote terms other than morphine sulfate such as mental status, mitral stenosis, or multiple sclerosis. Since we could not isolate the alert to the medication list, we believed that including it would cause alerts for the non-medication 'MS' terms and lead to documentation errors and clinician frustration.

Randomization

Fifty-nine interns were randomized to one of three study arms using a computer-generated random numbers table. Group 1 received a forced or 'hard-stop' alert that appeared when interns attempted to enter unapproved abbreviations into the electronic progress notes. This alert identified the unapproved abbreviation(s), informed interns of the correct non-abbreviated notation, and forced them to correct the abbreviation before allowing them to save or print their note (figure 1). Group 2 also received an alert when an unapproved abbreviation was entered, but instead of forcing the interns to make a correction, an autocorrection feature displayed the correction and automatically replaced the abbreviation with the acceptable non-abbreviated notation (figure 1). Group 3 was a control group and received no alerts. The alert intervention was introduced 3 months after the study began to allow for observation of baseline medical record documentation practices (figure 2).

Participants did not receive any training sessions about the computerized enhancements and were not informed of their study-group assignment. All groups were exposed to the hospital's standard education for unapproved abbreviations that consisted of reminders to avoid unapproved abbreviations on printed medical note templates.

Table 1 Official 'Do Not Use' List of Abbreviations from the Joint Commission[4]

Do not use*	Potential problems	Use instead
U (unit)	Mistaken for '0' (zero), the number '4' (four) or 'cc'	Write 'unit'
IU (international unit)	Mistaken for IV (intravenous) or the number 10 (ten)	Write 'International Unit'
Q.D, QD, q.d, qd (daily)	Mistaken for each other	Write 'daily'
Q.O.D,. QOD, q.o.d., qod (every other day)	Period after the Q mistaken for 'I' and the 'O' mistaken for 'I'	Write 'every other day'
Trailing zero (X.0 mg)	Decimal point is missed	Write X mg
Lack of leading zero (.X mg)		Write 0.X mg
MS	Can mean morphine sulfate or magnesium sulfate; confused for one another	Write 'morphine sulfate'
MSO4 and MgSO4		Write 'magnesium sulfate'

*Applies to all orders and all medication-related documentation that is handwritten (including free-text computer entry) or on preprinted forms.

Primary outcomes

Retrospective reviews of the medication lists within interns' non-computer-assisted handwritten H & Ps were performed at study conclusion. The medication lists were reviewed to identify the presence or absence of the seven previously defined unapproved abbreviations, and an audit tool was developed to measure the frequency of these abbreviations. In order to estimate the opportunity for an abbreviation error, we had to define the frequency of an absence of the abbreviation. This absence was defined as the frequency with which a correct notation (non-abbreviation) was used. The total opportunity for error was the sum of all present and absent abbreviations. The percentage of unapproved medication abbreviations was defined as the number of abbreviation errors divided by the opportunity for error. Four study investigators (SG, JM, AL, SA) independently reviewed 100 H & Ps to assess reliability of the audit tool. One study investigator (SG) reviewed the remaining H & Ps after reliability statistics were obtained. All reviewers were blinded to the participants' study-group assignment.

A maximum of 15 H & Ps were randomly selected for each participant during each of four study time periods to determine the rate of unapproved abbreviations used over time (figure 2). The numbers of available H & Ps per quarter varied because interns were on vacation, on outpatient rotations, or on rotations at affiliated hospitals. If an intern did not have 15 H & Ps available during a study period, the total number of available H & Ps for that time period was used in the analysis. Interns spent an average of 7 months on inpatient rotations at the hospital where the study was performed.

Secondary outcomes

Secondary outcomes included the frequency of computerized alerts over time and intern knowledge of unapproved abbreviations before and after the study intervention. Knowledge was measured by a test created by the investigators in which interns were asked to identify error-prone abbreviations (unapproved) versus acceptable abbreviations (approved) out of a list of 30 total abbreviations in random order. Additional test items surveyed interns about prior exposure to medication safety education, experiences during medical school (pre-test), and their attitudes about the alerts (post-test).

Statistical analysis

Baseline characteristics among the three groups were compared using the Fisher exact test for categorical variables and Kruskal–Wallis test for continuous variables. Comparisons of the percentages of unapproved medication abbreviations at follow-up periods were done by fitting a pooled logistic regression model which included group indicator, indicator of follow-up time, and their interaction terms (group×follow-up time) as predictors. In this model, each H & P was considered a separate

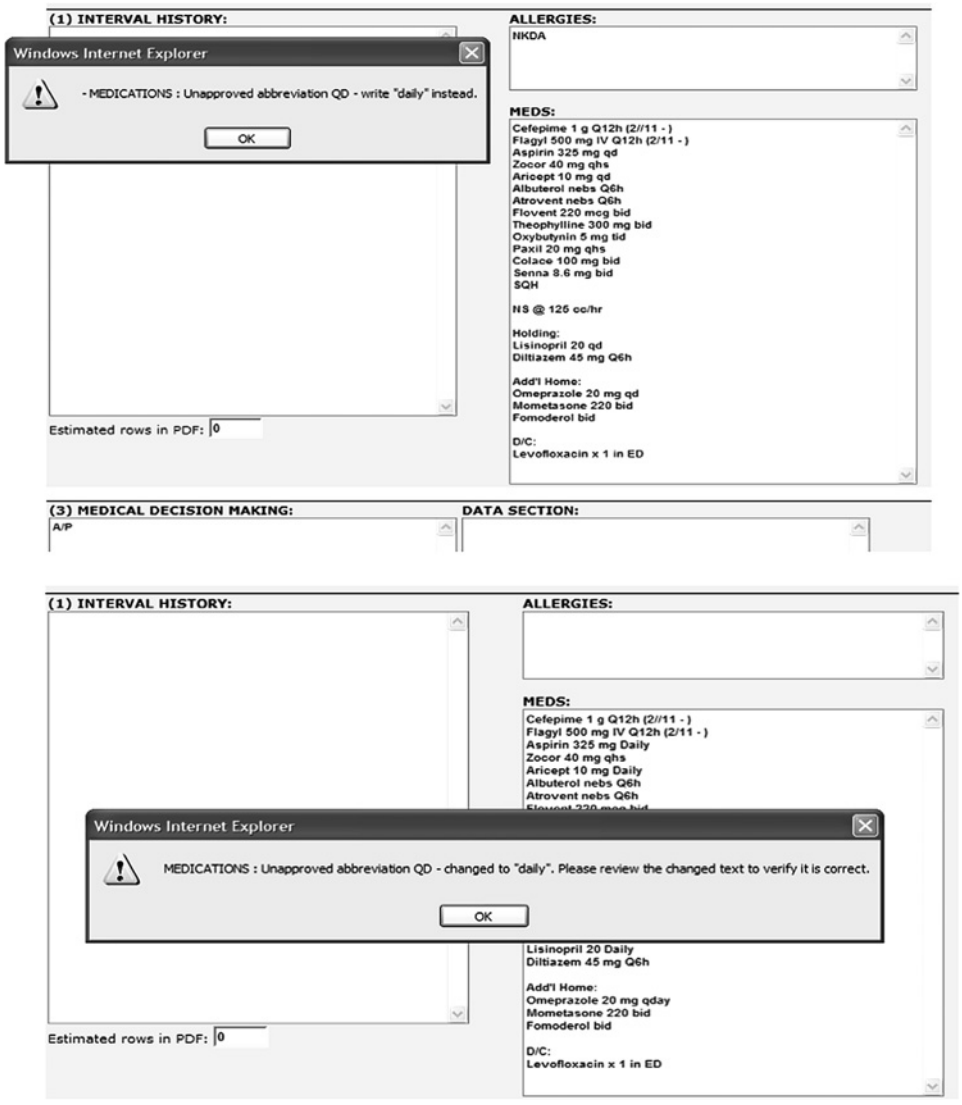

Figure 1 Examples of computerized alert screens used in the intervention. (Top) Example of alert with forced functionality ('hard stop'). (Bottom) Example of alert with an auto-correction feature.

record. Compared to a method in which the percentages for each subject were calculated first and then compared across groups, this method may result in a better precision of estimates by putting less weight on subjects who had fewer H & Ps. Robust variance estimation with a first-order autoregressive (AR (1)) working correlation structure was used to account for repeated measurements within each subject. Both estimated percentages for each group at each follow-up period and the p values for comparisons of the estimated percentages between groups and their change within each group were reported. κ Statistics were used to assess the degree of congruency among four raters of the medication list audit tool. Pre- and post-knowledge differences between the groups were assessed using the Wilcoxon signed-rank test and overall with the Kruskal–Wallis test. All analyses were carried out in SAS version 9.1.

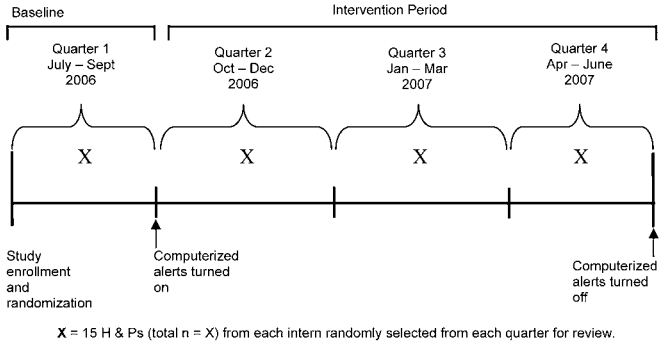

Figure 2 Study design overview.

RESULTS

One hundred per cent (n=59) of interns randomized completed the study and had primary data available for review. Interns had previously attended 23 different medical schools, and their characteristics are listed in table 2. There was no difference among the three groups in their ability to correctly identify unapproved medication abbreviations at baseline (p=0.20).

The median number of H & Ps per study period was 12 (range 0–39). Of the 236 study periods available (59 interns×4 study periods each), there were 13 interns (four control, four hard stop, and five auto-correct) who had one study period with zero H & Ps to review. Based on these numbers, a total of 2371 H & Ps were evaluated with a mean of 42 H & Ps per intern (median=41, range 20–59).

Overall there were 4191 total opportunities to use a 'Do Not Use' abbreviation. Unapproved abbreviations were used 1832 times or 44% of the time. The median number of abbreviation

Table 2 Characteristics and baseline knowledge of unapproved medication abbreviations among study participants (interns)

	Control group (N=19)	Hard stop alert group (N=20)	Auto-correction alert group (N=20)	Total (N=59)	p Value
Men, n (%)	9 (47%)	7 (35%)	9 (45%)	25 (42%)	0.80
Received education in medical school about medication errors related to abbreviations, n (%)	11 (58%)	15 (75%)	9 (45%)	35 (59%)	0.15
Involved in the care of a patient who experienced a medication error, n (%)	10 (53%)	13 (65%)	13 (65%)	36 (61%)	0.67
Baseline knowledge of error-prone abbreviations, mean (IQR)*	8.0 (3.46 to 11)	8.7 (1.87 to 10)	9.2 (2.78 to 11)	8.6 (2.77 to 11)	0.20

*Number of unapproved abbreviations identified correctly out of a list of 11.
IQR, interquartile range.

errors per H & P was 2.5 (range 0–17). The frequency of errors for each abbreviation type was as follows: QD 1672 (91.4%); U 92 (5%); QOD 39 (2.1%); naked decimal point: 20 (1.1%); trailing zero: 5 (0.3%); MgSO4 1 (0.06%); MSO4 1 (0.06%); IU 0 (not written in any H & Ps). Many H & Ps contained more than one abbreviation error. The inter-rater agreement for the medication list audit tool was excellent (κ=1).

Primary outcome

The percentages of unapproved medication abbreviations in each quarter are shown in table 3. At baseline (Quarter 1), there were no significant differences in the frequency of unapproved abbreviations in the non-computer-assisted handwritten notes among the three study groups (p=0.54) (table 3). Interns in each group significantly reduced their use of non-computer-assisted, written unapproved abbreviations over time (control: p=0.004; hard stop: p<0.0001; autocorrect p=0.04) (figure 3). When compared with controls, interns in the hard-stop alert group had a lower rate of unapproved abbreviations in their non-computer-assisted handwritten notes during the alert intervention (p=0.02), whereas interns in the auto-correction group did not (p=0.21). Interns in the hard-stop alert group had a significantly lower rate of unapproved abbreviations in their non-computer-assisted handwritten notes when compared with interns in the auto-correction group. (p=0.0005).

Secondary outcome

The number of alerts that fired decreased over time (p<0.01) in both alert intervention groups. There was a trend toward fewer alerts firing in the 'hard-stop' group compared with the auto-correction group (p=0.06).

Forty-seven interns (80%) completed the knowledge test at study conclusion. Knowledge of unapproved abbreviations did not improve after the alert intervention. At baseline, interns correctly identified 8.6 (range 5–11; 73% correct) unapproved abbreviations compared with 9.0 (range 5–11; 82% correct) after the intervention. This was true for the entire sample (p=0.81), within individual groups (hard-stop, p=0.67; auto-correction, p=0.09; control, p=0.31), and between groups (p=0.39). Intern attitudes about the alerts were assessed in the post-test. Among interns who received alerts, nine (26%) believed that the alerts interfered with their ability to efficiently complete their documentation, 14 (41%) did not, and 11 (32%) were neutral. No attitude differences were detected between the two alert groups.

Power analysis

Repeated measurements in this study allowed for an increase in statistical power to detect treatment differences among study conditions. The correlation between two successive measurements was 0.62. In randomized trials with repeated measurements, an important determinant of the minimum detectable difference is the design effect, which is defined as 1+ICC(k−1), where ICC is the intraclass correlation coefficient, that is, the correlation between two successive measurements, and k is the number of repeated measurements. The three repeated measurements in this study yielded a design effect of 2.24. The effective sample size for each group is 20×3/2.24=27. Using an estimated SD of the percentage of unapproved abbreviations of 0.5 (table 3), the study has 80% power to detect a difference in percentages of abbreviations of 0.39 between groups with a type I error of 0.05.

DISCUSSION

This randomized-controlled trial compared two types of computerized alerts designed to reduce the use of unapproved medication abbreviations by physicians. We demonstrated that alerts embedded within an electronic progress note program reduced the use of abbreviations within the electronic program (as measured by frequency of alerts fired) and within the non-computer-assisted handwritten H & Ps authored by physicians over the same time period. Alerts with a forced correction feature decreased the use of abbreviations to a much greater extent than alerts with an auto-correction feature. Moreover, an unanticipated but particularly interesting finding in our study was that reductions in abbreviation use were observed in a control group who were unexposed to alerts, but who were exposed to the overall study environment.

Table 3 Summary of the percentage of unapproved medication abbreviations in handwritten notes among interns exposed to no alerts, hard stop alerts, or auto-correction alerts in an electronic note writing program

	Control group			Hard stop alert group			Auto-correction alert group		
Follow-up time	Total no of opportunities for error	No of unapproved medication abbreviations	Percentage of unapproved medication abbreviations	Total no of opportunities for error	No of unapproved medication abbreviations	Percentage of unapproved medication abbreviations	Total no of opportunities for error	No of unapproved medication abbreviations	Percentage of unapproved medication abbreviations
Quarter 1 (baseline)	317	191	0.60	426	214	0.50	231	155	0.67
Quarter 2	386	188	0.49	299	79	0.26	182	99	0.54
Quarter 3	281	63	0.22	373	31	0.08	252	150	0.60
Quarter 4	366	49	0.13	324	36	0.11	271	94	0.35

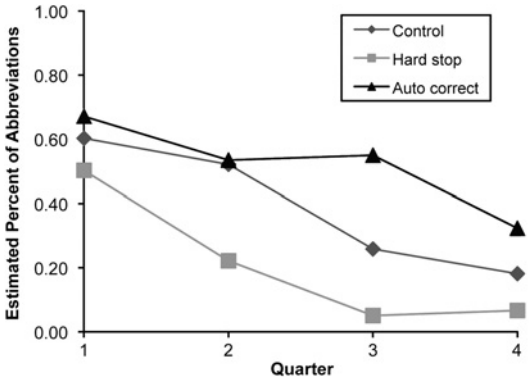

Figure 3 Comparisons of estimated percentages of unapproved abbreviations in handwritten notes across different groups. Error rate for Quarter 1 (baseline) was estimated using the raw data; error rates for Quarters 2–4 were estimated using a pooled logistic regression model which includes group indicator, indicator of follow-up time, and their interaction terms (group×follow-up time), and specifies autoregression working correlation matrix. p Value for comparisons of error rates across the three groups at baseline is 0.54. p Values for trend test within each group are 0.004, <0.0001, and 0.04 for control, hard stop, and auto-correction group respectively. p Value for comparisons of the error rate between hard stop and control groups is 0.02; 0.21 between auto-correction and control groups, and p=0.0005 between auto-correction and hard stop groups.

Eliminating error-prone medication abbreviations has been extremely challenging for hospitals, and there are very few effective interventions in the literature for this vexing problem. An educational intervention designed to reduce prescribing errors in the handwritten medication orders of residents reduced overall prescribing errors among surgery but not medicine residents.[11] Enforcement strategies at the level of medical staff leadership proved more effective than education alone in a single study[10]; however, enforcing physician accountability for documentation skills is difficult. Given the strong and repeated association between abbreviation use and medication errors,[3 8] it will be necessary and important for healthcare leaders to use multiple strategies to improve this unsafe and therefore unacceptable practice. Health information technology is just one of those strategies. As demonstrated in this study, a clinical decision-support system designed to reduce abbreviations may be an effective addition to administrative oversight and routine education.

Of the 2371 H & Ps reviewed, there were 4191 unapproved abbreviations noted, which equates to approximately two unapproved abbreviations per H & P. On the surface, this average seems low considering the high numbers of patients in our hospital treated with multiple medications. However, when considering the frequency of these occurrences in H & Ps (range 0–17; median=2.5), one can see that significant abbreviation use with the opportunity for medication errors exists. Significant reductions in abbreviations were demonstrated in the non-computer-assisted handwritten notes over time and across all three study groups, further reducing the abbreviation errors in the H & Ps.

The ability for health information technology to intercept unsafe practices and prevent serious medication errors has been described.[20–22] Improvements in medication safety with the use of CDSS occur through both direct and indirect effects. Direct effects alter medication prescribing or management at the time practitioners interact with system. Indirect or 'spillover' effects result from the carry-over into practice of knowledge or behaviors learned during exposure to the system.[23] Few studies of CDSSs have been designed to measure indirect effects. Glassman *et al* reported that exposure to automated drug alerts had little effect on the recognition of selected drug–drug or drug–condition interactions as measured by a cross-sectional survey.[23] Studies of drug-utilization reviews describe indirect effects of interventions on future clinician behavior.[24 25] For example, a time-series study that involved mailing letters to physicians about drug interactions and monitoring their subsequent prescribing patterns found no effect on future prescribing behavior as a result of the intervention.[24] In contrast, our study found large indirect effects by demonstrating significant reductions in the frequency of medication abbreviations in physicians' non-computer-assisted handwritten notes when they were prompted to correct the abbreviations in the electronic notes over the same time period.

The rapid expansion of alert systems in medical informatics calls for more research comparing the effects of different alert systems on the same outcome. Previous studies have described the over-riding of drug safety alerts[26] and demonstrated that the nature of alerts influences clinician behavior.[22 27 28] Thus, the inability to detect significant reductions in abbreviation use in the non-computer-assisted handwritten notes in the auto-correction alert group compared with the forced correction alert group is not surprising. One reason for this is that interns who received auto-correction alerts disregarded the educational message or simply acknowledged the alert without reading the information given human factors such as time pressure, competing priorities, and alert fatigue. In contrast, interns exposed to the forced alert were unable to complete their electronic notes without making manual corrections. It is known that mere repetition facilitates long-term memory,[29 30] and it may be that by forcing physicians to correct abbreviations, their knowledge of these abbreviations was solidified and translated into improvements in written practice. In summary, our study found direct evidence that passive alerts do little to influence clinician behavior. Additional studies will be important to substantiate these findings and advance the field of health informatics.

Reductions in abbreviation use in the control group were not anticipated by the investigators, but there are several possible explanations for the observation. Experimental diffusion, which occurs when a treatment effect applied to one group unintentionally spills over and contaminates another group,[31] may explain our findings. Interns in the control group were working in a study environment designed to modify physician behavior. Even though they were not directly exposed to alerts, their behavior may have been influenced by the improving documentation patterns of the interns exposed to the intervention who worked with them. Diffusion of effects threatens the internal validity of research, but it is difficult to control for in quality improvement research. While it is possible that the hospitals' educational strategies to reduce unapproved abbreviations contributed to the documentation improvements, this seems unlikely given the historical failure of routine education related to abbreviation avoidance.[10–12]

Despite the improvements in documentation practices, we failed to find any significant improvements in physician knowledge of unapproved abbreviations. This apparent 'disconnect' in knowledge versus practice is intriguing and has been demonstrated previously by Glassman *et al*.[23] There are several possible explanations for this finding. Our sample size may have been too small to detect a meaningful difference. The participants had varying degrees of exposure to the abbreviation

alerts and thus may have been unable to remember the abbreviations when they were presented to them in the post-test. The alerts may not have been perceived as important or relevant to the interns, especially since they were alerted when writing notes rather than when ordering medications. Nonetheless, it is hard to ignore the substantial reductions in abbreviation use in the non-computer-assisted handwritten notes as a result of the intervention, and this could be interpreted as a surrogate for knowledge acquisition.

The Joint Commission has strictly prohibited the use of seven common and unsafe medication abbreviations,[4] and The Institute for Safe Medication Practices has promulgated a list of over 50 abbreviations that have been associated with harm in their error-reporting systems and should never be used.[5] However, given the fact that any medication abbreviation creates an opportunity for misinterpretation and error potential, some organizations have attempted to limit all medication abbreviations by creating policies with 'approved' (rather then unapproved) abbreviation lists in which all medication abbreviations are prohibited. Since clinicians are in the habit of using medication abbreviations frequently, it is unlikely that one intervention alone will eliminate this practice, and it will be necessary to consider electronic interventions such as this to curb their use in free text entries in prescription writing and medical records.

Our study has several limitations. Because our hospital has an integrated CPOE system, we were unable to assess whether our intervention would have affected handwritten medication prescribing errors related to abbreviations. Handwritten abbreviations in prescriptions present a larger risk to patients than handwritten abbreviations in medical records. However, it is possible that documentation skills learned by physicians in an electronic environment and practiced in handwritten notes will carry over into their future handwritten or electronic free text prescriptions, and recommendations for prescriptions are often made in medical record documentation, so the potential for abbreviation errors exists even outside of the prescription-writing environment. Feasibility issues prevented retrospective reviews of the handwritten medication prescriptions of study participants.

We did not study the documentation practices of the participants after the alerts were turned off. Consequently, we cannot be certain of the long-term sustainability of our intervention and whether the documentation improvements would have improved further, plateaued, or waned had the alerts been turned off or continued. Additionally, given that exposure to the alerts was not continuous over time based upon the sequence of intern rotations and that these alerts varied in frequency among all interns, we may have reduced our ability to detect important differences among the groups and within certain participants. We did not evaluate documentation practices in the year(s) prior to our intervention and thus cannot completely exclude the possibility that a trend towards reduction in unapproved abbreviations occurred from a natural history effect encountered with introducing electronic platforms for documentation.

Finally, our study has several features that may limit its generalizablity. We studied only interns at a single academic medical center with a hybrid information system comprising both paper and electronic documentation. Since many organizations currently practice in hybrid systems, and many physicians practice in multiple information systems over the course of their career, we believe that the information related to the secular trends in physician non-computer assisted handwritten notes as a result of exposure to computerized alerts is relevant. Compared with interns, residents, attending physicians, non-physician providers, or practitioners in community hospitals may have responded differently to the intervention; however, there are elements of practitioner performance that are not unique to interns or academic medical centers, and some generalizations can be made from this study. The undergraduate and graduate medical training years are an ideal time to introduce information technology designed to improve medication safety, since trainees have not yet been influenced by unsafe medication documentation practices in the hospital and may be more open to changes in practice.

In summary, our study contributes important information to the health information technology literature by describing the effect that CDSS can have on physician behavior in the absence of knowledge and demonstrating that an informatics intervention can create large behavioral changes in a control group unexposed to the actual intervention but exposed to the study environment in which the intervention was performed. The methods used in this study to examine the indirect effects of health information systems to modify physician behavior outside of the electronic environment are unique and may have relevance for other health information technology interventions. We have established a methodology within a randomized-controlled trial to evaluate the effects of alerts embedded within a clinical decision-support system on physician knowledge and practice. Estimates for the percentage of unapproved abbreviation use were calculated based on the number of opportunities for error and offer additional endpoints to measure practice changes with technology-based interventions. These estimates can be used to determine samples sizes for adequate statistical power to evaluate the effects of interventions to reduce medication errors and test information systems in patient safety research. We found that alerts for unapproved medication abbreviations within electronic medical record systems are effective in changing physician documentation and thus promoting medication safety. Given that many healthcare organizations do not have fully integrated health information technology systems, researchers and patient safety leaders will continue to be challenged with ways to promote safe medication practices through electronic tools and education.

Acknowledgments The authors are grateful to L Fleisher and S Williams, for their comments on earlier versions of this manuscript. We also thank S Kratowicz for his technical support in building the computerized alerts.

"Gray area" alcohol consumption and the U.S. Dietary Guidelines: A comment on Dawson and Grant (2011)

Dear Editor:

The research by Dawson and Grant (*Journal of Studies on Alcohol and Drugs,* May 2011) exploring the "gray area" of alcohol consumption was a well-executed and important article, demonstrating that drinking at levels initially proposed for the 2010 Dietary Guidelines for Americans was associated with an increased risk of prevalent and incident alcohol dependence, incident alcohol-related interpersonal problems, and prevalent job loss compared with the limits in the 2005 Dietary Guidelines. The proposed revision would have changed the limits from *daily* consumption not exceeding 2 drinks for men and 1 for women to *average* consumption not exceeding 2/1 drinks for men/women, while stipulating that risky drinking precluded drinking 5/4 or more drinks daily (Dawson and Grant, 2011).

Their findings underscore the wisdom of the ultimate decision to retain the 2005 Dietary Guidelines for Americans limits in the 2010 version (U.S. Department of Health and Human Services and U.S. Department of Agriculture, 2005, 2010) and illustrates that the mere absence of clearly risky drinking does not necessarily constitute low-risk drinking, particularly in a document meant to apply to the entire adult population of the United States. Because most people drinking within 2/1 average limit drink 10 or fewer days per month (Naimi et al., 2010), the effect of the proposed change would have been to condone drinking up to 4 drinks daily for men or up to 3 drinks daily for women, as long as the average limits were not exceeded. Such an interpretation would be analogous to suggesting that driving a car with a blood alcohol concentration of .079% (a level just short of legal intoxication) is safe or desirable. Finally, were a low-risk drinking guideline developed on the basis of average alcohol consumption, the nadir of risk (or the zenith of potential benefit, depending on one's perspective) for all-cause mortality is approximately one third of a U.S. standard drink for women and approximately one half of a drink for men (DiCastelnuovo et al., 2006), both substantially less than what was proposed.

The Dietary Guidelines do not recommend alcohol consumption but rather recommend low-risk drinking limits *for those who choose to consume alcohol*. To date, there have been no randomized trials of low-dose alcohol and any morbidity and mortality outcome, and existing observational studies may be biased in favor of moderate drinkers (Fillmore et al., 2006; Naimi et al., 2005) Both the 2005 and 2010 Dietary Guidelines explicitly recommend against initiating drinking or drinking more frequently on the basis of potential health benefits (U.S. Department of Health and Human Services and U.S. Department of Agriculture, 2005, 2010).

The Cost of Alcohol and Its Corresponding Taxes in the U.S.

A Massive Public Subsidy of Excessive Drinking and Alcohol Industries

Timothy S. Naimi, MD, MPH

In an invaluable update using a standard cost-of-illness approach, Bouchery et al.[1] estimated the financial impact of excessive alcohol consumption in the U.S. for 2006, the most recent year for which data were available. The results ($223.5 billion or $746 per capita that year) are staggering and exceed the costs of the other leading preventable causes of death in the U.S., including cigarette smoking and physical inactivity. This is partly because excessive alcohol consumption involves many second-hand or external costs (i.e., costs that are incurred by those other than the consumers, sellers, or producers of alcohol) and because many alcohol-related outcomes begin at relatively young ages, which results in large future productivity losses and prolonged or recurrent expenditures related to health care and the criminal justice system.

Although this method is not the only way to estimate the cost of public health problems, it is commonly used and generally accepted. The method is conservative in that it does not include costs related to pain and suffering, which can account for more than half of the costs in studies where this is valued using a willingness-to-pay approach. The study by Bouchery et al.[1] is also conservative principally because of limitations around delineating alcohol-attributable health effects, which has a large influence on health and productivity costs. On the other hand, this approach considers the future cost of lost productivity but not averted economic consumption, which is the equivalent of savings that could offset costs. Finally, this is a study about the costs of excessive drinking, and low-risk alcohol consumption may have some economic benefits. In this light, however, one could argue that the costs from excessive drinking are conservative in that they also represent an unmeasured opportunity cost associated with failing to achieve possible savings from low-risk consumption by, for example, raising alcohol prices to the point where they would mitigate excessive drinking and instead promote low-risk drinking among those who drink.

An important advance in this article is that it takes the cost estimate, which is difficult to grasp, and translates it on a cost-per-drink basis that makes it comprehensible to policymakers, as is, for example, the cost per pack of cigarettes. The cost-per-drink metric also facilitates a comparison with current alcohol taxes, which can be derived on a per-drink basis. This, in turn, highlights perhaps the most important contribution of this study, which is to illustrate the gross disparity that exists between the cost of alcohol consumption and its taxes.

Based on federal tax rates for standard alcohol beverage categories (5% alcohol-by-volume [ABV] beer; 12% ABV wine; and 40% ABV liquor), and after weighting those taxes on the basis of beverage-specific consumption in the U.S. and standard drink size (14 g of ethanol per drink), the average federal tax in the U.S. is approximately 8.5 cents per drink.[2-5] Further, since federal alcohol taxes are based on a fixed amount per volume of alcohol, they continuously erode as a result of inflation. For example, the federal beer tax has declined by 41% in real terms since it was last adjusted in 1991. Historically, alcohol taxes accounted for approximately 40% of federal revenues; they now account for less than 0.5% of revenue.[6]

States typically have substantially lower taxes on alcohol than does the federal government (approximately 5 cents per drink). Moreover, although these state taxes are enacted primarily through volume-based excise taxes (similar to federal taxes), in some cases they include ad valorem taxes (alcohol-specific taxes based on a percentage of the price) or general sales taxes. In Massachusetts, my home state, the weighted average tax per drink is only 2.6 cents,[4] which is levied in the form of volume-based excise taxes. In addition, as in a number of other states, alcohol is not subject to the state's 6.25% sales tax or any ad valorem taxes, meaning that alcohol is taxed far less than items such as durable medical equipment, automobiles, or other general merchandise.

The study's estimated $1.90 cost per drink in 2006 has increased to $2.13 per drink in 2011, after adjustment for

doi: 10.1016/j.amepre.2011.08.001

inflation. Because federal plus state taxes are (and were) approximately 14 cents per drink, this is a current disparity between cost and tax of approximately $2 per drink. In addition, this study found that 41.5% of costs were incurred by drinkers themselves, meaning that 58.5% of costs (or approximately $1.25 per drink in 2011 and $1.11 in 2006) were external to drinkers, a disparity of $1.11 per drink for external costs in 2011 and $0.97 per drink in 2006. Therefore, in 2006 alone, the 117.4 billion standard drinks consumed in the U.S. resulted in $113.9 billion in net (i.e., un-recouped) external costs that accrued to the general public; for comparison, this was almost half the size of the federal budget deficit that year.

External economic costs are an important justification for, and basis of, taxation on items such as alcohol, cigarettes, or businesses that generate environmental pollution.[6] Failing to recoup these external costs amounts to a massive public subsidy, in which the 80% of the U.S. population that doesn't drink or that drinks in low-risk ways pays for costs incurred by excessive drinkers and those who produce, distribute, or sell alcohol. Were this subsidy addressed through commensurate taxation, it would have an adverse effect on alcohol-related businesses. However, by making people pay the true cost of alcohol, the additional revenue would promote economic efficiency through re-allocation to other sectors of the economy and could be used to finance state and federal debt obligations, pay for education or publicly financed health care, or increase personal income by offsetting income or property taxes. Based on the above, increased taxes would result in net savings for most taxpayers, and excessive drinkers would pay almost five times as much per capita as low-risk drinkers according to their differences in consumption. And unlike tobacco taxes, increased alcohol taxes would be borne principally by those who are relatively socially and economically advantaged.[7]

In addition to recouping external economic costs, there is another overriding rationale for increasing alcohol taxes: to improve public health and well-being. Maintaining higher prices generally, and raising alcohol taxes specifically, is the most effective population-based means of preventing and reducing excessive alcohol consumption and related harms.[8] Unlike cost-of-illness valuations, pain and suffering do matter when it comes to health and well-being, and most would value a life more highly than the sum of wages earned while living it. In other words, raising alcohol taxes by an order of magnitude is ultimately a matter of economic fairness that will result in societal benefits that are, to many, beyond measure.

Abstract

Testosterone concentrations in men are associated with cardiovascular morbidity, osteoporosis, and mortality and are affected by age, smoking, and obesity. Because of serum testosterone's high heritability, we performed a meta-analysis of genome-wide association data in 8,938 men from seven cohorts and followed up the genome-wide significant findings in one *in silico* (n = 871) and two *de novo* replication cohorts (n = 4,620) to identify genetic loci significantly associated with serum testosterone concentration in men. All these loci were also associated with low serum testosterone concentration defined as <300 ng/dl. Two single-nucleotide polymorphisms at the sex hormone-binding globulin *(SHBG)* locus (17p13-p12) were identified as independently associated with serum testosterone concentration (rs12150660, $p = 1.2 \times 10^{-41}$ and rs6258, $p = 2.3 \times 10^{-22}$). Subjects with ≥3 risk alleles of these variants had 6.5-fold higher risk of having low serum testosterone than subjects with no risk allele. The rs5934505 polymorphism near *FAM9B* on the X chromosome was also associated with testosterone concentrations ($p = 5.6 \times 10^{-16}$). The rs6258 polymorphism in exon 4 of *SHBG* affected SHBG's affinity for binding testosterone and the measured free testosterone fraction ($p < 0.01$). Genetic variants in the *SHBG* locus and on the X chromosome are associated with a substantial variation in testosterone concentrations and increased risk of low testosterone. rs6258 is the first reported *SHBG* polymorphism, which affects testosterone binding to SHBG and the free testosterone fraction and could therefore influence the calculation of free testosterone using law-of-mass-action equation.

Author Summary

Testosterone is the most important testicular androgen in men. Low serum testosterone concentrations are associated with cardiovascular morbidity, metabolic syndrome, type 2 diabetes mellitus, atherosclerosis, osteoporosis, sarcopenia, and increased mortality risk. Thus, there is growing evidence that serum testosterone is a valuable biomarker of men's overall health status. Studies in male twins indicate that there is a strong heritability of serum testosterone. Here we perform a large-scale genome-wide association study to examine the effects of common genetic variants on serum testosterone concentrations. By examining 14,429 men, we show that genetic variants in the sex hormone-binding globulin (*SHBG*) locus and on the X chromosome are associated with a substantial variation in serum testosterone concentrations and increased risk of low testosterone. The reported associations may now be used in order to better understand the functional background of recently identified disease associations related to low testosterone. Importantly, we identified the first known genetic variant, which affects SHBG's affinity for binding testosterone and the free testosterone fraction and could therefore influence the calculation of free testosterone. This finding suggests that individual-based SHBG-testosterone affinity constants are required depending on the genotype of this single-nucleotide polymorphism.

Introduction

Testosterone, the most important testicular androgen in men, is largely bound to two plasma proteins. Most of the circulating testosterone (~50–60%) is bound with high affinity to sex hormone-binding globulin (SHBG), while a smaller fraction (40–50%) is bound loosely to albumin, and 1–3% is unbound and termed free testosterone [1]. In prospective cohort studies, low serum testosterone concentrations are associated with cardiovascular morbidity, metabolic syndrome [2,3], dyslipidemia [4], hypertension [5], type 2 diabetes mellitus [6], stroke [7], atherosclerosis [8–10], osteoporosis, sarcopenia, and increased mortality risk [11–13]. Thus, there is growing evidence that serum testosterone is a valuable biomarker of men's overall health status. Since age, body mass index (BMI), and smoking are known to affect serum testosterone concentrations [14], we used these parameters as common set of covariates in all association models. Studies in male twins indicate that there is a strong heritability of serum testosterone, with genetic factors accounting for 65% of the variation in serum testosterone [15]. However, the genetic determinants of serum testosterone and the genetic risk factors for low concentrations are poorly understood. Given the current gap in knowledge of the genetic factors that contribute to the inter-individual variability in serum testosterone concentration in men we conducted a meta-analysis of genome-wide association studies (GWAS). This two-stage meta-analysis included data from 14,429 Caucasian men from 10 independent cohorts within the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium. In stage one, the discovery stage, genome-wide association data from seven cohorts were meta-analyzed (n = 8,938) and all genome-wide significant findings that fulfilled the criteria described in the methods section were followed up in the three replication cohorts: one *in silico* replication cohort (n = 871) and two replication cohorts with *de novo* genotyping (n = 4,620). All association analyses of the discovery stage were conducted both with and without additional adjustment for serum SHBG concentrations. Our primary aim was to identify genetic variants reproducibly associated with serum testosterone concentrations in men, evaluated as a continuous trait. We also assessed whether the lead single-nucleotide polymorphisms (SNPs) from the continuous trait analyses had a significant influence on the risk of having low serum testosterone, defined as <300 ng/dl [16]. This level is slightly lower than that suggested recently by Wu et al. [11 nmol/l = 317 ng/dl] as one of the clinical criteria for late onset hypogonadism [17].

Results

Meta-analyses of genome-wide association studies for autosomal SNPs

We performed a GWAS of serum testosterone concentrations, investigating ~2.5 million SNPs in 8,938 men of Caucasian ancestry, 18 to 98 years, from seven cohorts. Genome-wide significant SNPs were found in the discovery analysis at one locus on chromosome 17 (17p13-p12) using the criteria described in the methods. The strongest association was found for rs12150660 ($p = 1.9\times10^{-17}$), located 11.5 kb upstream of the major transcription start site of *sex hormone-binding globulin* (*SHBG*), with a minor allele frequency (MAF) of 23% (Table 1 [SNPs rs12150660 and rs6258], Figure 1A and Figures S1A, S2 and S3). Tests for independently associated SNPs with serum testosterone in this region revealed a second SNP, rs6258 ($p = 4.1\times10^{-14}$), which represents a missense (P→L) polymorphism located in exon 4 of *SHBG* (Table 1 [SNPs rs12150660 and rs6258], Figure 1B) and which had a MAF of 2%. Based on HapMap release 22 (CEU), the r^2 between rs12150660 and rs6258 was 0.004. To validate the independence of these two SNPs, conditional meta-analysis of the discovery cohorts including both rs12150660 and rs6258 in an additive genetic linear model adjusted for covariates was calculated. Because the associations remained significant and mostly unchanged (rs12150660, $p = 7.0\times10^{-14}$; rs6258, $p = 1.6\times10^{-13}$), both SNPs were independently associated with serum testosterone concentrations. No additional autosomal locus fulfilled the criteria for genome-wide significance.

Replication of autosomal hits

The associations of rs12150660 and rs6258 were confirmed in the three replication cohorts (*in silico* replication in YFS and *de novo* replication in MrOS Sweden and EMAS), demonstrating a combined p-value in the discovery and the replication cohorts of 1.2×10^{-41} and 2.3×10^{-22}, respectively (Table 1 [SNPs rs12150660 and rs6258]). Both SNPs showed considerable heterogeneity of results across the studies as measured by the I^2 statistic [18]. The I^2 values for the discovery meta-analysis using the untransformed total testosterone values were 76.7% and 81.6% for rs12150660 and rs6258, respectively. The heterogeneity was reduced to 39.3% and 75.5% for rs12150660 and rs6258, respectively, by meta-analysing the z-score based untransformed total testosterone values and to 30.9% and 78.0%, respectively, by meta-analysing the inverse-normal transformed testosterone values. For rs12150660, a substantial amount of heterogeneity could be explained by phenotypic variation among the cohorts, whereas for rs6258 one cohort (InCHIANTI) showed consistent opposite effect directions in all models used. To take into account this heterogeneity, we additionally calculated a random effects model for untransformed total testosterone values. The association for rs12150660 remained genome-wide significant in the combined discovery and replication stage meta-analysis, the association for

Effects size is given per minor allele. All seven discovery cohorts (n = 8,938) were included in the GWAS of chromosomes 1–22 while only the two largest cohorts (FHS and SHIP. n = 5,067) had GWAS data available for the X chromosome. A1 = allele 1. A2 = allele 2. FREQ* = Frequency of allele 1. In the KORA cohort, testosterone was measured using plasma but the analyses after excluding KORA yielded similar results. Calculated free testosterone was calculated for all subjects with both testosterone and SHBG available by using a modified law of mass action equation. The concentrations of testosterone and SHBG and a fixed value for SHBG's dissociation constant were used in these calculations.

doi:10.1371/journal.pgen.1002313.t001

rs6258 reached genome-wide significance after excluding the InCHIANTI cohort (Table S3).

The genetic influence on low serum testosterone concentrations

In Table 2, the serum testosterone concentrations according to genotype are given for the three replication cohorts. As expected, mean serum testosterone concentrations were found to be lower in men with GG than in those with TT genotype for rs12150660. Similarly, men with the CT genotype for rs6258 had lower serum testosterone concentrations than those with CC genotype. The TT genotype of rs6258 was extremely rare and only found in two subjects in the replication cohorts. The two autosomal SNPs identified by GWAS had a significant influence on the risk of having low serum testosterone (serum testosterone <300 ng/dl) in both the discovery and the replication cohorts with a combined odds ratio (OR) per minor allele of 0.72 (95% CI, 0.65 – 0.79) and 2.7 (95% CI, 2.1 – 3.5) for rs12150660 and rs6258, respectively (Figure 2A). We analyzed the combined effect of the two SNPs on the risk of having low serum testosterone concentrations according to the number of combined risk alleles for rs12150660 (G) and rs6258 (T) in the three replication cohorts (MrOS Sweden, EMAS, and YFS). The risk of having low serum testosterone concentrations increased by the number of risk alleles with an OR of 1.62 (95% CI, 1.41 – 1.86) for each risk allele (Figure S4). Low serum testosterone concentrations were 6.5-times more prevalent in men with ≥3 risk alleles (30.1% prevalence of low serum testosterone) compared to men without any risk allele (4.6% prevalence of low serum testosterone; Figure 2B).

The role of SHBG in the observed associations

As SNP rs12150660 is located 11.5 kb upstream of *SHBG* and SNP rs6258 is non-synonymous and located in exon 4 of *SHBG*, we evaluated the influence of these polymorphisms on SHBG concentrations. Both of these polymorphisms demonstrated a significant association with SHBG concentrations in both the discovery and replication cohorts (Table 1 [SNPs rs12150660 and rs6258]). However, even after adjusting for SHBG concentrations, the associations between these two SNPs and serum testosterone concentrations were still significant ($p = 9.0 \times 10^{-8}$ for rs12150660 and $p = 4.5 \times 10^{-7}$ for rs6258). Free testosterone calculated using law-of-mass-action equation was not associated with either of the two polymorphisms (Table 1 [SNPs rs12150660 and rs6258]). As serum testosterone and SHBG are highly correlated (e.g., in MrOS Sweden $r_s = 0.53$), variations in SHBG concentration might have influenced the observed associations of serum testosterone with other non-SHBG-related loci. Therefore, we performed an additional SHBG-adjusted genome-wide meta-analysis among the discovery cohorts, wherein none of the non-SHBG-related autosomal SNPs reached genome-wide significance (Figure S1B).

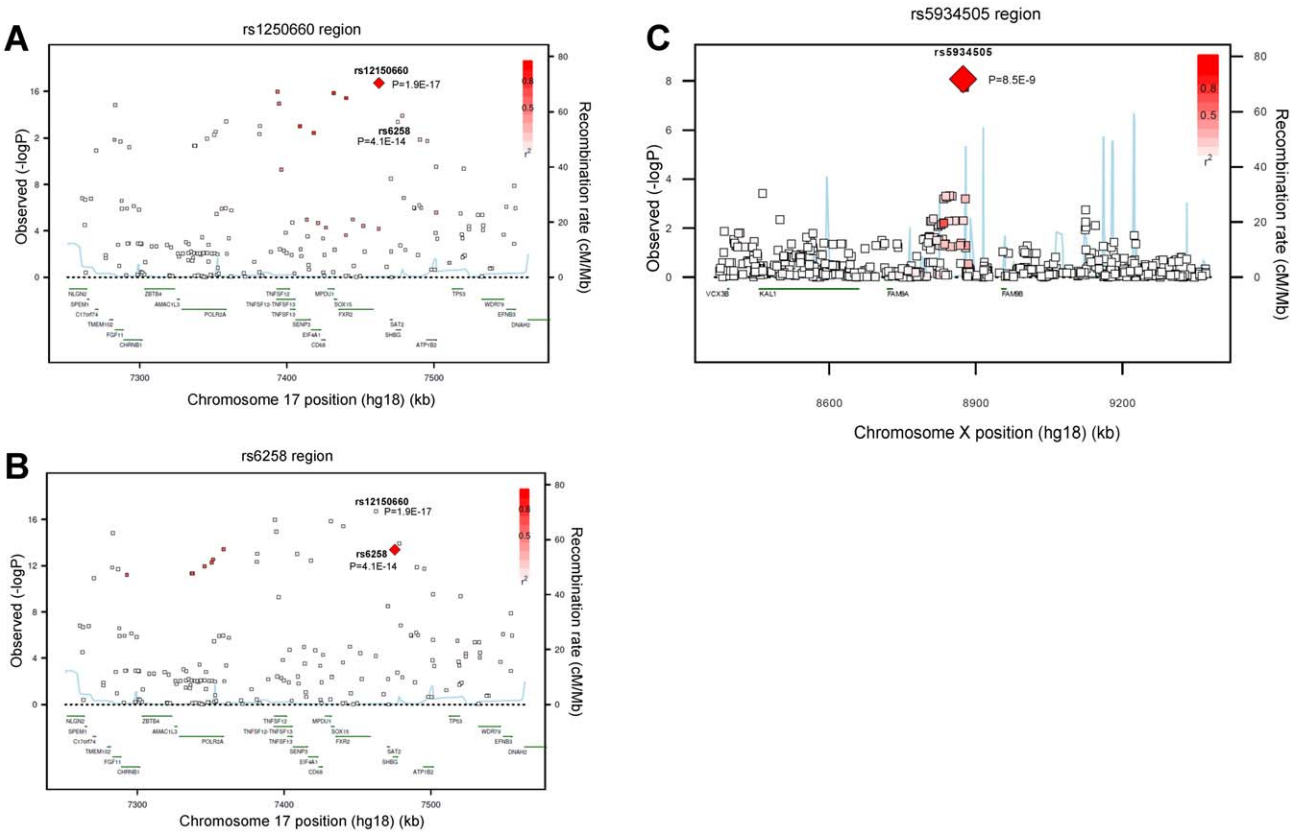

Figure 1. Regional association plots for single-nucleotide polymorphisms rs12150660, rs6258, and rs5934505. Regional association plot of the two independent signals on chromosome 17 with either (A) rs12150660 or (B) rs6258 indicated by red diamond to evaluate linkage with other single-nucleotide polymorphisms in the region. In addition, the association plot of the (C) rs5934505 signal on chromosome X is given. The r^2 is based on the CEU HapMap II samples. The blue line and right hand Y axis represent CEU HapMap II based recombination rates. (A) and (B) show the top SNPs of the inverse-variance weighted discovery stage meta-analysis of untransformed serum testosterone and (C) show the top SNP of the SHBG-adjusted serum testosterone using an imputation quality filter (observed/expected variance ratio) >0.4 at the individual cohort level during meta-analysis.
doi:10.1371/journal.pgen.1002313.g001

The rs6258 polymorphism affects SHBG binding affinity for testosterone and the measured free testosterone fraction

As rs6258 is non-synonymous (P156L) and located in exon 4 of *SHBG*, we evaluated the serum SHBG steroid-binding capacity of the different rs6258 genotypes. As shown in Figure S5, serum SHBG from CT but not CC subjects had a lower steroid-binding capacity than expected from values obtained by an SHBG immunoassay ($p = 0.003$). Therefore, we analyzed the SHBG affinity for testosterone using Scatchard plots of SHBG in serum of men with the rs6258 genotype (Figure 3A), and revealed (Figure 3B) a higher mean dissociation constant (Kd) indicative of a lower affinity in CT (Kd = 4.5 nM) and TT (Kd = 4.9 nM) individuals than in CC individuals (Kd = 2.8 nM). Recombinant SHBG corresponding to the T genotype demonstrated a higher dissociation constant (lower affinity) compared with recombinant SHBG corresponding to the C genotype (T genotype Kd 2.5 nM; C genotype Kd 1.2 nM, Figure 3C). In addition, the free testosterone fraction measured by an equilibrium dialysis method was 22% higher ($p = 1.4\times10^{-5}$) in serum from CT subjects than in serum from CC subjects (Figure 3D).

X chromosome analyses

Imputed values for X chromosome-located SNPs were available for the two larger discovery cohorts (SHIP and FHS; n = 5,067). We performed meta-analyses of imputed X chromosome SNPs for serum testosterone concentrations both with and without SHBG adjustment, revealing one genome-wide significant association for SNP rs5934505 ($p = 8.5\times10^{-9}$) in the SHBG-adjusted model (Table 1 [SNP rs5934505] and Figures S1B and S3). This SNP was confirmed in the two replication cohorts with *de novo* genotyping (MrOS Sweden $p = 3.6\times10^{-3}$; EMAS $p = 1.5\times10^{-7}$). Meta-analysis of discovery and replication cohorts resulted in a combined p-value of 5.6×10^{-16}. The rs5934505 SNP is located in a CNV-insertion area (Xp22), 145 kb upstream of the *family with sequence similarity 9, member A (FAM9A)* and 79 kb downstream of the *family with sequence similarity 9, member B* (*FAM9B*) (Figure 1C). In addition, rs5934505 is located 214 kb upstream of Kallmann syndrome 1 sequence (*KAL1*). SNP rs5934505 was associated with serum testosterone without SHBG-adjustment (combined p-value of 1.7×10^{-9}) and with free testosterone (combined p-value of 6.7×10^{-15}), but not with SHBG (Table 1 [SNP rs5934505]). The mean serum testosterone and calculated free testosterone but not SHBG concentrations were lower in men with T genotype than in those with C genotype for rs5934505 (Table 2).

Discussion

This GWAS revealed novel genetic variants that significantly affect circulating testosterone concentrations in men. The presence of three or more risk alleles for the two polymorphisms in the

doi:10.1371/journal.pgen.1002313.t002

SHBG loci resulted in markedly decreased testosterone concentrations compared to men with two or less risk alleles. Importantly, one of the identified genetic variations was associated with an alteration in SHBG's binding affinity for testosterone and the measured free testosterone fraction. In addition, we identified a locus on the X chromosome influencing serum testosterone concentrations. The genetic contribution of the polymorphisms to testosterone concentrations reported here is substantial; as a reference for comparison, the effect of these polymorphisms on testosterone concentrations in men is similar or greater than that for known risk factors such as age, smoking, and BMI [19,20].

These findings improve our understanding of the genetic factors that affect serum testosterone concentrations and contribute to the variation in testosterone concentrations in men. These polymorphisms may assist in the identification of men at risk of low serum testosterone, although the clinical usefulness of these findings remains to be established. As rs12150660 and rs6258 were strongly associated with SHBG concentrations, both SNPs may at least partly affect total testosterone concentrations by modulating SHBG concentrations. Our findings that rs6258 substantially affects SHBG binding affinity and the measured free testosterone fraction raise questions about the use of a single consensus value for SHBG's dissociation constant in the law of mass action equations used to calculate free testosterone concentrations. As emphasized by the Endocrine Society's expert panel on androgen deficiency syndromes, low testosterone concentrations alone should not necessarily be viewed as evidence of androgen deficiency [16]. Whether rs593405 near the *FAM9B* and *KAL1* genes on Xp22 renders men susceptible to the increased risk of androgen deficiency remains to be determined. Further studies are required to determine the impact of these genetic variations on sex steroid-related disorders, including osteoporosis, cardiovascular diseases, prostate cancer, and male infertility [21].

Our studies add to the evidence that genetic variations within the *SHBG* gene may explain some of the inter-individual differences in SHBG concentrations. Our finding that SNP rs6258 results in the production of an *SHBG* variant with reduced affinity for testosterone provides an explanation for the association between rs6258 and low serum testosterone concentrations. This is the first described genetic variant associated with altered SHBG binding for testosterone. As rs6258 is non-synonymous (P156L), located in exon 4 of *SHBG* and associated with altered SHBG binding for testosterone and free testosterone fraction, rs6258 is likely a functional polymorphism with impact on testosterone binding to SHBG as well as testosterone bioavailability and action at target tissue level.

The SNP rs12150660 that is strongly associated with testosterone concentrations is located 11.5 kb upstream of the coding sequence for SHBG mRNA production in the liver. However, it still resides within the human *SHBG* locus because several other alternative exon 1 sequences are located up to ~13 kb upstream of the exon 1 sequence that encodes the secretion signal polypeptide of the SHBG precursor in the liver [22]. There are no obvious nuclear protein binding sites within the sequences spanning SNP rs12150660, and it remains to be determined whether this SNP disrupts a cis-element that directly influences *SHBG* transcription. We have found that rs12150660 is in strong LD ($r^2 = 0.89$) with another common SNP (rs1799941) in the *SHBG* proximal promoter that was shown to be associated with serum SHBG concentrations [23–25]. Thus, it is highly likely that only one of these polymorphisms is actually functional and therefore both SNPs represent the same signal. It should also be noted that rs1799941 is linked to the number of TAAAA repeats within an Alu sequence upstream of *SHBG* promoter [26] and that the rs1799941 (A allele) is linked with the presence of six TAAAA repeats in this location which has been reported to be associated with higher SHBG concentrations [27]. In addition, while there does not appear to be any putative transcriptional factor binding sites with the sequence comprising rs12150660, it remains to be determined whether rs12150660 or these other associated SNPs in

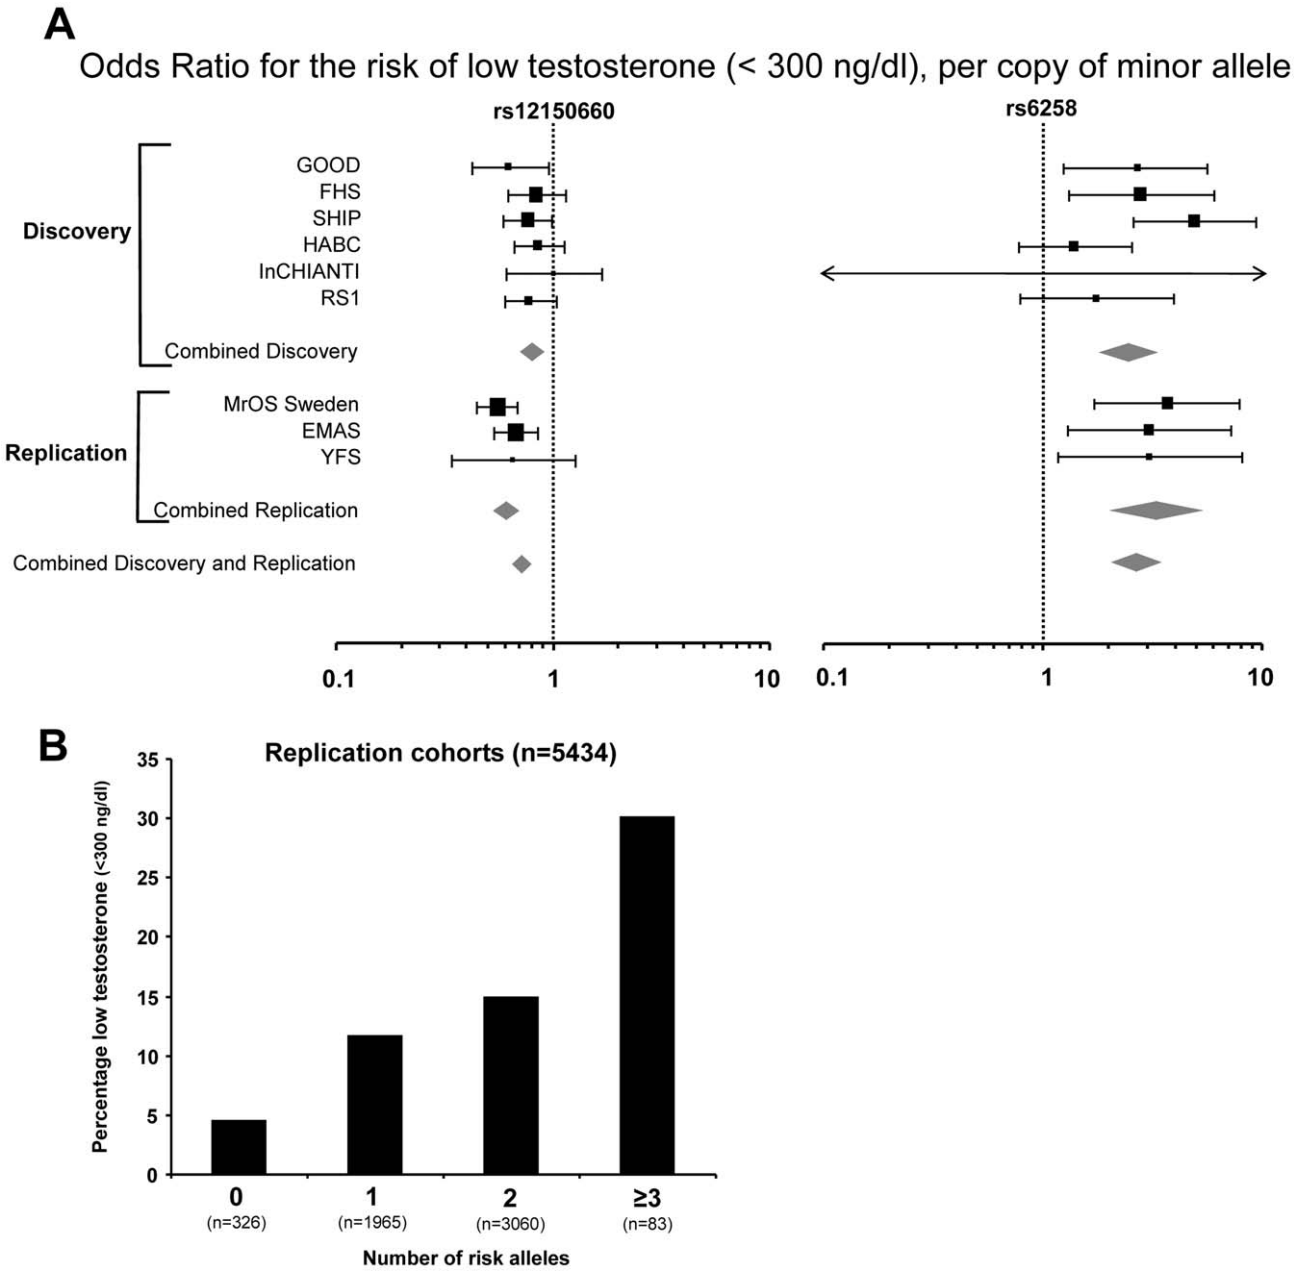

Figure 2. The genetic influence on low serum testosterone concentrations. (A) Odds ratio (OR) for risk of low serum testosterone concentrations (serum testosterone <300 ng/dl), per copy of minor allele. Summary estimates of the OR and their 95% confidence intervals (CI) are given. The size of the data markers is proportional to the weight (inverse of the variance) of each study. Combined discovery (n = 8,030, low serum testosterone 13%; KORA was not included as testosterone was analyzed in plasma rather than in serum, combined replication (n = 5,504, low serum testosterone 13%), and combined discovery and replication (n = 13,534, low serum testosterone 13%). (B) Percentage of men with low serum testosterone concentrations (serum testosterone <300 ng/dl), according to the number of combined risk alleles for rs12150660 (G) and rs6258 (T) in the three replication cohorts (MrOS Sweden, EMAS, and YFS). Only two individuals in the three replication cohorts had four risk alleles and therefore individuals with three and four risk alleles were pooled into one group with ≥3 risk alleles.
doi:10.1371/journal.pgen.1002313.g002

the *SHBG* gene are functionally important or simply represent proxies of SHBG and testosterone concentrations in men.

Our meta-analyses of imputed X chromosome SNPs revealed one genome-wide significant association for SNP rs5934505, located in a CNV-insertion area (Xp22), 145 kb upstream of *family with sequence similarity 9, member A* (*FAM9A*) and 79 kb downstream of *family with sequence similarity 9, member B* (*FAM9B*). Both genes, *FAM9A* and *FAM9B*, are expressed exclusively in the testis [28] and described here for the first time to be associated with total as well as free testosterone concentrations. rs5934505 is located 214 kb upstream of Kallmann syndrome 1 sequence (*KAL1*). Although the Kallmann syndrome, a type of hypogonadotropic hypogonadism associated with anosmia and other congenital anomalies, has been linked to mutations in the *KAL1* gene on the X chromosome, only 11–14% of Caucasian patients with hypogonadotropic hypogonadism have detectable *KAL1* mutations [29], reflecting the considerable genetic heterogeneity of this syndrome.

doi:10.1371/journal.pgen.1002313.g003

The strengths of our study include a discovery sample size of 8,938 men, which allowed us at the threshold $\alpha = 5 \times 10^{-8}$,a 90% power to detect SNPs accounting for 0.5% of the total variance in serum testosterone concentrations, and 99% power to detect SNPs accounting for 1% of the total variance. The SNPs rs12150660, rs6258, and rs5934505 explained 2.3%, 0.9%, and 0.6%, respectively, of the variance in serum testosterone concentrations when evaluated in the MrOS Sweden replication cohort. Future meta-analyses including larger samples will probably reveal additional loci associated with serum testosterone. Further research into the functional significance of these variants will be needed to enable the translation of these findings into the mechanisms of sex steroid-related diseases and strategies for risk assessment. As the causal or etiological role of these polymorphisms in the genesis of low testosterone has not been established, the reported polymorphisms associated with low serum testosterone concentration may be viewed currently as risk markers rather than causal risk factors.

In conclusion, genetic variants in the *SHBG* locus and on the X chromosome are associated with a substantial variation in testosterone concentrations and increased risk of low testosterone in men. Further studies are needed to determine the impact of these genetic variations on sex hormone-related disorders. rs6258 is the first reported *SHBG* polymorphism, which affects testosterone binding to SHBG and the free testosterone fraction and could therefore influence the calculation of free testosterone using law-of-mass-action equation.

Methods

Study samples and genotyping

The discovery stage of the GWAS included 8,938 Caucasian men of European descent drawn from seven epidemiological cohorts: the Framingham Heart Study (FHS), the Study of Health in Pomerania (SHIP), the Gothenburg Osteoporosis and Obesity Determinants (GOOD) study, the Cooperative Health Research in

the Region of Augsburg (KORA) study, the Health, Aging and Body Composition (HEALTH ABC) study, the Rotterdam Study (RS1), and the Invecchiare in Chianti (InCHIANTI) (Table S1). The replication stage consisted of 4,620 men from two epidemiological cohorts (the European Male Ageing Study [EMAS] and the Osteoporotic Fractures in Men [MrOS] Sweden study) for *de novo* genotyping of the top SNPs and one additional cohort (the Young Finns Study, [YFS, n = 871]) with genome-wide association data available and joining the study after stage one was finished for *in silico* replication (Table S2).

Exclusion criteria included chemical or surgical castration and/or medications affecting sex hormones such as steroid 5-alpha reductase inhibitors, and sex hormone antagonists. All studies were approved by local ethics committees and all participants provided written informed consent. Characteristics of the study samples and detailed descriptions of the participating cohorts, genotyping methods, quality control, and imputation procedures are provided in Text S1.

Genotyping and statistical analyses

Altogether, ~2.5 million SNPs, imputed using the HapMapII CEU population, were tested for association with serum testosterone in the discovery stage. Genome-wide association analyses using an additive genetic linear regression model adjusted for age, BMI, and current smoking were conducted twice within each of the discovery cohorts using serum testosterone expressed as ng/dl, as well as inverse-normal transformed serum testosterone as outcomes.

To examine the robustness of the discovery results and to reduce the risk of spurious associations due to possible testosterone measurement heterogeneity between the individual cohorts, three different types of meta-analyses were performed in the discovery stage: 1) an inverse-variance weighted fixed effect model; 2) a z-score based analysis of the untransformed serum testosterone concentrations; and 3) a z-score based meta-analysis of the inverse-normal transformed values. Model 1) was used as main analysis since it allowed the computation of effect estimates, whereas the other two analysis models were used for verification and quality control checks of the main findings. All meta-analyses were performed using METAL (www.sph.umich.edu/csg/abecasis/metal/). The random effects model of the two *SHBG* locus SNPs was calculated using the R-package *metafor* (www.r-project.org). Imputed genotypes were analyzed in all cohorts taking the genotype uncertainties into account. Genomic control was applied to each individual cohort's results and to the discovery stage meta-analysis to correct p-values for potential effects of mild population stratification. The estimated genomic control lambda was low for both the individual cohorts (range of λ_{GC}: 1.00–1.07) and the meta-analyses (range of λ_{GC}: 1.01–1.02), suggesting little residual confounding due to population stratification (Figure S2).

To reduce the variance on serum testosterone induced by SHBG concentration, the GWAS included a genome-wide test for association of untransformed serum testosterone concentrations adjusted for age, BMI, current smoking, SHBG and $SHBG^2$ concentrations, again using both an inverse-variance weighted fixed effect as main analysis and a z-score based meta-analysis for quality control purposes.

A threshold of $p<5\times10^{-8}$ was established *a priori* as the level for genome-wide significance in the discovery analyses [30]. SNPs that reached genome-wide significance in the inverse-variance weighted meta-analysis of untransformed serum testosterone concentrations with or without adjustment for SHBG and which had association results in at least five of the seven cohorts (for chr X: two cohorts with data available) were selected for further analyses. Notably, all autosomal SNPs that fulfilled these criteria also reached genome-wide significance in the other two types of meta-analyses. From these SNPs, all independent SNPs were taken to the replication stage.

We also assessed whether the lead SNPs from the continuous trait analyses were associated with low serum testosterone concentration (defined as <300 ng/dl [16]; this level is slightly lower than that suggested recently by Wu et al [11 nmol/l = 317 ng/dl] [17]) by binary logistic regression including the same covariates in the model used for the main analysis and meta-analyzing the within-cohort results using inverse-variance weighted fixed-effect model. The KORA cohort was not included in the meta-analyses of low serum testosterone as testosterone was measured using plasma in this cohort.

We determined the number of low serum testosterone concentration risk alleles (0 to 4) for the two lead SNPs of the *SHBG* locus in each individual and assessed the risk of low serum testosterone concentrations in the three replication cohorts (MrOS Sweden, EMAS, and YFS) using a trend test. Since only two subjects in the replication cohorts had four risk alleles, individuals having three and four risk alleles were grouped into one category to obtain more reliable effect estimates during the subsequent analyses. Details of test for independence, SHBG related analysis of the top SNPs and quality control steps performed can be found in Text S1.

Sex hormone measurements

Methods for the measurement of serum testosterone and SHBG are given in Text S1. Calculated free testosterone was for all subjects with both testosterone and SHBG available (n = 13833; Table 1 and Table 2) calculated by using a modified law of mass action equation, as described by Mazer [31]. The concentrations of testosterone and SHBG and a fixed value for SHBG's dissociation constant were used in these calculations.

Free testosterone fraction

Free testosterone fraction was measured by an equilibrium dialysis method in 87 subjects with the CC genotype and 32 subjects with the CT genotype of rs6258 (Figure 3D) [32]. Detailed description of the free testosterone fraction measurements is provided in Text S1.

Sex hormone-binding globulin assays

In experiments evaluating SHBG binding capacity, serum SHBG concentrations were determined by two-site immunofluorometric assay (PerkinElmer Life Sciences, Turku, Finland) [33], or by a steroid-binding capacity assay [34]. For steroid-binding assays, serum samples were pre-incubated with dextran-coated charcoal (DCC) to remove endogenous steroids, prior to incubation with either [^{3}H]5α-dihydrotestosterone ([^{3}H]DHT; specific activity 50 Ci/mmol) or [^{3}H]testosterone (specific activity 40 Ci/mmol), bound from free [^{3}H]steroid were separated using DCC as the separation reagent [34]. The steroid-binding properties of SHBG in diluted serum samples or tissue culture medium were determined by Scatchard analysis [34]. For the expression of SHBG protein, wild type (corresponding to the C genotype of rs6258) and rs6258 (corresponding to the T genotype of rs6258) SHBG cDNAs in the pRC/CMV expression vector were transfected into CHO cells, and G418 was used for selection of stably transfected cells. At near confluence, cells were washed with PBS and cultured in serum-free SFM4CHO medium (Thermo Scientific HyClone, Logan, UT) for four days before the SHBG-containing medium was harvested.

Supporting Information

Figure S1 Manhattan plots giving genome-wide $-\log_{10}$ p-value according to chromosomal location for inverse-variance weighted meta-analysis of untransformed serum testosterone (A) and SHBG-adjusted serum testosterone (B) using an imputation quality filter (observed/expected variance ratio) >0.4 at the individual cohort level during meta-analysis. All seven discovery cohorts (n = 8,938) were included in the GWAS of chromosomes 1–22 while only the two largest cohorts (FHS and SHIP, n = 5,067) had GWAS data available for the X chromosome.

Abstract

This is a prospective cohort study to identify factors associated with receipt of substance abuse treatment (SAT) among adults with alcohol problems and HIV/AIDS. Data from the HIV Longitudinal Interrelationships of Viruses and Ethanol study were analyzed. Generalized estimating equation logistic regression models were fit to identify factors associated with any service utilization. An alcohol dependence diagnosis had a negative association with SAT (adjusted odds ratio [AOR] = 0.36, 95% confidence interval [95% CI] = 0.19–0.67), as did identifying sexual orientation other than heterosexual (AOR = 0.46, CI = 0.29–0.72) and having social supports that use alcohol/drugs (AOR = 0.62, CI = 0.45–0.83). Positive associations with SAT include presence of hepatitis C antibody (AOR = 3.37, CI = 2.24–5.06), physical or sexual abuse (AOR = 2.12, CI = 1.22–3.69), social supports that help with sobriety (AOR = 1.92, CI = 1.28–2.87), homelessness (AOR = 2.40, CI = 1.60–3.62), drug dependence diagnosis (AOR = 2.64, CI = 1.88–3.70), and clinically important depressive symptoms (AOR = 1.52, CI = 1.08–2.15). While reassuring that factors indicating need for SAT among people with HIV and alcohol problems (e.g., drug dependence) are associated with receipt, nonneed factors (e.g., sexual orientation, age) that should not decrease likelihood of receipt of treatment were identified.

Keywords: Substance abuse; Treatment; Addiction; HIV/AIDS; Alcohol

1. Introduction

An estimated 44% of adults living with HIV/AIDS have alcohol and other drug (AOD) use disorders, which is much higher than the general population (Bing et al., 2001; Galvan et al., 2002; Galvan, Burnam, & Bing, 2003; Rabkin, Ferrando, Jacobsberg, & Fishman, 1997; Rabkin, McElhiney, & Ferrando, 2004). AOD use by people with HIV has particularly deleterious results, including an increased burden on support and medical systems (Masson, Sorensen, Phibbs, & Okin, 2004), a higher likelihood of engagement in risk behaviors that result in infection transmission (Palepu et al., 2005), nonadherence with HIV/AIDS treatments and faster biomedical decline (Conigliaro et al., 2004; Dausey & Desai, 2003; Kelley & Petry, 2000; Lucas, Gebo, Chaisson, & Moore, 2002; Meyerhoff, 2001; Petry, 1999), and liver complications, particularly considering the impact of co-occurring alcohol use, HIV/AIDS medications, and hepatitis C (Lucas et al., 2002; Moore, Keruly, & Chaisson, 2004; Palepu et al., 2003; Petry, 1999; Samet et al., 2007). Despite the magnitude of

substance abuse problems among people living with HIV, individual factors other than need influence receipt of SAT for those who might benefit (Burnam et al., 2001).

Substance abuse treatment (SAT) can be effective in reducing these consequences (Klinkenberg & Sacks, 2004; Loughlin et al., 2004; Palepu, Horton, Tibbetts, Meli, & Samet, 2004), although outcomes are more complex than mere attendance. These include characteristics of the treatment system, such as staff characteristics and availability (Hser, 1995; Najavits & Weiss, 1994; Najavits, Crits-Christoph, & Dierberger, 2000) and the relationship with the client outside of what occurs within treatment sessions (Najavits & Weiss, 1994). SAT outcomes are also dependent on the severity of other significant life problems, such as family relations, employment, or medical and mental health problems (McLellan & Weisner, 1996), which necessitates matching clients to specific treatment services that best treat co-occurring problems (Gastfriend & McLellan, 1997). Ultimately, the interaction of many interpersonal and intrapersonal factors may impact the potential for relapse or chronic relapse of a client utilizing SAT (Marlatt, 1985, 1996a, 1996b; Marlatt, Barrett, & Daley, 1999; McLellan & McKay, 2003).

Burnam et al. (2001) analyzed the HIV Cost and Services Utilization Study data, a national probability survey of adults with HIV receiving medical care in 1996. Controlling for need, outpatient AOD service utilization was positively associated with lower income levels and lower educational levels. African Americans were more likely to access AOD treatment services. Respondents who identified as gay were less likely to utilize AOD services but were more likely to seek treatment through medical providers and use psychiatric medications. Insurance coverage had little impact on utilization. Those who are not employed and those with disability were more likely to use outpatient treatment. Only one indicator of HIV severity, lower CD4 cell count, was positively associated with AOD services.

The identification of individual-level factors is particularly important because HIV/AIDS disproportionately strikes vulnerable populations who may experience barriers, such as people living in poverty and racial/ethnic minorities, particularly African American women, gay men, and other disenfranchised populations (Orwat, 2004). This exploratory analysis adds to the literature by examining the factors associated with SAT in the context of contemporary HIV-related medical practice including highly active antiretroviral therapies and examined factors associated with SAT utilization in a prospective cohort of individuals living with HIV/AIDS and AOD problems. Secondary analyses of the factors associated with four specific types of treatment (detoxification program, residential, outpatient, and "other" treatment) were also conducted. Andersen's socio-behavioral model, as adapted for vulnerable populations, guided the identification and organization of factors of interest (Andersen & Newman, 1973; Aday & Andersen, 1974; Andresen, Malmgren, et al., 1994).

2. Materials and methods

Data from the HIV Longitudinal Interrelationships of Viruses and Ethanol (HIV-LIVE) study were analyzed, a prospective cohort study of 400 adults with HIV infection and alcohol problems. Eligibility criteria included documentation of HIV infection, a current or lifetime alcohol problem as evidenced by two or more positive responses to the CAGE (Cut down, Annoyed, Guilty, and Eye opener) alcohol screening questionnaire (Ewing, 1984; Samet, Phillips, Horton, Traphagen, & Freedberg, 2004) or an alcohol use disorder in the judgment of a physician investigator, an ability to speak English or Spanish, a score of 21 or greater on the Mini Mental State Examination (Folstein, Folstein, & McHugh, 1975; Smith, Horton, Saitz, & Samet, 2006), and plans to remain in the area for at least 1 year. Classification of an alcohol problem ("none," "moderate," "at risk") was derived from the National Institute on Alcohol Abuse and Alcoholism's (NIAAA's) definition of amounts that risk consequences (Samet et al., 2007). The current analysis included subjects with at least two study interviews. All subjects were 18 years or older and provided written informed consent. A certificate of confidentiality was provided by NIAAA as an additional protection of subject privacy.

Subjects were recruited from two urban hospital-based outpatient practices (an intake clinic for HIV-positive clients at Boston Medical Center and a specialty clinic for HIV primary care at Beth Israel Deaconess Medical Center in Boston) by referral of a practicing physician and from flyers posted in the community, medical clinics, and SAT facilities. Approximately 38% of participants were recruited from previous observational studies conducted by these investigators. The largest proportion of subjects was recruited from the Boston Medical Center (43%), and all subjects resided in the Boston area.

After informed consent was obtained, subjects were enrolled from August 2001 to July 2003. Data were collected at baseline and every 6 months thereafter for up to 42 months. Data collection ended in March 2006. Domains of data collected included demographics, HIV risk behaviors, AOD severity and diagnosis, health care utilization, SAT service utilization, indicators of HIV disease progression, and medical comorbidities. Extensive efforts were used to maximize follow-up: 100% had at least one follow-up interview (two total interviews) with a median of three follow-up interviews (four total); the 25th percentile was two follow-up interviews (three total), and the 75th percentile was five follow-ups (six total interviews).

2.1. Dependent variables

The primary outcome was self-reported receipt of any SAT in the past 6 months, which was assessed by asking subjects, "During the past 6 months, did you receive any substance abuse services?" For the four secondary outcomes of specific types of SAT (i.e., detoxification program,

residential, outpatient, and other treatment), self-reported utilization was evaluated by asking, "How many days did you receive substance abuse services from each of the following programs during the past 6 months?" Subjects were asked about the following specific types of SAT: a detoxification program, a halfway house or residential facility, a substance abuse counselor in an outpatient program, a day treatment program, and/or some other type of treatment, such as a doctor, a priest or a rabbi, or an employee assistance program. Because of low rates of participation, day treatment was excluded from multivariable analysis (Table 2). Attendance at Alcoholics Anonymous and Narcotics Anonymous Groups was not examined in this analysis and was reported separately (Orwat et al., 2011).

2.2. Independent variables

The Andersen model was used to identify independent variables potentially associated with SAT and organize them into predisposing characteristics, enabling resources, and need variables (Andersen, 1995; Weisner, Matzger, Tam, & Schmidt, 2002). This model is commonly used in studies to understand utilization of health care by examining three individual-level domains: those factors that predispose people to utilize care (e.g., demographics), factors that enable use (e.g., ability to pay), and factors associated with need for the specific service (Andersen, 1995). The rich database allowed for the exploration of other factors, which have yet to be tested in the literature (e.g., literacy, hepatitis C).

Predisposing characteristics consisted of age (defined as greater than the median, 44.5), gender, race (Black, White, and other; because of small sample sizes, other includes other race and Hispanic), marital status (single, married, or partnered but not married), sexual orientation (gay, bisexual, other vs. heterosexual), education level (high school education), living alone, born in the United States, sexual or physical abuse or trauma, and high school literacy level (defined as a score >60 on the Rapid Estimate of Adult Literacy in Medicine (Davis et al., 1991). HIV/AIDS disease severity was considered predisposing variable to remain consistent with the literature (Burnam et al., 2001) and was assessed using CD4 cell count (greater than vs. less than or equal to 350 cells/mm^3, the median, CD4 count), the presence of opportunistic infections or cancers, and the HIV symptom index score—a measure of how often and bothersome clients experience 20 common HIV symptoms (Justice et al., 2001; Kilbourne et al., 2002). The presence or absence of hepatitis C virus (HCV) antibody indicated exposure. Testing for HCV was completed at the first opportunity if the results of HCV testing for clinical purposes were not available.

Enabling resources included employment status, social support use of alcohol or drugs, social support that is supportive of sobriety, living with children, receipt of government disability income, and homelessness (spending one or more nights "on the street, without shelter" over the past 6 months). Social support use of alcohol or drugs was assessed by asking, "how many of the people you spend time with," followed by three prompts, "currently drink alcohol," "are currently heavy or problem drinkers," and "currently use drugs." Social support for sobriety was assessed by asking, "How many of the people that you spend time with support your sobriety or abstinence." The use of HIV antiretroviral medications was assessed by asking about specific medication use over the previous 6 months as listed with photographic prompts and generic and brand names. Cohort members were not assessed with regard to use of naltrexone or other medications used to treat substance use disorder at the time of the study; its use for alcohol problems, although indicated, occurred rarely in practice.

Need/Severity for SAT included alcohol dependence in the past 6 months, which was assessed using the Composite International Diagnostic Interview Short Form (CIDI-SF; Kessler, Andrews, Mroczeek, et al., 1998), and the diagnosis of drug dependence in the previous 6 months. Depressive symptoms were assessed using the Center for Epidemiologic Studies Depression scale (CES-D; Andresen, Malmgren, Carter, & Patrick, 1994; Radloff, 1977) and dichotomized at a score of 16 or greater, which indicates clinically important depressive symptoms in the general population (Eaton & Kessler, 1981; Weissman, Sholomskas, Pottenger, Prusoff, & Locke, 1977). Involvement in the criminal justice system was measured by asking respondents if they were in jail during the previous 6 months.

2.3. Analysis

To account for correlation in the data due to incorporating repeated measures from the same subject, the multivariable analysis that explored the association between selected factors and SAT utilization was conducted using generalized estimating equations (GEE; Zeger & Liang, 1986; Liang & Zeger, 1986) logistic regression models. Models were fit using a logit link, an exchangeable working correlation structure, and standard errors were based on the empirical sandwich estimator for all analyses. The GEE approach yields robust results (i.e., valid estimates can be obtained from the empirical variance estimator even if the correlation structure is misspecified), is flexible, and can accommodate analyses where subjects have varying numbers of follow-up interviews. The following predisposing characteristics were modeled as time-dependent variables: married, partnered, living alone, and all HIV status variables; all enabling resources and need/severity variables were modeled as time-dependent variables. Time-varying independent variables were "lagged" to predict SAT utilization in the subsequent interview to ensure such factors preceded the episode of SAT. If a participant missed a follow-up interview, the outcome at the next available interview was used; the models adjusted for the duration of time between interviews for the

lagged independent variables and outcomes. In addition, the time that the outcome was assessed (number of months since baseline) was included as a covariate to account for potential temporal trends in the data. Preliminary crude analyses were performed that included only a single independent variable. A full multivariable model was then fit including all independent variables in the same model. Potential collinearity was initially assessed by verifying that no pair of independent variables was highly correlated (>0.40). In addition, the variance inflation factor (VIF) was calculated for each independent variable and covariate to further evaluate potential collinearity. A criterion of VIF greater than 10 was used to indicate collinearity (Kutner, Nachtsheim, & Neter, 2004). The largest observed VIF was 1.84, suggesting multicollinearity was likely not an issue in our regression models.

Analyses of the four secondary outcomes were performed using the same approach as described for the primary outcome. Analyses were conducted using two-sided tests and a significance level of .05. Because of the exploratory nature of the analyses, we did not adjust for multiple comparisons. All analyses were conducted using SAS version 9.0 (SAS Institute, Inc., Cary, NC).

3. Results

3.1. Sample characteristics

Of the 400 HIV-LIVE subjects, 369 completed at least two research interviews and therefore constituted the study sample. Baseline characteristics are displayed in Table 1. Most subjects were non-White and male, and the mean age was 42.7 years. A small minority were gay or bisexual, whereas a vast majority had experienced sexual or physical trauma or abuse. Few had an opportunistic condition, mean CD4 count was 462 cells/mm^3, and more than half had a positive hepatitis C antibody test (58%). Most reported spending time with people who use alcohol, whereas less than half spent time with people who use drugs; a majority had social support for sobriety. At baseline, 31.5% were classified as "at-risk" drinkers by the NIAAA classification for an alcohol problem, 10.8% as "moderate" drinkers, and 57.8% as nondrinkers. These numbers varied somewhat over time and across observations (Bertholet, Cheng, Samet, Quinn, & Saitz, 2010). Criteria for a current (past 6 months) alcohol dependence diagnosis were met by 12% of the sample, and 43% met the criteria for a current (past 6 months) drug dependence diagnosis. At study entry, almost half (45%) had used SAT services in the preceding 6 months, 18% detoxification services, 20% residential, 17% outpatient counseling, and 6% some other treatment (Table 1). In subsequent interviews, 40% (n = 133) utilized SAT in the 6 months prior to the second interview, 34% (n = 94) prior to the third, 35% (n = 64) prior to the fourth, 30% (n = 35) prior to the fifth, 28% (n = 14) prior to the sixth, and 33% (n = 1) prior to the eighth.

Table 1
Baseline characteristics of 400 subjects recruited for HIV-LIVE study (N = 369)

Variable	Study sample
SAT utilization [a]	
Any SAT services [b]	167 (45.3)
Detoxification [c]	65 (17.6)
Residential	74 (20.1)
Outpatient counseling	63 (17.1)

Depressive symptoms [j]	230 (62.3)
In jail [g]	67 (18.2)

Note. Values are number (percentage) unless otherwise indicated.

[a] High school graduate (12 or more years of education).

[b] Any SAT was assessed by "…did you receive any substance abuse treatment services?"

[c] *Detoxificaion* is defined as any in- our outpatient program.

[d] Other treatment such as a doctor, a priest or a rabbi, or an employee assistance program.

[e] Literacy score higher than 60 (Davis et al., 1991).

[f] Sexual or physical trauma or abuse.

[g] In the past 6 months.

[h] Justice et al. (2001) and Kilbourne et al. (2002).

[i] Alcohol diagnosis assessed using CIDI-SF (Kessler et al., 1998).

[j] Measure of depressive symptoms where CES-D score 16 or higher indicates substantial depressive symptoms.

3.2. Multivariable models: Predictors of any SAT

Predisposing characteristics positively associated with any SAT included physical or sexual trauma or abuse

and the presence of HCV antibody (Table 2). Identifying as gay, bisexual, or other (compared with heterosexual) and CD4 cell count were negatively associated with SAT. Enabling resources positively associated included social support help with sobriety, living without children, and homelessness; a social support system using alcohol and/or drugs was negatively associated. Alcohol dependence was negatively associated with SAT; a drug dependence diagnosis and depressive symptoms were positively associated.

3.3. Multivariable models: Predictors of specific types of SAT

3.3.1. Detoxification

Older age and lower CD4 count were associated with lower odds of participation in a detoxification program, whereas the presence of HCV antibody was positively associated (Table 3). As for enabling resources, homelessness was positively associated with detoxification, as were the need factors of drug dependence and depressive symptoms.

3.3.2. Residential treatment

Of the predisposing characteristics, living alone was negatively associated with residential treatment and the presence of HCV antibody was positively associated, as was the need factor of a drug dependence diagnosis, but no HIV disease severity variable was significantly associated with receipt of residential treatment (Table 3). Enabling resources positively associated with residential treatment included social support for sobriety, living without children, and homelessness; social support use of alcohol/drugs was negatively associated.

3.3.3. Outpatient treatment

The presence of HCV antibody was positively associated with outpatient treatment, the only statistically significant predisposing characteristic (Table 3). Living without children and homelessness were also positively associated, whereas social support use of alcohol and drugs was

negatively associated. A drug dependence diagnosis was associated with higher odds of outpatient treatment.

4. Discussion

This exploratory study of those living with HIV/AIDS and alcohol or drug problems identified a number of nonneed factors associated with receipt of SAT. These associations were found for any SAT and for each of four types of SAT: detoxification program, residential treatment, and outpatient treatment. Identification of the factors that facilitate or impede use of effective SAT suggests areas in need of improvement. Specifically, we identified a negative association between gay, lesbian, or other sexual orientation and SAT utilization, whereas past physical or sexual abuse or trauma was positively related. We detected a negative association between median CD4 cell count and utilization of SAT, although the presence of the HCV antibody was strongly and positively associated. Social supports were important factors related to receipt of SAT; supports that help with sobriety were positively associated, and those that used alcohol or drugs, negatively associated. Homelessness had a positive and strong association with SAT. In this sample of people with alcohol problems, most of whom had lifetime dependence, current alcohol dependence diagnosis was negatively associated with SAT, although a current drug dependence diagnosis and depressive symptoms were each positively associated.

This research partially supports studies that demonstrate SAT is underutilized by sexual minorities in the general population (Goldstein et al., 2005) and those living with HIV/AIDS (Burnam et al., 2001; Goldstein et al., 2005). Burnam et al. (2001) found that among those with HIV/AIDS, those who identify as gay were less likely to participate in residential or outpatient treatment. This study examined the effect of sexual orientation among people living with HIV/AIDS by controlling for variables such as homelessness, sexual or physical abuse or trauma, and social support for substance use or abstinence. Lower SAT utilization may be related to concerns about the following: the treatment setting (e.g., emotional and physical safety) if sexual orientation is disclosed; insensitivity to the experience of antigay discrimination; lack of appreciation for nontraditional support systems; attempts to change the person's sexual orientation; and/or the failure to understand nontraditional forms of socialization (Cochran & Cauce, 2006).

We did not detect an independent association of race and gender on utilization of treatment, which is somewhat inconsistent with previous studies that suggest that women are less likely than men to utilize treatment and African Americans are more likely than Whites to utilize treatment (Burnam et al., 2001; Goldstein et al., 2005; Greenfield et al., 2007). This may be due to regional differences, such as Boston's diverse SAT resources, which may have increased efforts to reach minorities and women as well as to design appropriate treatment programs (McAuliffe & Dunn, 2004). However, this important issue warrants further exploration, especially in light of the increasing prevalence of HIV/AIDS in ethnic and racial minorities and women.

The positive association of past sexual or physical abuse or trauma and SAT is congruent with the literature, although this analysis supported the association in a sample living with HIV/AIDS and controlling for factors often related to an increased likelihood of trauma, such as being female, gay, lesbian, or bisexual and race (Farley, Golding, Young, Mulligan, & Minkoff, 2004). Close to 90% of individuals seeking treatment for substance use disorders have had an experience of trauma (Farley et al., 2004). Individuals exposed to trauma are more likely to experience a wide range of negative outcomes that complicate SAT, including an increased likelihood of mental health problems, such as posttraumatic stress disorder (Kayo & Rojas, 2004), which increase the likelihood of relapse (Farley et al., 2004; Wadsworth, Stampneto, & Halbrook, 1995). Previous treatment experiences for these individuals may not have adequately addressed issues related to trauma (Farley et al., 2004).

Few measures of HIV disease severity were associated with treatment, although our findings suggested that people with more advanced HIV are more likely to receive SAT. This is consistent with previous studies (Burnam et al., 2001). The strong and positive association of hepatitis C and SAT may be the result of clinical and/or policy efforts to facilitate access to treatment or by patient concerns. Tsui et al. (2007) observed that people who knew their hepatitis C status were more likely to abstain from alcohol. We speculated that it may also be the case that when concern rises about hepatitis C, people make attempts to decrease substance use and seek SAT. Therapies for hepatitis C are complex, requiring weekly injections that have adverse effects and hold no guarantees of cure. With increased treatment complexities related to patients with AOD problems with co-occurring hepatitis C and HIV, clinicians may influence such patients being treated for hepatitis C to also address substance abuse issues (Mehta et al., 2005). However, most people in this cohort had barriers to treatment of hepatitis C (Nunes et al., 2006). Therefore, the association between hepatitis C and SAT may also be explained by testing occurring in or by referral from SAT programs. Ultimately, a multidisciplinary approach to SAT and co-occurring HIV and hepatitis C that includes pharmacotherapy, mental health services, along with medical care may be most effective (Nunes et al., 2006).

The social support findings in this study were consistent with the general population studies (Hasin & Grant, 1995; Kaskutas, Bond, & Humphreys, 2002; Witbrodt & Kaskutas, 2005). This analysis found that social support matters, as social support that is supportive of sobriety influences utilization of services, whereas social supports that are currently using substances, do not. Not only does research show the importance of social support in the utilization of

substance abuse services, but it also affirms the role of social support in HIV treatment adherence (Knowlton et al., 2006).

The significant positive association of homelessness with SAT utilization is consistent with Goldstein et al.'s (2005) analysis of people living with HIV/AIDS; the current analysis has similar findings when controlling for factors often found to be related to SAT among the homeless, such as gender, race/ethnicity, and social support (Kertesz et al., 2006; Song, 1999). The association of homelessness with detoxification services was particularly strong, which may be related to triage decisions in which few options exist for emergency housing, particularly for those that are currently using substances (Kertesz et al., 2006; Song, 1999). However, service utilization may also be the result of residing in temporary shelters or participation in long-term housing programs, which may require SAT as part of the programmatic requirements or as a condition of participation (Kertesz et al., 2006).

We found a significant positive association of a drug dependence diagnosis and depressive symptoms on the receipt of SAT, but a current alcohol dependence diagnosis was negatively associated. This finding may seem curious at first glance but may be related to the sample, almost all of whom likely have lifetime alcohol dependence and many have co-occurring drug dependence. Drug dependence may lead to seeking specific care (e.g., pharmacotherapy), whereas those with current alcohol dependence are less likely to do so.

This study had notable strengths and limitations. First, this analysis identified association, not causation, between various factors and SAT. For example, it may be that treatment led to social support rather than social support motivating SAT. We attempted to capture the temporal relationship between variables by "lagging" outcome variables so that they were taken from the period subsequent to explanatory factors. A second limitation may be the reliance on self-report of SAT utilization, although asking whether SAT occurred is valid and reliable, particularly when not seeking quantity of treatment (Goldberg, Seybolt, & Lehman, 2002). However, self-report of SAT may capture interventions that may not appear in comprehensive databases (e.g., from a personal physician or clergy member).

Because of concerns related to sample size, we do not report a subanalysis of those individuals with the highest need (i.e., meeting 6-month criteria for alcohol and/or drug dependence at follow-up time points), although that might have provided further insight into SAT utilization among those with the highest need. Additional limitations may relate to generalizability of the findings based on the recruitment site(s), urban setting with a spectrum of sexual orientation representation, many homeless, and minorities. This acknowledged limitation is also a strength given the epidemiology of this epidemic that disproportionately affects this population. Bias in self-report may have been attenuated in this study by use of validated survey questions and the minimization of contextual factors that may influence the possibility of biased self-report (Del Boca & Darkes, 2003).

Identifying as gay, lesbian, or some other sexual orientation was negatively associated with SAT; however, the association was not significant when specific types of SAT were examined. Although previous research supports this finding, additional analysis with sexual minorities is to further examine the interaction of sexual orientation with other factors that may be correlated, such as marital status or living with children.

Future analysis might include some variables not available in this analysis to address potential limitations of this study. One specific example is the lack of a measure concerning respondent health insurance status and benefit structure. People living with HIV in Massachusetts have access to health insurance (Orwat, 2004), so despite the absence of this variable, we assume all participants had access. Future studies may examine the impact of different insurance products (i.e., public, private, and none) and benefit structures (i.e., networks and copayments) on SAT utilization. Other variables potentially associated with SAT that were not included in this analysis included lifetime experience with SAT attendance at more than one type of SAT concurrently, the focus of treatment on admission (e.g., alcohol, drugs, substance abuse/mental health), clinical orientation of treatment programs utilized, or use of addiction pharmacotherapy (e.g., naltrexone).

One strength of the study is the clinical detail, which enabled consideration of variables not previously explored, including social support, HIV/AIDS disease severity, and hepatitis C. A second strength is the prospective research quality of assessments and follow-ups. Third, the analysis adjusted for several potential confounding variables and used lagged analyses to better capture the temporal relationship between the independent and dependent variables. Finally, the study used a strong theory-based approach in the use of the Andersen model.

This research provides a better understanding of the factors that facilitate or impede SAT for HIV-infected persons, particularly factors not related to treatment need, which informs the development of strategies to increase utilization. Barriers to treatment include having a sexual orientation other than heterosexual and social supports that use alcohol and/or drugs. Sexual or physical abuse or trauma, the presence of HCV antibody, a social network that supports sobriety, homelessness, drug dependence, and depressive symptoms were factors with a positive association with SAT. Removing barriers to SAT for affected HIV-infected persons includes the consideration of systemic and individual-level factors. Individuals can be helped to seek social networks that support sobriety. System-level interventions may include the development of specialty interventions for populations at risk, such programs for those who are not heterosexual. The findings of this study may assist clinicians as they motivate people living with HIV/AIDS to utilize SAT and administrators as they consider system design, particularly for those who access both SAT and medical services.

Acknowledgments

Support for this study came from the following grants from the NIAAA of the NIH: R01-AA13216 (Clinical Impact of HCV and Alcohol in HIV-Infected Persons), R01-AA11785 (Medication Adherence in Alcohol Abusing HIV Patients), R01-AA10870 (Enhanced Linkage of Alcohol Abusers to Primary Care), K24-AA015674 (Impact of Alcohol Use on HIV Infection—in the United States and Russia), and the Ruth L. Kirschstein National Research Service Award for Individual Predoctoral Fellows (National Institute on Drug Abuse—F31 DA021118 [Predictors of SA Treatment among Adults Living with HIV]). This research was conducted in part in the General Clinical Research Center at Boston University School of Medicine (USPHS Grant M01 RR00533) and the Beth Israel Deaconess General Clinical Research Center (USPHS Grant M01 RR01032).

The authors thank Carly Bridden for project support and organization; DM-STAT for meticulous data management; Tamara Faulkner for editorial and research assistance; the Clinical Addiction Research and Education Unit Staff Research Associates and Project Managers for the difficult tasks of enrollment, follow-up, and quality of the data collected; and the subjects for their contribution of time and effort.

Abstract

Background—Despite the value of 12-step meetings, few studies have examined factors associated with attendance among those living with HIV/AIDS, such as the impact of HIV disease severity and demographics.

Objective—This study examines predisposing characteristics, enabling resources and need on attendance at Alcoholic Anonymous (AA) and Narcotics Anonymous (NA) meetings among those living with HIV/AIDS and alcohol problems.

Methods—Secondary analysis of prospective data from the HIV-Longitudinal Interrelationships of Viruses and Ethanol study, a cohort of 400 adults living with HIV/AIDS and alcohol problems. Factors associated with AA/NA attendance were identified using the Anderson model for vulnerable populations. Generalized estimating equation logistic regression models were fit to identify factors associated with self-reported AA/NA attendance.

Results—At study entry, subjects were 75% male, 12% met diagnostic criteria for alcohol dependence, 43% had drug dependence and 56% reported attending one or more AA/NA meetings

Corresponding Author: John Orwat, Ph.D. Assistant Professor Loyola University Chicago School of Social Work, Room 1229 820 North Michigan Avenue Chicago, IL 60611 312-915-7494 phone 312-915-7645 fax jorwat@luc.edu.

(past six months). In the adjusted model, female gender negatively associated with attendance, as were social support systems that use alcohol and/or drugs, while presence of HCV antibody, drug dependence diagnosis, and homelessness associated with higher odds of attendance.

Conclusions—Non-substance abuse related barriers to AA/NA group attendance exist for those living with HIV/AIDS, including females and social support systems that use alcohol and/or drugs. Positive associations of homelessness, HCV infection and current drug dependence were identified. These findings provide implications for policy makers and treatment professionals who wish to encourage attendance at 12-step meetings for those living with HIV/AIDS and alcohol or other substance use problems.

Keywords

HIV-infection; alcohol addiction disorder; substance-related disorders; 12 step groups; HIV/AIDS

1. Introduction

Individuals living with the Human Immunodeficiency Virus or Acquired Immune Deficiency Syndrome (HIV/AIDS) are more likely to be diagnosed with alcohol and other drug (AOD) use disorders than those individuals within the general population (Bing et al., 2001; Galvan et al., 2002; Galvan et al., 2003; Rabkin et al., 1997; Rabkin et al., 2004). The impact of AOD use by those living with HIV/AIDS presents the potential for increased challenges upon the health care delivery system (Masson et al., 2004), the heightened likelihood of risky behavior potentially resulting in new HIV infections (Palepu et al., 2003), non-adherence with antiretroviral treatments (ART) (Hendershot et al., 2009; Samet et al., 2004; Conigliaro et al, 2004; Dausey and Desai, 2003; Lucas, et al., 2002), liver complications exacerbated by co-occurring alcohol and other drug use, HIV/AIDS medications, and the hepatitis C virus (HCV) (Lucas et al., 2002; Moore et al., 2004; Palepu et al., 2003; Petry, 1999; Samet et al., 2007). While Alcoholic Anonymous (AA) and Narcotics Anonymous (NA) groups have great potential for the mental and physical health of those living with HIV/AIDS, there are few studies examining factors associated with group meeting attendance.

AA/NA meetings are the most frequently utilized recovery resource for people with AOD related problems (Narrow et al., 1993; Weisner et al., 2002; Weisner and Schmidt, 2001) and more people with drinking disorders attend AA meetings than any other recovery resource (Weisner et al., 1995; Humphreys et al., 1998). As AA/NA groups are free and widely available, they are also associated with positive outcomes, making an independent contribution to the reduction of AOD use, higher levels of abstinence and reduced levels of drinking, lower levels of incarceration, greater psychological adjustment, and lower overall treatment cost (Watson et al., 1997; Timko et al., 2000; Fiorentine and Hillhouse, 2000; Humphreys and Moos, 2001; Kaskutas et al. 2002; Kissin et al., 2003; McCrady and Share, 2003). AA/NA groups may occur in conjunction with formal systems of treatment or mandated requirements by the court system (Speiglman, 1994; Wild et al., 2002). For many, attendance is life long (Fiorentine and Hillhouse, 2000). Over the past decade, research on the process of change and outcomes associated with mutual help groups such as AA/NA supports their significance as a resource for recovery, providing guidelines for living, increasing social support networks and linkage to ongoing care (McCrady and Share, 2003).

Meta-analyses or reviews of multiple studies (Emrick et al., 1993; Tonigan et al., 1996; Bogenschultz, 2008) have reported on sociodemographic factors (e.g., spirituality, race, gender) associated with AA/NA participation. Attendance is more common among racial and ethnic minority groups, those with lower incomes, and those with unstable employment,

suggesting that economic barriers may preclude formal treatment in favor of AA/NA attendance (Humphreys et al., 1998; Kaskutas et al., 1999). Prior formal substance abuse treatment is positively associated with AA/NA attendance, likely due to exposure to these groups (Humphreys et al., 1998; McCrady and Share, 2003).

Few studies of the factors associated with attendance among those living with HIV/AIDS have been published. An early paper addressed the impact of self help on HIV risk reduction, finding that in a sample of injection drug users, those who attended self help were almost twice as likely to reduce or eliminate the risk of HIV than those who did not attend (Sibthorpe, Fleming, and Gould, 1994). This study demonstrates that those attending self-help are amenable to HIV risk reduction interventions and the important role self-help can play in reducing risk. Among those living with HIV/AIDS, Burnam, et al. (2001) examined the factors associated with AA/NA attendance in the HIV Cost and Services Utilization Study (HCSUS), a national probability survey of 2,864 adults living with HIV/AIDS and receiving medical care in the United States in 1996. Controlling for need, African Americans were more likely than Whites to attend AA/NA group meetings, as were those in larger metropolitan areas and those in the Northeast, although sex, age, employment, income, and insurance were not associated with attendance. HIV clinical stage and symptom burden were not associated with attendance but lower CD4 cell count was positively associated with attendance.

This study advances previous research by examining factors associated with attendance at AA/NA group meetings among people living with HIV/AIDS in the era of antiretroviral treatments. In addition, the data set provides the opportunity to explore the impact of other factors, such as social supports, co-occurring depression, and, of particular interest, hepatitis C in a cohort with current or past alcohol problems.

2. Methods

We analyzed data collected for the HIV-Longitudinal Interrelationships of Viruses and Ethanol (HIV-LIVE) study, a prospective cohort study of 400 adults living with HIV/AIDS and alcohol problems. Eligibility criteria for this study included documentation of HIV infection, current or past alcohol problems defined as two or more positive responses to the CAGE (Cut down, Annoyed, Guilty, and Eye opener) alcohol screening questionnaire (Ewing, 1984; Samet et al., 2004) or an alcohol use disorder as assessed by a physician investigator, the ability to speak English or Spanish, a score of 21 or greater on the Mini Mental State Examination (Folstein et al., 1975; Smith et al., 2006) and plans to reside in the area for at least one year. The current analysis included subjects with two or more study interviews. All subjects provided written informed consent and were 18 years of age or older. A certificate of confidentiality was provided by NIAAA as an additional protection of subject confidentiality.

Recruitment of subjects for this study (n = 400) came from two urban hospital-based outpatient practices (30%) in Boston, MA as well as by referral of Boston Medical Center's (BMC) practicing physicians, flyers posted in the community, medical clinics, and addiction treatment facilities (32%). Approximately 38% of participants were recruited from previous observational studies conducted by the investigators (Samet et al., 2007). After obtaining informed consent, subjects enrolled during the period August 2001 until July 2003. Baseline data were collected, and every 6 months thereafter, up to 42 months ending in March 2006. In addition to demographics, interviewers assessed current and past alcohol/drug use and problems, health care utilization, indicators of HIV disease severity, and AA/NA attendance.

2.1 Dependent Variables

The main dependent variable was at least one contact with AA/NA in the previous six months. Subjects were asked the following: “During the past 6 months, did you attend AA or NA meetings?” Secondly, subjects were asked: “How often did you generally attend?” This was followed by prompts for daily, several times a week, weekly, every two weeks, monthly, less than once a month, or other. The second dependent variable was at least weekly attendance over the previous six months, which may approximate a higher level of engagement in self help. In the absence of clear and consistent guidelines for people with substance use disorders generally, we make this approximation.

2.2 Independent variables

were selected using the Andersen Behavioral Model for Vulnerable Populations (Andersen, 1995; Weisner et al., 2002). This model is commonly used in studies to understand utilization of health care by examining three individual level domains: those factors that predispose people to utilize care (e.g., demographics), factors that enable use (e.g., ability to pay), and factors associated with need for the specific service (Andersen, 1995). The comprehensive database allowed for the exploration of other factors, which have yet to be reported on in the literature (e.g., HCV antibody status and social supports).

2.3 Predisposing variables

included age (dichotomized at the median, 44.5), sex, race (Black, White or other), marital status (married, single, or partnered but not married), sexual orientation (gay, bisexual, other vs. heterosexual), education level (high school graduate), living alone, born in the USA, sexual or physical abuse or trauma, and literacy level (a score of >60 on the Rapid Estimate of Adult Literacy in Medicine (REALM), indicating literacy at the high school level) (Davis et al., 1991). Sexual or physical abuse or trauma is considered a predisposing variable to remain consistent with previous literature (Burnam et al., 2001) and since it is not an enabling or need/severity factor when examining utilization of 12-step groups as an outcome. HIV/AIDS disease severity was assessed using CD4 cell count (dichotomized at the median), the presence of opportunistic infections or cancers, and an HIV-Symptom Index score, which is a measure of how often and how bothersome a person experiences 20 common HIV symptoms (Justice, et al., 2001; Kilbourne, et al., 2002) and the presence or absence of the hepatitis C Virus (HCV) antibody (testing was done at the first opportunity if results of testing for clinical purposes were not available).

2.4 Enabling resources

included employment status, receipt of government disability income, homelessness (spending one or more nights “on the street, without shelter” in the past 6 months), and whether or not the subject lived with children. Social support for substance abuse was assessed by asking subjects “how many of the people you spend time with” followed by three prompts “currently drink alcohol,” “are currently heavy or problem drinkers,” and “currently use drugs.” To assess social support for sobriety, subjects were asked, “How many of the people that you spend time with support your sobriety or abstinence?” The use of HIV antiretroviral medications was assessed by asking respondents if they were taking any of a list of all available specific medications over the previous six months, using photographic prompts, generic and brand names.

2.5 Need

for AA/NA variables included alcohol dependence in the past six months assessed using the Composite International Diagnostic Interview Short Form (CIDI-SF) (Kessler et al., 1998) and a diagnosis of drug dependence in the previous six months. Depressive symptoms were

assessed using the Center for Epidemiologic Studies Depression scale (CES-D) (Radloff, 1977; Andresen et al., 1994) and a dichotomous variable was constructed based on a cutoff of 16 or greater. This cutoff has been shown to indicate clinically important depressive symptoms in the general population (Eaton and Kessler, 1981; Weissman et al., 1977). Involvement in the criminal justice system was measured by asking respondents if they were in jail during the previous six months.

3. Analysis

To explore the relationship between the various selected factors and AA/NA group attendance, multivariable analysis was conducted using generalized estimating equations (GEE) (Zeger and Liang, 1986; Liang and Zeger, 1986). This approach was chosen to account for correlation in the data due to incorporating repeated measures from the same subject. Models were fit using a logit link, an exchangeable working correlation structure, and the empirical variance estimator was used in all analyses. An advantage of the GEE approach is that the results are robust, i.e. valid estimates can be obtained from the empirical variance estimator even if the correlation structure is misspecified. In addition, the GEE approach is flexible and can accommodate settings where subjects have varying numbers of follow-up assessments. Independent variables were allowed to vary with time as appropriate and, to assess for potential collinearity, we verified that no pairs of independent variables were highly correlated (> 0.40). Preliminary crude analyses were performed that included only a single independent variable. A full multivariable model was then fit including all independent variables in the same model. To ensure that time varying independent variables preceded the episode of attendance, independent variables were “lagged” to predict report of AA/NA meeting attendance at the subsequent interview. If a participant missed a scheduled follow-up interview, then the outcome at the next available interview was used. We therefore also adjusted for duration of time between assessment of independent variables and outcomes. Similar analyses were used to evaluate the secondary outcome, “weekly or more frequent AA/NA attendance.” Analyses were conducted using two-sided tests and a significance level of 0.05. Due to the exploratory nature of the analyses we did not adjust for multiple comparisons. All analyses were conducted using SAS version 9.0 (SAS Institute, Inc., Cary, NC).

4. Results

4.1 Sample Characteristics

The study sample was comprised of 369 subjects who completed at least two research interviews. Of the initial 369 subjects, 91% completed three interviews, 82% (four interviews), 66% (five interviews), 63% (six interviews), 44% (seven interviews), and 6% completed an eighth interview. A majority of the sample was male, average age was 42.7 years, and was racially diverse (42.8% Black, 32.5% White, 24.7% Other) (Table 1). A majority had experienced sexual or physical abuse or trauma (80.4%), and about a third were gay, bisexual, or “some other” sexual orientation. As for HIV status, a minority had opportunitistic conditions, CD4 count averaged 462 cells/mm^3 and over half had a positive hepatitis C antibody test (58%). A majority of the sample studied reported spending time with people who use alcohol and who are supportive of their sobriety (61.7%) while less than half spent time with people who use drugs (47.3%). As for need variables, 12% met the criteria for a current (past 6-month) alcohol use disorder diagnosis, while almost half met the criteria for a current (past 6-month) drug dependence diagnosis (43.1%). At study entry, 58% had attended AA or NA group meetings during the six months prior, 50% of those in the third interview had attended, 48% in the fourth, 51% in the fifth, and 43% in the sixth, 48% in the seventh, and 67% in the eighth interview.

4.2 Predictors of AA/NA Attendance

The unadjusted and full model are displayed in Table 2. In the unadjusted model (Table 2), living alone, being gay, bisexual, or a sexual orientation other than heterosexual, and alcohol or drug use by social supports had a significant negative association with attendance at AA/NA groups, while social support for sobriety, sexual or physical abuse or trauma, and homelessness in the past six months were positively associated with attendance. Need variables associated with greater odds of attendance were having a current drug dependence diagnosis, depressive symptoms, and having been in jail in the past 6 months.

In the adjusted model, being female was associated with lower odds of attendance, as was a social support system that used alcohol and/or drugs. The presence of HCV antibody and homelessness in the previous 6 months were associated with higher odds of attendance at an AA/NA group, as was having a drug dependence diagnosis.

When the dependent variable was defined as AA/NA attendance weekly or more often (Table 3), few differences emerged in the multivariable model except for minor changes in magnitude and significance of odds ratios. Being female and social supports using alcohol or drugs were still associated with lower odds of AA/NA attendance, while the presence of hepatitis C antibody and meeting the criteria for drug dependence were associated with an increased odds. The association between homelessness and AA/NA attendance was attenuated and no longer statistically significant.

5. Discussion

AA/NA group attendance by those living with HIV/AIDS and alcohol problems is impacted by a variety of factors. Factors that facilitate AA/NA group meeting attendance include a drug dependence diagnosis, homelessness, and the presence of HCV antibody. The odds of attendance were lower for subjects who were female or had social supports that use alcohol or other drugs. When AA/NA was defined as weekly or more frequent attendance, results were similar except the effect of homelessness was no longer statistically significant.

This study underscores the unique differences with regard to attendance in AA/NA groups by those living with HIV/AIDS. While Burnam et al., (2001) did not find significance for demographics including certain geographic locations, sex, age, employment, income, and insurance status, this study revealed the relevance of gender, social supports, homelessness, a drug dependence diagnosis and presence of the HCV antibody with regard to a greater likelihood of attendance or non-attendance of AA/NA groups.

Female gender was negatively associated with attendance in AA/NA, and the negative association between gender and AA/NA group attendance found in this study is **not necessarily** congruent with much of the literature. Some population studies show that women are more likely to drop out of AA/NA (Humphreys et al., 1994) and may not participate for reasons related to program structure, challenges related to lack childcare or if they sense AA/NA is punitive and male dominated (Kaskutas, 1994). Other studies demonstrate that while women may drop out of 12 step attendance more than men after 12 months of treatment (Humphreys et al., 1991), they were more likely to attend in the first place (Humphreys et al., 1994). However, in those studies, after the initial dropout period, women were found to attend as regularly as men (Humphreys et al., 1994). Additionally gender and other sociodemographic variables have not been reliably found to be strongly associated with 12-step attendance in prior studies among general groups of substance abusers (Bogenschultz, 2008; Emrick et al., 1993; Tonigan et al., 1996) or among HIV+ substance users (Burnam et al., 2001).

Social supports currently using alcohol or other drugs were negatively associated with AA/NA group attendance. These findings are consistent with general population studies (Hasin and Grant, 1995; Kaskutas et al., 2002; Witbrodt and Kaskutas, 2005; Moos and Moos, 2006; Kaskutas et al., 2009) related to the negative impact of social supports using alcohol and other drugs on the attendance of those attending AA/NA. This study affirms the negative impact of social supports using alcohol and other drugs on those living with HIV/AIDS who likely would attend AA/NA groups.

There is also a strong and positive independent association with co-occurring hepatitis C, which may be the result of a multi-faceted approach to treatment that coordinates efforts and systematically integrates care. Attendance may also be motivated in an effort to abstain from alcohol or other drugs as it may further complicate their existing health conditions such as hepatitis C. The increased likelihood of AA/NA group attendance among those with co-occurring hepatitis C has implications for clinical practice and policy and is important that both medical and addiction treatment staff clearly understand HIV disease progression and a co-occurring diagnosis of hepatitis C.

On the system level, it would be useful to research the specific mechanisms that facilitate greater attendance of AA/NA groups. The strong and positive association of homelessness and attendance at AA/NA groups, may be due to placement of homeless individuals using substances into detoxification programs or residential services with programmatic requirements as a condition of entry or continuation in the shelters (Kertesz, et al., 2006). Such implications may include exploration of expansion of social networks for the homeless or holding AA/NA groups at convenient locations such as a shelter. Homeless and other low-income persons may be more likely than middle or high income persons to participate in cost-free services for several reasons (e.g., lack of access to other services).

There was also a positive association of those with a drug dependence diagnosis and increased attendance of AA/NA groups while findings were not as significant for those with an alcohol diagnosis or depressive symptoms. This finding, while consistent with other studies (Kaskutas et al., 2009) is curious, and may be related to the fact in addition to seeking specific care such as pharmacotherapy or detoxification, that those with a drug dependence diagnosis are more likely to seek attendance and maintain additional support during and after treatment through AA/NA groups (Timko et al., 2006).

This study offers insight with regard to the factors that may lead to AA/NA group attendance among those living with HIV/AIDS, particularly complementing the literature for those with long-term alcohol and substance use disorders. An additional strength of this study is that the data are quite detailed, which allows for the further examination of the negative impact of social supports that use alcohol or drugs, the role of gender, homelessness, a drug dependence diagnosis, and co-occurring hepatitis C status on AA/NA group attendance. However, limitations of the study are also worth noting. First, the analysis could be strengthened by considering contextual and ecological factors that play a role in participation in AA/NA for those living with HIV/AID, such as the availability of meetings as well as the degree to which the values of the individual are congruent with those manifest in the meetings (Mankowski, Humphreys, & Moos, 2001). Such variables, however, were not available in our data so these analyses were not performed. Second, generalizability of results is limited since data used for this study **were** collected on people living with HIV/AIDS and alcohol problems in the Boston area. The findings are likely applicable to people with HIV/AIDS in similar urban locations. In addition, the observed associations while informative may not be causal.

Reliance on self-reported data is another limitation of this study, which may lead to measurement bias, in that subjects may not accurately report specific behaviors or AA/NA group attendance. Studies do show that self-report is consistent when respondents are asked about service utilization, but may be less reliable when assessing quantity of services (Goldberg et al., 2002). Bias in self-report may have been attenuated in this study by use of validated interview questions as well as the minimization of contextual factors that may influence the possibility of biased self report (Del Boca and Darkes, 2003), along with trained research assistants who emphasized confidentiality and took a systematic approach to interviewing, and a certificate of confidentiality provided by NIAAA as an additional protection of subject privacy.

Despite these limitations, this study offers valuable insight into the factors leading to attendance of AA/NA groups among a cohort of people living with HIV/AIDS. Results have relevance for administrators, clinicians and direct service providers working within the realms of HIV/AIDS, alcohol and other drug treatment, and AA/NA groups. Few data are available about this hard to reach population and AA/NA group attendance. This study has examined these questions using a rich data set that includes detailed predisposing, enabling, and need variables and has made use of clinical data.

This study examined the individual level factors associated with AA/NA group attendance among a cohort of adults living with HIV/AIDS. Of particular interest are variables that are barriers to AA/NA group attendance, such as gender and social supports' use alcohol and drugs. A strong positive association of other variables, such as a drug dependence diagnosis, co-occurring hepatitis C and homelessness indicates the possibility that current policies and practices by medical professionals or amongst service providers are encouraging AA/NA group attendance. Alternatively, the medical challenge of a hepatitis C diagnosis may be a motivator to seek care in the form of AA/NA for one's addiction. Understanding the factors that facilitate or impede AA/NA group attendance may improve the development of strategies to increase attendance, service delivery, referral and care, which is of critical importance for most vulnerable populations.

More research concerning barriers for women and AA/NA attendance is worthwhile since AA/NA is valuable for women in maintaining their sobriety (Beckman, 1993) for many of the same reasons men find AA/NA useful, such as fellowship, group support, and guidance (Kaskutas, 1994). Strategies to increase attendance of women in self help programs may include: increased referrals by medical practitioners to specialty treatment, self help programmatic support to meet the needs of subgroups of women who may have child care challenges or would benefit from meetings for women only, encouragement of female mentorship and/or sponsorship early in the self help process, while paying particular attention to other forms of self-help in the community that may assist in maintaining sobriety. This important issue warrants further exploration, especially in light of the increasing prevalence of HIV/AIDS among ethnic and racial minorities, and most notably women (Orwat, 2004).

There are several potential solutions to increase access and attendance among the specific populations identified with AA/NA groups. Much of this will certainly depend upon the role of medical, mental health and addiction professionals' successful ability to assess needs and link individuals into the appropriate group. However, additional factors must be considered with regard to the elimination of barriers, such as how to work with individuals that have social supports that are using alcohol or other drugs and creating barriers to access and attendance of supportive services such as AA/NA groups.

Table 1

Baseline Characteristics of Subjects Recruited for HIV-LIVE Study

	Variable	Study Sample (n=369)
Predisposing Characteristics	Age, years, Mean (SD)	42.7 (7.5)
	Sex (female)	24.9%
	Race (White)	32.5%
	Race (Black)	42.8%
	Race (Other)	24.7%
	Married	6.7%
	High school graduate *(a)*	65.0%
	Lives alone	28.7%
	Born in the USA	87.5%
	Literacy, High school level *(b)*	63.7%
	Gay, Bisexual, Other Sexual Orientation	32.8%
	Any traumatic abuse, ever *(c)*	80.4%
	HIV Disease Severity Variables	
	Any opportunistic conditions *(d)*	16.6%
	HIV Quality of Life Scale, Mean (SD) *(e)*	9.6 (4.9)
	CD4 Count (cells/mm3), Mean (SD)	462.1 (299.4)
	HCV antibody present	58.0%
Enabling Resources	Employment status (unemployed) *(d)*	73.4%
	Social support uses alcohol or drugs	
	Social support drinks alcohol	61.7%
	Social support uses drugs	47.3%
	Social support helps with sobriety	88.8%
	Currently taking anti-HIV medications	63.7%
	Received disability *(d)*	73.4%
	Homeless *(d)*	24.1%

The Mechanisms Linking Health Literacy to Behavior and Health Status

Chandra Y. Osborn, PhD, MPH; Michael K. Paasche-Orlow, MD, MA, MPH; Stacy Cooper Bailey, MPH; Michael S. Wolf, PhD, MPH

***Objective*: To examine the mechanisms linking health literacy to physical activity and self-reported health. *Methods*: From 2005-2007, patients (N=330) with hypertension were recruited from safety net clinics. Pathanalytic models tested the pathways linking health literacy to physical activity and self-reported health. *Results*: There were significant paths from health literacy to knowledge (r=0.22, P<0.001), knowledge to self-efficacy (r=0.13, P<0.01), self-efficacy to physical activity (r=0.17, P<0.01), and physical activity to health status (r=0.17, P<0.01). *Conclusions*: Health education interventions should be literacy sensitive and aim to enhance patient health knowledge and self-efficacy to promote self-care behavior and desirable health outcomes.**

***Key words*: health literacy, health behavior, knowledge, self-efficacy, health status**

***Am J Health Behav.* 2011;35(1):118-128**

The association between limited health literacy and poor health has been supported across acute and chronic disease contexts.[1-3] Patients' health literacy skills may be the first step in a chain of factors impacting health outcomes.[4,5] Although an accumulation of literature on the issue has emerged in the last 2 decades, the mechanisms by which health literacy impacts health are still unclear.[5,6]

Conceptual Causal Model Linking Health Literacy to Health

Paasche-Orlow and Wolf propose plausible causal pathways to explain the well-established association between health literacy and health.[5] They describe systematic, interactional, and self-care mechanisms by which limited health literacy is most likely to lead to worse health outcomes.[5] Drawing from the literature, they argue that social factors (eg, income, social support, culture, language), cognitive/physical factors (eg, memory, hearing, vision), and demographic factors (race/ethnicity, education, and age) determine health literacy skills. They then illustrate how limited health literacy might impact health outcomes at 3 distinct points along a continuum of health care, focusing on (1) access and use of

health care,[1,3,7] (2) provider-patient interactions,[8] and (3) patient self-care.[5] At each respective point, Paasche-Orlow and Wolf explore system factors (complexity, acute care orientation, tiered delivery model), provider factors (communication skills, teaching ability, time, patient-centered care), and extrinsic factors (support technologies, mass media, health education, resources) that could modify and/or mediate the relationship between health literacy and health outcomes.[5]

Patient factors are also affected at each point along the continuum of health care.[5] At the point of access and use of health care, limited health literacy could influence a patient's navigation skills, self-efficacy, and/or perceived barriers to care.[9] During provider-patient interactions, limited health literacy could infringe upon a patient's knowledge, beliefs, and/or level of participation in clinical decision making.[8] Limited health literacy could also negatively influence a patient's motivation,[10] problem-solving ability,[11] self-efficacy,[12] and/or knowledge[4,12,13] required to accurately perform self-care behaviors. Paasche-Orlow and Wolf suggest these aforementioned relationships operate in conjunction with system-, provider-, and extrinsic-level factors noted above and that these relationships exist within the causal pathway linking health literacy to health outcomes.[5]

Health Literacy and Hypertension

Across chronic disease contexts, limited health literacy has been consistently related to determinants of self-care behavior (eg, knowledge and self-efficacy noted above),[4,12,13] poor performance of self-care behavior (or the lack thereof),[14] and worse health outcomes.[3] In hypertension, limited health literacy has been associated with poor disease-related knowledge, [4,15,16] poor medication-refill adherence,[17] unreconciled medications (ie, discrepancies in patient self-reported medication use with his or her medical record),[18] and worse blood pressure control.[15] Limited health literacy has also been associated with an increased risk of hypertension, lower levels of physical function and activity, and worse subjective health status.[19]

Hypertension, Self-care, and Health Status

Leading health organizations endorse regular physical activity to prevent and treat hypertension and its complications.[20] Regular physical activity has been shown to lower blood pressure,[21] enhance endothelial vasodilator function,[22] and prevent the development of left ventricular mass among individuals with hypertension.[23] Synthesizing the research noted above and consistent with the Paasche-Orlow and Wolf model, limited health literacy may affect both objective and subjective indicators of health status via compromised physical function and physical activity.[19] Although Paasche-Orlow and Wolf do not explicitly discuss "self-care behaviors" in their framework, they do focus on the "determinants of self-care," which by nature highlights the importance of "self-care behaviors" in the causal chain. Determinants of physical activity in the hypertension literature are also consistent with the Paasche-Orlow and Wolf framework. Specifically, motivation and self-efficacy have explained 44% of the variance in physical activity;[24] and hypertension treatment knowledge has also shown predictive value.[25]

Empirical Validation of the Causal Pathways

The Paasche-Orlow and Wolf framework highlights both promising areas for intervention research and important gaps in our current understanding of the pathways linking health literacy to health outcomes. Their theoretical paper is one step in what needs to be an iterative process of model specification and clarification. Analytic approaches that test, validate, and/or refine the framework are needed to inform professional responses to the widespread problem of limited health literacy.[26] For example, empirical support for the proposed relationships between health literacy, determinants of self-care, self-care behavior, and health outcomes would undoubtedly inform the design and content and improve the efficacy of patient-level interventions to address health literacy.

In this study, we sought to validate one third of the Paasche-Orlow and Wolf framework. We focused solely on patient self-care pathways using data from adults with hypertension who were receiving care at safety net clinics in diverse areas of the United States. These data include variables on patient demographics, health literacy, knowledge, self-efficacy, and

health status. Using a path analytic approach, we were able to test the following hypothesized paths in the Paasche-Orlow and Wolf framework:

1. Patient demographic characteristics (race/ethnicity, education, and age) predict health literacy.
2. Health literacy predicts patient-level determinants of self-care (knowledge and self-efficacy).
3. Patient-level determinants of self-care predict self-care behavior (physical activity).
4. Self-care behavior predicts health status (subjective health).

In this way, the association between health literacy and health is hypothesized to be accounted for by a sequence of intervening variables (knowledge, self-efficacy, and self-care behavior).

METHODS

Setting and Participants

We recruited consecutive patients with diagnosed hypertension at scheduled appointments from 6 primary care safety net clinics in Grand Rapids, Michigan; Chicago, Illinois; and Shreveport, Louisiana. Clinics in Grand Rapids (n=2) and Chicago (n=2) were federally qualified health centers. One clinic in Shreveport was a community health center; and the other, an ambulatory care clinic at a public hospital. The institutional review boards at each location approved the study procedures. Eligible participants were at least 18 years old, had a diagnosis of hypertension in their medical record, and had a clinic appointment between July 2006 and August 2007. Patients were ineligible if they did not speak English or if the clinic nurse determined (by interaction or chart documentation) they were too ill or cognitively impaired to participate. Nurses identified 377 potentially eligible patients scheduled for clinic appointments and referred them to onsite study personnel. Informed consent was obtained on 334 scheduled interviews. Four of these patients did not complete the interview (N=330). A response rate was determined following the American Association for Public Opinion Research (AAPOR) standards, estimating 87.5% of approached eligible patients participated in the study.[27]

Data Collection

Study personnel conducted in-person interviews at the clinics. Information on demographic characteristics, such as education (1= grades 1-8, 2=grades 9-11, 3=high school, 4=>high school), race/ethnicity (0=White, 1=African American), and age (continuous) were collected. Additional measures included health literacy, knowledge, self-efficacy, self-care behavior (physical activity), and health status.

Health Literacy

Health literacy was assessed using the short version of the Test of Functional Health Literacy in Adults (S-TOFHLA). The S-TOFHLA has 2 parts. One part is a reading comprehension assessment that involves passages of text about medical topics from which every fifth to seventh word is omitted. Respondents must select a suitable word to insert in the missing place from 4 multiple-choice options. The second part assesses numeracy by presenting respondents with questions to determine their ability to use and interpret numbers when reading hospital forms and labeled prescription vials. Scores on the S-TOFHLA range from 0 to 100 and can be categorized as follows: inadequate health literacy (0-53 correct answers), marginal health literacy (54-66), and adequate health literacy (67-100). The S-TOFHLA has demonstrated good internal consistency, reliability, and validity as a categorized and continuous measure of health literacy ($\alpha = 0.98$).[3,28-30] We relied on the continuous score to increase the predictive power in our path analytic models.

Knowledge

Hypertension knowledge was assessed by asking participants a series of questions about the characteristics and symptoms of high blood pressure. Fourteen multiple-choice items made up the scale, and a total score was taken from all questions. Participants were asked about a normal blood pressure reading, lifestyle activities that change blood pressure readings, symptoms of high blood pressure, and complications. The scale was developed for use in the Prudential Health Literacy Survey[4] and was derived from a reliable and valid measure of hypertension knowledge ($\alpha = 0.70$).[16]

Self-efficacy

Self-efficacy to manage high blood pressure was assessed by asking patients

how confident they were in (1) doing all the things necessary to manage their blood pressure; (2) judging when changes in their blood pressure mean they should visit a doctor; (3) doing different activities and tasks to mange their blood pressure so as to reduce the need to see a doctor; (4) reducing the emotional distress caused by their blood pressure; and (5) doing things, other than just taking medication, to reduce how much their blood pressure affects their everyday life. Response options were in Likert format ranging from 1 = not at all confident to 10 = totally confident. In the current study, internal consistency reliability for this measure was $\alpha = 0.76$.

Self-care Behavior (Physical Activity)

The frequency of physical activity was measured with a single-item taken from a 2-item scale that measures both the frequency and duration of physical activity over the past 4 weeks.[31] Response options were 1 = never, 2 = only once or twice, 3 = at least once a week, 4 = 3 to 4 times each week, and 5 = every day.

Health Status

Subjective health was assessed with a widely used general self-rated health question that asks respondents to report how they thought their health was in general.[32] Response options were in Likert format ranging from 1 = Poor to 5 = Excellent. This single question has demonstrated strong predictive validity with self-care behaviors,[33] objective indicators of health,[33] and mortality.[34] Relevant to our study is prior work showing that a single item of self-rated health is sensitive to changes in physical activity.[35,36]

Data Analyses

Patients were categorized as having inadequate health literacy (scores 0-53) or having marginal/adequate health literacy (scores 54-100) and compared using independent samples t-tests for continuous variables and chi-square tests for categorical variables. Pathanalytic models specifying the relationships among variables were estimated using AMOS, version 17. Advantages of this procedure include the generality and flexibility of model specification and the ability to assess fit of the hypothesized model to the observed data. Model fit was examined with the comparative fit index (CFI) and root mean error of approximation (RMSEA).[37] CFI values exceeding 0.90 and RMSEA values below 0.08 indicate reasonable model fit.[37] Hypotheses regarding the specific structural relations of the constructs in the model were also evaluated through inspection of the direction and magnitude of the path coefficients.

Two path analytic models were estimated with a correlation matrix generated by 330 cases, a sample size considered to be of adequate power to detect large effects.[38,39] Demographic information (education, race, and age), health literacy, knowledge, self-efficacy, self-care, and subjective health variables were used to estimate one third of the Paasche-Orlow and Wolf framework (ie, patient factors within the self-care domain). Model 1 (the full model) tested whether demographic factors predicted health literacy; whether health literacy predicted determinants of self-care (knowledge and self-efficacy); whether determinants of self-care predicted self-care behavior (physical activity); and whether self-care behavior predicted health status (subjective health). Although we were interested in only these pathways, all potential paths between variables were included to test both those hypothesized to be significant and those hypothesized to be nonsignificant. Model 2 (the trimmed model) omitted all nonsignificant paths from Model 1. Chi-square difference tests were performed between models 1 and 2 to identify the most parsimonious and final model.

RESULTS

Table 1 provides both an overall statistical description of the study population and stratifies the sample by inadequate and marginal/adequate health literacy categories. The mean age of participants was 53.6 years (SD=12.0); 67.9% were female, and 78.5% were African American. Approximately one-third of participants were recruited from each of the study sites: 30.6% from Chicago, 36.1% from Grand Rapids, and 33.3% from Shreveport. The majority of participants (65.8%) were unemployed/retired, and 43.9% did not have any health insurance. Participants reported having hypertension for an average of 11 years (SD=10.0), and 47.6% had chart-confirmed controlled blood pressure.

Thirteen percent of participants reported having left school prior to the ninth

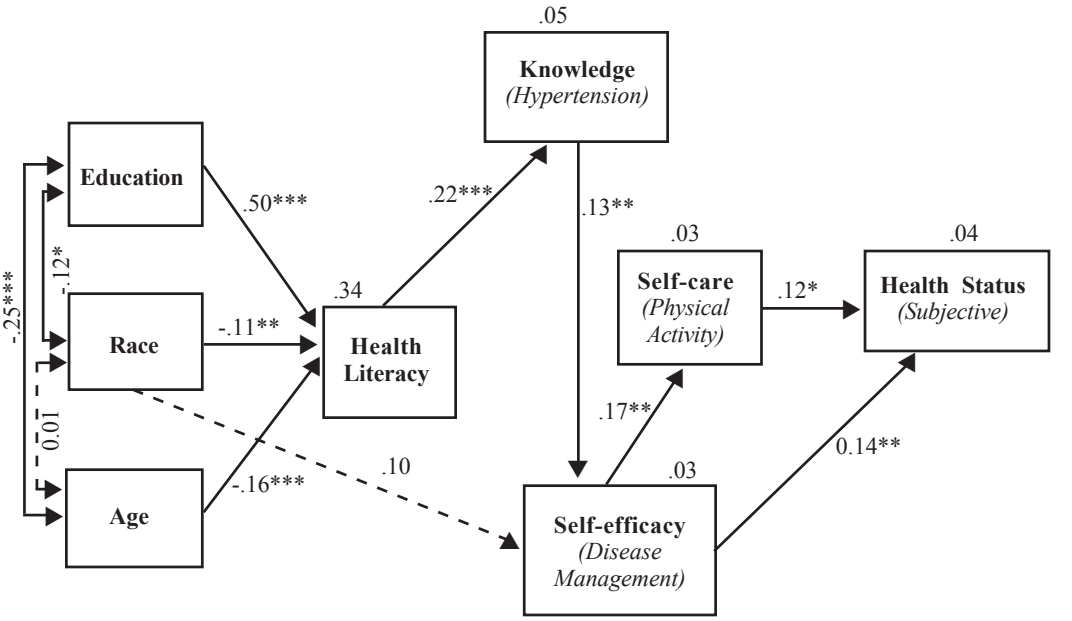
grade, and another 26.2% had not completed high school. Approximately one third (31.4%) of the sample were high school graduates; fewer years of schooling was significantly associated with inadequate health literacy skills, as well as older age, current unemployment, and greater number of years living with hypertension (Table 1). One third (30.3%) of patients were classified as having inadequate health literacy skills. Means and standard deviations for the knowledge, self-efficacy, self-care behavior (physical activity), and subjective health variables are presented in Table 1.

Model 1 demonstrated excellent data fit, χ^2(3 N=330) = 5.42, P=0.14, CFI=0.99, RMSEA=0.05 (90% CI: 0.00-0.11). There were significant, direct paths from education, race, and age to health literacy (ie, fewer years of education, African American race, and older age were independently associated with lower health literacy scores). Additional significant paths included health literacy to knowledge (ie, higher health literacy scores were associated with more knowledge); self-efficacy to self-care behavior (ie, greater self-efficacy was associated with more physical activity); and self-care be-

Figure 1
Estimated Trimmed Model With Predicted Pathways From Health Literacy to Health Status



Note.
Coefficients are standardized path coefficients. For tests of significance of individual paths, *P<0.05, **P<0.01 and ***P<0.001. Overall model fit, χ^2(16, N=330)=16.75, P=0.40, CFI=1.00, RMSEA=0.01 (90% CI: 0.00-0.05).

havior to health status (ie, more physical activity was associated with more favorable subjective health ratings). In addition, race was directly related to self-efficacy (ie, African American race was associated with greater self-efficacy); and self-efficacy was directly related to health status (ie, greater self-efficacy was associated with more favorable subjective health ratings). All remaining paths were not significant, including the paths from each demographic factor to knowledge, self-efficacy, self-care behavior, or health status; health literacy to self-efficacy, self-care behavior, or health status; and knowledge to self-care behavior or health status.

Model 2 estimated a trimmed version of Model 1, retaining all significant paths and omitting all nonsignificant paths in Model 1. The trimmed model with structural parameters and tests of significance of individual paths appears in Figure 1. Model 2 demonstrated excellent data fit, χ^2(16, N=330)=16.75, P=0.40, CFI=1.00, RMSEA=0.01 (90% CI: 0.00-0.05). All significant paths in Model 1 remained significant in Model 2 except for the path from race to self-efficacy (ie, African American race was no longer directly related to self-efficacy). Demographic factors explained 34% of the variability in the health literacy score, a percentage considered to be a moderate effect for multiple predictor models.[40] Health literacy explained 5% of the variability in knowledge; knowledge explained 3% of the variability in self-efficacy; self-effi-

cacy explained 3% of the variability in self-care behavior (physical activity); and self-efficacy and self-care behavior (physical activity) explained 4% of the variability in health status (subjective health). These are all small effects. A chi-square difference test was performed against Model 1, $\alpha^2(13, N=330)=11.33$, *ns*. The difference was nonsignificant permitting the retention of the trimmed version as the more parsimonious and final model.

DISCUSSION

Conceptual frameworks propose explicit linkages between known determinants of health, with the ultimate goal of locating strategic entry points for intervention. Rooted in prior research, these frameworks require empirical validation prior to their use in developing practical strategies for responding to relevant health problems. We performed a cross-sectional path analysis on data collected from patients with hypertension at safety net clinics in 3 states to evaluate the predicted pathways linking health literacy to health outcomes. Consistent with the Paasche-Orlow and Wolf framework[5] and hypothesis 1, demographic factors (education, race, and age) were directly related to health literacy, were unrelated to all other variables, and explained one third of the variability in health literacy. Consistent with the framework and hypotheses 2-4, health literacy was directly related to knowledge,[4] self-efficacy was directly related to self-care behavior (physical activity),[41,42] and self-care behavior (physical activity) was directly related to health status (subjective health).

Studies in the health literacy, hypertension, and health behavior change literatures support the aforementioned findings. Demographic characteristics, specifically education, race, and age, have been consistently related to health literacy across chronic disease contexts, including hypertension.[43] Prior research has also supported an independent, direct link between health literacy and hypertension knowledge, with limited health literacy being consistently associated with poor knowledge.[4,15,16] Other hypertension studies have supported an independent, direct link between self-efficacy and physical activity,[24,42] as well as an association between physical activity and subjective health.[24] Here, we explored whether knowledge, self-efficacy, and self-care behavior link health literacy to health, which had not been a focus of these latter studies. Although our findings are consistent with prior research, they uniquely extend what is known about the relationship between health literacy and health outcomes. Evidence in support of intervening upon a sequence of modifiable factors in health promotion programs is a significant contribution to both the health literacy and health behavior change literatures and, to our knowledge, has not been done to date.

Inconsistent with the Paasche-Orlow and Wolf framework[5] and hypothesis 2 were nonsignificant paths from health literacy to self-efficacy,[44] self-efficacy to health status, and knowledge to self-care behavior (physical activity). Instead, we found that knowledge was the only significant predictor of self-efficacy, allowing health literacy to be indirectly related to self-efficacy through knowledge. Some studies find health literacy predicts self-efficacy,[14] whereas others have no association.[44] We propose that health literacy may affect self-efficacy through knowledge, but more research is needed to support this. In our study, self-efficacy was an independent, direct predictor of health status. Studies in other chronic disease contexts have shown strong associations between self-efficacy and self-rated health.[45-48] However, less is known about this relationship in the context of hypertension. Lastly, knowledge was unrelated to self-care behavior (physical activity) in our study. This finding is both consistent with behavior change frameworks[49] and prior studies showing knowledge to be poorly correlated with behavior, specifically physical activity.[50,51]

Our findings ruled out several alternative relationships between variables. As illustrated in the Paasche-Orlow and Wolf framework, the impact of demographic factors (education, race, age) on hypertension knowledge, self-efficacy, self-care behavior (physical activity), and health status was entirely explained by health literacy. This is consistent with research showing that health literacy explains demographic differences in self-care behavior and health outcomes.[52,53] In our study, health literacy had no direct relationship with health status. Although this finding is consistent with the Paasche-Orlow and Wolf framework, it is inconsistent with studies in health literacy.[43,54]

One study in particular found a direct link between health literacy and health status that was not mediated by intermediate factors, such as knowledge and behavior.[54] However, because these findings were based on an elderly sample, additional research is needed to rule out cognitive decline as an alternative explanation. Lastly, we found that knowledge had no direct relationship with health status, which has been both theoretically argued[49] and empirically supported in other work.[54]

Several limitations are inherent in this study. First, the data were based on self-reported information, introducing the possibility of deliberate or unconscious misinformation.[55] Furthermore, the measures of self-care behavior (physical activity) and health status were both single-item measures, which have been criticized for introducing bias and not being comprehensive in measurement.[56,57] However, the single-item measures used in this study had been previously used and validated in other research.[31,32] The health status item in particular has demonstrated strong predictive validity with self-care behaviors,[33] objective indicators of health,[33,58] and mortality;[34,59] has been used as a dependent variable in path analytic models;[54,60] and does not violate SEM assumptions for endogenous variables.[38]

Second, although our findings propose causal relationships between variables, the cross-sectional nature of the data precludes causal conclusions and can most appropriately speak to associations between constructs observed at a single point in time. Consequently, we have relied on theory and the research literature to direct our conclusions. Future prospective research is needed to investigate the longitudinal effects of these factors on changes in self-care behaviors and health outcomes.

Third, our findings pertain most directly to populations similar to the participants in this study, and should be confirmed in other populations to see if they generalize. Future work guided by the model proposed in Figure 1 would also provide a more comprehensive conceptualization of the core constructs believed to implicate hypertension self-management.

Finally, although relations between the variables in our study were statistically significant, the magnitude of these relationships was rather modest. Future models should include measures of patient motivation and problem solving; additional self-care behaviors, and objective measures of health status, which may explain more of the variability in the sequence of intervening variables linking health literacy to health outcomes. Duration of and control of high blood pressure are important factors that are likely to impact both health behaviors and health outcomes among patients with hypertension. In an effort to be consistent with the Paasche-Orlow and Wolf framework, duration of disease (eg, hypertension) was not accounted for in our analyses. We also did not include blood pressure control, mainly because it is a very dynamic outcome (ie, patients can be controlled and uncontrolled by turns) – and being in control has a lot to do with activities of the clinicians (eg, providing the proper type and dosage of medication and being available to follow up with patients). We were also unable to classify patients as having prehypertension, stage 1 or stage 2 hypertension.

Despite these limitations, this study is the first to our knowledge to show an indirect pathway from health literacy to health status via widely recognized determinants of self-care (knowledge and self-efficacy) and actual self-care behavior (physical activity). Our findings are just one step in what should be an iterative process of model specification and clarification. Future studies that can both validate our findings and extend them would provide the most useful explanation of the relationship between health literacy and health outcomes and inform professional responses to the problem in many diverse contexts of health care.[61] In the meantime, we suggest, based on our findings, that health literacy-sensitive interventions should aim to enhance disease-specific knowledge that, in turn, will enhance self-efficacy, so that self-efficacy will, in turn, promote the performance of self-care behaviors needed for desirable health outcomes. Future qualitative and quantitative research to determine the most influential techniques to promote knowledge, self-efficacy, and self-care behavior among patients with limited health literacy is needed.

Our findings support the role patient knowledge plays in linking health literacy to health outcomes for patients with hypertension, highlighting the potential impact of patient education efforts as a means of

improving health outcomes. However, intervening to improve knowledge may be challenging. Providers do not have the time. Patients may have other priorities and competing cultural views about hypertension. Effective strategies to promote patient education regarding hypertension for patients with limited health literacy will need to be developed and integrated into care.

Acknowledgments

Funding for this study was provided in part by a research grant awarded to Cherry Street Health Services by the Michigan Department of Community Health. Dr Osborn performed this research under the support of a Diversity Supplement Award (NIDDK P60 DK020593) ■

Caring for Patients With Limited Health Literacy

A 76-Year-Old Man With Multiple Medical Problems

Michael Paasche-Orlow, MD, MA, MPH, Discussant

Health literacy is the degree to which individuals have the capacity to obtain, process, and understand health information, skills, and services needed to make informed health decisions and take informed actions. Narratives from Mr J, a 76-year-old man with multiple medical problems and limited health literacy, and his physician exhibit some of the difficulties experienced by patients with limited health literacy. Clinicians can help patients with limited health literacy by removing unneeded complexity in their treatment regimens and in the health care system and by using teach-back methods to assess and improve understanding. Rather than a selective screening approach for limited health literacy, a patient-based universal precaution approach for confirming patient comprehension of critical self-care activities helps ensure that all patients have their health literacy needs identified.

JAMA. 2011;306(10):1122-1129 www.jama.com

DR SHIP: Mr J is a 76-year-old man whose care has been complicated by difficulties understanding his health care and accessing treatment. He lives in the greater Boston area and has Medicare.

Mr J's medical history is significant for hypertension, type 2 diabetes, hyperlipidemia, obesity, and sleep apnea. He has had the same physician for the past 18 years. He was born in South Carolina, completed eighth grade, and then began working. He came to the Boston area about 40 years ago. He has worked a variety of jobs, largely doing manual labor. He stopped working when his vision failed from complications of hypertension, diabetes, cataracts, and a macular hole. When questioned about his ability to read, he invokes limitations due to his visual deficits. Mr J lives alone but has been in a romantic relationship with one woman intermittently for about 5 years. He attends a day program about 3 days a week. He does not smoke or drink alcohol.

Every aspect of Mr J's health and health care has been affected by his limited health literacy. His first visit to his physician of 18 years was after an emergency department visit for hypertensive urgency (blood pressure, 200/100 mm Hg, with visual changes, headache, and weakness) as well as a serum glucose level of 389 mg/dL (21.6 mmol/L).

Mr J's diabetes has been poorly controlled for long stretches of time because of poor adherence to diet and medications. His hemoglobin A_{1c} level has been as high as 14.2% and is currently 8.4%. When his caregivers initially started insulin therapy, they involved his girlfriend (who also has diabetes) in his care. This was successful until their relationship foundered. After another family member was unable to assist, a visiting nurse was brought in to teach him how to self-inject. He has been using a Lantus pen himself since then.

Mr J's challenges have limited the treatment of his severe obstructive sleep apnea, which is associated with short runs of ventricular tachycardia when his oxygen saturation decreases at night. He is not interested in using continuous positive airway pressure (CPAP) and has not kept repeated appointments in the sleep clinic. It is unclear whether he uses nocturnal oxygen and how much.

The conference on which this article is based took place at the Medicine Grand Rounds at Beth Israel Deaconess Medical Center, Boston, Massachusetts, on March 4, 2010.

Author Affiliations: Dr Paasche-Orlow is Associate Professor of Medicine, Department of Medicine, Section of General Internal Medicine, Boston University School of Medicine, Boston, Massachusetts.
Corresponding Author: Michael Paasche-Orlow, MD, MA, MPH, Boston University Medical Center, 801 Massachusetts Ave, Second Floor, Boston, MA 02118 (mpo@bu.edu).

Clinical Crossroads at Beth Israel Deaconess Medical Center is produced and edited by Risa B. Burns, MD, series editor; Tom Delbanco, MD, Howard Libman, MD, Eileen E. Reynolds, MD, Marc Schermerhorn, MD, Amy N. Ship, MD, and Anjala V. Tess, MD.
Clinical Crossroads Section Editor: Margaret A. Winker, MD, Deputy and Online Editor.

Recently, when Mr J was discharged after a hospitalization for pneumonia, he failed to take the prescribed antibiotic. His nonadherence was identified at his postdischarge visit with his nurse. He stated that he did not fill the prescription because he was told it would cost $98. Investigation by his nurse determined that the prescription would cost less than $2, and he agreed to fill it.

His current medications include amlodipine, 10 mg/d; atenolol, 100 mg/d; gabapentin, 300 mg/d at bedtime; glyburide, 10 mg twice per day; hydrochlorothiazide, 25 mg/d; insulin glargine pen, 10 units/d; lactulose, 2 to 3 tbsp/d as needed for constipation; lisinopril, 40 mg/d; pioglitazone, 45 mg/d; sildenafil, 50 mg before sexual intercourse as needed; simvastatin, 80 mg/d; tamsulosin, 0.4 mg/d; aspirin, 325 mg/d; capsaicin 0.075% cream, 3 to 4 times daily on feet; and terbinafine 1% cream, twice per day. He has no drug allergies.

On examination, Mr J had a blood pressure of 138/64 mm Hg; pulse of 72/min and regular; oxygen saturation of 96% on room air; weight of 215 lb (96.8 kg); and height of 66 in (167.6 cm). He appeared well and in no distress. His lungs were clear bilaterally, with good air movement. His heart examination results were normal, with a regular rate and rhythm, S_1, S_2, and no murmurs. He had no lower extremity edema or skin breakdown.

MR J: HIS VIEW

Well, the only problem I have is in my eyes. I mean, the sugar got my eyes the way it is. So, I mean, nothing can be done about it. I don't forget my medicine. What I mean, it don't do all that much good. I get weak sometimes, and I figure if I get real weak, I'll go and take my medicine. It might help. I mean, I don't know if they're not strong enough or I get the wrong medicine, the wrong kind of medicine. I couldn't say.

I try to take what the doctor prescribes and see whether I'll work with that. And, if that ain't doing too good—a lot of it don't do no good—then I tell him about it. He might change 1 pill.

The doctor give me medicine: "Well, you take this, here, 2 times a day," and so on, so on, so on. Okay, you take it. Tomorrow, you feel the same way. I mean, sometimes you feel worse. Doctors don't explain things very well a lot of times.

When I was a kid, we used to have a lot of colds and the mumps, and all like that. My mother fixed medicine out of different roots out of the ground . . . different types of tea. And that helped a lot. She did the best she could to try to keep us going. And, I mean, here I am.

DR Y: HIS VIEW

Unfortunately, Mr J has limited literacy. And I think, in his case, it's both language and it's health literacy. I believe he's illiterate, actually. We don't actually know when his blood pressure is high or his diabetes is getting out of control. We don't know if he is taking his medications or he's not taking them.

The biggest breakthrough for us has been when his nurse practitioner said, "Oh, why don't we get him prepackaged medications in little blister packs?" which has really been helpful. Because then, he doesn't have to know what he is taking.

He doesn't really feel that it's a priority to prevent heart disease. I don't think, despite numerous discussions, he understands what heart disease is, or understands dialysis, or the many consequences that are associated with chronically elevated blood sugars. He doesn't really get those things.

We didn't see him for a while. He says, "Well, I had to go to the hospital." And I said, "Oh, really? Well, what happened there?" He says, "I don't know. But they let me go, eventually." And, much to my shock, I learned that he had chest pain, required cardiac stenting. And, worse than that, he was supposed to be taking clopidogrel to keep his stents open. He didn't know a thing about this. It was shocking and terrifying.

I don't have a formal way to assess language literacy or general health literacy in my practice. I think that we just need to be conscious that this can be an issue. This is one of the causes of nonadherence to prescribed regimens. And we need to think about it. Should we be assessing our patients for health literacy? How should we be assessing them? And is it worth the time, if it's a time-consuming thing, to assess everyone?

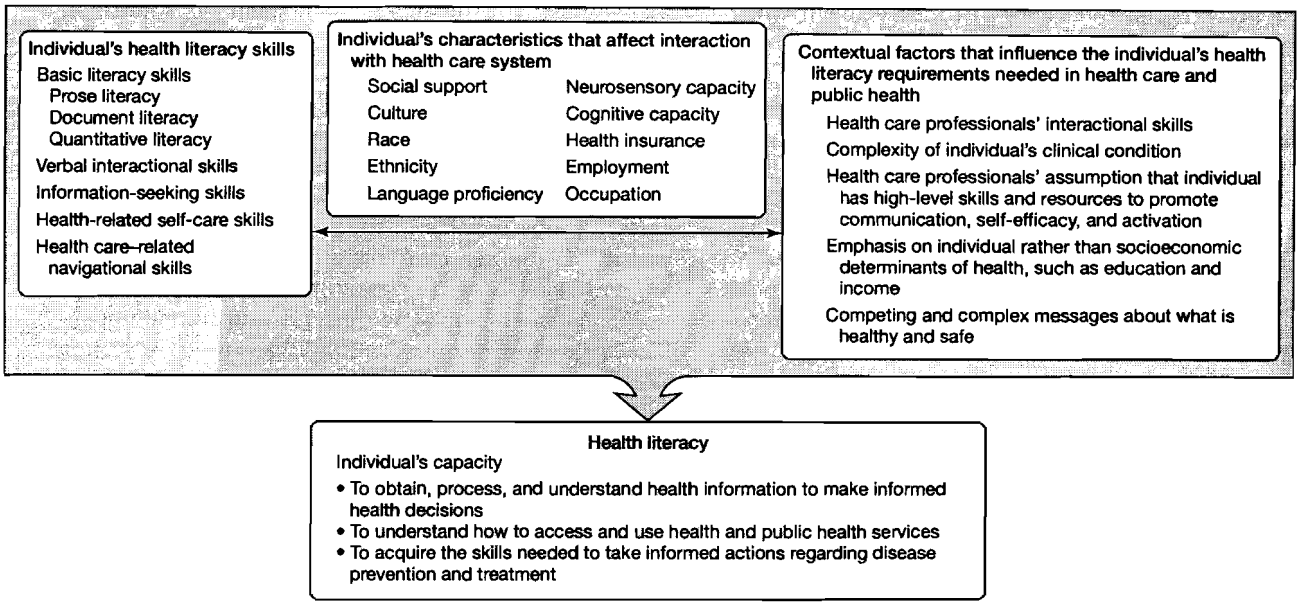
AT THE CROSSROADS: QUESTIONS FOR DR PAASCHE-ORLOW

What are the different conceptual domains that comprise health literacy? What is the "epidemiology" of health literacy issues? To what extent do these issues parallel poor socioeconomic status? What is known about the effects of poor health literacy on patient care or population health? Should clinicians screen for problems with health literacy? If so, how? What do you recommend for Mr J and his caregivers?

Health Literacy

DR PAASCHE-ORLOW: Literacy is inherently a functional concept; ie, it is competence in a set of skills relating to a specific domain of human endeavors. Health literacy is the degree to which individuals have the capacity to obtain, process, and understand health information, skills, and services needed to make informed health decisions and take informed actions. In fact, a broad range of skills is needed to function in relation to one's health. To start, obtaining, processing, and understanding health information often requires the capacity to comprehend written text (prose literacy), forms (document literacy), quantitative information (numeracy), and verbal interactions (interactional skills) (FIGURE). Beyond these fundamental domains of literacy, specific self-care skills are needed according to the tasks that need to be accomplished; eg, inhaler technique or operation of a glucometer. Additional domains of health literacy

Figure. Factors That Contribute to Health Literacy



include information-seeking skills and navigating health systems, although these have been studied less frequently.[1]

Health literacy is itself predicated on a range of linguistic, neurosensory, cognitive, psychiatric, medical, and cultural factors. Although limitations in any of these areas may limit an individual's health literacy and may mediate or moderate the impact of limited health literacy on a person's life, these factors are not themselves domains of health literacy (Figure). For example, patients who have a barrier to comprehension because of low English proficiency deserve language-concordant services and patients who cannot read because of cataracts typically benefit from extraction. It is important to determine patients' specific barriers to health literacy, and interventions should be designed to match a patient's particular issues.

In each domain of health literacy, the types of cognitive challenges faced in health care settings may be quite different from what individuals typically have to manage in their lives. Health care professionals frequently invoke mathematical concepts (eg, risk),[2] complex documents (eg, notices of privacy protection),[3] acronyms, and jargon.[4] Comparisons of different ways to present the rate of benefits or harms from treatment, for example, reveal that even the most successful format for the presentation of rates (as percentages) is misunderstood by one-third of study participants.[5] Even seemingly normal words often have specialized meaning in health settings. For example, health care professionals use the term *diet* to refer to all the calories a person consumes, but most people consider a "diet" to be an organized effort to lose weight. Communication failures are ubiquitous: Is a "negative" biopsy result supposed to be a good thing or a bad thing? Semantic constructions such as "fever spike," "needlestick," and "culture plate" are so routine for health care practitioners that they do not identify these as jargon.

Similarly, health care is replete with experiences that are outside the norm of most people's experience. Medicine's aspiration to promote informed consent and autonomy via shared decision making, although founded on important ethical principles, imparts a significant health literacy burden. For example, the complex issues surrounding prostate cancer screening are difficult to understand. Ultimately, health literacy is a contextually defined phenomenon. Consequently, the Institute of Medicine report on health literacy frames limited health literacy not as a patient problem but as a challenge to health care and public health professionals to communicate with patients more effectively.[6] Specifically, the concept of health literacy should not only incorporate the individual cognitive skills one uses when making health-related decisions but also should take into account the contextual demands placed on the individual by (1) the specific clinical condition; (2) the communication skills of health care professionals;(3) the complex and competing demands of the various health and public health messaging that are encountered; (4) the structure and function of clinical services and public health that assume adequate health literacy and require self-advocacy and vigilance; and (5) the emphasis that society places on individual rather than ecological determinants of health (Figure).

Epidemiology of Health Literacy Issues

The 2003 National Assessment of Adult Literacy (NAAL), the first nationally representative assessment of English health literacy among US adults aged 16 years or older, showed that 14% of the US adult population was found to have below basic health literacy skills and an additional 22% of the US adult population was found to have only basic health

literacy skills.[6] People with below basic health literacy on the NAAL have skills that range from being nonliterate in English to being able to locate easily identifiable information in short, commonplace charts or texts or being able to locate numbers and use them to perform simple operations such as addition when the mathematical information is very concrete and familiar. People with below basic health literacy cannot, for example, use information on the label of an over-the-counter medication to identify substances that may interact to cause an adverse effect. People with basic health literacy skills are able to read and understand information in short, commonplace charts or texts or to locate easily identifiable information and use it to solve simple, 1-step problems when the arithmetic operation is specified or easily inferred. These findings indicate that more than 75 million US adults have limited health literacy skills (ie, below basic or basic on the NAAL).[7]

Surveys of patients' health literacy indicate that the prevalence of limited health literacy is even higher in health settings. In a review of 85 studies from the medical literature including data on 31 129 participants, 46% had limited health literacy.[8] Individuals who are interested in the local prevalence of below basic literacy skills can view state and county estimates at the National Center for Education Statistics Web site.[9]

Effects of Limited Health Literacy

Compared with individuals with adequate health literacy, those with limited health literacy have been shown to have worse health-related knowledge[10] and worse markers of health care processes such as medication adherence,[11] visit adherence,[12] self-care skills,[13,14] intermediate disease markers,[15,16] use of prevention services,[17] delayed diagnoses,[18] and health services utilization.[19] Limited health literacy has also been associated with worse markers of health including health status,[20-22] quality of life,[23,24] hospitalization,[25,26] and mortality.[27-29] For example, in a cohort of 408 English- and Spanish-speaking adults with type 2 diabetes, after adjusting for sociodemographic characteristics, depressive symptoms, social support, treatment regimen, and years with diabetes, individuals with limited health literacy were less likely than those with adequate health literacy to achieve tight glycemic control (hemoglobin $A_{1c} \leq 7.2\%$; adjusted odds ratio [OR], 0.57; 95% CI, 0.32-1.00) and were more likely to have retinopathy (adjusted OR, 2.33; 95% CI, 1.19-4.57).[15] Similarly, in a cohort of 3260 Medicare managed-care enrollees, individuals with limited health literacy had a higher rate of mortality than those with adequate health literacy, with a hazard ratio for all-cause mortality of 1.52 (95% CI, 1.26-1.83) after adjusting for demographics, socioeconomic status, and baseline health.[28] Some reports have presented findings that do not support the relationship between health literacy and health outcomes for topics such as medication adherence and glycemic control.[30,31] The health literacy literature has been reviewed in 2 evidence-based reports presented by the Agency for Healthcare Research and Quality.[32,33]

Socioeconomic Status and Health Literacy

The United States has a significant health literacy gap by educational attainment, income, race, and ethnicity. More than half of African American adults and two-thirds of Hispanic adults have limited health literacy, while less than one-third of white adults have limited health literacy.[7] This gap is parallel to the racial/ethnic gap in general literacy skills, level of educational attainment, and income.[34]

Research has begun to emerge showing how limited health literacy may be an important source of health disparities. Although more research is needed, health literacy has been shown to explain racial disparities in prevention activities,[35] prostate cancer,[36] human immunodeficiency virus (HIV) medication adherence,[37] glycemic control,[38] and end-of-life preferences.[39] For example, in a cohort of 204 persons with HIV infection, health literacy was shown to mediate the observed association between African American race and low medication adherence. In fact, in the final model, the effect of race diminished to nonsignificance and health literacy was the primary predictor of medication nonadherence, such that persons with limited health literacy had a 2.12 (95% CI, 1.93-2.32) higher odds of nonadherence.[37] Such findings suggest that addressing health literacy barriers should help reduce racial/ethnic health disparities.

Screening for Health Literacy

Some have suggested clinical screening for health literacy. Powers et al[40] identified screening tests for reading ability that have been shown to measure literacy with a reasonable degree of accuracy. The validation studies for health literacy screening tools each had their own enrollment criteria to differentiate literacy barriers from visual and cognitive limitations. As such, clinical screening of health literacy should not be performed independently; a positive screening result necessitates additional testing. However, there are reasons to question the underlying premise of clinical screening for health literacy. To my knowledge, the only published trial of screening that assessed clinical outcomes, among patients with diabetes, showed that health literacy screening did not improve outcomes.[41] Studies of patient responses to screening have varied results; patients may have considerable,[42] modest,[43] or low[44] feelings of shame. Regardless, screening should only be performed if there is potential for benefit.[45] In a clinical setting, the most important information to determine is not a health literacy score but whether a patient understands his or her medical conditions, the purpose of the treatment regimen including medications, and how to adhere to the treatment regimen. Other important considerations relate to informed consent for medical procedures. Mr J's literacy screening test result clearly would have been abnormal, but that result would not have addressed his lack of understanding of his illnesses and treatment regimen.

The process of screening for comprehension of the clinical plan has been called "universal precautions for comprehension."[46] Screening a patient for comprehension of the

clinical plan includes identifying any lack of understanding of the plan, simplifying the treatment, and working with the patient until the treatment regimen is understood. For example, in a patient with recalcitrant asthma, mastery of inhaler use is assessed by evaluating the patient's understanding of specific self-care tasks (eg, "Show me which inhaler you should use if you are wheezing. Now show me how you use the inhaler."). This assessment can help direct patient education efforts.

RECOMMENDATIONS FOR MR J AND HIS CAREGIVERS

Mr J has had suboptimal control of his chronic diseases, and his primary care physician has identified limited health literacy as a major cause. In addition to his health literacy, there are additional phenomena that may have impaired Mr J's health care. It is important to consider other types of barriers not only because they may require specific intervention but also because the ensuing evaluation and intervention may be complicated by limited health literacy.

Mr J's history includes his forgetting almost any details of his hospital admission with chest pain that resulted in coronary stent placement and the addition of clopidogrel to his medication list. This episode highlights many additional issues that affect patients' "adherence" to care. First, patient education in transitions of care is notoriously limited. Makaryus and Friedman[47] found that only 42% of patients discharged from the Mayo Clinic could state their diagnosis and even fewer could recall all their medications or common adverse effects. Also, it is common for discharge instructions to lack critical information, to be written in a way that patients do not understand, and not to be sent to primary care clinicians.[48] An alternative possibility for why Mr J did not mention the stent procedure is that he may have been in denial. This is a common phenomenon in coronary artery disease and may have played a role in limiting his self-care activities for medical problems throughout his life.[49]

Important cultural factors may have limited Mr J's health care as well. In many situations, it is difficult to discern between cultural factors and domains of health literacy. For example, understanding what to do with a bottle of prescription medicines requires a number of culturally defined details. The concept of a 30-day supply with refills, the location of this information on the medication label, and how one goes about getting a refill are not standardized.[50] In some respects, persons who do not understand how to interpret medication labels should be regarded as having limited health literacy; however, if such a misunderstanding is due to a lack of familiarity with medical conventions, the issue may need to be regarded as cultural in origin and not due to health literacy. But more fundamental cultural differences can be harder to manage. Mr J appears to take medications for his chronic diseases in a periodic manner in response to symptoms. He is disappointed in the medicines and questions their efficacy when he still feels bad the next day. This pattern of nonadherence may be consistent with not believing in or understanding the concept of chronic asymptomatic disease. The notion of a chronic asymptomatic disease is challenging for many persons because it is not reinforced by personal experience of symptoms as is typical for many other conditions.[51]

To help Mr J, it is vital to understand his cognitive and sensory limitations. Poor vision is actually his chief concern, and this should be tested. Does he have a primary cognitive disability, a dementia process, or pseudodementia? To answer this question, more may be required than performing a Mini-Mental State Examination (MMSE) and depression evaluation. A borderline MMSE score may be confusing because the MMSE score is influenced by education level and limited literacy skills may directly decrease a patient's score (eg, read a sentence, serial 7s).[52] Does he have a psychological (ie, chronic "deniabetes") barrier? Similarly, it would be useful to understand more about his current social milieu. The answers to these questions may alter any other potential interventions.

Mr J should be asked to identify his goals for his medical care, and any gaps that may exist between his goals and his actual self-care activities should be discussed. In this setting, there might be opportunities to examine issues comparing his views with the allopathic model of chronic disease and secondary prevention. Although this approach has not been evaluated in clinical trials, it may lead to an opportunity for his clinicians to compare their goals for Mr J with his own stated goals and potentially to negotiate common ground.

It would be reasonable to ask Mr J to describe his satisfaction with his diabetes care and to compare his comments with Dr Y's degree of satisfaction. This can help clarify differences in their perceptions of how things have been going. While Dr Y is frustrated with nonadherence, Mr J is frustrated with medication adverse effects. It would be good to understand why he forgets to get medications and supplies and why he frequently does not take insulin or other medications. Although evidence has been mixed in trials of patient-centered interviewing to improve diabetes control, such an approach may improve satisfaction and communication regarding adherence.[53]

These approaches may reveal some of the barriers Mr J encounters. Individuals with limited literacy have been shown to be particularly passive in medical encounters.[54] In many clinical scenarios, the default dynamic is that patients need to assert themselves to obtain more information; unfortunately, many patients do not have the self-efficacy required. The concept of universal precautions places a duty on the clinician to affirmatively ascertain patient comprehension.[55]

It is possible that Mr J needs additional training to know what to do. This can be done with a "teach-back" assessment and educational approach,[56] which has been shown to improve asthma self-management[13] and lead to better comprehension of informed consent[57] and to be associated with better metabolic control for patients with diabetes.[58] There are 3 parts to the teach-back. In the first part, the clinician assesses the patient's comprehension (eg, "I want to make sure I explained your medicines well; let's go through each one. I'd like you to tell me how you plan to take each one."). In the second part, the clinician offers feedback that is focused on aspects not understood. In the third part, the clinician reevaluates comprehension ("closes the loop") and provides additional feedback until mastery has been exhibited. Performing the teach-back can help dispel misunderstandings and confirm comprehension but it may also help motivate Mr J in a completely different manner, as this approach exhibits that his clinicians care about him.

It is clear that with support from his former girlfriend, Mr J's medication adherence improved. It is unclear if he has the capacity for independent behavioral change to a life of improved medication adherence. Mr J's care should be made as simple as possible: simplify his medication regimen, expunge all jargon, limit the amount of information discussed per encounter, make a short, action-oriented list of steps Mr J needs to take, review and reinforce the items on his list, and make frequent contact. This is the type of scenario that highlights the potential benefits of a medical home.

It is also appropriate to remember that what Mr J is being asked to do is quite difficult and demanding. Although his medication list is medically reasonable and evidence-based, he is being asked to adhere to a regimen of 16 dose administrations of 12 different medications every day as well as several as-needed prescriptions and to use a CPAP machine. Polypharmacy is an independent risk factor for low adherence.[58] Similarly, adherence to CPAP is notoriously low, with approximately 15% adherence reported among control group participants in a Cochrane review.[59]

Some authors have described warning signs or screening tests that suggest that a patient may have limited health literacy.[60] An alternative approach for clinicians to consider is to examine themselves (and their practice environments) for evidence of unneeded complexity and barriers to effective patient empowerment and education. For example, what are the aspects of your practice that make it hard for patients to ask questions? For a large portion of patients—not just for patients with profound literacy limitations like Mr J—medical practice can be transformed to find ways to elicit questions and concerns and make patient education and empowerment a central activity of patients' health and public health care.[61]

QUESTIONS AND DISCUSSION

QUESTION: Do you think Mr J should find a clinician who speaks his dialect of English?

DR PAASCHE-ORLOW: I do not think he needs a clinician who speaks a different dialect. I would not disrupt the good relationship he has with his physicians but might recommend bringing other individuals into the conversation to see if together Mr J and his girlfriend—and anyone else who could be supportive—might be willing to help him improve his adherence. Although studies about mobilizing family support or peer mentors for diabetes self-care have had mixed outcomes, this still seems like a reasonable approach.[62,63] This would be a big commitment for all involved. Guideline-concordant care for Mr J would likely take several hours a day.[64]

QUESTION: Where would you focus resources? You've talked about both patient factors and basic education as well as physician and system factors. Should clinicians be offering basic health education and literacy as courses for patients or should they focus on patient-physician communication, changing the systems so that they will be accessible and available to limited-literacy patients?

DR PAASCHE-ORLOW: It is hard to choose, and there may be opportunities at all levels. Most of my intervention work to date has been with nonphysician practitioners. It has been much easier for me to train nurses or clinical pharmacists to do the "teach-back" method than to change physicians' behavior. In addition, a lot of documents get thrown at people. Materials need to be markedly simplified and supported by interactive personalized education. I don't think we should regard quality communication as a limited resource. Part of the idea of the medical home is to create a model of care with efficient use of physician extenders to expand patient education and support chronic disease management.

QUESTION: What are your thoughts about the use of multimedia and the Internet with patients?

DR PAASCHE-ORLOW: The first question is "For what purpose?" At this point, there has been an explosion of health information technology activity, but I worry that this is actually likely to increase disparities in the short term.[65] If we can figure out how people with limited health literacy will be able to access such interventions and if we can design easy-to-use interfaces for people with limited health literacy, then maybe we can decrease health disparities down the road. I think it's probably best to use resources to help those who are failing and to focus on the specific issues that each person faces. Multimedia is not always better.[66]

QUESTION: I wonder about closing the loop in the teach-back process you describe. In some ways it can be like an assessment tool when the patient can't close the loop. If you can't close the loop in your session, do you

have a standardized resource or protocol to turn to at that point?

DR PAASCHE-ORLOW: It is quite rare to be unable to close the loop and confirm comprehension. When evaluating comprehension, for instance for use of an inhaler, one sees what the patient's skill level is and provides directed feedback. This typically works. I conducted a study in which we tried to teach to the point of mastery, to close the loop with the inhaler, and almost everyone could be trained.[13] Also, it took about the same number of times around the loop for patients both with limited and with higher health literacy.

Conflict of Interest Disclosures: Dr Paasche-Orlow has completed and submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. He reports receiving funding from multiple grants from the Agency for Healthcare Research and Quality, National Institute on Aging, National Heart, Lung, and Blood Institute, National Cancer Institute, and National Institute on Minority Health and Health Disparities to conduct research in the area of health literacy.
Additional Contributions: We thank the patient and his physician for sharing their stories and for providing permission to publish them.

Assessment

ABSTRACT

Web-based screening and brief interventions that include personalized feedback about their alcohol use have proven to be particularly promising for reducing hazardous drinking among university students. Despite the increasing use of these approaches, there is still relatively little known about how the content of these interventions may influence outcomes and who may benefit most from these approaches. The current study sought to address these issues by examining how individual differences in alcohol consequences influence outcomes of a laboratory-based computerized intervention.

Methods: One-hundred and nineteen introductory psychology students who either had two episodes of heavy episodic drinking in the past month or scored ≥8 on the AUDIT participated in this randomized controlled trial for course credit. Participants were assigned to 1 of 4 conditions in this 2 Intervention (Alcohol Feedback vs. Control)×2 Assessment (Motivational Assessment vs. No Motivational Assessment) between-subjects design. Quantity of alcohol consumed per week and heavy episodic drinking one month later were the primary dependent variables.

Results: Controlling for corresponding baseline alcohol measures, hierarchical linear regression analyses showed a significant interaction between intervention condition and baseline alcohol-related consequences. For those who reported more alcohol consequences at baseline, the alcohol intervention resulted in significantly less alcohol use and fewer heavy drinking episodes at follow-up, while no difference was observed between intervention conditions for those with few baseline consequences. Assessment did not moderate intervention effects.

Discussion: These findings suggest that a feedback-based computerized intervention that includes normative information about alcohol use and consequences may be more effective for hazardous drinking students who are experiencing higher levels of alcohol-related consequences.

1. Introduction

A large proportion of college students drink in a manner that puts them at risk for alcohol related harm (Hingson, Heeren, Zakocs, Kopstein, & Wechsler, 2002; Wechsler, Lee, Kuo, & Lee, 2000). Such findings have led to increasing efforts to develop effective intervention approaches that may be widely disseminated to a population of drinkers who typically do not seek treatment or identify their drinking behavior as problematic. One of the more promising approaches has been the use of web-based, personalized feedback about alcohol use (Elliott, Carey, & Bolles, 2008). Interventions that have included alcohol feedback (e.g., comparison of participant use to descriptive norms regarding alcohol frequency and quantity) have been shown to be effective at reducing alcohol use among college students (Neighbors, Larimer, & Lewis, 2004; Walters, Vader, & Harris, 2007). In addition to providing corrective information about peer drinking norms in a salient manner, personalized feedback may be used to enhance motivation to change by making individuals aware of the discrepancies between current alcohol use behavior and personal goals, standards, and values (Walters & Neighbors, 2005).

Although there is increasing evidence that students may be responsive to feedback-based interventions for alcohol use, there are a number of unanswered questions regarding how to optimize the efficacy of these approaches. Feedback-based interventions for college students have included different types of information (e.g., drinking norms, costs, and consequences) that have been delivered over varying durations. Despite the wide range of available interventions for college students, there is relatively little known about what information is most effective for promoting change in alcohol use behavior and whether this information may depend on individual differences (Carey, Scott-Sheldon, Carey, & DeMartini, 2007; Elliott et al., 2008; Zisserson, Palfai, & Saitz, 2007).

Previous work has suggested that students who are heavier drinkers may be more responsive to brief alcohol interventions (see Elliott et al., 2008; Murphy et al., 2001), as heavier drinking students may be more influenced by information provided in feedback and have greater discrepancies with perceived drinking norms. The main objective of the current study was to examine the question of whether a web-based alcohol intervention that provided personalized feedback about both alcohol use and alcohol-related consequences would be differentially effective for hazardous drinkers who had experienced more frequent alcohol-related consequences. A secondary objective of this study was to examine whether assessments would differentially influence the effect of the intervention. Given previous work on assessment reactivity effects (e.g., Kypri, Langley, Saunders & Cashell-Smith, 2006; Walters, Vader, Harris, & Jouriles, 2009), we sought to examine whether the influence of the intervention would be moderated by whether students completed additional assessment instruments about psychological processes related to alcohol use and change.

2. Methods

2.1. Participants

Hazardous drinking students (30% male) volunteered to participate in the present study as part of their introductory psychology class. The study was approved by the institutional review board and students provided written informed consent. One hundred and nineteen students were enrolled in the study based on screening instruments completed in the first month of the academic year as part of a "health behaviors and college life" study. Hazardous drinking students were identified as those who either (1) consumed alcohol in the past month and scored 8 or above on the Alcohol Use Disorders Identification Test (AUDIT) (Saunders, Aasland, Babor, de la Fuente, & Grant, 1993) or (2) reported two or more heavy drinking episodes in the past month. In the current study, the mean age of students was 18.6 years (SD = 1.45). Ethnic/racial minorities comprised 20.5% of the sample (5% Hispanic, 14% Asian/Pacific Islander, and 1.5% Black).

2.2. Measures

Students completed some assessments by computer and others using pencil-and-paper. Computerized alcohol assessments provided the basis for feedback delivered to students in the alcohol intervention condition. Alcohol use and consequence measures were delivered by computer while other alcohol variables were assessed using paper and pencil. Quantity of alcohol use and heavy drinking episodes (five or more drinks for males and four or more for females) in the past month were assessed with the Daily Drinking Questionnaire-Modified (Dimeff, Baer, Kivlahan, & Marlatt, 1999). Alcohol-related problems were assessed with the Young Adult Alcohol Problems Screening Test-36 (YAAPST-36; Hurlbut & Sher, 1992). In the present study, students were asked to report the presence of problems [Y/N] over the past month. Students also completed six questions about general health-behaviors (i.e., sleep, smoking, exercise, and diet).

2.3. Procedure

Students completed screening questionnaires on health behaviors during the first month of the academic year. Those who were hazardous drinkers were scheduled for another appointment within 7 days. At this baseline session, hazardous drinkers were randomized to one of 4 conditions based on the 2 Intervention × 2 Assessment factorial design. Following alcohol assessment, those in the Control condition were provided with information on health guidelines for sleep and consumption of fruits and vegetables. Those in the Intervention condition were provided with personalized feedback about norms of total consumption and heavy drinking episodes that were university and gender specific. The intervention also included norms about low frequency alcohol-related consequences (<40%) which were personalized by highlighting specific consequences identified by each student. Finally, the intervention provided information about costs and calories associated with use (e.g., Walters et al., 2007) and information about peak blood alcohol levels associated with heavy drinking episodes. Half of the participants in each condition completed an additional series of assessments designed to assess alcohol-related motivational variables. Some measures were completed prior to the computerized screening, namely the Drinking Motives Questionnaire (Cooper, 1994) and the Alcohol Outcome Expectancies Scale (Leigh & Stacy, 1993). Other measures were completed after the intervention, specifically, (1) the Readiness to Change Questionnaire (Rollnick, Heather, Gold, & Hall, 1992), (2) the Alcohol Use Discrepancy (McNally, Palfai, & Kahler, 2005), and (3) a goal striving measure on which students listed 8 personal life goals then rated the degree to which their alcohol use facilitated or inhibited each of these strivings (e.g., Cox & Klinger, 2004; Simons, Christopher, & McLaury, 2004). Upon completion, students were scheduled for follow-up appointments to complete an additional set of alcohol measures 1-month later which served as the primary dependent measures.

3. Results

3.1. Alcohol involvement at baseline

At baseline, students reported a mean of 12.14 (SD = 7.2) drinks per week, 5.3 (SD = 3.2) heavy drinking episodes in the past month, and 6.40 (SD = 3.8) alcohol-related consequences in the past month. Of the 119 students, 77% had AUDIT scores of 8 or greater. There were no differences by intervention or assessment condition at baseline on these variables.

3.2. Weekly drinking

Hierarchical linear regression analysis was used to examine whether the effects of the intervention on weekly drinking was moderated by negative consequences. Intervention and Assessment conditions and gender were all dummy coded and the alcohol consequence variable was centered prior to calculating the interaction terms (Cohen & Cohen, 1983). Gender and weekly drinking at baseline were entered in the first step, followed by Intervention, Assessment, and Consequences on the second step. Two-way and three-way interactions were entered on steps three and four respectively. No gender interaction effects were observed in these analyses.

Analyses of the influence of intervention on number of drinks per week on Step 2 showed a significant effect of intervention on follow-up alcohol consumption, beta = −.10, $p < .05$, but no main effect of Assessment, beta = −.06, $p = .24$. However, this intervention effect was qualified by an interaction with baseline alcohol-related consequences, beta = −.18, $p < .05$. This interaction, which is depicted in Fig. 1, showed that the intervention was associated with less alcohol use at follow-up than the control condition for those with high levels of alcohol consequences but not those with low levels. Simple slope analyses showed that students with high levels of alcohol-related consequences (+1SD) exhibited significantly less drinking when exposed to the intervention condition B [SE] = −3.93 [1.068], t = −2.03, $p < .05$, whereas those who had few alcohol-related consequences (−1SD) did not, B [SE] = .71 [1.01], t = .57, p = ns. The Assessment × Intervention interaction was not significant, beta = .004, $p = .94$, nor was the assessment condition interaction with consequences, beta = .04, $p = .504$.

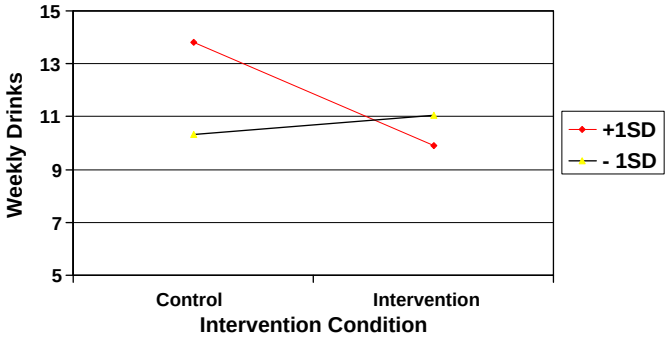

Fig. 1. Weekly total alcohol consumption at 1 month follow-up by intervention condition and baseline alcohol-related consequences.

3.3. Heavy episodic drinking

Examination of heavy drinking episodes at follow-up showed little difference between groups (Intervention M = 4.39; SD = 3.03; and Control M = 4.37; SD = 3.23). Although regression analyses did not show a main effect of intervention on heavy drinking episodes, beta = −.01, p = ns, the intervention × consequences interaction was significant, beta = −.28, p < .01. As shown in Fig. 2, the intervention appeared to influence heavy episodic drinking differentially for those with higher levels of baseline consequences. Simple slope analysis showed that students with high levels of alcohol-related consequences (+1SD) exhibited significantly fewer heavy drinking episodes when exposed to the intervention condition, B [SE] = −1.197 [.50], t = −2.29, p < .05, whereas the simple slope analysis was not significant for those with lower levels of alcohol-related consequences (−1SD), B [SE] = .93 [.51], t = 1.84, p = ns.

4. Discussion

The current study suggests that providing web-based personalized feedback about alcohol use and consequences may be a particularly effective strategy for reducing alcohol use among hazardous drinking students who have experienced high levels of alcohol-related negative consequences. Hazardous drinkers who reported high levels of alcohol-related negative consequences showed less weekly alcohol use and heavy episodic drinking if they were exposed to the alcohol intervention compared to controls. These results parallel previous work that suggests that those who experience higher levels of alcohol involvement may experience feedback as more relevant and salient (e.g., Murphy et al., 2001). Computerized feedback about norms for alcohol use and alcohol-related consequences among peers may have particular impact for students who have experienced a number of alcohol-related consequences. These students receive personally salient information that suggests that most students do not drink as much as they do and also that most students do not have the same number of negative alcohol outcomes (e.g., blackouts).

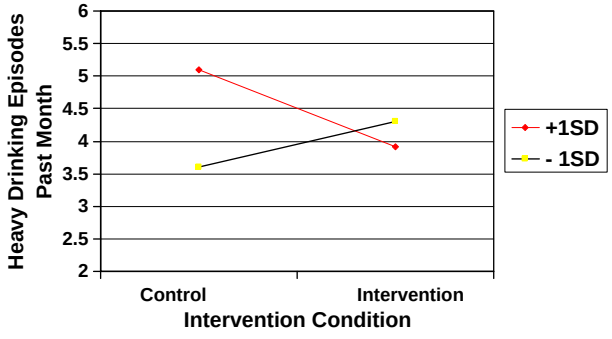

Fig. 2. Heavy drinking episodes at 1 month follow-up by intervention condition and baseline alcohol-related consequences.

Conversely, those who experienced low levels of alcohol-related negative consequences did not appear to benefit from the intervention. The findings of this study are consistent with the view that web-based interventions for hazardous alcohol use may be more efficacious if they are tailored to individual risk factors. Students may be more likely to attend to information that is relevant to personal risks which may be more likely to promote behavior change. For those who do not share those risks, however, the addition of information associated with alcohol risks may be ineffective or even detract from intervention elements. Clearly, these data cannot address this point directly as these are issues that must be explored in more detail through dismantling studies (e.g., Walters et al., 2009) to better understand how specific intervention components may interact with individual differences.

Analyses of assessment effects did not show a main effect nor was there a significant interaction between assessment and intervention. It should be noted that the comparison of assessment conditions in this study focused on the differences in the extent of motivational assessment as all participants completed multiple measures of alcohol use and problems. As a number of studies have shown that assessment may influence alcohol outcomes (e.g., Kypri et al., 2006; Walters et al., 2009) the field would clearly benefit from a more careful analysis of how the assessment of specific variables (e.g., use, problems, and psychological processes) may influence drinking outcomes and interact with the intervention effects.

In sum, web-based interventions provide a promising approach to decrease hazardous drinking among students as they expand the base of students that may be reached with screening and brief intervention approaches and provide increased flexibility for the intervention content that may be delivered. Better understanding of how intervention content may be tailored to student differences in order to maximize reductions in hazardous drinking remains a central issue in this field (Carey et al., 2007).

Role of Funding Sources

Funding for this research study was provided in part by NIAAA Grant P60 AA013759 (David Rosenbloom, PI). NIAAA had no role in the study design, collection, analysis, interpretation of data, writing of the manuscript, or decision to submit the paper for publication.

Contributors

The first author contributed to all aspects of the research including the study design, intervention development, analysis and manuscript writing. Author #2 contributed to the study design and writing of the manuscript. Author #3 contributed to the intervention development, analysis planning, and writing of the manuscript.

Conflict of Interest

There are no conflicts of interest for any of the authors.

Patient Navigation to Increase Mammography Screening Among Inner City Women

Christine E. Phillips, MD, Jessica D. Rothstein, BA, Kristine Beaver, MPH, Bonnie J. Sherman, PhD, Karen M. Freund, MD, MPH, and Tracy A. Battaglia, MD, MPH

Women's Health Unit, Section of General Internal Medicine, Department of Medicine, and Women's Health Interdisciplinary Research Center, Boston University School of Medicine, Boston, MA, USA.

BACKGROUND: Lower mammography screening rates among minority and low income women contribute to increased morbidity and mortality from breast cancer.
OBJECTIVE: To evaluate the effect of a patient navigation intervention on adherence rates to biennial screening mammography among women engaged in primary care at an inner-city academic medical center.
DESIGN: Quality improvement intervention with a concurrent control group, conducted from February to November of 2008.
STUDY SUBJECTS: All women in a hospital-based primary care practice aged 51–70 years. Subjects were randomized at the level of their primary care provider, such that half of the patients in the practice received the intervention, while the other half received usual care.
INTERVENTIONS: Intervention subjects whose last mammogram was >18 months prior received a combination of telephone calls and reminder letters from patient navigators trained to identify barriers to care. Navigators were integrated into primary care teams and interacted directly with patients, providers, and radiology to coordinate care. Navigators utilized an electronic report to track subjects. Adherence rates to biennial mammography were assessed in intervention and control groups at baseline and post-intervention.
KEY RESULTS: A total of 3,895 women were randomized to intervention (n=1,817) and control (n=2,078) groups. Mean age was 60, 71% were racial/ethnic minorities, 23% were non-English speaking, and 63% had public or no health insurance. At baseline, there was no difference in mammography adherence between the control and intervention groups (78%, respectively, p=0.55). After the 9-month intervention, mammogram adherence was higher in the intervention group compared with the control group (87% vs. 76%, respectively, p<0.001). Except among Hispanic women who demonstrated high rates in both the intervention and control groups (85% and 83%, respectively), all racial/ethnic and insurance groups demonstrated higher adherence in the intervention group.
CONCLUSIONS: Patient navigation improves biennial mammography rates for inner city, low income, minority populations.

KEY WORDS: mammography screening; patient navigation; quality improvement; disparities; women's health.

INTRODUCTION

Breast cancer remains the second leading cause of cancer-related death in women; in 2009, breast cancer was responsible for an estimated 40,170 deaths in the United States[1]. While advances in early diagnosis and treatment contribute to the overall decline in breast cancer mortality, certain vulnerable populations, including racial/ethnic minorities and the poor or uninsured, are burdened with a disproportionate share of this mortality[2]. The etiology of these disparate outcomes is complex, yet delays in diagnosis and treatment have been demonstrated to play a role[3–6]. Breast cancer screening rates among medically underserved populations, including the uninsured [7] and non-Whites[3], remain substantially lower than among insured white populations.

In an effort to reduce these cancer disparities, interventions to improve mammography utilization have been tested in diverse settings, with varying success. The most effective programs have incorporated multiple strategies that target individual and system barriers[8]. Patient navigation is emerging nationally as a culturally tailored, system-based intervention that targets individual barriers in an effort to reduce cancer health disparities[9]. A growing body of literature has documented the success of navigation after an abnormal screening test is identified[10–14], but the evidence for improving mammography utilization is limited to non-generalizable target populations[15,16] or lack of rigorous control groups[17]. The purpose of this study was to examine whether a quality improvement patient navigation program could improve adherence to biennial mammography screening in a safety-net practice that

serves a largely minority, inner-city, and underinsured patient population.

METHODS

We implemented a quality improvement patient navigation intervention in 2008 to improve mammography utilization as defined by HEDIS (Healthcare Effectiveness and Data Information Set) criteria[18] among patients served in the three internal medicine practices of an academic safety-net hospital in Boston. Due to limited resources of navigators' time and the need to address a large population, navigation could not be offered to all eligible patients at the time of program implementation. In order to equitably provide services and provide an equivalent comparison group for our evaluation, we randomized at the level of the provider to initially target half the population, since randomization at the practice level may be imbalanced because of system and provider characteristics. At the end of 9 months, the concurrent control group also received the navigation services. We report here findings from the initial 9-month intervention (February–November 2008) period. The Boston Medical Center Institutional Review Board approved this study.

Study Population

Eligibility was based on HEDIS criteria and included women aged 51 to 70 who were assigned a primary care provider and had a documented visit with that provider in the previous 2 years. Women were excluded if they had documentation of bilateral mastectomy. Prior to randomization, providers were stratified into high (≥50%) versus low (<50%) HEDIS scores to balance the intervention and control groups. At baseline, provider HEDIS scores had a median value of 76% (interquartile range of 68%–82%). Half of each group of practicing providers was then randomly selected to have their eligible patients enrolled into navigation. Patients of four providers were excluded because they had five or fewer eligible patients indicating that they were not actively practicing primary care at the initiation of the study.

Patient Navigation Intervention

Navigation services targeted only women in the intervention group whose last documented mammogram was more than 18 months prior at any point during the intervention period. Three patient navigators were hired based on experience providing navigation services[10] for diverse, inner-city patients and knowledge of existing local health systems. Each completed national[19] and local navigation training programs[20] that emphasize barriers-focused culturally tailored services based upon the care management model[21]. Two were bilingual such that one spoke fluent Spanish and another fluent Portuguese and Cape Verdean Creole in addition to English.

The navigation protocol[21] included four main activities: (1) use of an electronic medical record (EMR)-based tracking system to identify eligible women, (2) identifying and (3) helping overcome individual barriers to care, and (4) tracking women through completion of mammograms. Navigators were incorporated into the primary care team in that they had regular contact and interaction with the provider about specific patient care issues. Prior to initiating navigation services, the navigator reviewed eligible patients with each provider to identify known barriers to care or recommendations from providers to not initiate navigation due to comorbidities that made screening undesirable (e.g., terminal illness from another condition). Navigators completed a series of at least three outreach telephone call attempts over a 2-week period (during daytime and early evening), followed by two letters if no contact was made, the last registered, to inform women of their need for a mammogram and the availability of the navigator to support them (see Appendix online for a detailed navigation protocol flow sheet). Upon contact, navigators inquired about individual barriers to accessing care—including but not limited to transportation issues, work scheduling conflicts, and fear—and then utilized available resources to address those barriers. The language line was available for interpreter support for non-English-speaking women if the navigator did not speak their native language. Navigators were granted scheduling access to radiology to schedule a mammogram directly.

An electronic system was developed for navigators to track patients over time. The tracking system organized women by time since the last mammogram, easily demonstrated how many telephone calls or letters had been completed as part of the protocol, and highlighted the next step needed for the protocol. When the navigator completed the entire protocol, the reason for non-adherence was documented, the provider was notified, and that subject was removed from the tracking list. Once a subject completed the mammogram, results were documented, and navigation was ended if the results were normal. Tracking of abnormal results was continued until a diagnosis was reached and the provider was aware of the results.

Data Collection

Socio-demographic data were collected directly from the electronic administrative database SDK® (Software Development Kit) and included age, race/ethnicity, health insurance coverage, primary language, marital status, and education level. Race/ethnicity was collected using a single question asked by registration clerks and has previously been shown to correlate with patient self-report in a similar population[22]. The database collapsed Portuguese Creole and Cape Verdean Creole into one category, and we report these two languages together with Portuguese in order to account for language concordance between the navigator and the patients. All commercial and employer-based insurance plans were coded as private insurance. Public insurance consisted of Medicaid, Medicare, or Commonwealth Care, the Massachusetts subsidized health insurance plan which began in November 2006[23]. Uninsured patients were covered primarily through the Massachusetts uncompensated care pool or the Centers for Disease Control breast cancer screening program[24]. We collapsed public insurance and uninsured into one category because both groups received coverage for screening mammography.

Clinical data were obtained electronically from the medical records in the Centricity® EMR. Using ICD-9 billing codes in the past 24 months, we calculated the Charlson comorbidity score[25] using the Deyo method[26]. Completion of screening mammography was determined by electronic query of the EMRs that search patient charts for evidence of an internal radiology report or outside films received. The HEDIS criterion[18] for mammography adherence was defined as completion of a bilateral screening mammogram in the past 24 months.

Navigators documented all activities in an electronic template within the EMR. These logs included the number of encounters and type of patient contacts and reason for non-adherence for those with outstanding mammograms (i.e., unable to contact, moved or transferred care, declined services, comorbidities that made screening undesirable, insurance issues, and did not keep appointment on two or more occasions).

Data Analysis

Descriptive statistics on patient socio-demographics were performed for all eligible subjects in the intervention and control arm. Statistical differences were identified using the chi-square test or t-test.

Unadjusted rates of adherence to biennial screening mammography were compared for the intervention and control groups at baseline and post intervention time periods. Unadjusted logistic regressions were performed for each demographic subgroup for the post intervention groups, while adjusted logistic regressions were performed for both time period groups. Regressions modeled adherence to biennial screening mammography (bivariate), and to control for the influence (clustering effect) of each provider on the association between the outcome and intervention group, models were performed using GEE (generalized estimation equation) logistic regression controlling for clustering on the provider level. Adjusted models controlled for all socio-demographic variables.

Adherence rates for intervention and control groups by the interval from their last mammogram at study initiation were computed along with adjusted models for each interval and group, also controlling for clustering on the provider level.

All tests were two-tailed, with a statistical significance level set at p=0.05. Individual regressions were performed for each socio-demographic variable in order to assess the benefit of the intervention for specific subgroups of the sample. All data were analyzed using Statistical Analysis System version 9.1 (SAS Institute, Cary, NC).

RESULTS

A total of 3,895 women were included in the study (1,817 intervention, 2,078 control). Table 1 shows baseline characteristics by control and intervention groups. The average age in the total population was 60 years (SD 5 years). Most women were from racial/ethnic minority groups (47% African American, 11% Hispanic). Primary language was English for most (77%), while 9% spoke a non-English language also spoken by the navigator (Spanish, Portuguese, and Cape Verdean Creole) and 14% required a interpreter services support. The majority had a public form of insurance and low educational attainment, with 7% never attending school and 34% not completing high school. Most (64%) were not married, and 34% had a Charlson comorbidity score[25] of one or greater. There was a greater percentage of Hispanic and Spanish-speaking women in the control group compared with the intervention group, reflecting that Hispanics are clustered with specific provider panels and not randomly distributed in the practice. There were two Spanish-speaking providers, one randomized to the intervention and the one to the control group.

Table 2 shows the unadjusted adherence rates and the adjusted odds ratios for mammography adherence between intervention and control patients at baseline and post intervention. At baseline, adherence rates were the same for the intervention and control groups, 78% respectively. By the end of the 9-month intervention, 87% of patients in the intervention group demonstrated biennial mammography adherence compared to 76% in the control group. After adjusting for all socio-demographic variables and using cluster analysis to adjust for provider, the odds of adherence in the intervention group was 2.5 (95% CI, 1.9–3.2) compared with the control group. Table 3 shows the odds ratios, across each demographic subgroup, for mammography adherence between intervention and control patients while clustering on the provider level, demonstrating that the intervention had a positive impact in all subgroups categorized by age, education level, marital status, insurance type, and level of comorbidity. The same was true for each racial/ethnic and language group with the exception of Hispanic women who demonstrated high baseline adherence rates in the intervention and control groups (85% and 83%, respectively).

By design, only women whose last mammogram had occurred more than 18 months ago received navigation services. Table 4 describes adherence rates for intervention and control patients by the interval from their last mammogram at study initiation in an effort to demonstrate the effect of navigation on the targeted population. This breakdown shows that the greatest improvement occurred in the two groups (18–24 months; >24 months) with the longest gaps since their previous mammography. Of those with mammograms more than 24 months before the start of the intervention, navigation adherence was 50% compared with only 17% in the control group. Navigated patients whose last mammogram had been performed more than 18 months but less than 24 months prior to the beginning of the intervention had an adherence rate of 74% compared with 37% of those in the control group. Women in the 12 to 18 month group are included here because a subset of them became eligible for navigation at some point during the study period, and indeed the intervention group showed a greater rate of adherence (97%) compared with the control group (93%).

Of the 1,817 women in the intervention group, 661 received navigation services with a mean of two telephone calls and one letter per subject. This resulted in 271 scheduled and 251 completed mammograms. Of these mammograms, 6% were abnormal [Breast Imaging Reporting and Data System (BIRADS) 0, 3, 4, or 5]. No cancers were identified during the 9-month study period. Of the patients randomized to the navigation group who remained non-adherent at the conclu-

sion of the study, 61% could not be contacted despite multiple telephone calls and letters, 14% moved or transferred care to another facility, and 14% declined mammography.

DISCUSSION

Using a comparable continuous control group, our study demonstrates the impact of a patient navigation program in primary care at achieving expected mammography screening rates in a diverse inner-city underserved population. With the exception of Spanish speakers and the Hispanic population, who at baseline had high rates, the navigation intervention increased adherence across all ages, insurance groups, education levels and all other languages and races. Our study design, evaluating a quality improvement navigation program in an entire practice of vulnerable patients, demonstrates the feasibility of adopting this method of care to a clinical setting that mirrors urban safety net settings throughout the country.

Our findings of improved mammogram utilization with a patient navigation intervention are consistent with existing literature[15–17]. Dignan and colleagues[15] showed improved adherence to mammogram screening over an 18-month period in a randomized controlled trial (RCT) of 157 Native American women utilizing direct patient contact or telephone calls versus a control group. Paskett and colleagues' RCT[16] of 851 subjects also showed improved adherence of mammogram screening in a rural, low income population of white, African American and Native American subjects. Han and colleagues' study[17] utilized patient navigation to improve mammogram adherence of 102 Korean American women after 6 months, but lacked a control group for comparison. Our study findings, designed as a practice improvement within an urban safety-net setting, included a more diverse, yet vulnerable population and thus provide further evidence for the generalizability of navigation as a means to reduce cancer health disparities.

At baseline, more Hispanic and Spanish-speaking women were present in the group allocated to the control group, reflecting that patients are not randomly distributed throughout the practice, but rather are more likely to be seen by Spanish-speaking providers. Prior research has shown both lower[27,28] and higher[29,30] mammography screening rates among Hispanic as compared with white women and may reflect a variety of local factors, including the community's overall acculturation and education levels, as well as access to insurance and to bilingual health care providers.

Our study was developed to improve HEDIS rates as a quality improvement project within primary care and thus

performed as a population-level analysis. The study design responded to a growing emphasis on HEDIS rates as a quality performance measure of individual providers. Interventions like this patient navigation program are becoming increasingly important in order to ensure that practices serving populations with historically lower screening rates achieve benchmarks, both for patient care and for practice reimbursement under pay-for-performance plans. One strength of our study is that it was integrated into the practice with provider "buy-in," and was designed to evaluate the benefit and effectiveness of integration of this type of program into a busy primary care practice. As such, this model of care fits the Medical Home Model, which is increasingly recognized as a standard way to transform care delivery in primary care settings[31–34].

We designed our intervention to improve our practice HEDIS measures of biennial screening for all women 51–70 years of age, at a time when the providers were recommending annual screening. Best practice guidelines for patient navigation and timing of the intervention have yet to be defined as reflected by the different intervention protocols implemented in prior studies. Paskett and colleagues[16] navigated those ≥12 months overdue for a mammogram and followed them for an additional 12–14 months, while Han and colleagues[17] navigated women 2 years overdue and followed up at 6 months. Dignan and colleagues[15] navigated for patients 18 months overdue. We chose to initiate navigation after an 18-month screening interval and found this to be an effective strategy in the rational use of the navigator resources, as evidenced by the fact that our greatest effect of the intervention was seen among the groups with the longest time interval since their last mammogram. Even with changes in recent guidelines, our protocol is consistent with recommended mammography frequency in this age group[27,35–37]. There is still a subset of women who remain non-adherent to mammography screening using this protocol; the majority of these women were not reachable by phone or mail based on available contact information. This reflects

Table 4. Mammography Adherence by Time Since Last Mammogram for Control and Intervention Subjects with Adjusted Patient Navigation Intervention Odds Ratios

	Control		Intervention		
Time since last mammogram at baseline	N	Subjects adherent post intervention	N	Subjects adherent post intervention	Adjusted OR (95% CI)*
>24	447	78 (17)	405	202 (50)	5.6(3.9–8.2)
18–24	126	47 (37)	89	66 (74)	6.0(2.8–12.7)
12–18	626	585 (93)	547	531 (97)	3.5 (1.8–6.5)

communication challenges in caring for an inner city, at-risk population and suggests a different approach is necessary for this group.

Our study is somewhat limited in its generalizability because it was conducted in only three practices at a single academic safety net institution and required the use of an EMR and information technology support. However, our system reflects standard EMR support and practice systems that have become federal mandates[38,39]. Due to limited resources, we were unable to assess costs of the program or patient or provider satisfaction, all of which are crucial to sustainability of such programs.

Our findings support the benefit of patient navigation programs in the primary care setting as one approach to reduce cancer health disparities. While financial support is necessary for primary care providers to develop and maintain such programs, the Medical Home Model[31–34] could be one venue to provide the infrastructure and personnel necessary for sustainable navigation implementation. Health care policy-makers should continue to explore advocacy efforts in order to determine how to sustain these programs.

Hylek, MD, MPH,[f] Peter R. Kowey, MD,[g] Kenneth W. Mahaffey, MD,[a] Laine E. Thomas, PhD,[a] Melissa H. Kong, MD,[a] Renato D. Lopes, MD, PhD, MHS,[a] Roger M. Mills, MD,[h] and Eric D. Peterson, MD, MPH[a,i] *Durham, NC; New York, NY; Boston, MA; Los Angeles, and Oakland, CA; Rochester, MN; Wynnewood, PA; and Raritan, NJ*

Background Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia and is associated with an increased risk of stroke, heart failure, and death. Data on contemporary treatment patterns and outcomes associated with AF in clinical practice are limited.

Methods/Design The Outcomes Registry for Better Informed Treatment of Atrial Fibrillation is a multicenter, prospective, ambulatory-based registry of incident and prevalent AF. The registry will be a nationwide collaboration of health care providers, including internists, primary care physicians, cardiologists, and electrophysiologists. Initial target enrollment is approximately 10,000 patients to be recruited from approximately 200 US outpatient practices. Enrolled patients will be observed for ≥2 years. A patient-reported outcomes substudy in ≥1,500 patients will provide serial quality-of-life assessments. The goal is to characterize treatment and outcomes of patients with AF, thereby promoting better quality of AF care and improved patient outcomes.

Conclusion The Outcomes Registry for Better Informed Treatment of Atrial Fibrillation will provide insights into "real-world" treatment including rate and rhythm control, stroke prevention, transitions to new therapies, and clinical and patient-centered outcomes among patients with AF in community practice settings (ClinicalTrials.gov NCT01165710). (Am Heart J 2011;162:606-612.e1.)

Atrial fibrillation (AF) is the most common sustained arrhythmia in the United States. By 2020, an estimated 7 million Americans will have AF.[1] Atrial fibrillation is associated with significant morbidity and mortality[2-4]; in particular, it increases the risk for stroke by 2- to 5-fold[5] and impairs quality of life in many patients. In economic terms, AF has a significant impact on the US health care system; treatment of newly diagnosed AF costs the Medicare program >$15 billion annually.[6]

New therapies for both stroke prevention and rhythm control are emerging from phase III trials, but data on their clinical effectiveness and safety outside clinical trial settings are lacking.[7-9] Randomized, controlled trials include selected populations, often enrolling patients with a lower burden of comorbid disease and excluding those with severe or end-stage comorbidities; thus, results of these trials may not translate well into contemporary clinical practice populations.[10,11] In addition, clinical trial participants are often treated by disease experts using standardized study protocols with frequent monitoring and closer follow-up than would be observed in routine clinical practice.

The Outcomes Registry for Better Informed Treatment of Atrial Fibrillation (ORBIT-AF) is a prospective, multicenter, outpatient registry that will identify treatment patterns of AF and variation in contemporary clinical practice according to patient demographics, clinical factors, risk stratification, provider specialty, and geographic region. Patient health status, health resource use, and clinical outcomes will be collected for ≥2 years of follow-up. This registry will focus on the adoption, use, effectiveness, and safety of novel and emerging treatments for AF, including antithrombotic therapy for stroke prophylaxis. The registry is also designed to identify reasons and predictors for lack of anticoagulation in appropriate candidates as well as noncompliance, quality

Table I. The ORBIT-AF enrollment criteria

Inclusion criteria	Exclusion criteria
Age ≥18 y	Anticipated life expectancy <6 m
Incident or prevalent AF with electrocardiographic documentation	Transient AF secondary to a reversible condition (eg, hyperthyroidism, pulmonary embolism, postcardiothoracic surgery)
Anticipated ability to adhere to regularly scheduled follow-up visits	Employee or immediate family member of the investigator/study center
Signed informed consent document indicating that patients understand the purpose and procedures of the study and are willing to participate in the registry	Current enrollment in a randomized clinical trial of antithrombotic therapy for AF

of care (time in therapeutic range), and discontinuation of therapy. Finally, ORBIT-AF will assess the adoption and use of AF therapies in an era marked by multiple, novel, emerging pharmacologic and nonpharmacologic interventions for the maintenance of sinus rhythm, including antiarrhythmic drug therapy and catheter ablation.

Methods

Registry objectives

The ORBIT-AF registry has 5 main objectives: (1) characterize and describe a large representative AF population in the United States, including demographics, comorbidities, and risk profiles; (2) define current practice patterns for the treatment of patients with AF, particularly stroke prevention therapies; (3) identify how patterns of care and subsequent outcomes vary by risk stratification (ie, low risk vs high risk), including existing and novel risk prediction schema; (4) assess adherence and resource use associated with current anticoagulant prophylaxis as recommended by current guidelines[12,13]; and (5) assess the adoption and impact of emerging antithrombotic and antiarrhythmic therapies on outcomes in AF, including patient-reported outcomes (PRO) and health care resource use.

Site selection

To ensure inclusion of a broad spectrum of representative patients with AF, a variety of outpatient practices, including internal medicine, cardiology, and electrophysiology clinics, were targeted for this registry. Although investigator specialty identification represents the most robust and reproducible method to ensure site heterogeneity, geographic diversity will also be considered in final site selection and patient enrollment. To further enhance heterogeneity, an adaptive registry design will be used, allowing for modifications to the registry after study initiation without affecting its validity and integrity.[14] Approximately 200 centers are expected to participate.

Study population

Investigators will enroll consecutive patients meeting inclusion criteria (Table I). All patients ≥18 years with electrocardiographically documented AF will be eligible. Patients with atrial flutter only will not be enrolled. Upon study entry, patients will be classified by type of AF (paroxysmal, persistent, and permanent AF/long-standing persistent), per the ACC/AHA/ESC 2006 Guidelines for the Management of Patients with AF and the 2007 HRS/EHRA/ECAS Expert Consensus Statement on Catheter and Surgical Ablation of Atrial Fibrillation.[2,15] If the type of AF cannot be classified at study entry (first-detected AF), it will be categorized after follow-up evaluations.

Data collection and follow-up

The primary data source will be the medical record of each enrolled patient. Sites will transmit data via a Web-enabled case report form. Patient-reported outcome questionnaires will be administered to a subsample of approximately 1,500 patients. For patients who consent to answer PRO questionnaires, the questionnaires will be administered at the baseline visit and during follow-up visits.

Data collection will occur at 6-month intervals for a minimum of 2 years after enrollment (Table II). Data collection windows will be wide (3 months in either direction) to maximize data collection during the patients' regularly scheduled follow-up visits. Data capture will include age, sex, race/ethnicity, insurance status, education level, cardiovascular risk factors, date of diagnosis, type of AF, pharmacologic treatment strategy (rate control vs rhythm control), AF ablation history, cardioversion history, transthoracic and transesophageal echocardiographic findings, antithrombotic therapy and monitoring (international normalized ratios [INRs]), concomitant medications, insurance status and provider information, comorbidities, and outcomes. The case report form also captures the specialty of the enrolling physician and that of each physician participating in the patient's AF-related care.

Outcomes

The primary outcome event in ORBIT-AF is stroke or non–central nervous system (CNS; systemic) systemic embolism. Consistent with recent clinical trials, stroke will be defined as a new, sudden, focal neurologic deficit that persists beyond 24 hours and is not due to a readily identifiable, nonvascular cause (eg, seizure).[16,17] Primary outcome events will be verified by single-source document submission (eg, hospital discharge report) and central review at the data coordinating center. The major safety outcome of interest will be major bleeding as defined by the International Society of Thrombosis and Haemostasis.[18]

Secondary outcomes will include *major adverse cardiac events* (MACE), defined as stroke or non-CNS systemic embolism, myocardial infarction, and cardiovascular death (online Appendix A). Additional secondary outcomes will include all-cause mortality, cardiovascular death, intracranial bleeding, myocardial infarction, sudden cardiac death, heart failure–related death, AF-related quality of life, and all-cause hospitalization (subcategorized as cardiovascular; bleeding related; and noncardiovascular, non–bleeding related). Anticoagulation-related secondary outcomes of interest will include

* Sites will consecutively screen and enroll eligible patients whenever possible.
† Symptoms *include* palpitations, lightheadedness/dizziness, syncope/fainting, dyspnea at rest, dyspnea on exertion, fatigue, exercise intolerance, chest tightness/discomfort, and the European Heart Rhythm Association score.

anticoagulation-related treatment satisfaction and quality of anticoagulation as assessed by time in therapeutic range and primary discontinuation of oral anticoagulation. Use of AF-related procedures, including but not limited to transesophageal echocardiography, cardioversion, atrioventricular node ablation, pacemaker implantation, left atrial appendage closure, and pulmonary vein isolation, will also be recorded for analysis.

The INR collection will include all available prior INR measurements as recorded in the medical record for all patients receiving warfarin at enrollment. The INR measurements will also be captured prospectively in all patients.

Patient-reported outcomes: AF and anticoagulation-related quality of life

Given the prominence of quality of life considerations in AF treatment decisions, the Atrial Fibrillation Effect on QualiTy-of-life questionnaire (AFEQT; St Jude Medical, St Paul, MN) will be administered in the PRO cohort (n = 1,500) at study entry, at 12 months, and at 24 months. The AFEQT is a 20-item questionnaire assessing 3 domains of AF-related quality of life, including activity, symptoms, and treatment concerns.[19]

To determine the degree of satisfaction and quality of life in patients receiving antithrombotic therapy, the Anti-clot Treatment Scale (ACTS) questionnaire will be administered to PRO cohort patients taking an antithrombotic medication at study entry, at 6 months, at 12 months, and at 24 months. The ACTS questionnaire is a 17-item scale assessing the burdens (eg, bleeding risks, limitations, inconveniences) and benefits (confidence, reassurance, and satisfaction) of anticoagulation. For patients starting oral antithrombotic therapy at enrollment, the ACTS for incident patients will be completed and returned to the site 1 month after the patient starts anticoagulation treatment. The ACTS questionnaire will only be administered to patients receiving antithrombotic therapies.

Statistical analyses

Initial analyses will examine patient characteristics, pharmacoepidemiology, and quality of care, including guideline-based use of oral anticoagulation in eligible patients. Subsequently, attention will turn to the relationship between risk stratification, treatment, adherence, and outcomes. The association between primary and secondary outcomes, INR control, and discontinuation of oral anticoagulation will also be reported. Variables with <15% missing will routinely be imputed, although missing data will be addressed on an analysis-specific basis. Univariate and multivariable approaches will be used to identify factors associated with primary and secondary outcomes. Propensity score techniques will be used to balance comparison groups according to baseline factors.

The ORBIT-AF will also explore variation in care, including variation in performance measures for AF management, including stroke prophylaxis.[12] Characteristics of interest will include sex; race; age; prior stroke/transient ischemic attack (TIA); geographic region; socioeconomic status; $CHADS_2$, CHA_2DS_2-VASc, and HAS-BLED scores; management strategies (eg, rate control vs rhythm control, catheter ablation vs medical management, and combination therapy with antiplatelet agents); and provider specialties.[2,20,21] Pharmacologic and nonpharmacologic methods of maintaining sinus rhythm will also be analyzed in the registry. Comparative effectiveness and safety analyses will be conducted, including comparisons of individual antiarrhythmic drugs, comparisons of rhythm and rate control, and catheter ablation versus medical therapy.

Continuous variables will be summarized by medians with 25th and 75th percentiles, and categorical variables will be reported as counts with percentages. Associations will be reported using hazards ratios (for time-to-event analyses) or odds ratios (for logistic regression analyses) with 95% CIs. Statistical significance will be declared when a 2-sided α is <.05.

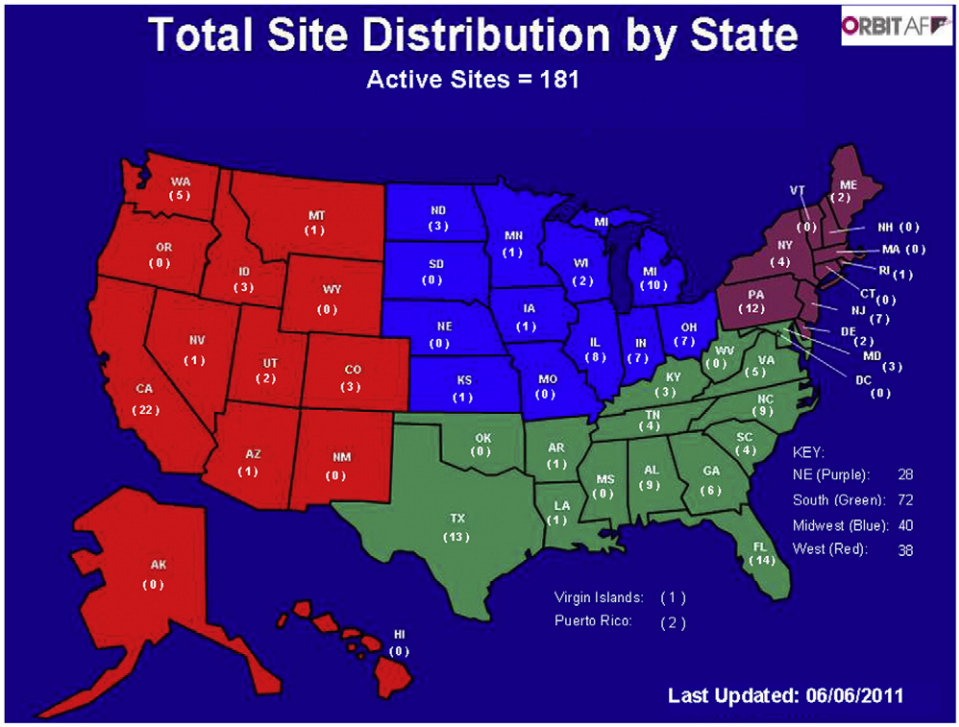
Sample size

The goal of enrolling 10,000 patients is to capture a large, representative population of patients with AF in the United States. Based on recently completed clinical trials and observational studies, we anticipate an incident stroke rate of 1.5% to 2.2% in our unselected ORBIT-AF population.[9,22,23] This would correspond to approximately 150 to 220 strokes in the first year of follow-up. We anticipate that annual warfarin discontinuation rates will range from 15% to 25% based on previous community-based studies.[24] Assuming that >50% of the cohort will be taking warfarin, we anticipate >750 therapeutic discontinuations over the first year of follow-up. This event rate will allow for even more robust model construction to identify risk factors for long-term warfarin intolerance.

Because the registry design is adaptive in nature, sample size can be modified during the course of the study to ensure adequacy of the registry to answer targeted research questions. Adaptive changes to the sample size and eligibility criteria for substudies will be considered during the late phase of patient enrollment when sufficient patient characteristic data are available to make the determination. Overall patient characteristics will be compared before and after adaptive changes to ensure that generalizability is not impaired.

The PRO substudy will compare quality of life and treatment satisfaction in 4 analytic groups (2 study groups [warfarin and

Figure 1



Geographic distribution of ORBIT-AF enrolling sites.

non-warfarin] and 2 strata [incident and prevalent]). Using the 5-point Likert scale as the basis for sample size estimation (such as the items in the ACTS), we will require 253 patients in each group to have 80% power to detect a 0.25-point difference in the mean score of an item between 2 groups (assuming an SD of unity, a 2-sided $\alpha = .05$). Accounting for the incident and prevalent strata as well as treatment discontinuation and switching, a PRO subsample of approximately 1,500 is robust for the proposed analyses.

Registry organization and funding

The study protocol was reviewed and approved by the Duke University Medical Center Institutional Review Board (IRB) and the IRB at each enrolling center. The registry is funded by Ortho-McNeil Janssen Scientific Affairs, LLC. Duke University and Duke Clinical Research Institute, along with the sponsor, will be responsible for ORBIT-AF and its design, implementation, and leadership. The Scientific Leadership Committee will include the study chair, the executive committee, and the steering committee (online Appendix B).

Results

Initial enrolling site characteristics

Given the adaptive design of the registry, the composition of the enrolling sites is continuously monitored to ensure adequate provider, demographic, and geographic diversity and representativeness. Across the United States, 161 of 181 active sites enrolled the first 7,294 patients: 58 (36%) primary care and internal medicine clinics, 86 (53%) cardiology clinics, and 17 (11%) electrophysiology clinics. At the time of this writing, 181 sites were IRB approved and activated to enroll patients. As shown in Figure 1, the sites are distributed across the United States: West (n = 38), Midwest (n = 40), South (n = 72), Northeast (n = 28), Puerto Rico (n = 2), and the Virgin Islands (n = 1).

Discussion

The Institute of Medicine has identified the management of AF as a top priority for comparative effectiveness research.[25] Atrial fibrillation increases the risk of stroke, cognitive impairment, and disability. Despite the presence of effective pharmacologic therapy for the prevention of stroke, anticoagulation prophylaxis in patients with AF is underused.[26] Because many patients with AF do not receive anticoagulation therapy or discontinue therapy within 1 year,[27] a key goal of ORBIT-AF will be to identify reasons and risk factors for nonreceipt and discontinuation of anticoagulation therapy.

Prior registry efforts

Prior registries have examined the prognosis and management of AF in clinical practice (Table III). The Euro Heart Survey on Atrial Fibrillation enrolled 5,333

Table III. Characteristics of large AF registries

	Population	Enrollment	Follow-up	Study period	No. of countries	No. of sites	Quality-of-life measures
ORBIT-AF	Outpatient	10 000	Minimum 2 y	2009-present	1 (United States)	~200	AFEQT and ACTS

ATRIA[32]	Large integrated health care delivery system	13 559	Cross-sectional	1996-1997	1 (United States)	18	None

Registries of ≥1,000 patients. The ORBIT-AF, Realise AF, RECORD AF, and AFFECTS are formal registries that prospectively enrolled patients after obtaining informed consent.

patients with AF from 2003 to 2004.[30] At baseline, 44% of these patients were taking oral anticoagulants. The international REgistry on Cardiac rhythm disORDers (RECORD AF) enrolled 5,814 patients in 21 countries from 2007 to 2008.[29] At study entry, 55% of the cohort was treated with a rhythm control strategy, 10% had a history of stroke or TIA, and 61% were receiving oral anticoagulation. The Atrial Fibrillation Focus on Effective Clinical Treatment Strategies (AFFECTS) registry enrolled 1,165 patients and found that among eligible patients ($CHADS_2$ >1), only 69% were receiving oral anticoagulation.[26] Although these and other registries have advanced our understanding of AF, they have been limited by relatively short follow-up and the absence of formal quality-of-life and other patient-centered outcomes (Table III). The ORBIT-AF will enroll ≥10,000 patients with planned follow-up of ≥2 years. This long-term follow-up will have several important advantages, including greater ascertainment of infrequent events such as stroke and intracranial hemorrhage as well as the opportunity to assess temporal changes in treatment strategies and their association with quality of life and other important outcomes.

Importance of registry data in the evaluation of emerging therapies

During the course of this registry, we anticipate that several novel antithrombotic agents will become available for the prevention of stroke in patients with nonvalvular AF. Following the results of the RELY trial in 2009, dabigatran was approved for the prevention of stroke in patients with nonvalvular AF.[7] More recently, the ROCKET-AF trial demonstrated that rivaroxaban, a novel factor Xa inhibitor, may be a safe and effective alternative to warfarin in patients with AF and moderate to high risk of stroke.[9] Additional oral anticoagulants are currently undergoing study in phase III trials, including the factor Xa inhibitors apixaban and edoxaban.[33] These anticoagulants may improve therapeutic efficacy and safety with less monitoring and inconvenience and are expected to have a substantial effect on clinical practice. Finally, nonpharmacologic interventions for stroke prevention are also under regulatory review and may reach approval; trial results suggest that left atrial appendage occlusion may be noninferior to warfarin with an acceptable safety profile in highly selected patients.[34] The ORBIT-AF will be well positioned to monitor the diffusion of these new therapies and their safety profiles in clinical practice.

New rhythm control therapies are also emerging from clinical trials. In 2009, dronedarone, a novel antiarrhythmic, was approved by the Food and Drug Administration for the reduction of cardiovascular hospitalization in the treatment of AF.[8] Catheter-based strategies for the treatment of AF continue to evolve and are being deployed in wider patient populations, including patients with heart failure.[13,35] Beyond rhythm control, new research challenges the paradigm that strict rate control leads to improved outcomes in patients relegated to a rate-control strategy.[13,36] ORBIT-AF will also provide the opportunity to examine the impact of recent guideline changes regarding rate-control recommendations.[13] Although observational data, in general, cannot inform treatment decisions regarding efficacy, registry-based analyses can address several key components of quality care, including safety, comparative effectiveness, and equity.[37] The coordinated collection of patient characteristics, laboratory parameters, concomitant pharmacotherapies, quality-of-life data, and cardiovascular outcomes will enable timely assessment of these emerging therapies in clinical practice, outside the controlled environment of clinical trials.

Quality of life in AF

Atrial fibrillation is associated with significantly impaired quality of life.[38] Accordingly, many treatment decisions in AF are predicated upon improving both short- and long-term quality of life.[2] Prior studies of quality of life have been informative but have suffered from several limitations, including relatively small sample size, restricted follow-up, and the lack of validated AF-specific qualify-of-life instruments.[39] The ORBIT-AF PRO cohort will allow for large-scale examination of AF-

related quality of life in a heterogeneous group of patients over long-term follow-up using a rigorously derived and validated quality-of-life instrument.[19] Future analyses will attempt to determine if quality of life differs according to the type/pattern of AF, treatment strategies, or comorbidity. Additional analyses will address whether these differences in AF-related quality of life (if observed) are associated with differences in physician decisions related to rhythm control and anticoagulation strategies. Similarly, the anticoagulation-related quality-of-life assessment (ACTS) may also identify monitoring strategies,[40] existing therapies, and emerging antithrombotic therapies that engender patient satisfaction and improved adherence. Taken together, the PRO data will provide much needed information regarding quality of life among patients with AF. These data can also serve as a reference population for indirect comparisons of quality of life in experimental studies or comparative effectiveness research.

Limitations

As with any observational study, this registry will have limitations. Participation in the registry is voluntary. The patients and practices enrolled may not be entirely representative. Participation in this study, particularly as a part of a quality improvement effort, may alter practice patterns at a study site.[41] However, prior studies suggest that registry observations are comparable with those for general clinical practice.[42-44]

Conclusions

Although recent advances in the treatment of AF show promise for improved outcomes, no data exist to show how the results of these trials have influenced or will influence clinical practice. Prior studies have suggested that the application of evidence-based therapies remains suboptimal in patients with AF. The ORBIT-AF registry will examine current practice patterns, quality of care, and associated outcomes in the management of AF. These data will inform comparative effectiveness, comparative safety, and future research to improve quality of life and outcomes in patients with AF.

Disclosures

The ORBIT-AF registry is sponsored by Ortho-McNeil Janssen Scientific Affairs, LLC, Raritan, NJ.

Appendix A. Event definitions

Major adverse cardiac events will be defined as the occurrence of cardiovascular death, myocardial infarction, or stroke or non-CNS (systemic) embolism. Cardiovascular death will include (but not be limited to) deaths due to heart failure, sudden cardiac death, stroke, arrhythmia, conduction disorders, vascular events, and non-CNS emboli.

Stroke is defined as a new, sudden, focal neurologic deficit, which results from a presumed cardiovascular cause that is not reversible within 24 hours and is not found to be due to a primary brain parenchymal abnormality (eg, tumor, mass-effect, primary CNS infection). Strokes will be classified as hemorrhagic or ischemic by the site investigator. Events in which symptoms do not persist for 24 hours (and without imaging evidence of infarction) will be defined as a TIA.

Myocardial infarction will be defined as clinical signs and symptoms consistent with myocardial infarction, accompanied by cardiac biomarker elevation (eg, creatine kinase–MB or troponin above the upper limit of normal).

Sudden cardiac death will be adjudicated according to the modified Hinkle-Thaler criteria, as used in several landmark cardiovascular trials. Patients who are well and (1) have a witnessed sudden collapse or (2) are found dead but were known to be alive and well in the previous 24 hours (eg, no signs or symptoms of cardiorespiratory distress) will be considered as sudden cardiac deaths.

Major bleeding will be adjudicated according to the International Society of Thrombosis and Haemostasis criteria. *Major bleeding* will be defined as clinically overt bleeding that is associated with any of the following: (1) a fall in hemoglobin level of $\geq$2 g/dL; (2) a transfusion of $\geq$2 U of packed red blood cells or whole blood; (3) bleeding in a critical site: intracranial, intraspinal, intraocular, pericardial, intra-articular, intramuscular with compartment syndrome, retroperitoneal; or (4) a fatal outcome. The 4 qualifying criteria will also be captured to allow for further classification of bleeding events.

Appendix B. Executive and steering committee members

An Executive Committee will govern the operations of ORBIT-AF. The Steering Committee will comprise the members of the executive committee as well as cardiologists, electrophysiologists, internists, and other hospital personnel from all regions of the United States. Responsibilities of the steering committee include program development, regional support and recruitment of principal investigators, participation in regional educational meetings, generation of publication topics/ideas, and participation in regional quality improvement initiatives.

The quality of care for adults with epilepsy: an initial glimpse using the QUIET measure

Mary Jo Pugh[1,2*], Dan R Berlowitz[3,4], Jaya K Rao[5], Gabriel Shapiro[4,6], Ruzan Avetisyan[4], Amresh Hanchate[7], Kelli Jarrett[4], Jeffrey Tabares[1], Lewis E Kazis[3,8]

Abstract

Background: We examined the quality of adult epilepsy care using the *Quality Indicators in Epilepsy Treatment (QUIET)* measure, and variations in quality based on the source of epilepsy care.

Methods: We identified 311 individuals with epilepsy diagnosis between 2004 and 2007 in a tertiary medical center in New England. We abstracted medical charts to identify the extent to which participants received quality indicator (QI) concordant care for individual QI's and the proportion of recommended care processes completed for different aspects of epilepsy care over a two year period. Finally, we compared the proportion of recommended care processes completed for those receiving care only in primary care, neurology clinics, or care shared between primary care and neurology providers.

Results: The mean proportion of concordant care by indicator was 55.6 (standard deviation = 31.5). Of the 1985 possible care processes, 877 (44.2%) were performed; care specific to women had the lowest concordance (37% vs. 42% [first seizure evaluation], 44% [initial epilepsy treatment], 45% [chronic care]). Individuals receiving shared care had more aspects of QI concordant care performed than did those receiving neurology care for initial treatment (53% vs. 43%; $X^2 = 9.0$; $p = 0.01$) and chronic epilepsy care (55% vs. 42%; $X^2 = 30.2$; $p < 0.001$).

Conclusions: Similar to most other chronic diseases, less than half of recommended care processes were performed. Further investigation is needed to understand whether a shared-care model enhances quality of care, and if so, how it leads to improvements in quality.

Background

While existing quality indicators have focused on a number of highly prevalent chronic conditions (e.g., diabetes, hypertension) they do not address the quality of care for less prevalent, but serious conditions, such as epilepsy. Epilepsy care presents complexity in the sense that providers must balance seizure control, adverse drug effects, and complicated issues associated with epilepsy itself (e.g. mood disorders [1-3]) while also being mindful of consequences related to long-term treatment with antiepileptic drugs (e.g. bone health [4-6]). Thus, it is important to begin examining the quality of care provided to patients with epilepsy using quality measures and identifying gaps in quality of care. The United Kingdom has begun this process [7] due to the availability of not only clinical guidelines for care for patients with epilepsy[8,9], but also quality indicators from the Quality and Outcomes Framework [7]. While no comprehensive national guidelines for care of patients with epilepsy exist in the United States, the development of the QUality Indicators for Epilepsy Treatment in adults (QUIET) allows us to begin to examine the quality of epilepsy care in the United States.

The purpose of this study is to describe the quality of care received by adults with epilepsy in a major medical center in a Northeastern US city using the QUIET indicators-quality indicators developed as part of a larger study funded by the Centers for Disease Control and Prevention (CDC; Additional file 1)-and to assess the quality of epilepsy care in primary care and general neurology settings. Similar to other countries, in the US a substantial number of patients continue to receive their epilepsy care solely within the context of primary care

Full list of author information is available at the end of the article

(55% in one study) [10]. Studies of quality of care for other chronic diseases have found better quality of care among patients receiving care from medical sub-specialists or within a shared care context [11-13]. Thus, we examine the extent to which variations exist in quality of care among patients who received epilepsy care only within primary care, only within neurology subspecialty care, and within both neurology and primary care (shared). Based on findings from previous studies, we hypothesize that patients with epilepsy are more likely to receive high quality care when they receive specialty care exclusively or have epilepsy care shared by both primary care and neurology specialty care [14-16].

Methods

Data

Data from the electronic medical record of a single medical center in the northeastern United States were used in this study to identify patients with epilepsy and assess the extent to which recommended processes of care were performed. The electronic medical record includes templates for certain aspects of care such as vital signs, medications, and lab tests. However, as progress notes are not disease specific or used for examining quality of care at the institution, they are primarily free text, which allows substantial variation in documentation of the care provided. Data were acquired from the demographic information, diagnosis codes, patient problem list, pharmacy, laboratory, inpatient, and outpatient components of the medical record. These data were entered into a specially designed chart abstraction form, and entered into a spreadsheet and exported to SPSS (Version 17.0, Chicago, IL) for subsequent analysis. This study was approved by the Institutional Review Board of the Medical Center.

Sample

Eligible participants received care at the medical center, were at least 18 years of age, able to speak English and, due to an additional component of the larger study, were able to complete a telephone interview. Probable epilepsy patients were identified by searching the electronic medical record system for all patients who had at least one ICD-9 code of 345.x or 780.39, or mention of the terms “epilepsy” or “seizure disorder” in the medical record problem list between 2004 and 2007. In order to assure there would be adequate data to assess the quality of epilepsy care we further required that individuals have two or more visits to the primary care or neurology clinics, or one visit to the primary care or neurology clinic and at least one hospitalization [17] between 2004 and 2007.

Individuals identified as eligible for the study based on diagnosis of epilepsy and who were confirmed to have epilepsy by their primary care provider or neurologist and received a letter from their physician informing them about the study and inviting their participation. Chart abstractions examining the quality of epilepsy care were completed by trained clinical chart abstractors only for those participants who contacted the study team after receiving the letter and provided written consent to participate in the study.

Quality Indicators

QUIET quality indicators were developed using the RAND appropriateness method-a process that integrates a systemic literature review with an expert consensus process to identify items that are considered appropriate and feasible measures of quality healthcare. Since existing evidence based guidelines from international sources existed, we adapted some items from those existing guidelines (e.g,, National Institute for Clinical Excellence [NICE] and Scottish Intercollegiate Guidelines Network [SIGN]), for use in the US healthcare setting [8,9]. Other items were developed using systematic literature review. A panel of 10 epilepsy experts and 1 primary care provider completed three rounds of ratings to identify items for which there was consensus regarding appropriateness, feasibility and necessity. Additional file 1 shows the QI’s that were rated appropriate and feasible indicators of epilepsy care quality, and further identifies QI’s that were adapted from the NICE or SIGN guidelines, and items which are parallel to measures included in the Quality and Outcomes Framework measure used in the United Kingdom [18]. Additional detail about this process is provided elsewhere [19].

Because of the large number of individual evidence-based QI’s during the development of the quality measures, we categorized the 22 QI’s into four aspects of epilepsy care: First Seizure Assessment (3 QI’s), Initial Epilepsy Treatment (7 QI’s), Chronic Epilepsy Care (9 QI’s), and Aspects of Care Unique to Women (3 QI’s). Additional file 1 shows specific QI’s for each aspect of care.

Operational definitions of quality indicators

Prior to chart abstraction, the research team consisting of physicians, nurses and health services researchers with expertise in conducting chart abstractions created operational definitions that identified specific data elements that would be used to score each QI. These definitions were then used to determine if applicable conditions were present for measuring each QI (i.e. the IF portion of the quality indicator), and then whether the process of care defined by the quality indicator was provided (i.e. the THEN portion). For example: IF the patient is diagnosed with a seizure disorder/epilepsy and started on therapy (denominator) THEN the patient

should be treated with monotherapy (numerator). Thus, there was variation in the denominator by QI. While some QI's focused on a single visit (at the time of the first seizure), most QI's examined the construct in question over time. For instance, a number of QI's recommended that a certain type of care be provided on a yearly basis (e.g. yearly depression screening). For these, we assessed visits within the designated time frame. Thus, our analysis is at the patient level for each QI, and the total number of individuals who met criteria for each QI was unique.

A specially designed chart abstraction instrument was developed, and data regarding processes of care provided was collected and entered using Microsoft Access. Research assistants with clinical background were specifically trained to perform chart reviews (Additional file 2). The final chart abstraction instrument was subjected to multiple layers of review by the research team. Initially, 25 charts were reviewed by two raters to assess concordance. Comparison of ratings for the quality indicators in those charts found that raters agreed 76% of the time. After finalization of the instrument, a second review of 25 charts conducted by independent raters found that there was agreement on 86% of ratings.

Initial assessment of concordance between QI's and care provided used an all-or- nothing approach: if all aspects of care were performed, the patient received a positive score for that indicator unless the indicator specifically stated that one of several aspects of care would fulfill the requirement (e.g. QI15; see Additional file 1). However, we also examined the proportion of recommended processes of care completed for each of the four aspects of epilepsy care described above.

Patient Characteristics

Demographic characteristics including age, sex, race/ethnicity, marital status, and education were abstracted from the electronic medical record. Epilepsy history (new-onset vs. chronic care), type of seizure (if documented), and medication information was ascertained based on longitudinal review of medical records and intake history for patients new to the medical center. Finally, the presence of continued seizures was identified by documentation of seizures in the medical record during the study period.

Setting of Epilepsy Care

Epilepsy care was identified by review of outpatient progress notes that described epilepsy and epilepsy care. For each epilepsy-focused medical encounter (encounter in which progress notes mentioned epilepsy) within the healthcare system, the type of provider was defined as being a primary care provider (general internist, family practitioner, or nurse practitioner), neurologist, or other specialty care. Individuals who received care only within primary care or neurology settings were classified as such. Those receiving epilepsy care in both settings were classified as receiving shared care.

Analysis

We first describe the variation in concordance among individual QI's (i.e., the concordance between the recommended and actual care received), followed by examination of the proportion of patients who received the care outlined for each aspect of epilepsy care (First Seizure, Initial Epilepsy Treatment, Chronic Care, Aspects of Care Unique to Women; Additional file 1 shows indicators included in each aspect of care). This analysis was conducted at the patient level, but included all recommended aspects of care for which each patient was eligible based on the individual indicators in each aspect of epilepsy care. This process is described in more detail below. Finally, we examine receipt of care by the setting of epilepsy care received using the chi square statistic. Haberman's adjusted residual statistic was used to identify significant cells within the chi-square analysis [20]. SPSS® version 17 (Chicago, IL, USA) was used to conduct data analysis.

Results

The sample for this study consisted of 311 individuals. Table 1 shows demographics for the sample overall and by source of care. Overall, approximately 58% were women, 62% were between 18 and 49 years of age; the sample was racially diverse with similar numbers of whites and African Americans. Over half had some college or a college degree. With regard to epilepsy, approximately 21% had new-onset epilepsy (within the past two years) and the median number of antiepileptic drugs (AEDs) prescribed at the last visit for this sample was 1 (mean = 1.41, SD = .90). Forty seven percent continued to have seizures during the study period, and 66% had no change in AED during the course of the study. Examination of demographic characteristics (Table 1) by source of care found that African Americans were more likely to be in shared care and primary care groups and less likely to be in the neurology group than expected (X^2 = 18.8, df = 2; $p < 0.01$). Individuals with continued seizures were less likely to be the primary care group and more likely to receive shared care than expected by chance (X^2 = 21.5, df = 2; $p < 0.01$). Individuals within the primary care group were less likely to have a medication change over the course of the study than expected by chance (X^2 = 9.6, df = 2; $p = 0.01$).

There was substantial variation in concordance between recommended care and actual care for individual QI's (Table 2). Excluding indicators with a total

Education is self-reported

*$p < 0.01$.

denominator of less than 25 (to ensure precision of analyses) concordance ranged from 2% for QI16 to 99% for QI's 15 and 18. The mean proportion of concordant care by indicator was 54.0 (standard deviation = 28.0); the median was 59.26.

Table 2 shows the proportion of patients who received QI concordant care for each QI overall and by the setting of epilepsy care. The only QI's where sufficient primary care patients were represented for the purposes of analysis were in chronic epilepsy care: QI 14, 15 16, 20, 21, and 23. For these aspects of chronic epilepsy care we found no statistically significant differences in the extent to which patients received referral for treatment after a positive depression screen (QI 21; $X^2 = 0.73$, df = 2; p = 0.7), or folate supplementation for women of childbearing age (QI 23: $X^2 = 3.6$, df = 2; p = 0.2) by the setting of epilepsy care. Haberman's Adjusted Residual analysis of statistically significant analyses indicated that patients who received primary care were less likely than expected to have documentation of approximate seizure count since their last visit (QI 14; $X^2 = 13.6$, df = 2; p = 0.001) or interventions performed in light of continued seizures documentation of patient education (QI 15: $X^2 = 47.6$, df = 2; $p < 0.001$). Individuals who received care in neurology and primary care settings were less likely to receive depression screening than those who received shared care (QI 20 $X^2 = 6.2$, df = 2; 26.21; $p < 0.001$).

Table 3 shows the proportion of QI concordant care among the four aspects of epilepsy care (first seizure evaluation, initial epilepsy treatment, chronic epilepsy care, and aspects of care unique to women) overall and by setting of epilepsy care. The number reported in each column represents the proportion of all possible care processes that were performed among the care processes outlined by the QI for those who met QI inclusion criteria. For evaluation of a first seizure, of the 65 individuals who received a first seizure evaluation there were 151 possible opportunities for care among individuals who met inclusion criteria regarding QI's for first seizure assessment (QI 1-3). Of those 151 opportunities for QI concordant care, 64 were completed (42.38%). Among the 65 individuals who met criteria for QI's examining initial treatment of epilepsy, there were 297

QI 21.	88/125 = 70.4%	53/73 = 72.6%	22/34 = 64.71%	13/18 = 72.22%
QI 22.	11/14 = 78.57%	6/7 = 85.71%	5/7 = 71.43%	
Aspects of Care Specific to Women				
QI 23. I	38/111 = 34.23%	24/73 = 32.88%	13/29 = 44.83%	1/9 = 11.11%
QI 24.	1/5 = 20%	0/2 = 0%	1/3 = 33.33%	
QI 25.	8/12 = 66.67%	3/6 = 50%	5/5 = 100%	

QI number is based on the original QI's reported in Pugh MJ, Berlowitz DR, Montouris G *et al*. What constitutes high quality of care for adults with epilepsy? Neurology 2007; 69(21):2020-7. QI were not deemed appropriate and necessary (QI 10, 12, 13) are not presented in this paper.

opportunities for recommended care. QI concordant care was provided for 131 (44.11%) of those opportunities. Among the 311 individuals who met criteria for many of the chronic epilepsy care QI's, there were 1,409 opportunities for recommended care; 45.07% of the time QI concordant care was provided. Among the 111 women of child-bearing age included in the study there were 128 opportunities for recommended care; 36.72% of the time QI concordant care was provided. These data indicate that overall, less than half of all possible QI identified care processes (877/1985; 44.2%) were completed in this sample. The lowest concordance between recommended care and actual care was for aspects of care unique to women.

Further examination of quality within each aspect of epilepsy care suggests that there were also significant differences by the setting in which care was received. Our examination of differences between settings of care was restricted to neurology vs. shared care for First Seizure Assessment and Aspects of Care Unique to

Table 3 Proportion of all Possible Opportunities Taken for Quality Epilepsy Care by Setting of Epilepsy Care

Aspect of Epilepsy Care	N***	All	Neurology Only	Shared care	Primary Care Only
First seizure assessment[$]	63	64/151 = 42.38%	41/106 = 38.70%	20/35 = 57.14%	3/10 = 30.00%
Initial epilepsy treatment	63	131/297 = 44.11%	88/203 = 43.35%	40/75 = 53.33%	**3/19 = 15.79%**
Chronic epilepsy care	302	635/1409 = 45.07%	381/897 = 42.47%	**218/393 = 55.47%**	36/119 = 30.25%
Aspects of care unique to women[$]	108	47/128 = 36.72%	27/81 = 33.33%	19/37 = 51.35%	1/10 = 10.00%

[$] Insufficient N for Primary Care Only; unable to compare.

* $p < 0.05$.

** $p < .01$.

***N that could potentially qualify for inclusion in analysis if all inclusion criteria for a specific quality indicator are met.

The numerator in each column represents the number of possible care processes that were performed; the denominator represents the number of possible care processes. For specific numbers of patients, and specific indicators included in each aspect of epilepsy care please refer to Table 2.

Women due to low numbers of patients receiving Primary Care Only. For First Seizure Assessment, we found a trend approaching significance with individuals receiving shared care having more aspects of QI concordant care performed than did those receiving care in a neurology setting (Table 3; $X^2 = 3.7$; $p = 0.06$). For Initial Epilepsy Treatment concordance by setting of care varied from 16% for those receiving primary care only to 53% for those receiving shared care; individuals receiving primary care were significantly less likely to receive QI concordant care than expected ($X^2 = 9.0$; $p = 0.01$). Concordance for QI's included in Chronic Epilepsy Care ranged from 30% for those receiving primary care only to 55% for those receiving shared care. Individuals receiving shared care were more likely to receive QI concordant care than those receiving neurology or primary care ($X^2 = 30.2$; $p < 0.001$). For Aspects of Care Unique to Women, there was a trend approaching significance, with individuals receiving shared care being more likely to receive QI concordant care than those receiving neurology care ($X^2 = 3.5$; $p = 0.06$).

Discussion

This study used data from electronic medical records to assess the extent to which patients with epilepsy receive processes of epilepsy care identified as QI's designed for use in primary and general neurology care. We were able to reliably assess the extent to which recommended care was documented in patient records. However findings for several indicators where fewer than 5% of the sample received recommended aspects of care suggest additional evaluation of those indicators or data sources is needed.

Consistent with studies examining QI concordant care in other chronic diseases, less than half of all possible care processes were completed [21]. There was wide variation in the extent to which all recommended processes of care were provided, with Aspects of Care Unique to Women having the lowest rates of concordance.

Our data provide limited support for our hypothesis that individuals receiving shared care have better quality of care than individuals receiving only primary care or only neurology subspecialty care. The only QI's for which there were significant differences between patients receiving neurology care and those shared care was QI20 which suggests that persons with epilepsy should receive an annual depression assessment. Our data do not indicate who conducted the depression assessment. It is possible that the neurologist was more likely to attend to these items immediately for a patient that would be seen only once for referral, than the more complex patients with competing demands who were seen continuously in neurology settings [22]. The more complex patients who were seen exclusively in neurology settings likely had acute issues associated with their seizures that required immediate attention, leaving little or no time at the end of an office visit to address chronic disease management issues. Alternatively, these chronic disease management issues may have also been addressed by the neurologist but not documented due to the intensive documentation required to address more acute seizure care.

Further examination of the aggregate measures where there is more power to detect differences between individuals receiving shared vs. primary or neurology care only, our analysis revealed that there was a significant difference between shared care and neurology only care only for chronic disease management.

Shared care has been examined in a variety of contexts with mixed results. A number of studies have found no difference in quality for patients in shared care compared to those in specialty care exclusively [23,24]. Rosendal and colleagues found that individuals with hip fracture and receiving shared care had more home care after discharge, and lower scores on the short version of the Sickness Impact Profile indicating improved recovery [25]. Pugh and colleagues found that patients with diabetes were more likely to receive guideline concordant diabetes medications if they received care from both primary and specialty care compared to primary care or specialty care exclusively [26].

Our analysis suggests that, for epilepsy, QI's associated with types of care that are more technical in nature (e.g., QI 2, 7, 15, 18) tended to have higher rates of concordance, while those associated with discussion, patient education, and chronic disease management (e.g., QI 5, 8, 16) tended to have lower rates of concordance. It is possible that these aspects of patient care that are more interpersonally oriented were actually performed, but not documented. However, documentation of these aspects of care is in and of itself an indicator of quality. Because several of these interpersonally oriented items are ones included in the UK's Quality and Outcomes framework, there is broad international consensus that they are critical components of the quality of epilepsy care (e.g., particularly documenting seizure frequency and reviewing medication management). Accordingly the QUIET indicators could be used to develop electronic templates for use in documenting care for patients with epilepsy in organizations with electronic medical records (or a paper template for settings with paper records). Such a template would facilitate documentation of these important processes of care when they occur, and guide providers who do not commonly provide care for patients with epilepsy.

Beyond our hypothesis, we found that chronic disease management issues specific to women tended to have lower rates of concordance than other aspects of care. Again, it is possible that women were taking over-

the-counter medications or vitamins with the recommended dose of folate and did not need a prescription. However, the drug-drug interaction between lamotrigine and oral contraceptives was not addressed in four of five eligible patients. Because the numbers of women meeting criteria was low for QI 24 women's issues should be highlighted as a concern not only for clinicians to address, but also as a concern requiring additional quality assessment.

Finally, our findings suggest that issues recently highlighted in the literature-bone health and mood disorders [27,28] -are being addressed for many patients with epilepsy. Approximately 62% of individuals on AEDs for two or more years received testing for Vitamin D or a DXA scan. With regard to mood disorders, 46% received recommended screening. Of those with evidence of anxiety or depression, 71% received treatment with medications or a referral to a mental health practitioner.

These findings must be interpreted in light of several limitations. First, this study was in a single medical center in which study participants appeared to have higher rates of uncontrolled seizures than estimates from the literature [29]. The complexity of these patients may be such that competing demands for physician time make addressing less acute issues more difficult, so these findings may not reflect the quality of care provided for less complicated patients. Attempts to adjust these results for disease severity, however, did not change results since there were no significant differences in QI concordant care for those with and without continued seizures. This limited sample, from a single geographic location provides a point of reference for future studies from other geographic regions and multi-site studies with power to detect geographic variations in care that may exist.

Related to this single-site study is the fact that the total number of patients (N = 311) was relatively small, particularly after stratifying patients into groups of neurology care, shared care and primary care. The primary care group was particularly small for all groups except chronic epilepsy care. Thus, findings for the primary care group must be interpreted with caution.

Next, quality of care was assessed primarily using the electronic medical record. As described above, it is possible that interpersonal aspects of care were addressed but not documented. A number of aspects of care that are more interpersonal in nature may be better assessed using patient reported survey measures. Future studies examining the quality of epilepsy care using a broad measure such as the QUIET indicators may benefit from an approach that utilizes not only medical chart abstraction, but a targeted survey that provides a second assessment of patient reported receipt of care which allows one to triangulate data to assess the care received by patients. Moreover, such a survey would benefit by adding quality of life measures, and other potential outcomes that may be linked to higher quality care such as employment, relationship status, and education.

We further found that scoring compound QI's (e.g., 1, 8 and 16) in an all or nothing fashion may lead to loss of useful information. Adaptation and/or disaggregation of specific aspects of these QI's may be needed in future research on the quality of epilepsy care. However, our assessment of broad areas of epilepsy care (Table 3) examined the proportion of possible care processes that were completed. Even in this analysis where credit was given for completing even one aspect of care for complex QI's, fewer than half of all possible processes of care were completed, suggesting room for improvement in all aspects of epilepsy care.

Finally, because these QI's were designed for use in primary or general neurology care settings, it is possible that some very important aspects of care may not be as clearly articulated. For instance we indicated numerous points where referral to a higher level of specialty care is recommended. Due to the structure of care in the US, we did not specifically identify a point in time where a patient should be referred to a tertiary epilepsy center for comprehensive evaluation. This limitation should be addressed by future versions of this measure.

Conclusion

This study provides a snapshot of the quality of care provided to adults with epilepsy in one metropolitan healthcare system. While results are only from a single hospital, these findings suggest that assessment of quality using most of the QUIET QI's is feasible, and that care for epilepsy can in large part be reliably measured using medical chart abstraction. This tool will allow identification of gaps in quality for epilepsy care within other healthcare systems, and eventually it can be used to improve the care provided for adults with epilepsy. However additional evaluation of the QUIET measure using patient surveys and development of QI's for use in specialty care is also needed.

Trends in Use of High-Risk Medications for Older Veterans: 2004 to 2006

Mary Jo V. Pugh, PhD,[ab] Joseph T. Hanlon, PharmD, MS,[cd] Chen-Pin Wang, PhD,[ab] Todd Semla, PharmD,[efg] Muriel Burk, PharmD,[efg] Megan E. Amuan, MPH,[h] Ashlei Lowery, MD,[i] Chester B. Good, MD,[dj] and Dan R. Berlowitz, MD, MPH[gk]

OBJECTIVES: To examine the change in use of high-risk medications for the elderly (HRME), as defined by the National Committee on Quality Assurance's Healthcare Effectiveness Data and Information Set (HEDIS) quality measure (HEDIS HRME), by older outpatient veterans over a 3-year period and to identify risk factors for HEDIS HRME exposure overall and for the most commonly used drug classes.

DESIGN: Longitudinal retrospective database analysis.

SETTING: Outpatient clinics within the Department of Veterans Affairs (VA).

PARTICIPANTS: Veterans aged 65 by October 1, 2003, and who received VA care at least once each year until September 30, 2006.

MEASUREMENTS: Rates of use of HEDIS HRME overall and according to specific drug classes each year from fiscal year 2004 (FY04) to FY06.

RESULTS: In a cohort of 1,567,467, high-risk medication exposure fell from 13.1% to 12.3% between FY04 and FY06 ($P<.001$). High-risk antihistamines (e.g., diphenhydramine), opioid analgesics (e.g., propoxyphene), skeletal muscle relaxants (e.g., cyclobenzaprine), psychotropics (e.g., long half-life benzodiazepines), endocrine (e.g., estrogen), and cardiac medications (e.g., short-acting nifedipine) had modest but statistically significant ($P<.001$) reductions (range -3.8% to -16.0%); nitrofurantoin demonstrated a statistically significant increase ($+36.5\%$; $P<.001$). Overall HEDIS HRME exposure was more likely for men, Hispanics, those receiving more medications, those with psychiatric comorbidity, and those without prior geriatric care. Exposure was lower for individuals exempt from copayment. Similar associations were seen between ethnicity, polypharmacy, psychiatric comorbidity, access-to-care factors, and use of individual HEDIS HRME classes.

CONCLUSION: HEDIS HRME drug exposure decreased slightly in an integrated healthcare system. Risk factors for exposure were not consistent across drug groups. Future studies should examine whether interventions to further reduce HEDIS HRME use improve health outcomes. **J Am Geriatr Soc 59:1891–1898, 2011.**

Key words: inappropriate prescribing; quality of care; aged; pharmacoepidemiology

Dr. Mark Beers first developed explicit criteria for potentially inappropriate prescribing in the elderly (PIPE), defined as medications rated by an expert panel as those whose risks outweigh their potential benefit in older adults, in 1991. They were subsequently updated in 1997 and 2003. Numerous studies have shown the rates of PIPE based on the Beers criteria over the past decade to be between 20% and 30% in older outpatients.[1–8] Several recent studies have identified small but significant reductions in PIPE as defined according to different versions of the Beers criteria.[9,10] For example, one study found a 3.9% reduction in PIPE (2003 Beers Criteria) between 1996 and 2005 in the United Kingdom despite a trend for an increase in the number of prescriptions overall during this time.[11]

In 2006, the National Committee on Quality Assurance (NCQA) developed a Healthcare Effectiveness Data

and Information Set (HEDIS) quality measure to examine use of high-risk medications in the elderly (HRME) developed by an expert panel and based in part on the most-recent version of the Beers criteria.[12,13] The HEDIS HRME measure included some, but not all, of the drugs included in the Beers criteria, retaining those for which there was consensus that they should be avoided and that outcomes were considered to be of high severity. This more-refined measure is now used to benchmark the quality of medication management in older adults enrolled in Medicare and other managed care plans and thus is of interest to the Department of Veterans Affairs, Veterans Health Administration (VA).

Using VA data from October 1, 1999 to September 30, 2000, it was previously reported that the overall 1-year prevalence of HEDIS HRME exposure in older veteran outpatients was 19.6%.[14] To the best of the knowledge of the authors of the current study, the only published studies examining longitudinal use of HEDIS HRME as defined by this HEDIS quality measure have been reports by the NCQA.[15]

The objective of the current study was to examine the change in HEDIS HRME exposure in older veteran outpatients between 2004 and 2006 and to examine risk factors for HEDIS HRME exposure. Given that the foundation for the HEDIS HRME measure existed for longer than a decade before the refinement of the measure itself, it was hypothesized that reductions in the rates of HEDIS HRME drug use overall and within specific drug classes should have been evident by the mid-2000s. Moreover, it was hypothesized that risk factors for HEDIS HRME would be similar to those reported in previous studies using the Beers criteria and that they would be consistent across the major drug groups that constitute the HEDIS HRME measure.

METHODS

Study Design, Setting, and Sample

A longitudinal retrospective data analysis study was conducted using data from all VA outpatient clinics. The sample consisted of veterans aged 65 by October 1, 2003 (beginning fiscal year 2004 (FY04)) who received VA care at least once each year between FY03 and FY06. To examine change in a consistent sample over time, individuals who received sporadic VA care or who died during this period were not included in the analysis. Institutional review boards at three sites (University of Texas Health Science Center at San Antonio, Hines VA, and Bedford VA) approved this study.

Data Sources

National VA inpatient, outpatient, and pharmacy data from FY03 (October 1, 2002–September 30, 2003) through FY06 (October 1, 2005–September 30, 2006) were obtained for individuals aged 65 and older at the beginning of FY04. A merged database was created using information from the VA National Patient Care Database records and all outpatient pharmacy prescription data from the VA Pharmacy Benefits Management database. Records were merged using an encrypted identifier that is consistent for each person across VA data sets.

Measures

Exposure: HRME

Use of any of the HEDIS HRME drugs was identified using VA pharmacy data each year between FY04 and FY06. A measure of exposure was then created for overarching groups of drugs based on the VA Medication class system (Table 1) (http://www.pbm.va.gov/natform/vaclass.xls).

Independent Variables

Patient demographic characteristics (age, sex, race and ethnicity) were identified using data fields from VA administrative databases between FY03 and FY06. With the exception of race, these demographic characteristics are well documented and complete in the medical record. Because the process of recording race changed in 2002, race data are more likely to be missing than other aspects of VA administrative data. Findings from prior studies indicate that those with missing data were most often white and had low healthcare utilization and disease burden. For these demographic variables, a process was used in which VA data for previous years was looked back at and data in subsequent years was looked forward at to minimize missing data.

Health Status Variables

Health status variables in the analyses predicting HEDIS HRME exposure in FY06 included several measures of disease burden. Because prior studies indicated that individuals with greater disease burden as defined by more medications, more physical comorbidities and psychiatric conditions are at greater risk for potentially inappropriate prescribing,[7,16–18] these variables were controlled for. The number of unique medication classes each individual received during FY05 was first counted. *International Classification of Diseases, Ninth Revision, Clinical Modification*, codes found in VA inpatient and outpatient data (diagnoses in two outpatients or one inpatient) (FY03–05) were also used to identify individuals with physical and psychiatric conditions using the Selim comorbidity indices that were developed to control for disease burden in research studies involving veterans.[19,20] For physical conditions, the number of chronic disease states from 30 possible conditions included in the Selim Physical Comorbidity index was counted. The following psychiatric conditions included in the Selim Psychiatric Comorbidity Index were also identified: schizophrenia, bipolar disorder, depressive disorder, posttraumatic stress disorder, substance use disorder, and anxiety disorders. Because of the highly skewed distribution, individuals with zero, one, or two or more psychiatric conditions were identified. These measures of comorbidity have been previously associated with mortality, measures of health status, and PIPE.[14,21,22]

Access-to-Care Variables

Access-to-care variables in the analyses included a measure of copayment exemption and measures of geriatric care and primary care utilization in FY05. Copayment exemption was measured using the VA priority group. VA priority groups are associated with physical or mental health status and illness severity and socioeconomic status. Veterans with a service-connected disability of 50% or greater, or individuals who were catastrophically disabled, had very

Table 1. High-Risk Medications in Older Adults

Drug Group	Drugs Included	Concerns Regarding Use
Amphetamines	Amphetamine/dextroamphetamine, benzphetamine, dexmethylphenidate, pemoline, dextroamphetamine diethylpropion, methamphetamine, methylphenidate, phendimetrazine, phentermine	Dependence, hypertension, angina pectoris, and myocardial infarction
Antibiotics	Nitrofurantoin	Potential for renal impairment; safer alternatives available
Antihistamines	Diphenhydramine	Confusion and sedation
	hydroxyzine, promethazine, cyproheptadine, dexchlorpheniramine, tripelennamine	Potent anticholinergic properties
Cardiac medications and vasodilators	Dipyridamole (short acting)	Risk of orthostatic hypotension
	Nifedipine (short acting)	Potential for hypotension and constipation
	Isoxsuprine, ergot mesyloids	Lack of efficacy
Endocrine drugs	Estrogens	Carcinogenic potential
	Chlorpropamide	Syndrome of inappropriate antidiuretic hormone secretion; hypoglycemia
	Desiccated thyroid	Concerns about cardiac effects; safer alternatives available
Gastrointestinal antispasmodics	Dicyclomine, hyoscyamine, propantheline, atropine belladonna, scopolamine	Highly anticholinergic with uncertain effectiveness
	trimethobenzamide	Poor efficacy; can cause extrapyramidal effects
Nonsteroidal anti-inflammatory drugs	Ketorolac	Commonly causes asymptomatic gastrointestinal pathological conditions
Opioid pain relievers	Propoxyphene	Lack of efficacy; more adverse effects
	Meperidine	Lack of efficacy; confusion, falls, fractures, dependency
	Pentazocine	Falls, fractures, confusion, dependency, withdrawal
Psychotropic drugs	Diazepam, chlordiazepoxide, flurazepam	Prolonged sedation and increase the risk of falls
	Thioridazine, meprobamate	More central nervous system and extrapyramidal adverse effects than others
	Barbiturates	Highly addictive; more adverse effects than others
Skeletal muscle relaxants	Methocarbamol, cyclobenzaprine, carisoprodol, chlorzoxazone, metaxalone, orphenadrine	Anticholinergic adverse effects, sedation, and weakness; effectiveness at doses tolerated by older adults questionable

low income, or had specific war-related experiences generally received a waiver for copayments associated with VA care.[21,23]

Because prior work found that geriatric care at some point the year before assessment was associated with lower risk of exposure to drugs included in the Beers criteria, individuals who received care in geriatric outpatient clinics or inpatient geriatric evaluation and management in FY05 were identified as having prior geriatric care.[24] Finally, because prior literature found that patients with many primary care visits the previous year were more likely to have an exposure to potentially inappropriate medications as measured by the Beers criteria, those with more-frequent visits to primary care ($\geq$5 in a year) may be sicker and thus at higher risk of HEDIS HRME exposure.[16,17] Based on prior studies and the empirical distribution, patients were classified as having 0 to 1, 2 to 4, or 5 or more primary care visits.

Analysis

The demographic and health status characteristics of the cohort are first described, and then changes in exposure to HEDIS HRME overall and individual medication classes of older VA outpatients over the 3-year study period (FY04-06) were identified. Generalized estimating equation (GEE) analyses with a logit link (exchangeable working correlation) were used and applied to five unique samples of 100,000 randomly selected individual to determine whether changes over time in HEDIS HRME overall and drug classes were statistically significant. The averaged parameter estimates (change over time only) obtained from the five random samples were used, and standard errors were approximated for the entire population using the pooled standard errors.[25] Statistical significance of these pooled estimates was examined using the *Z*-score threshold: $\pm$ 2.33 ($-$ 2.33 and 2.33 are 0.005 and 0.995 quantiles of the standard normal distribution). Logistic regression analyses were then used to identify demographic, health status, and access-to-care factors associated with risk of HEDIS HRME exposure overall in 2006 and for the four most commonly used HEDIS HRME drug classes. All statistical analyses were performed using SAS software (version 9, SAS Institute, Inc., Cary, NC).

RESULTS

Of the 1,933,291 individuals who met age criteria in FY04, 1,567,467 received care between FY03 and FY06 and were included in this study. The mean age of individuals in this cohort in 2004 was 74.4 $\pm$ 5.8. Similar to other studies of older veterans, this cohort was primarily male (1,539,324, 98.2%) and white (1,060,366, 67.7%). Table 2 provides additional descriptive statistics for this cohort.

Longitudinal Change in HEDIS HRME Exposure

Overall, the rates of HEDIS HRME exposure decreased over the study period (FY04, 205,179, 13.1%; FY05, 200,326, 12.8%; FY06, 193,456, 12.3%). This represents an absolute difference of 0.8% and a relative difference of 6.1% between FY04 and FY06. Figure 1 shows changes in HEDIS HRME exposure according to drug category over the study period. Most categories experienced small reduc-

HEDIS HRME = high-risk medications for the elderly defined according to the Healthcare Effectiveness Data and Information Set quality measure; SD = standard deviation.

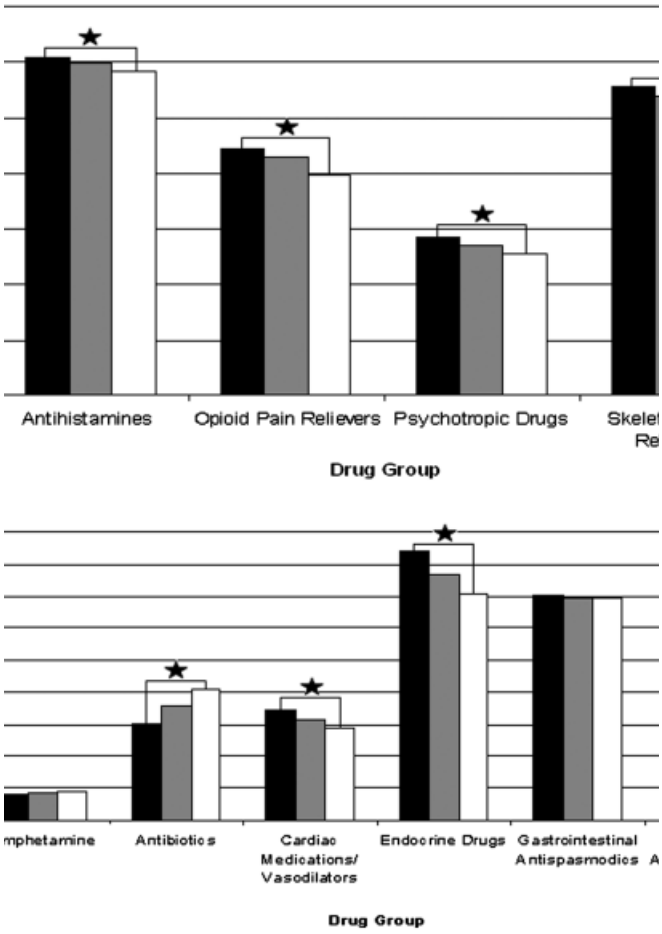

Figure 1. Exposure to high-risk medications in the elderly (HRME) according to drug group.
Trends in use of HRME: 2004 to 2006.
Significant at $P < .01$.
Changes in the number of older veterans exposed to specific high-risk medication classes between FY04 and FY06. Different scales are used for the most commonly used high-risk medication classes and those less commonly used to visualize the change in use over time: [■] FY04; [▩] FY05; [□] FY06

tions in use between FY04 and FY06, although there were relative increases of 36.5%, 10.3%, and 8.0% for antibiotics, amphetamines, and ketorolac (a nonsteroidal anti-inflammatory drug), respectively. Table 3 shows results of GEE analyses examining the statistical significance of HEDIS HRME over time in the five random samples of the population. Overall, exposure to HEDIS HRME was significantly lower in FY06 than FY04 (estimate −0.07, standard error 0.004, *Z*-score −15.59). There was no significant change in exposure for gastrointestinal antispasmodics, amphetamines, or ketorolac, but there were statistically significant reductions in high-risk opioid pain relievers (primarily propoxyphene), skeletal muscle relaxants, psychotropic drugs, endocrine drugs, and cardiac and vasodilator medications. There was also a statistically significant increase in exposure to nitrofurantoin.

Table 4 shows results of logistic regression models predicting HEDIS HRME exposure in FY06. Similar to a previous report using data from FY00, older individuals, African Americans (vs whites), those required to make copayments, and those with previous geriatric care were significantly less likely to have HEDIS HRME exposure. Women; Hispanics; and those with higher numbers of medications the prior year, psychiatric comorbidity, or higher primary care utilization were significantly more likely to have HEDIS HRME exposure.

Examination of the four types of the most commonly used HEDIS HRME suggested some consistency across medication types but also some variation with regard to predictors of HEDIS HRME exposure (Table 4). The effect of age, sex, number of medications, copayment requirement, and prior geriatric care were consistent across all drug groups. African Americans and Hispanics were less likely than whites to have opioid HEDIS HRME exposure and more likely to have antihistamine and skeletal muscle

Table 3. Results of Pooled General Estimating Equations Assessing Change in Proportion of Exposure to Healthcare Effectiveness Data and Information Set (HEDIS) High-Risk Medications in the Elderly (HRME) According to Drug Category FY06 (vs FY04)

Drug Group	Estimate	Standard Error	*Z* Score

* $P < .01$.

relaxant HEDIS HRME exposure. African Americans were also significantly less likely than whites to have psychotropic HEDIS HRME exposure, whereas Hispanics were significantly more likely to have such exposure. Individuals who were not married were more likely to have antihistamine and opioid HEDIS HRME exposure and less likely to have psychotropic or skeletal muscle relaxant HEDIS HRME exposure. The effect of high primary care utilization was associated with greater likelihood of HEDIS HRME exposure, with the exception of psychotropics, for which the effect was not significant for those with two to four visits and significantly greater for those with five or more visits. Finally, psychiatric comorbidity was not significantly associated with exposure to opioids or musculoskeletal relaxants.

DISCUSSION

Findings from this study suggest that small, but statistically significant reductions in exposure to HRME overall defined using the HEDIS criteria occurred between 2004 and 2006 for older VA patients. Although the reductions in overall exposure were small during this time period (13.1% in FY04 to 12.3% in FY06), exposure was markedly lower than in a previous assessment of 19.6% in FY00 and similar to the rate of 12.9% reported in a previous national sample of retirees who had worked for the same company in 2003 to 2005.[26] The rates of exposure in the current study were considerably lower than those reported by the NCQA for 2006 among Medicare enrollees, with 23.1% of individuals meeting criteria for the denominator in 2006 having one or more HEDIS HRME exposures.[15] The VA's leadership in geriatric care, the active role of pharmacists in the VA, and VA formulary management may have contributed to the reduction. The VA created its One-National Formulary in

HEDIS = Healthcare Effectiveness Data and Information Set.

2002 by freezing formularies at the facility and regional level and then creating a uniform formulary, which resulted in excluding drugs that had previously been on a number of regional formularies, such as propoxyphene.

Examination of change over time according to individual drugs and drug classes revealed some reduction in most drug classes, stability in others, and increases in nitrofurantoin. Reductions in use of skeletal muscle relaxants, psychotropic drugs, and opioid pain relievers is notable because recent studies have demonstrated that the use of these medications increases the risk of falls and fractures in older adults.[27–29]

One possible explanation for the increase in nitrofurantoin use is related to increasing resistance to common urinary tract pathogens such as *Escherichia coli* with common antibiotics (e.g., ciprofloxacin, trimethoprim/sulfamethoxazole). One in vitro study found that nitrofurantoin was effective in killing *E. coli* isolates in 98.1% of those with trimethoprim/sulfamethoxazole resistance and 89.6% of those with ciprofloxacin resistance.[30] Unfortunately, in vitro testing does not translate to nitrofurantoin being effective in older adults. The use of nitrofurantoin, a primarily renally cleared medication, should be avoided in individuals with estimated creatinine clearances less than 60 mL/min because insufficient concentrations reach the bladder to be capable of killing bacteria such as *E. coli*.[31,32] A recent study of veterans residing in a VA community living center found that this agent was in the top four suboptimally prescribed medications.[33] Of concern is a greater risk for serious adverse drug events with nitrofurantoin that include chronic, subacute, or acute pulmonary hypersensitivity reactions and peripheral neuropathy.

This study also adds to the understanding of risk factors for potentially inappropriate prescribing. Prior studies have examined a single drug such as propoxyphene or potentially inappropriate drugs in the Beers or HEDIS criteria as a single entity.[7,14–18,34,35] Neither of the aforementioned studies examined risk factors for the use of high-risk medications.[15,26] Consistent with a prior report and other studies examining exposure to potentially inappropriate medications, it was found that whites, women, and those with more medications were more likely to be exposed.[7,18] Examination of the four most commonly prescribed HEDIS HRME groups suggests that findings from studies of HEDIS HRME as a whole provide insufficient insight into this problem. In particular, the effects of race and psychiatric comorbidity and primary care utilization depend upon the type of potentially inappropriate medication.

With regard to race, African Americans were less likely to have exposure to suboptimal opioid and psychotropic medications than were whites, and Hispanics were also significantly less likely than whites to have exposure to opioid medications. The finding for African Americans is consistent with literature finding lower use of psychotropic medications and analgesics in blacks than in whites.[36,37] The finding for Hispanics is less clear, in part because many previous studies have not distinguished between blacks and Hispanics but rather evaluated them as "nonwhites."

Individuals with multiple psychiatric comorbidities had a lower risk of being prescribed high-risk opioids (e.g., propoxyphene). This finding may result from clinicians being less likely to prescribe opioids for pain in individuals receiving psychotropic medications for psychiatric comorbidities because of concern of that greater total central nervous system medication burden (e.g., opioids, benzodiazepines, antidepressants, antipsychotics) increase the risk of falls in older adults.[38]

A number of potential limitations should be noted. First, restriction of the assessment to individuals who received VA care between FY03 and FY06 may lead to selection bias. Although this was necessary to understand change in a consistent population, this may bias the results because individuals who were sicker and died during this 3-year period are not represented in the findings, but examination of the entire population revealed similar rates of exposure and trends overall and for HEDIS HRME drug groups (range 14.1% in FY04 to 12.6% in FY06) and predictors of exposure. Second, the assessment was restricted to medications received within the VA. It is possible that some HEDIS HRME were purchased outside the VA, and thus the assessment may be conservative. One potential problem is with medications that can be purchased over the counter (OTC), such as diphenhydramine. Substantial variation in the relationship between copayment status and HEDIS HRME exposure for antihistamines would support the idea that OTC medications affected lower risk for exposure differently in those with required copayments. Although small variations existed, the direction and magnitude of the copayment variable was similar across drug classes. A second concern regarding use of medications received from the VA is that implementation of Medicare Part D in January 2006 may have affected the findings.[39] Because a sudden, marked decrease in the average number of prescriptions per patient or marked decreases in exposure between 2005 and 2006 were not seen (Table 2), it is unlikely that the findings for FY06 were affected substantially. Moreover, the assessment occurred using data from a timeframe before the implementation of the HEDIS HRME measure. Because the Beers criteria from which the HEDIS HRME measure was derived have been in existence in various forms for nearly a decade, the time period examined for this assessment is not unreasonable. Moreover, this study provides a foundation for subsequent study of change in exposure by chronicling the years up to and including the first year of HEDIS HRME implementation. Residual confounding due to potential important factors for which information was not available (e.g., smoking) and HEDIS HRME cannot be excluded. Because this study provides information on change in prescribing on a national sample of older primarily male VA patients, it does not reflect prescribing in non-VA settings. Finally, because propoxyphene was removed from the market, it is expected that rates of HEDIS HRME exposure will fall significantly nationally. This would follow a consistent trend in the VA, where rates fell considerably due to formulary restrictions, but because opioids rank third among the most common high-risk drug classes, high-risk medication exposure continues to be of concern.

CONCLUSION

This study found a small decrease in HEDIS HRME exposure between FY04 and FY06. These rates of exposure were lower in the VA than in 2006 Medicare data. Comparison

of the findings with those of an earlier study[14] suggests that exposure in the VA has fallen substantially between 2000 and 2006 but that only small changes occurred between 2004 and 2006. Moreover, variation in risk factors was found for different groups of HEDIS HRME drugs. Future studies should examine the effect of these reductions on overall health outcomes and measure the effects according to drug class because variation in outcomes may also be evident, depending on the medications and the conditions they treat.

Exposure to Potentially Harmful Drug–Disease Interactions in Older Community-Dwelling Veterans Based on the Healthcare Effectiveness Data and Information Set Quality Measure: Who Is at Risk?

Mary Jo V. Pugh, PhD,[abc] Catherine I. Starner, PharmD,[d] Megan E. Amuan, MPH,[e] Dan R. Berlowitz, MD, MPH,[ef] Monica Horton, MD,[cg] Zachary A. Marcum, PharmD,[h] and Joseph T. Hanlon, PharmD, MS[hijkl]

OBJECTIVES: To identify prevalence and risk factors for exposure to drug–disease interactions included in the Healthcare Effectiveness Data and Information Set (HEDIS) Drug–Disease Interaction (Rx-DIS) measure.

DESIGN: Cross-sectional retrospective database analysis.

SETTING: Outpatient clinics within the Department of Veterans Affairs (VA).

PARTICIPANTS: Individuals aged 65 and older who received VA outpatient care between October 1, 2003, and September 30, 2006.

MEASUREMENTS: Rx-DIS exposure based on the HEDIS measure was identified in VA patients with dementia, falls, and chronic renal failure using VA pharmacy and administrative databases. Factors associated with Rx-DIS exposure were examined, including demographic, health status, and access-to-care factors, including VA outpatient health services use and copayment status.

RESULTS: Of the 305,041 older veterans who met criteria for inclusion, the 1-year prevalence of Rx-DIS exposure was 15.2%; prevalence was 20.2% for dementia, 16.2% for falls, and 8.5% for chronic renal failure. Patients with high disease burden (physical, psychiatric, number of medications) were significantly more likely to have Rx-DIS exposure, regardless of condition. Hispanics and individuals with no copayments were more likely to have Rx-DIS exposure than whites or those with required copayments. There was variation in other predictors based on the type of Rx-DIS.

CONCLUSION: The prevalence of Rx-DIS was common in older VA outpatients. Future studies should examine the risk of Rx-DIS exposure on health outcomes using separate analyses for each type of Rx-DIS separately before combining all Rx-DIS into a single measure of exposure. Studies that examine the effectiveness of interventions to reduce Rx-DIS exposure will also be helpful in improving the quality of care for older adults. **J Am Geriatr Soc 59:1673–1678, 2011.**

Potentially inappropriate prescribing in the elderly (PIPE) has been a growing concern over the past decade. Although most studies have examined use of high-risk drugs for older adults (e.g., Beers criteria), concern has begun to expand to other realms of PIPE such as drug–disease interactions.[1–5] Studies have examined exposure to drug–disease interactions defined by Beers in a variety of settings.[1,2,6–13] Previous research has shown that drug–disease interactions (medication(s) exacerbating preexisting conditions) are common and are associated with adverse drug reactions in older adults, thus representing an important area of inquiry.[14,15]

0002-8614/11/$15.00

The National Committee on Quality Assurance (NCQA) developed a drug–disease interaction measure as part of the 2007 Healthcare Effectiveness Data and Information Set (HEDIS) Drug–Disease Interaction (Rx-DIS) measure based on an earlier measure of 28 drug–disease interactions involving 14 diseases or conditions developed by Lindblad and colleagues (e.g., peptic ulcer disease and aspirin and nonaspirin nonsteroidal anti-inflammatory drugs (NSAIDs), syncope and alpha blockers, and systolic heart failure and first-generation calcium channel blockers).[7] From the Lindblad measure, the NCQA expert panel reached consensus on a subset of drug–disease interactions that could be readily measured using administrative data and that were potentially associated with adverse outcomes. The three conditions and medication groups considered inappropriate for individuals with those conditions are included in the HEDIS Rx-DIS measure that is now used to monitor quality of prescribing in older patients diagnosed with dementia, falls, and chronic renal failure. Although NCQA has published rates of HEDIS Rx-DIS in their report on the state of healthcare quality in 2009,[16] other studies examining Rx-DIS have used broader measures. Because the HEDIS Rx-DIS measure is a nationally accepted quality measure, the focus of the current study was assessment of the three conditions included in that measure.

The purpose of this article is to examine the extent to which HEDIS Rx-DIS exposure occurs in older community-dwelling VA patients and factors associated with that exposure. Mirroring the HEDIS Rx-DIS quality measurement, the prevalence of HEDIS Rx-DIS exposure was examined overall and then according to disease or condition. To determine whether risk factors were consistent across conditions, risk factors for HEDIS Rx-DIS exposure were also identified overall and according to disease or condition.

METHODS

Data and Study Population

After institutional review board approval national Veterans Affairs (VA) inpatient, outpatient and pharmacy data were obtained from fiscal year 2004 (FY04; October 1, 2003–September 30, 2004) through FY06 (October 1, 2005–September 30, 2006) for individuals aged 65 and older at the beginning of FY05. Pharmacy and diagnostic datasets were merged using the encrypted identifier included in each data set. To ensure that there were adequate data to identify comorbid conditions and prior medication use, individuals who received care regularly in the VA healthcare system (having at least one outpatient or inpatient visit each year) were selected from that population. Individuals who resided in VA community living centers (previously called nursing home care units; based on VA extended care file data) for all of FY2006 and those who died before 2006 were not included. Individuals who were admitted to a community living center during 2006 or who died after receiving care in 2006 were included. Analyses were further restricted to individuals with International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) code–based diagnoses or medications indicative of falls, dementia, or chronic renal failure as outlined by the NCQA, which required a single diagnosis.

Measures

Drug–Disease Interaction

Individuals with dementia, falls, and chronic renal failure in VA inpatient and outpatient databases (FY04–06) were first identified using ICD-9-CM codes (and medications for dementia) identified by the NCQA.[17] For those with a diagnosis indicative of dementia, falls, or chronic renal failure or dementia medications (donepezil, galantamine, rivastigmine, tacrine, and memantine), use of potentially harmful medications in FY06 (Table 1) was identified using the VA product variable in the VA Pharmacy Benefits Management database.

Individuals diagnosed with dementia, falls, or chronic renal failure and who later had an order for and were dispensed medications considered relatively or potentially contraindicated in FY06 were classified as having Rx-DIS exposure for that condition. The overall prevalence of any Rx-DIS in individuals who met criteria for dementia, falls, or chronic renal failure and the prevalence for individuals within each condition of interest were then calculated.

Patient Demographic Characteristics

Patient demographic characteristics included age, sex, race, and marital status. Demographic characteristics were identified using VA administrative data. With the exception of race, these demographic characteristics are well documented and complete in the medical record. Because the process of recording race changed in 2002, race data are more likely to be missing than other aspects of VA administrative data. Thus, a process was used in which VA data for previous and subsequent years was looked at to fill in missing race values. Individuals with missing race data (n = 44,513, 14.6% of the cohort meeting inclusion criteria for quality indicators) were excluded from the analysis

Table 1. Description of Drug–Disease Interactions (Rx-DIS) Identified Using the Healthcare Effectiveness Data and Information Set (HEDIS) Rx-DIS Measure

Disease State (n with Condition or Disease)	Drugs to Avoid	With Condition, n (%)	Exposure in 2006 in National Committee on Quality Assurance Study Using Medicare Data, %[16]
Dementia (131,808)	Anticholinergics,* tricyclic antidepressants	26,640 (20.2)	24.6
Fall or hip fracture (54,393)	Antipsychotics, tricyclic antidepressants, sleep agents	8,806 (16.2)	14.6
Chronic renal failure (154,278)	Nonsteroidal anti-inflammatory drugs	13,165 (8.5)	9.5
≥1 Rx-DIS overall (305,041)		46,481 (15.2)	19.4

* For example, diphenhydramine, dicyclomine, promethazine, cyclobenzaprine, chlorpheniramine, and oxybutynin.

of risk factors for HEDIS Rx-DIS exposure because inclusion of these individuals in a separate missing category complicated interpretation of race findings, and findings were essentially the same in analyses in which they were included.

Health Status Factors

Clinical characteristics included in this study included counts of chronic physical comorbidities, mental health comorbidities, and unique medication classes prescribed the previous year. Preexisting comorbidities were identified between FY04 and FY05 to assure adequate time for accurate assessment.[18] ICD-9-CM codes included in VA inpatient and outpatient databases were used to identify conditions included in the Selim Physical and Mental Comorbidity Indices.[19] The Physical Comorbidity Index includes 30 comorbid conditions (e.g., cerebrovascular disease, diabetes mellitus, hypertension) that are counted to create a physical disease burden score ranging from 0 to 30. The Mental Comorbidity Index includes six comorbid conditions (anxiety, depression, posttraumatic stress disorder, bipolar disorder, alcohol abuse and dependence, and schizophrenia) that are similarly summed to create a score indicating psychiatric disease burden. Previous work has shown that creation of categorical variables assists in interpretation of mental health conditions (0, 1, $\geq$2 conditions). The Physical and Mental Comorbidity Indices have been found to be associated with mortality and suboptimal prescribing in previous research.[5,20] In addition to comorbid conditions, a count of unique medication classes prescribed for each patient in FY05 (the year before Rx-DIS identification) was also used.[21]

Access-to-Care Factors

The first variable measuring access to care was an indicator identifying those for whom pharmacy copayments were required based on VA priority group. VA priority groups are associated with physical and mental health status, illness severity, and socioeconomic status. As defined here, priority group status that warranted a waiver of pharmacy copayments ($8 in 2006) included veterans with a service-connected disability of 50% or greater and individuals who were catastrophically disabled, had very low income, or had specific war-related experiences.[22] The second variable measuring access to care was prior receipt of geriatric care. Individuals who received care in geriatric outpatient clinics or inpatient geriatric evaluation and management in FY05 were identified as having prior geriatric care.[23] The third variable measuring access to care was a count of primary care visits. Because prior research found that patients with many primary care visits the previous year were more likely to have exposure to potentially inappropriate medications as measured according to the Beers criteria, those with more-frequent visits to primary care ($\geq$5 in a year) may be sicker and thus at higher risk of RX-DIS exposure.[3,24] Based on prior studies and the empirical distribution, patients were classified as having 0 or 1, 2 to 4, or 5 or more primary care visits.

Analysis

The prevalence of HEDIS Rx-DIS overall in participants meeting criteria for dementia, falls, and chronic renal failure and the prevalence of HEDIS Rx-DIS exposure according to specific condition is first provided. Then, risk factors for HEDIS Rx-DIS overall and within each condition of interest were identified using logistic regression analysis. Collinearity diagnostic testing was conducted to assure that multicollinearity did not exist between the variables included in the logistic regression models. SAS version 9.1 (SAS Institute, Inc., Cary, NC) was used for all analyses.

RESULTS

Of the 1,780,787 older community-dwelling veterans who received care regularly within the VA each year between FY04 and FY06, 305,041 met criteria for dementia, falls, or chronic renal failure. Table 1 shows the prevalence of drug–disease interactions according to disease state or condition. Based on the HEDIS Rx-DIS criteria, 46,481 (15.2%) of this cohort had one or more Rx-DIS exposures during FY06; 20.2% of the veterans with a history of dementia, 16.2% of those with a history of falls, and 8.5% of those with a history of chronic renal failure had Rx-DIS exposure.

Table 2 shows descriptive statistics for individuals with one or more and no Rx-DIS and for individuals with and without Rx-DIS exposure according to condition. There were statistically significant differences between those with and without Rx-DIS exposure for all bivariate analyses except for marital status in dementia and falls and sex in chronic renal failure. Table 3 shows adjusted odds ratios and 95% confidence intervals from logistic regression models examining the association between Rx-DIS exposure and independent variables overall and for each condition. In the overall analysis, risk factors included age, sex, ethnicity, psychiatric comorbidities, and level of primary care utilization, although there was some variation when examining Rx-DIS exposures within specific disease conditions with regard to race, sex, psychiatric comorbidities, and geriatric and primary care utilization.

DISCUSSION

This study of community-dwelling veterans is the first to report prevalence of exposure to Rx-DIS and potential risk factors for exposure based on the HEDIS measure. The prevalence of Rx-DIS is similar to rates of PIPE as defined according to the Beers criteria and other measures of high-risk medications in older adults (15–40%).[1,8,9,25] Given recent data showing a strong relationship between Rx-DIS exposure and adverse drug reactions, this form of suboptimal prescribing is a serious public health concern.[14,15]

Although other published studies using measures of Rx-DIS exposure that included more conditions and medications had much higher rates of exposure (5.7%,[12,13] 15.3%[26]), in this context, fewer conditions and fewer medications were considered suboptimal. Overall rates of any exposure were lower than population estimates according to the NCQA using the same measure in Medicare data in 2006, but the differences were primarily due to lower Rx-DIS exposure in individuals with dementia and chronic renal failure.[16] Consistent with other studies examining Rx-DIS, the number of unique medications had a strong association with Rx-DIS exposure,[10] although unlike in one study, women and Hispanics (but not men or African Americans) were at greater risk of Rx-DIS overall. These differences in demographic characteristics may be due to the smaller number of

Rx-DIS included in the HEDIS measure than the more-comprehensive measure used in that study.[10]

The current study demonstrated the importance of examining exposure and risk factors according to the specific type of Rx-DIS exposure. Although rates of exposure for dementia and falls were between 15% and 20%, exposure for renal failure was only 8.5%, perhaps indicating more care when prescribing medications for patients with renal failure. Alternatively, the measure may underestimate exposure to NSAIDs that can be obtained over the counter because generic forms may be obtained outside the VA pharmacy system at relatively low cost.

Although some risk factors were consistently associated with Rx-DIS exposure (e.g., younger age, number of unique medications, psychiatric comorbidity, exempt from copayment), it was found that the relationship between certain characteristics varied according to the specific Rx-DIS (e.g., race, sex, geriatric care and primary care utilization). The only race category that had consistently higher rates of Rx-DIS exposure than whites was Hispanic. For African Americans, likelihood of Rx-DIS exposure was lower than that for whites only in those with dementia; there was no significant difference for falls and a slightly higher likelihood for renal failure. These findings are consistent with higher rates of PIPE in whites based on the Beers criteria[3,25] and a broad literature identifying racial disparities in care for patients ranging from cardiac disease, hypertension, epilepsy, and mental health conditions.[27–29] Alternatively, examination of bivariate data according to race indicated that Hispanics were more likely to have multiple mental health conditions and that African Americans were more likely than whites to have arthritis, which may be treated with potentially problematic medications. Although the interaction effect was not statistically significant, variation in comorbidity profiles may influence Rx-DIS exposure.

Studies of PIPE based on the Beers criteria consistently find that women are at greater risk for exposure,[4,30] but the current study found that women were only at higher risk for dementia Rx-DIS exposure. Thus, it appears that higher risk for women is not comprehensive but is instead specific to dementia or the types of drugs that are problematic for dementia (e.g., anticholinergics, tricyclic antidepressants).

Geriatric care the prior year was associated with greater risk for Rx-DIS exposure overall, which is inconsistent with prior studies examining exposure to Beers criteria drugs, which have found that geriatric care reduced the likelihood of exposure.[30,31] However, examination of Rx-DIS exposure according to condition revealed less likelihood of dementia and renal Rx-DIS exposure and greater likelihood of falls Rx-DIS exposure. Because fall assessment and prevention is an important component of geriatric care, it is possible that the finding results from better screening and documentation of falls in the electronic medical record by geriatricians. Thus, these data may reflect not only a selection bias, with the most complicated patients being seen by geriatricians, but also a detection bias, with patients receiving care from a geriatrician

Table 3. Predictors of Drug–Disease Interactions in Community-Dwelling Department of Veterans Affairs Patients According to Condition or Disease

Characteristic	Odds Ratio (95% Confidence Interval)			
	Any	Dementia	Falls	Chronic Renal Failure

being more likely to have conditions such as falls documented in the electronic medical record.

These data have several limitations. First, they reflect only medications and healthcare utilization received in the VA. It is possible that other medications were ordered and dispensed outside the VA because the study period was after the initiation of Medicare Part D (January 1, 2006).[32] However, because patterns of Rx-DIS and prescribing were similar in 2004, 2005, and 2006, it is likely that the potential effect on the findings is limited. Second, in identifying the Rx-DIS conditions, access was available only to VA administrative data. Although Medicare data may improve ascertainment of the conditions of interest, 2 years of prior data was available to assess comorbid conditions, which is the recommended period to identify chronic disease states within VA data.[18] With regard to healthcare utilization, the criterion requiring at least one inpatient or outpatient visit per year may have excluded individuals who frequently received outside care, biasing the cohort to individuals who were sicker. Examination of Rx-DIS exposure using looser inclusion criteria, but all available data since 2003, resulted in similar rates of exposure and similar risk factors.

Moreover, this study assessed Rx-DIS exposure before the final approval of the HEDIS Rx-DIS measure. Thus, providers were not aware of this quality measure at the time of the study. Because this measure includes many Rx-DIS described previously in the Beers and McLeod criteria and because the selected Rx-DIS are a small, but clinically important, component of these measures, the Rx-DIS themselves or data supporting the Rx-DIS were available to clinicians for a number of years.[1,2,6,11,33] Although it is possible that publication of this measure in 2007 may have led to reductions in Rx-DIS because this measure may have had broader diffusion into clinical practice, data provided by the NCQA suggest that rates of exposure have sustained small increases (approximately 1% increase for each condition) over the past 3 years.[16] It is possible that increases are due to more attention to documenting conditions such as falls, but similar increases occurred for all three conditions, including chronic kidney disease, which is less commonly undercoded. This study provides a baseline to determine the extent to which diffusion of information included in this measure is reflected in VA clinical practice in the future, preferably in FY11 or FY12.

Finally, because falls are routinely undercoded, it is likely that the estimates of Rx-DIs are conservative because only veterans with severe falls tend to be identified as such using administrative data.

This study found a high rate of exposure to potentially harmful Rx-DIS for patients with dementia, falls, and chronic renal failure but generally lower rates than were found in Medicare data during the same time period.[16] Other studies have not examined the link between exposure and adverse outcomes using this less-comprehensive HEDIS measure of Rx-DIS. The current study suggests that research examining outcomes should examine outcomes and risk factors for individual conditions separately before combining them as a single measure of exposure. If links between Rx-DIS are demonstrated, the VA is uniquely positioned to use health information technology to reduce Rx-DIS exposure by implementing prescribing alerts within the electronic medication order process. As a leader in geriatric care, the VA is also in a position to test interven-

tions such as use of pharmacists or geriatricians within Patient Aligned Care Teams (patient-centered medical home) to improve the quality of care for older veterans and to conduct investigations on how shared decision-making between patient and provider may contribute to, or be used to reduce, Rx-DIS exposure.

HEALTH CARE REFORM

Effectiveness of Collaborative Care for Depression in Human Immunodeficiency Virus Clinics

Jeffrey M. Pyne, MD; John C. Fortney, PhD; Geoffrey M. Curran, PhD; Shanti Tripathi, MS; J. H. Atkinson, MD; Amy M. Kilbourne, PhD; Hildi J. Hagedorn, PhD; David Rimland, MD; Maria C. Rodriguez-Barradas, MD; Thomas Monson, MD; Kathryn A. Bottonari, PhD; Steven M. Asch, MD; Allen L. Gifford, MD

Background: Depression is common among persons with the human immunodeficiency virus (HIV) and is associated with unfavorable outcomes.

Methods: A single-blind randomized controlled effectiveness trial at 3 Veterans Affairs HIV clinics (HIV Translating Initiatives for Depression Into Effective Solutions [HITIDES]). The HITIDES intervention consisted of an offsite HIV depression care team (a registered nurse depression care manager, pharmacist, and psychiatrist) that delivered up to 12 months of collaborative care backed by a Web-based decision support system. Participants who completed the baseline telephone interview were 249 HIV-infected patients with depression, of whom 123 were randomized to the intervention and 126 to usual care. Participant interview data were collected at baseline and at the 6- and 12-month follow-up visits. The primary outcome was depression severity measured using the 20-item Hopkins Symptom Checklist (SCL-20) and reported as treatment response (≥50% decrease in SCL-20 item score), remission (mean SCL-20 item score, <0.5), and depression-free days. Secondary outcomes were health-related quality of life, health status, HIV symptom severity, and antidepressant or HIV medication regimen adherence.

Results: Intervention participants were more likely to report treatment response (33.3% vs 17.5%) (odds ratio, 2.50; 95% confidence interval [CI], 1.37-4.56) and remission (22.0% vs 11.9%) (2.25; 1.11-4.54) at 6 months but not 12 months. Intervention participants reported more depression-free days during the 12 months (β = 19.3; 95% CI, 10.9-27.6; $P < .001$). Significant intervention effects were observed for lowering HIV symptom severity at 6 months (β = –2.6; 95% CI, –3.5 to –1.8; $P < .001$) and 12 months (β = –0.82; –1.6 to –0.07; $P = .03$). Intervention effects were not significant for other secondary outcomes.

Conclusion: The HITIDES intervention improved depression and HIV symptom outcomes and may serve as a model for collaborative care interventions in HIV and other specialty physical health care settings where patients find their "medical home."

Trial Registration: clinicaltrials.gov Identifier: NCT00304915

Arch Intern Med. 2011;171(1):23-31

DEPRESSION IS ONE OF THE most common mental health disorders that afflict persons infected with the human immunodeficiency virus (HIV).[1-3] Despite available and efficacious treatments for depression, evidence suggests underdiagnosis and undertreatment of depression in routine HIV care.[4,5] Depression in persons with HIV may be associated with accelerated HIV disease progression,[6,7] decreased immune functioning,[7-9] nonadherence to HIV medication regimens,[10-12] and increased risk of mortality.[13-15] Depression is a modifiable risk factor, and effective treatment may improve HIV outcomes.[16-18]

In general adult primary care, collaborative care for depression is effective[19] and cost-effective.[20-22] Collaborative care models are based on the chronic care model,[23] facilitating collaboration between primary care and specialty mental health care providers to improve the quality of depression care and outcomes. Compared with referral specialty mental health care models, collaborative care allows patients to receive care in more accessible and less stigmatizing settings.

To our knowledge, no one has tested the collaborative care model for depression in a long-term specialty physical health care setting. This is an important gap because, for many patients with complex chronic illnesses, specialty physical health care clinics become their primary source of health care or "medical home."[24] For several reasons, the treatment of HIV and depression may be a potential model for testing the exportability of a collaborative care approach, first developed for primary care settings, to specialty-driven

long-term care of disease. Modern combination antiretroviral therapy has transformed HIV into a chronic disease, and the complexity of HIV care may be shifting care from primary to specialty care settings.[25] Organizational complexities are also associated with collaborative care interventions in HIV clinic settings given specialty care training, organizational structure, and culture.[26]

The goal of this study was to adapt an evidence-based primary care model of collaborative care of depression[27] to HIV clinic settings and evaluate the model's clinical effectiveness. We hypothesized that depressed patients who were assigned to the HIV Translating Initiatives for Depression Into Effective Solutions (HITIDES) intervention would report improved depression severity (primary outcome) and improved health-related quality of life, health status, HIV symptom severity, and medication regimen adherence (secondary outcomes) compared with patients receiving usual care.

METHODS

DESIGN

The HITIDES study was a randomized controlled effectiveness trial comparing depression collaborative care with enhanced usual care. Three Veterans Affairs (VA) HIV treatment facilities participated in the study. The study was approved by the research and development committees at the Central Arkansas Veterans Healthcare System, Michael E. DeBakey VA Medical Center, and Atlanta VA Medical Center.

PARTICIPANTS

Inclusion criteria were (1) a current 9-item Patient Health Questionnaire (PHQ-9) depression score of 10 or higher and (2) current treatment in the VA HIV clinic. A PHQ-9 score of at least 10 has strong psychometric properties in primary care settings (eg, >99% sensitivity and a 91% specificity).[28] Exclusion criteria were (1) no access to a telephone, (2) current acute suicidal ideation, (3) significant cognitive impairment as indicated by a score higher than 10 on the Blessed Orientation-Memory-Concentration Test,[29] and (4) history of bipolar disorder or schizophrenia. There were no exclusions based on physical health criteria, substance abuse or dependence, or current specialty mental health treatment.

The VA health care system provides health care to US veterans at more than 1400 medical centers and clinics nationwide. The VA is the largest national health care system and the largest single provider of HIV care. Veterans treated for HIV infection are older than the average US adult with HIV and more often male. Most of the 23 463 individuals in VA HIV care in 2008 were men (97%) and older than 50 years (64%). The proportion of African American patients (46%) is similar to the US HIV population (VA Clinical Case Registry, available at http://www.hiv.va.gov/). In general, veterans are eligible for care based on the length and character of their military service and current annual income level. In 2003, the VA stopped enrolling higher-income veterans.

After completing the eligibility and written informed consent processes, participants were randomly assigned to the intervention or to usual care and completed the baseline assessment. Participants were randomized to the intervention or to usual care in a 1:1 ratio according to a computer-generated random assignment sequence stratified by clinic and generated in advance. Research assistants at each clinic were provided envelopes labeled by participant number and containing randomized assignment. Participants were enrolled from February 1, 2007, through June 30, 2008.

DEPRESSION SCREENING AND INTERVENTION ADAPTATION BY CLINIC

Consistent with other collaborative care research, depression screening methods were adapted and adopted at each clinic as part of routine care using the PHQ-9 (2 clinics) or the 8-item PHQ (PHQ-8) (1 clinic)[30] and completed in person (2 clinics) or in person and by mail (1 clinic) before each HIV clinic visit. The intent was to complete the depression screen at each HIV clinic visit. The patient delivered a hard copy of the PHQ-9 or PHQ-8 to the HIV clinician at the time of the clinic visit. The PHQ-9 was completed by research personnel to confirm eligibility for the clinic that used the PHQ-8 as the depression screening instrument. A recent expert panel supported the use of the PHQ-9 in patients with HIV.[31]

Intervention adaptations were consistent across all clinics and included adding a clinical pharmacist to the intervention team, allowing substance-dependent patients to participate, adding brief alcohol and other drug interventions to the intervention, allowing patients engaged in specialty mental health care to participate, and formatting the intervention electronic medical record notes. The HIV staff conducted the depression screening, and the research team delivered the intervention.

HITIDES INTERVENTION

The purpose of the HITIDES intervention was to support HIV and mental health clinicians in delivering evidence-based depression treatment. The HIV depression care team consisted of a registered nurse depression care manager (DCM), a clinical pharmacist, and a psychiatrist (J.M.P.). This team was located offsite at the Little Rock VA Medical Center and convened once a week and as needed by telephone or in person. The depression care team communicated with treating clinicians via electronic medical record progress notes. The DCM communicated with patients via telephone. The HITIDES depression care team made treatment suggestions. Treatment decisions were made by the HIV or mental health clinicians at each site.

The DCM delivered the following intervention components: participant education and activation,[32] assessment of treatment barriers and possible resolutions, depression symptom and treatment monitoring, substance abuse monitoring, and instruction in self-management (eg, encouraging patients to exercise and participate in social activities).[33,34] The DCM used prewritten scripts, which are standardized instruments that were supported by the Web-based decision support system (NetDSS, available at https://www.netdss.net) during these telephone encounters.

The intervention used a stepped-care model for depression treatment.[35] The 5-step model included the following components plus DCM monitoring: (1) watchful waiting, (2) depression care team treatment suggestions (counseling or pharmacotherapy, considering participant preference), (3) pharmacotherapy suggestions after review of depression treatment history by the clinical pharmacist, (4) combination pharmacotherapy and specialty mental health counseling, and (5) referral to specialty mental health. Specific treatment suggestions were based on the Texas Medication Algorithm Project[36] and VA/Department of Defense Depression Treatment Guidelines.[37] Although the depression care team did not suggest watchful waiting, patient/provider treatment negotiations could result in this approach. At any time, HIV health care providers were free to refer participants directly to specialty mental health care. The stepped-care model was used to increase treatment intensity when participants did not respond to treatment.

The DCM conducted telephone-based monitoring every 2 weeks during acute treatment (before achieving a sustained 50% decrease in PHQ-9 score) and every 4 weeks during watchful waiting or continuation treatment (for 2 months after maintaining remission [PHQ-9 score, <5] or 6 months after maintaining a 50% decrease in the PHQ-9 score). The NetDSS system identified potential treatment nonresponse as (1) antidepressant regimen adherence of less than 80% during the past 14 days, (2) counseling nonadherence of less than 75% during the past month, (3) participant report of severe adverse effects during 2 consecutive DCM encounters, (4) participant report of a 5-point increase in depression severity from the enrollment PHQ-9 score based on 2 consecutive DCM encounters, or (5) lack of participant response (<50% decrease from enrollment PHQ-9 score during 2 consecutive DCM encounters) during an 8-week antidepressant or 12-week counseling trial.

USUAL CARE

Intervention and usual care participants completed PHQ depression screens as described, and patients delivered hardcopy results to their HIV clinicians at most clinic visits. These results were used to identify depression and monitor treatment response. Usual care depression treatment was provided by HIV or mental health clinicians without involvement of the HITIDES depression care team. Before starting the study, all HIV health care providers received 1 hour of HIV and depression training. Specialty mental health referral procedures were reviewed at all sites and typically included at least 1 failed depression treatment trial before referral.

DATA COLLECTION

Baseline and 6- and 12-month data were collected by telephone interviewers who were blinded to treatment assignment and used scripted computer-based assessments. At baseline, demographics (including self-reported race according to categories provided by the interviewers), depression history, and chronic physical health conditions (besides HIV) were measured using the Depression Outcomes Module.[38,39] Mental health comorbidity was measured using the Mini International Neuropsychiatric Interview.[40,41] Acceptability of antidepressant treatment was measured using an item developed for the Quality Improvement for Depression studies.[42,43] Follow-up data-collection interviews were completed for 226 of 249 participants (90.8%) at 6 months and 215 of 249 (86.3%) at 12 months (**Figure 1**).

OUTCOME MEASURES

The primary outcomes listed in clinicaltrials.gov were depression severity, implementation process, and quality of care. Implementation process and quality of care will be addressed in separate reports. Secondary outcomes were health status, health-related quality of life, HIV symptom severity, HIV medication regimen adherence, antidepressant regimen adherence, treatment satisfaction, and cost-effectiveness. Treatment satisfaction and cost-effectiveness also will be addressed in separate reports.

Depression symptom severity during the past 2 weeks was measured using the 20-item Hopkins Symptom Checklist (SCL-20),[44] which includes the 13-item depression scale plus 7 depression-related items from the Hopkins Symptom Checklist 90–Revised. The items are scored from 0 to 4 and averaged to provide a mean depression severity score ranging from 0 to 4.

Depression treatment response at 6 and 12 months was defined as a 50% or greater decrease in the mean SCL-20 score compared with baseline, and remission at 6 and 12 months was defined as a mean SCL-20 score of less than 0.5. Depression-free days (DFDs) were calculated as a summative measure of depression severity based on baseline and 6- and 12-month SCL-20 data using formulas originally developed by Lave and colleagues[45] and adapted for the SCL-20.[46] For each assessment, an SCL-20 score of 0.5 or less was considered depression free, a score of 2.0 or higher was considered fully symptomatic, and scores in between were assigned a linear proportional value. Derivation of DFDs from the SCL-20 has been used in several influential primary care studies.[47-49]

Health status was measured using the physical and mental health component summary scores from the Medical Outcomes Study Veterans 12-Item Short-Form Health Survey.[50] Health-related quality of life was measured using the Quality of Well-Being Self-administered Scale (QWB-SA).[51,52] The QWB-SA score is derived from general population preference weights and ranges from death (0.0) to perfect health (1.0). Severity of HIV symptoms was measured using the 20-item Symptoms Distress Module, which summarizes the degree to which each symptom bothered the participant in the past 4 weeks on a scale from 0 ("I do not have this symptom") to 4 ("This symptom bothers me a lot").[53] Bothersome HIV symptoms were defined as scores of 3 or 4.

Antidepressant and HIV medication regimen adherence were measured separately using the AIDS Clinical Trial Group assessment, which asks participants to report the number of pills per day they are supposed to take and the number of pills they

Table 1. Baseline Sociodemographic and Clinical Characteristics of Intervention and Usual Care Groups

Variable	Group[a]	
	Intervention (n=123)	Usual Care (n=126)

Abbreviations: AD, antidepressant; HIV, human immunodeficiency virus; MCS, mental component summary; PCS, physical component summary; PHQ-9, 9-item Patient Health Questionnaire; QWB-SA, Quality of Well-Being Self-administered Scale; SCL-20, 20-item Hopkins Symptom Checklist; SF-12V, Medical Outcomes Study Veterans 12-Item Short-Form Health Survey.

[a] Unless otherwise indicated, data are expressed as number (percentage) of participants. Percentages reflect the following missing data: race, 1 usual care participant; annual income, 5 intervention and 4 usual care participants; any depression treatment in the past 6 months, 1 intervention participant; and antidepressant acceptable, 1 intervention and 1 usual care participant.

[b] $P<.01$ for intervention vs usual care.

[c] $P<.05$ for intervention vs usual care.

[d] The PHQ-9 was used as depression screening measure. The SCL-20 was used as the depression outcome measure.

[e] Mental health comorbidity was identified using the Mini International Neuropsychiatric Interview.

skipped taking for each medication for each of the past 4 days.[54] Percentage of adherence equaled the total number of prescribed pills taken divided by the total number prescribed during the past 4 days. Dichotomous antidepressant regimen adherence was defined as greater than or equal to 80% adherence, and HIV medication regimen adherence was defined as greater than or equal to 95% adherence.

ANALYSIS

Participants were the unit of the intent-to-treat analysis. Sample size calculations were based on preliminary 6-month data from the Telemedicine Enhanced Antidepressant Management Study. The Telemedicine Enhanced Antidepressant Management Study was a depression collaborative care study conducted in VA community-based outpatient clinics. We based the power calculation on detecting an 11% difference in the percentage of responders between intervention and usual care using a 1-tailed t test ($\alpha=.05$). A sample size of 280 (140 subjects per arm) would provide 74% power. We did not adjust for potential nesting of participants within parent VA medical centers because the intraclass coefficient (0.02) was close to zero with respect to changes in SCL-20 scores $P=.30$), and there were no significant differences in outcomes across sites. Missing values were imputed using multiple imputation methods (ie, SAS statistical software, version 9.2, PROC MI and PROC MIANALYZE; SAS Institute Inc, Cary, North Carolina). Because of the large number of available case-mix variables, only those found to significantly predict dependent variables at $P<.20$ in bivariate analyses were included in multivariate analyses.

In **Table 1**, categorical variables were compared using a χ^2 test, and continuous variables were compared using a 2-tailed t test or its nonparametric analogue. Logistic and ordinary least squares regression analyses were used to estimate intervention effects for dichotomous and continuous outcomes, respec-

tively. For the continuous outcome measures DFDs and HIV symptom severity, the residual plots indicated nonconstant variance; therefore, we used weighted least squares regression methods to correct for heteroskedasticity. Residual plots for other continuous outcome measures did not indicate nonconstant variance. Separate regression analyses were conducted to examine the 6- and 12-month outcomes except for DFDs, which were measured for the entire 12-month follow-up period. Hierarchical linear modeling methods were not used because 2 of the primary outcomes (depression response and remission) were defined at only 2 time points, and for consistency we also used this approach with the secondary outcomes. The 9.2 version of the SAS software was used for all analyses.

RESULTS

In general, the HITIDES sample consisted of middle-aged, high school–educated, single, African American men of low to middle income who were experiencing mild to moderate symptoms of HIV disease and reported moderate reductions in health-related quality of life. Most had a history of mood disorder, expressed moderate depression symptom severity, and had received treatment for depression in the preceding 6 months. An important minority (18.1%) met criteria for at-risk drinking. Intervention and usual care participants were similar at baseline on demographic and clinical characteristics, except that intervention participants reported higher (better) health-related quality of life (QWB-SA scores, 0.49 vs 0.44; $P=.007$) and lower scores for physical health comorbidities (3.2 vs 3.8; $P=.046$) (Table 1).

INTERVENTION FIDELITY

Of the 123 intervention patients, 119 (96.7%) were contacted by the DCM. Initial patient education and activation was completed for 118 (99.2%), initial treatment barriers assessment was completed for 116 (97.5%), and 100% of all DCM contacts completed the PHQ-9 and medication regimen and/or counseling adherence assessment, depending on the current treatment. During the acute phase of treatment, a total of 231 intervention group treatment trials (mean, 1.94) included 110 (47.6%) watchful waiting, 94 (40.7%) pharmacotherapy, 7 (3.0%) counseling, and 20 (8.7%) combination pharmacotherapy and counseling trials. The mean number of DCM intervention telephone contacts per patient during the acute and continuation phases of treatment was 7.2 (SD, 4.5; range, 0-19).

PRIMARY OUTCOME: DEPRESSION SEVERITY

Figure 2 shows the unadjusted total SCL-20 scores over time. The unadjusted SCL-20 scores were not significantly different between the intervention and usual care groups at the 6- or 12-month follow-up. However, the unadjusted treatment response rates at 6 months were 17.5% (22 of 126 patients) for usual care and 33.3% (41 of 123 patients) for the intervention ($P=.004$) (**Table 2**). The adjusted intervention effect on treatment response at 6 months was also significant (odds ratio [OR], 2.60; 95% confidence interval [CI], 1.39-4.86; $P=.003$). The

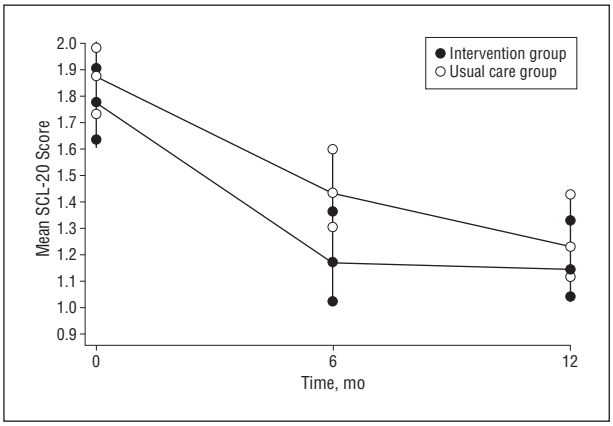

Figure 2. Unadjusted mean (95% confidence intervals) 20-item Hopkins Symptom Checklist (SCL-20) scores for the intervention and usual care groups over time.

unadjusted treatment remission rates at 6 months were 11.9% (15 of 126 patients) for usual care and 22.0% (27 of 123 patients) for the intervention ($P=.03$). The adjusted intervention effect on treatment remission at 6 months was also significant (OR, 2.40; 95% CI, 1.10-5.22; $P=.03$). Unadjusted and adjusted intervention effects on 12-month response and remission were not significant. Unadjusted (147.3 vs 120.0, $P=.04$) and adjusted intervention effects on DFDs were significantly greater in the intervention vs the control group ($\beta=19.3$; 95% CI, 10.9-27.6; $P<.001$) (**Table 3**).

SECONDARY OUTCOMES

Significant intervention effects were observed for HIV symptom severity but not for health-related quality of life, health status, antidepressant prescribing, or antidepressant or HIV medication regimen adherence. The adjusted intervention effect resulted in significantly lower 6- and 12-month HIV symptom severity compared with usual care at 6 months ($\beta=-2.6$; 95% CI, −3.5 to −1.8; $P<.001$) and 12 months ($\beta=-0.82$; 95% CI, −1.6 to −0.07; $P=.03$) (Table 3). The depression items in the SCL-20 and the HIV symptom severity measure overlapped (eg, baseline correlation, $r=0.54$; $P<.001$). However, after removing 7 depression-related items from the HIV symptom severity measure, the adjusted intervention effect on HIV symptom severity remained significant at 6 months ($\beta=-0.62$; 95% CI, −1.16 to −0.08; $P=.03$) but not at 12 months ($\beta=-0.09$; 95% CI, −1.58 to 1.40; $P=.88$). The unadjusted and adjusted intervention effects on 6- and 12-month antidepressant prescribing rates, antidepressant regimen adherence, HIV medication regimen adherence, QWB-SA, and Medical Outcomes Study Veterans 12-Item Short-Form Health Survey mental and physical component summary scores were not significant.

COMMENT

To our knowledge, this is the first effectiveness trial of a depression collaborative care intervention in a long-term specialty physical health care setting. Other successful collaborative depression care interventions tar-

Abbreviations: AD, antidepressant; CI, confidence interval; HIV, human immunodeficiency virus; NNT, number of patients needed to treat to achieve 1 additional successful outcome; OR, odds ratio.

[a] Attrition weights were used for AD prescription, AD regimen adherence, and HIV medication regimen adherence equations. Multiple imputation was used in other analyses.

[b] Number needed to treat was calculated for a given outcome only when the intervention *P* value was less than .05.

[c] The 6-month baseline covariates were intervention, 20-item Hopkins Symptom Checklist (SCL-20) score, physical health comorbidity, HIV symptom severity, race, any lifetime inpatient mental health admission, and HIV medication prescription. The 12-month baseline covariates were intervention, physical health comorbidity, HIV symptom severity, marital status, any lifetime inpatient mental health admission, any depression treatment in the past 6 months, and HIV medication prescription.

[d] The 6-month baseline covariates were intervention, SCL-20 score, physical health comorbidity, HIV symptom severity, race, comorbid mental health diagnosis, any lifetime inpatient mental health admission, any depression treatment in the past 6 months, and HIV medication prescription. The 12-month baseline covariates were intervention, age, SCL-20 score, physical health comorbidity, HIV symptom severity, and marital status.

[e] The 6-month baseline covariates were intervention, AD prescription, SCL-20 score, HIV symptom severity, race, annual household income, comorbid mental health diagnosis, any lifetime inpatient mental health admission, any depression treatment in the past 6 months, and acceptability of AD medications. The 12-month baseline covariates were intervention, AD prescription, SCL-20 score, physical health comorbidity, HIV symptom severity, race, comorbid mental health diagnosis, any lifetime inpatient mental health admission, any depression treatment in the past 6 months, and acceptability of AD medications.

[f] The 6-month baseline covariates were intervention, age, and education. The 12-month baseline covariates were intervention, age, education, and acceptability of AD medications.

[g] The 6-month baseline covariates were intervention, age, and race. The 12-month baseline covariates were intervention, age, HIV symptom severity, marital status, education, annual household income, any depression treatment in the past 6 months, and acceptability of AD medications.

geted depressed primary care patients generally,[48,55-58] depressed primary care patients with diabetes,[59] or depressed patients in an oncology clinic.[60] Depression is one of the most common co-occurring illnesses among people with complex chronic comorbidities; therefore, developing treatment strategies that are effective in specialty physical health care settings is vital to improving treatment outcomes for these patients. Human immunodeficiency virus may be a particularly important chronic condition model because depression is so prevalent and because treating depression can improve depression outcomes and has the potential to improve a wide range of life-saving self-management and adherence behaviors.[18,61]

The primary outcomes of this study were a more than doubling of the odds of depression response and remission at 6 but not 12 months and improved DFDs during the 12 months of treatment. Improved depression response and remission outcomes at 6 but not 12 months suggests that depression symptoms improved more rapidly in the intervention group compared with the usual care group. By 12 months, usual care participants caught up with intervention participants in terms of response and remission rates. The adjusted incremental 12-month DFDs result from the HITIDES intervention (19.3 days) compares with 20 to 72 DFDs in non-VA samples[45,56,62,63] and 14.6 incremental DFDs during 9 months in a VA sample.[22] Secondary outcomes included improved HIV symptom severity but no improvement in health-related quality of life, health status, or self-reported antidepressant or HIV medication regimen adherence.

The usual care depression response and remission outcomes appear to catch up with the intervention group at 12 months. Possible explanations include the following. First, the intervention was tested in settings where clinicians clearly accepted the need for improving depression recognition and treatment in the HIV clinic setting. Second, depression screening was completed on a hard copy form that most patients presented to their HIV clinician at every visit; therefore, over time, the HIV clinicians became more familiar with depression diagnosis and tracking treatment response. Third, DCM notes for intervention patients resulted in HIV clinicians becoming more familiar with treatment options for all patients in the HIV clinic.

Significant improvement in depression and HIV outcomes and the lack of detectable differences in prescribing or adherence suggest that other mechanisms lead to

Abbreviations: CI, confidence interval; DFDs, depression-free days; HIV, human immunodeficiency virus; MCS, mental component summary; PCS, physical component summary; QWB-SA, Quality of Well-Being Self-administered Scale; SF-12V, Medical Outcomes Study Veterans 12-Item Short-Form Health Survey.

[a] Effect sizes were not calculated when the intervention effect was not significant in the adjusted analysis.

[b] Covariate baseline measures were intervention, 20-item Hopkins Symptom Checklist (SCL-20) score, physical health comorbidity, HIV symptom index, marital status, annual household income, comorbid mental health, any inpatient mental health admission, and any depression treatment in the past 6 months.

[c] The 6-month baseline covariates were intervention, HIV symptom severity, SCL-20 score, physical health comorbidity, marital status, education, comorbid mental health, any inpatient mental health admission, any depression treatment in the past 6 months, acceptability of antidepressant (AD) medications, and HIV medication prescription. The 12-month baseline covariates were intervention, HIV symptom severity, SCL-20 score, physical health comorbidity, marital status, annual household income, comorbid mental health, any inpatient mental health admission, any depression treatment in the past 6 months, and HIV medication prescription.

[d] The 6-month baseline covariates were intervention, QWB-SA score, SCL-20 score, physical health comorbidity, HIV symptom severity, education, annual household income, comorbid mental health, any inpatient mental health admission, acceptability of AD medications, and HIV medication prescription. The 12-month baseline covariates were intervention, QWB-SA score, SCL-20 score, physical health comorbidity, HIV symptom severity, education, annual household income, comorbid mental health, any inpatient mental health admission, acceptability of AD medications, and HIV medication prescription.

[e] The 6-month baseline covariates were intervention, SF-12V MCS score, SCL-20 score, physical health comorbidity, HIV symptom severity, education, annual household income, comorbid mental health, any inpatient mental health admission, any depression treatment in the past 6 months, acceptability of AD medications, and HIV medication prescription. The 12-month baseline covariates were intervention, SF-12V MCS score, age, SCL-20 score, HIV symptom severity, comorbid mental health, any inpatient mental health admission, any depression treatment in the past 6 months, and HIV medication prescription.

[f] The 6-month baseline covariates were intervention, SF-12V MCS score, age, SCL-20 score, physical health comorbidity, HIV symptom severity, annual household income, and HIV medication prescription. The 12-month baseline covariates were intervention, SF-12V PCS score, SCL-20 score, physical health comorbidity, HIV symptom severity, marital status, and education.

improved depression outcomes. We may have failed to detect medication prescription or adherence effects because of self-report measurement error.[64,65] The intervention may have led to greater dose intensification or treatment switching not detected by our measurement methods. Another mechanism for depression improvements may have been DCM promotion of self-management activities and/or brief interventions for alcohol and other drug abuse. Possible mechanisms for improved HIV symptom severity include depression intensifying patients' experience of physical symptoms[66] and/or DCM promotion of patient self-management activities.

The organization of health care into medical homes to provide integrated, accessible, and comprehensive services to patients with chronic and complicated medical needs has been widely promoted.[67] High-quality medical home services from specialists would require provision of specialty and primary care treatments, first-contact/comprehensive care responsibility, and patient affiliation with the clinic as the central hub of care.[24] Long-term care clinics for HIV infection and other complex conditions could, with adoption of appropriate care models, satisfy these criteria. There are also specialty clinics that provide comprehensive care for a shorter period that could satisfy most if not all medical home criteria for that period (eg, clinics that provide long-term treatment for hepatitis C virus infection).

The HITIDES study design had strengths and weaknesses. Strengths included adapting an evidence-based collaborative care intervention to HIV clinic settings, generalizability to the real-world patient population (eg, substance-dependent patients were not excluded), use of Web-based decision support to ensure fidelity to the intervention protocol, and use of an electronic medical record to facilitate communication between the HITIDES depression care team and the HIV and mental health care providers. Weaknesses included the potential lack of generalizability from VA to other treatment settings and the use of self-reported medication adherence data. However, a general VA outpatient depression collaborative care intervention found a significant correlation between self-report and administrative adherence data.[68]

In conclusion, the HITIDES intervention was successfully implemented in HIV clinic settings and improved depression and HIV symptom outcomes. The HITIDES intervention may serve as a model for collaborative care interventions in other specialty physical health care settings where patients find their medical home.

(*Received 11 November 2010; final version received 16 February 2011*)

To describe sex risk behaviors of HIV-infected female sex workers (FSWs) and HIV-infected male clients of FSWs, to evaluate associations between risky transactional sex and number of unprotected transactional sex episodes, and to assess the association between unprotected transactional sex and self-reported sexually transmitted infection (STI). Adult HIV-infected FSWs ($n = 211$) and HIV-infected male clients ($n = 205$) were surveyed in Mumbai about demographics, STI, and past 90-day and past year sex and substance use histories. Gender-stratified Poisson regression models were used to evaluate associations between four risky transactional sex behaviors (number of transactional sex partners; alcohol use before transactional sex; anal transactional sex; and transactional sex with a known HIV-infected partner) and number of unprotected transactional sex episodes; logistic regression was used to assess the association between unprotected transactional sex and self-reported STI. Twenty-nine percent of females and 7% of males reported any unprotected transactional sex episodes in the past 90 days. Thirty-nine percent of females and 12% of males reported past year STI. Among males, a greater number of transactional sex partners was associated with more unprotected transactional sex episodes (adjusted incidence rate ratio [IRR] = 8.2, 95% confidence interval [CI] = 1.8–38.4 highest vs. lowest tertile), and any unprotected transactional sex was associated with a higher odds of self-reported STI in the past year (adjusted odds ratio [AOR] = 5.6, 95% CI = 1.4–22.4). For women, risky transactional sex behaviors were not associated with condom non-use, and unprotected sex was negatively associated with STI (AOR = 0.4, 95% CI = 0.2–0.9). Reports of condom use during transactional sex were high for these samples. However, standard predictors of unprotected transactional sex (i.e., greater number of partners) and STI (i.e., unprotected sex) only held true for males. Further research is needed to guide an understanding of sex risk and STI among HIV-infected FSWs in India.

Keywords: female sex workers; male clients of female sex workers; HIV-infected; sex risk; India

Introduction

India has more than two million HIV-infected people, and female sex workers (FSWs) and male clients of FSWs maintain substantially higher HIV prevalence rates than that seen in the general population (National AIDS Control Organization [NACO], 2007; NACO, 2010). While the national HIV rate in India is estimated at 0.2–0.3% (NACO, 2007, NACO, 2010; Joint United Nations Programme on HIV/AIDS (UNAIDS), 2007, 2010), such rates among FSWs and their male clients in high HIV epidemic states such as Maharashtra are 18 and 12%, respectively (NACO, 2007). Ongoing sex risk among these populations poses a threat both to the transactional sex-involved and general population. To date, however, secondary prevention efforts in general and those specific to HIV-infected transactional sex-involved populations have received little attention from national prevention plans (NACO, 2010). More focus is needed toward such efforts and will benefit from understanding the sex risks occurring among these groups.

Within India, there is little research on sex practices among HIV-infected men and women of any population, but particularly those at risk of transmitting the virus via heterosexual sex. As of October 2010, we identified only two published studies examining sex risk behaviors among heterosexual HIV-infected adults in India (Chakrapani, Newman, Shunmugam, & Dubrow, 2010; Sri Krishnan et al., 2007), in addition to work from the current study (Samet et al., 2010). Overall, these studies indicate that although condom use is reported by the majority of HIV-infected adults, inconsistent and non-condom use is common, and barriers to condom use include both behavioral issues such as alcohol as well as attitudinal factors. More detailed consideration of transactional sex

behaviors, such as several partners or alcohol use before transactional sex, factors linked with increased risk for HIV/sexually transmitted infection (STI) among FSWs and male clients in India generally (NACO, 2010), was not identified. Nor was there consideration of differences in risk by gender, a likely scenario given the strong affect of gender role dynamics on condom use in India and elsewhere.

To build upon this nascent but growing literature on sex risk among HIV-infected adults in India, the following study examines sex behaviors among HIV-infected adults reporting past year transactional sex involvement. In addition, this study assesses whether risky transactional sex behaviors (e.g., alcohol use at transactional sex) are associated with the number of unprotected transactional sex episodes. Secondarily, this study examined the association between unprotected sex and STI in these populations. Findings can be used to inform the development of secondary prevention efforts in India and with HIV-infected individuals involved with transactional sex, globally.

Methods

The Transactional sex and Alcohol: Justification for a research initiative (TAJ) research team completed surveys on HIV-infected FSWs and HIV-infected male clients of FSWs in Mumbai, India ($n = 416$) from November 2008 to February 2009. Participants were recruited by way of service and health agencies focused on these populations in Mumbai, India; details on these agencies are available in previous publication from this study (Samet et al., 2010).

HIV-infected outreach workers at partnering agencies reviewed client lists and selected every fifth individual from the list to be approached and screened for study participation. Those contacted were asked to come to their respective recruitment sites for eligibility screening for the research study. A total of 326 women and 418 men were contacted for study recruitment, of which 246 (75%) women and 372 (89%) men came into their respective recruitment sites. Of these, 216 women and 210 men met the study's eligibility criteria: 18 years or older; HIV-infected; and reporting sex trade involvement in the past year (i.e., selling sex for women, purchasing sex for men) *and* penile-vaginal or anal sex in the past 30 days. HIV infection was confirmed by medical records brought by the participants. Of those eligible for the study, 5 women and 5 men were unwilling to participate and complete their interviews; they were excluded from the analyses, providing the final sample size of 211 female and 205 male participants.

Participants received a 45 minute interviewer-administered survey in Hindi assessing demographics, alcohol use, sex risk behaviors, and health status. Instruments were developed in English, translated into Hindi and then reviewed by a study investigator fluent in both languages. Discrepancies were resolved in consultation with the US investigators. Participants were given 100 rupees ($2.50) as compensation for their time in this study. Study procedures were reviewed and approved by the Institutional Review Boards (IRB) of Boston University Medical Campus, Network in Maharashtra by People Living with HIV (NMP+) and the Indian Council of Medical Research.

Measures

Demographic data were single item measures including age, level of education, income, religion, marital status, and number of children.

Sex risk behaviors were assessed for each of the following types of sex partners: spouses, transactional sex partners, and other sex partners. For each of these types of partners, participants were asked the number of these partners they had, as well as the number of vaginal or anal sex episodes and the frequency of unprotected sex episodes (indicated by 1 = always, 2 = usually, 3 = sometimes, 4 = rarely, and 5 = never) they had with these partners in the past year. They were also asked, again by partner type, whether any of the partners were HIV-infected and what their frequency of alcohol use before sex was with these partners (indicated by 1 = always, 2 = usually, 3 = sometimes, sometimes, 4 = rarely, and 5 = never). In addition, for each of these types of partners, participants were asked, using a past 90-day timeframe, the number of vaginal sex episodes, unprotected vaginal sex episodes, and occasions of alcohol use before sex; using this same time frame, they were then asked if they had engaged in anal sex with each type of partner and the frequency of condom use during anal sex, if the behavior was reported. All of these items were used to provide descriptive data on sex behaviors of the population; in addition, using data on transactional sex partners in the past 90 days, the following primary outcome variable was developed: number of unprotected transactional sex acts in the past 90 days.

To determine STI history, participants were asked whether they had contracted a sexually transmitted disease other than HIV, such as syphilis, gonorrhea, Chlamydia, trichomoniasis, or genital warts in the past year. Those indicating yes to any of these were classified as having an STI, which also served as one of our outcome variables. We were not able to

confirm STI history with medical record. We assessed date of HIV diagnosis to determine length of time since diagnosis.

Data analysis

All analyses for this study were stratified by gender. Poisson regression models were used to assess factors associated with number of unprotected transactional sex episodes in the past 90 days, as this outcome was not normally distributed. The Pearson Chi-square correction was used to account for overdispersion in the data. Four risky transactional sex behaviors were the main independent variables of interest: (1) number of transactional sex partners in the past year (categorized using tertiles; (2) any alcohol use before transactional sex in the past year; (3) any anal transactional sex in the past 90 days; and (4) any known HIV-infected transactional sex partners. The regression models controlled for the following potential demographic confounders: age, religion (Hindu vs. other), any formal education, and marital status (currently vs. formerly vs. never married). A multivariable regression model was fit including the four main independent variables and potential confounders. To avoid possible collinearity, pairwise Spearman correlations between the independent variables and covariates were assessed prior to regression modeling, and no pair of variables with correlation greater than 0.40 was included in the same model. The association between each independent variable and number of unsafe sex acts was quantified using an incidence rate ratio (IRR).

Multiple logistic regression models adjusting for potential confounders were used to assess the association between any unprotected transactional sex in the past 90 days and self-reported past year STI diagnosis. These analyses also controlled for age, religion, education, marital status, and the above described four risky transactional sex behaviors. Secondary analyses were also conducted evaluating any unprotected transactional sex in the past year (rather than past 90 days) as the main independent variable. As described above, to minimize the potential for collinearity, no pair of variables included in the same model was highly correlated. Analyses were performed using SAS software (version 9.1; SAS Institute, Cary, NC).

Results

Demographic characteristics of study participants

Female participants ranged in age from 22 to 49 years; women largely reported no history of formal education (78%) and were unmarried (91%) (Table 1). Male participants ranged in age from 20 to 49 years. Few men reported no formal education (11%), and 63% were unmarried.

Sex partners, unprotected sex and transactional sex behaviors

Among women, sex with spouses and other non-transactional sex partners in the past year was not common; however, for those reporting these behaviors ($n = 18$ and $n = 33$, respectively), the vast majority ($> 70\%$) reported unprotected sex in these contexts (Table 2). All women reported past year transactional

Table 1. Demographic characteristics of HIV-Infected FSWs ($n = 211$) and HIV-infected male clients of FSWs ($n = 205$) in Mumbai, India.

	Female sample		Male sample	
Characteristic	Mean	SD	Mean	SD
Age, years	30.6	5.0	32.8	5.5
Number of months since diagnosis	6.0	8.9	28.5	36.5
Income, rupees, past month	3107.9	1912.4	4878.9	2004.2
	n	Percentage (%)	*n*	Percentage (%)
Married				
Currently married	20	9.5	76	37.1
reviously married	105	49.8	41	20.0
Never married	86	40.8	88	42.9
Religion				
Hindu	164	77.7	157	76.6

Other	22	10.4	29	14.1
No formal education	165	78.2	23	11.2

sex, as it was an entry criterion for the study, and almost all women (98.6%) reported transactional sex in the past 3 months; 90.5% of women reported unprotected transactional sex in the past year, whereas 28.6% reported this behavior in the past 3 months.

Sex with spouses in the past year appeared more common for men than women in this sample (reported by 39.0% of males vs. 8.5% of females), as did sex with non-transactional sex partners (reported by 22.8% of males vs. 15.6% of females) (Table 2). Among men reporting sex with spouses ($n = 80$), one-third reported unprotected sex with these wives; among men reporting sex with other non-transactional sex partners ($n = 47$), almost two-thirds reported engaging in unprotected sex in this context.

All participants reported transactional sex in the past year, as it was an inclusion criterion for the study; as expected the mean number of partners reported by women in the past year was far greater than those reported by men: 554 partners (standard deviation [SD] = 28.7) vs. 9 partners (SD = 8.9), respectively (Table 2). As almost half of women reported HIV diagnosis in the past 3 months, we explored whether in the past 90-day unprotected sex was significantly different for those diagnosed in the past 3 months relative to those diagnosed more than 3 months ago; no significant association was observed. Among men, 26% reported unprotected transactional sex in the past year, and 7% reported unprotected transactional sex in the past 90 days (Table 2).

Alcohol use before transactional sex in the past year was common for both female and male participants, reported by 48 and 67%, respectively; 12% of females and 33% of males reported always using alcohol before transactional sex involvement (Table 3). Anal transactional sex in the past 90 days was reported by 5% of females but only 0.5% of males. Less than 4% of males and females reported transactional sex with known HIV-infected partners.

Past year STI and time since HIV diagnosis

Among females, 39% reported an STI in the past year (Table 3). Mean number of months since HIV diagnosis among women was 6 months (SD = 8.9 months). Among males, 12% reported STI in the past year. Mean number of months since diagnosis was 28.5 months for males (SD = 36.5 months).

Associations between risky transactional sex behaviors and unprotected transactional sex

Poisson analyses revealed no significant associations between higher risk transactional sex behaviors and number of unprotected transactional sex episodes

Table 2. Types of sex partners and unprotected sex practices by partner type among HIV-infected FSWs ($n = 211$) and HIV-infected clients of FSWs ($n = 205$) in Mumbai, India.

	Female sample				Male sample			
Characteristics	Median	IQR	*n*	Percentage (%)	Median	IQR	*n*	Percentage (%)
Sex with a spouse, past year			18	8.5			80	39.0
Number of sex episodes	120.0	(80.0–200.0)			70.0	(41.5–96.0)		
Any unprotected sex			13	72.2% (no./*n* = 13/18)			31	38.8% (no./*n* = 31/80)
Sex with other (non-transactional) partners, past year			33	15.6%			47	22.8%
Number of sex episodes	82.0	(40.0–300.0)			16.0	(7–50)		
Any unprotected sex			31	93.9% (no./*n* = 31/33)			30	63.8 (no./*n* = 30/47)
Transactional sex, past year			211	100%			205	100%
Number of sex episodes	650	(420.0–800.0)			6	(4–12)		
Number of partners	600	(360.0–720.0)			6	(4–10)		
Any unprotected transactional sex			191	90.5% (no./*n* = 191/211)			53	25.9 (no./*n* = 53/205)
Transactional sex, past 3 months			208	98.6%			199	97.1%
Number of sex episodes	90.0	(60.0–190.0)			2.0	(1–3)		
Any unprotected sex			60	28.6% (no./*n* = 60/211)			13	6.5% (no./*n* = 13/205)

Table 3. High risk transactional sex behaviors and STI among HIV-Infected FSWs ($n = 211$) and HIV-infected clients of FSWs ($n = 205$) in Mumbai, India.

	Female sample		Male sample	
	n	Percentage (%)	*n*	Percentage (%)
Frequency of alcohol use before transactional sex				
Always	25	11.8	68	33.3
Usually	11	5.2	13	6.4
Sometimes	39	18.6	54	26.5
Rarely	13	6.2	2	1.0
Never	122	57.8	67	32.8
Any anal transactional sex, past 3 months	11	5.2	1	.5
Any transactional sex with known HIV+ partners	8	3.8	7	3.4
Any STI, past year	82	38.9	25	12.3

among female participants; among males, only a high number of transactional sex partners was significantly associated with unprotected sex in the past 90 days (adjusted IRR = 8.2, 95% confidence interval [CI] = 1.8–38.4, highest vs. lowest tertile) (Table 4). Due to the large proportion of female participants reporting recent HIV diagnosis, exploratory analyses were conducted, stratifying the female sample by whether or not HIV diagnosis occurred in the past 3 months; no difference in findings was observed across these groups in terms of the association between higher risk transactional sex behaviors and number of unprotected transactional sex episodes.

Associations between unprotected transactional sex and STI

For women, unprotected sex in the past 90 days was associated with a lower odds of STI (AOR = 0.4, 95% CI = 0.2, 0.9), but for men, it was a significant risk factor for STI (AOR = 5.6, 95% CI = 1.4, 22.4) (Table 5). Again, exploratory analyses were conducted, stratifying the female sample by whether or not HIV diagnosis occurred in the past 3 months; no difference in findings was observed.

Among women, alcohol before transactional sex (AOR = 2.0, 95% CI = 1.0, 3.8) and having the highest number of transactional sex partners

Table 4. Associations between risky transactional sex behaviors and number of unprotected sex episodes in the past 90 days among HIV-Infected FSWs ($n = 211$) and HIV-infected male clients of FSWs ($n = 205$).

[b]This variable was created based on tertiles. For women, low = 10–440 partners, mid-range = 450–672 partners, highest = 799–1344 partners. For men, low = 1–4 partners, mid-range = 5–8 partners, high = 9–80 partners.
*Reported by too few participants to allow for analyses.

(AOR = 3.0, 95% CI = 1.4, 6.7, highest vs. lowest tertile) were, however, significantly associated with STI; though this was not revealed to be the case for men. In addition to these behavioral predictors of STI, marital status was also found to be significantly associated with STI for both females and males. For females, those formerly married had a higher odds of reporting an STI diagnosis in the past year compared with those currently married (AOR = 3.6, 95% CI = 1.0, 12.4). For males, those never married had significantly higher odds of reporting an STI in the past year compared to those currently married (AOR = 3.5, 95% CI = 1.0, 12.3).

Discussion

The current study documents high rates of condom use among HIV-infected men and women involved in transactional sex, a finding consistent with that seen in previous studies with non-transactional sex involved HIV-infected adults in India (Chakrapani et al., 2010; Sri Krishnan et al., 2007). Such findings are also consistent with growing evidence from India indicating a slowing of the HIV epidemic and substantial reductions in HIV transmission among those involved in transactional sex, which have largely been attributable to increased condom use in this population (NACO, 2007, NACO, 2010; UNAIDS, 2007, 2010).

Nonetheless, unprotected sex is still occurring among a substantial number of these individuals, with patterns differing for women and men. Although the proportion of sex episodes reported as unprotected is relatively low for both male and female participants, it was more likely among FSWs. Further, the large number of sex episodes reported by HIV-infected FSWs (a median of 90 episodes in the past 3 months) maintains a notable number of unprotected transactional sex encounters in this population. Male clients, in contrast, were more likely than FSWs to report non-transactional sex partners, with unprotected sex being more likely with these partners than with FSWs. Overall, these findings indicate that the risk for sex transmission among this HIV-infected sample persists, though to different classes of partners for FSWs and male clients.

As unprotected sex patterns varied by gender, so did associations between unprotected transactional sex and past year STI diagnosis. For men, a greater number of transactional sex partners was associated with more unprotected transactional sex, which in turn was associated with a higher odds of past year STI diagnosis. These findings clearly support the potential utility of behavioral risk reduction approaches to intervention for this population. For women, we were unable to detect associations between risky transactional sex behaviors and frequency

of unprotected sex, and unprotected sex was actually associated with lower odds of past year STI. These conflicting findings for females may be indicative of their having less control than male partners or others over condom use in the transactional sex encounter. The observed relationship between unprotected sex being associated with STI may be a consequence of the timeframes used to assess this association or the cross-sectional nature of the study. Such findings demonstrate the need for greater research to understand unprotected sex and STI risk among HIV-infected sex workers, with an eye toward what interventions can reduce these risks.

Some insight into this issue is provided via our secondary analyses, which demonstrate higher odds of STI among FSWs reporting the highest number of transactional sex partners and alcohol use before the transactional sex encounter. Increased STI risk as a consequence of greater exposure from more partners is understandable, but increased risk for STI among those FSWs using alcohol is less clear, particularly as current findings did not demonstrate a significant association between alcohol use and the frequency of unprotected transactional sex episodes. Rather, use of alcohol before transactional sex may be a marker for a context of increased risk. In India, there are venues that provide alcohol and sex together for clients (Go et al., 2011; Schensul, Singh, Gupta, Bryant, & Verma, 2010), and these may pose a greater risk for STI among FSWs working within them. More research is needed to examine whether this in fact may be the case and the potential utility of alcohol venue-based interventions to address both HIV and STI transmission between FSWs and male clients.

Limitations

The current study must be considered in light of a number of study limitations. The sample was drawn from individuals linked to agencies serving HIV-infected FSWs and men in a single metropolitan area (Mumbai), limiting generalizability of findings. In addition, much of the data in this study came from self-report and is thus subject to both social desirability and recall biases. Finally, associations are based on the use of different timeframes for the assessment period for certain variables and cross-sectional rather than longitudinal data; the latter precludes assumptions of causality based on the observed associations. More research with larger samples and longitudinal data would be useful to confirm current findings and explore in greater detail issues unable to be examined in this study due to reported low frequency events, such as anal sex and sex with HIV-infected partners. The latter issues have been seen to be a major predictor of STI in a previous study within India (Subramanian et al., 2008).

Conclusion

The current study contributes to the small but growing literature on sex risk among HIV-infected adults in India by examining these issues among those at greatest risk for transmission – HIV-infected FSWs and HIV-infected male clients of FSWs. The findings document that ongoing unprotected sex persists at low levels, concentrated for FSWs within transactional sex, and for male clients within non-transactional sex (e.g., sex with wives). In addition, among women, issues of alcohol use at transactional sex and very high numbers of transactional sex partners heighten their odds for STI, whereas unprotected sex did not appear to do this; in contrast among men, unprotected sex does heighten the risk for STI. These findings support the need for gender-tailored secondary HIV prevention efforts in India.

Effects of Dram Shop Liability and Enhanced Overservice Law Enforcement Initiatives on Excessive Alcohol Consumption and Related Harms

Two Community Guide Systematic Reviews

Veda Rammohan, MPH, Robert A. Hahn, PhD, MPH, Randy Elder, PhD, Robert Brewer, MD, MSPH, Jonathan Fielding, MD, MPH, MBA, Timothy S. Naimi, MD, MPH, Traci L. Toomey, PhD, Sajal K. Chattopadhyay, PhD, Carlos Zometa, PhD, MSPH, Task Force on Community Preventive Services

Context: Dram shop liability holds the owner or server(s) at a bar, restaurant, or other location where a patron, adult or underage, consumed his or her last alcoholic beverage responsible for harms subsequently inflicted by the patron on others. Liability in a state can be established by case law or statute. Overservice laws prohibit the sale of alcoholic beverages to intoxicated patrons drinking in on-premises retail alcohol outlets (i.e., premises where the alcohol is consumed where purchased); enhanced enforcement of these laws is intended to ensure compliance by premises personnel. Both of these interventions are ultimately designed to promote responsible beverage service by reducing sales to intoxicated patrons, underage youth, or both. This review assesses the effectiveness of dram shop liability and the enhanced enforcement of overservice laws for preventing excessive alcohol consumption and related harms.

Evidence acquisition: Studies assessing alcohol-related harms in states adopting dram shop laws were evaluated, as were studies assessing alcohol-related harms in regions with enhanced overservice enforcement. Methods previously developed for systematic reviews for the *Guide to Community Preventive Services* were used.

Evidence synthesis: Eleven studies assessed the association of state dram shop liability with various outcomes, including all-cause motor vehicle crash deaths, alcohol-related motor vehicle crash deaths (the most common outcome assessed in the studies reviewed), alcohol consumption, and other alcohol-related harms. There was a median reduction of 6.4% (range of values 3.7% to 11.3% reduction) in alcohol-related motor vehicle fatalities associated with the presence of dram shop liability in jurisdictions where premises are licensed. Other alcohol-related outcomes also showed a reduction. Only two studies assessed the effects of enhanced enforcement initiatives on alcohol-related outcomes; findings were inconsistent, some indicating benefit and others none.

Conclusions: According to *Community Guide* rules of evidence, the number and consistency of findings indicate strong evidence of the effectiveness of dram shop laws in reducing alcohol-related harms. It will be important to assess the possible effects of legal modifications to dram shop proceedings, such as the imposition of statutes of limitation, increased evidentiary requirements, and

caps on recoverable amounts. According to *Community Guide* rules of evidence, evidence is insufficient to determine the effectiveness of enhanced enforcement of overservice laws for preventing excessive alcohol consumption and related harms.

(Am J Prev Med 2011;41(3):334–343) Published by Elsevier Inc. on behalf of American Journal of Preventive Medicine

Introduction

Excessive alcohol consumption, including binge and underage drinking, is responsible for approximately 79,000 deaths per year in the U.S., making it the third-leading cause of preventable death in the nation.[1] In 1998, the economic cost of excessive drinking was estimated to be $184.6 billion, most of which was due to lost productivity.[2] The reduction of excessive alcohol consumption is thus a matter of major public health and economic interest.

Among a representative sample of U.S. adults from 13 to 14 states, interviewed anonymously by telephone in 2003 and 2004, respectively, 16.3% reported binge drinking (defined as consuming ≥5 drinks per occasion for men, and ≥4 drinks per occasion for women in the past 30 days).[3] Approximately 30% of high school students in the U.S. report binge drinking in the past 30 days,[4,5] and among full-time college students, almost half (48.6%) of male adolescents and 34.4% of female adolescents reported binge drinking.[6]

Among binge-drinking adults, half consumed ≥7 drinks during their most recent drinking episode; 32.7% had their most recent binge episode in a bar/club or restaurant; and between 16.3% and 20.8% of those who drank at a bar or restaurant drove a motor vehicle after binge drinking. Among all episodes of self-reported binge drinking, drinking in a bar/club or restaurant accounted for 54.3% of episodes, compared with 35.7% consumed in a home, and 10% elsewhere.[3] Thus, drinking in bars and restaurants is strongly associated with binge drinking and with alcohol-impaired driving among U.S. adults who report binge drinking. In the U.S., the overservice of alcoholic beverages in on-premises alcohol outlets is a major source of public health problems. Approximately 13,000 U.S. residents die annually from alcohol-related motor vehicle crashes, and many others are injured.[7]

Alcohol control policies have been shown to be effective instruments for preventing alcohol-related harms.[8] Systematic reviews of alcohol policy by the *Guide to Community Preventive Services* (*Community Guide*) have demonstrated the public health benefits of increasing alcohol excise taxes,[9] enhanced enforcement of laws prohibiting alcohol sales to minors,[10] limiting alcohol outlet density,[11] and limiting the days and hours when alcoholic beverages can be sold.[12,13]

This report assesses two law-based interventions for preventing excessive alcohol consumption and related harms, which focus on promoting responsible beverage service in on-premises retail alcohol outlets (e.g., bars or restaurants): dram shop liability and enhanced enforcement of overservice laws. Dram shop liability involves holding the owner or server(s) at an on-premises retail alcohol outlet liable for alcohol-attributable harms (e.g., an alcohol-attributable motor vehicle crash death) caused by a patron who was illegally served alcoholic beverages because the patron was underage or already intoxicated. For there to be liability for service to an intoxicated person, it must be shown that the server either knew or should have known that the patron was intoxicated.

Liability can be established in states either by case law or statute. Most states have enacted dram shop statutes; several states have established dram shop policies by case law/precedent; seven states (Delaware, Kansas, Louisiana, Maryland, Nevada, South Dakota, and Virginia) have neither statutory nor precedent dram shop liability.[14] Most dram shop statutes create barriers to lawsuits not present in common law liability, such as damage caps or stringent evidentiary requirements. Dram shop suits are generally brought by those harmed or by their families. The existence of dram shop liability in a state is thought to promote caution on the part of on-premises owners and staff; owners may purchase liability insurance to protect themselves from financial loss resulting from dram shop law suits.

The second law-based intervention assessed was enhanced enforcement of laws prohibiting "overservice" (defined as sale of alcohol to intoxicated patrons). As with dram shop liability, states vary widely regarding the evidence needed to establish a violation. Enforcement activities are usually carried out by plainclothes or uniformed police, Alcohol Beverage Control personnel, or both. Alcohol Beverage Control Boards are state-operated organizations charged to regulate the sale of alcoholic beverages.

In addition to these direct enforcement actions, this intervention may involve prior notification of retail alcohol outlets of planned enforcement actions, and the training of outlet managers and staff in responsible beverage service, including how to recognize intoxicated patrons and prevent overservice. Legal penalties for overservice may include fines or criminal sanctions for alcohol servers; fines or licensing actions against license holders (including revocation of alcohol sales license); or both. However, a recent systematic review of overservice laws in the U.S. concludes, "The single most notable finding

from the qualitative enforcement research is that enforcement of laws that prohibit alcohol sales to intoxicated patrons is relatively rare."[15]

Both interventions are assumed to work by deterrence, the notion that if premises owners or servers perceive a high probability of incurring substantial penalties by overserving, they will be more likely to avoid doing so. The effect of deterrence depends on three key elements: perceived certainty of detection and punishment, perceived swiftness of punishment, and the perceived severity of punishment.[16] Although both interventions have all the elements, dram shop liability may present a greater perceived threat of meaningful consequences among alcohol premises personnel.[17] This is supported by survey research indicating that actual and perceived threat of dram shop liability are associated with more responsible service practices, but levels of enforcement tend not to be.[18]

Findings, Recommendations, and Directives from Other Reviews and Advisory Groups Related to Dram Shop Liability and Overservice Enforcement

The WHO has published a review that identifies both the enforcement of overservice laws and dram shop liability as effective methods for reducing alcohol-related harms.[8] The Substance Abuse and Mental Health Services Administration's Prevention Enhancement Protocols System[19] recommended "that jurisdictions strictly and uniformly enforce the laws regarding the sale of alcohol to such individuals" (i.e., those who were intoxicated or underage) and "that States and jurisdictions undertake efforts to keep the burden of legal responsibility [for intoxication-related problems caused by patrons] on the owners of drinking establishments and alcohol licensees rather than their employees, such as servers. Jurisdictions might, in fact, consider increasing such liability burdens, not decreasing them."

Evidence Acquisition

The *Community Guide* systematic review process was used to assess whether dram shop liability or overservice law enforcement initiatives lead to decreases in excessive alcohol consumption and related harms. Details of the *Community Guide* review process are presented elsewhere.[20,21] The process involves forming a systematic review team; developing a conceptual approach to organizing, grouping, and selecting interventions; prioritizing these interventions; systematically searching for and retrieving the existing research evidence on the effects of the interventions; abstracting information from each study that meets qualifying criteria; assessing the quality of each study; drawing conclusions about the body of evidence on intervention effectiveness; and translating the evidence on effectiveness into recommendations.

The systematic review team consists of systematic review methodologists and subject matter experts from a range of agencies, organizations, and academic institutions. The review team works under the oversight of the nonfederal, independent Task Force on Community Preventive Services (Task Force), which directs the work of the *Community Guide*.

The systematic review team (the team) collects and summarizes evidence on (1) effectiveness of interventions in improving health-related outcomes of interest and (2) additional benefits and potential harms of the intervention on other health and nonhealth outcomes. When an intervention is shown to be effective, information is also included about (3) the applicability (i.e., generalizability) of the evidence to diverse population segments and settings, (4) the economic impact of the intervention, and (5) barriers to implementation. Such information may also be provided in the absence of sufficient evidence of effectiveness. The team then presents the results of this review process to the Task Force, which determines whether all of the evidence presented is sufficient to warrant a recommendation for practice or policy.[20]

The rules of evidence under which the Task Force makes its determination address several aspects of the body of evidence, including the number of studies of different levels of design suitability and execution, the consistency of the findings among studies, the public health importance of the overall effect size, and the balance of benefits and harms of the intervention.

Conceptual Approach and Analytic Framework

Dram shop liability. The effect of dram shop liability on alcohol-related outcomes may be influenced by at least two factors (Figure 1). In states with dram shop liability, premises owners perceive a potential for liability suits,[22] which may be communicated by public and trade media and word of mouth. Such perception may result in increased training of outlet personnel in responsible beverage service, increased motivation, increased oversight, and increased compliance with liquor laws.

These changes may result in reduced illegal beverage service, including service to intoxicated patrons and underage youth, and ultimately reduced excessive consumption and related harms. In states with dram shop liability, many owners of on-premises outlets commonly purchase liability insurance and thus have some financial protection against possible legal action. Because of this protection, insurance may reduce the deterrent effect of liability; the team encountered no evidence regarding this conjecture.

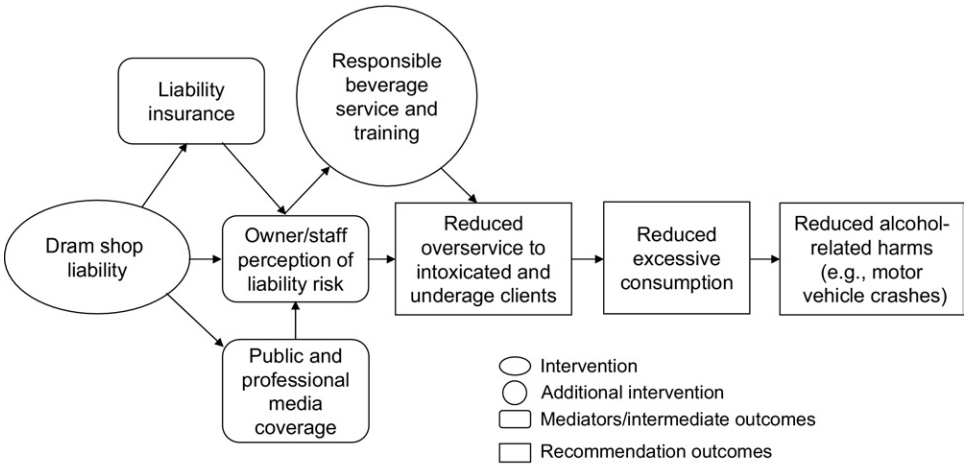

Figure 1. Analytic framework: dram shop liability

Enhanced enforcement of overservice laws. Overservice enforcement initiatives are designed to increase the perceived risk by servers and managers of on-premises retail alcohol outlets of sanctions resulting from serving intoxicated patrons (Figure 2). In response to such initiatives, establishment personnel may undergo training to improve the ability of servers to detect patrons who are intoxicated, so that they can then refuse to serve additional alcohol. These intermediate consequences of enhanced enforcement are hypothesized to reduce excessive alcohol consumption and alcohol-related harms.

Inclusion Criteria

To qualify as a candidate for inclusion in this review, a study had to:

- Evaluate the effectiveness of dram shop liability or initiatives for enhanced enforcement of overservice regulations that could and did apply legal or administrative sanctions.
- Be conducted in a country with a high-income economy,[a,23] be primary research (rather than a review of other research), and be published in English.
- Compare attributes of participants before and after the implementation of the intervention or compare a group receiving the intervention with a group not receiving it.
- Report outcomes related to excessive alcohol consumption or related harms, such as alcohol-impaired driving or alcohol-related motor vehicle crashes.

Search for Evidence

The following databases were searched for this review: CINAHL, EconLit, Embase, ERIC (CSA), NLM Gateway, NTIS (National Technical Information Service), PsycINFO, PsycNET (APA), MEDLINE, Science Direct, Social Services Abstracts, and Sociological Abstracts (CSA) Web-of-Science. All publication years covered in each database were searched up to October 2007. (Details of the search strategy are available at www.thecommunityguide.org/alcohol/supportingmaterials/SSalcoholuse.html.) Reference lists of articles reviewed as well as lists in review articles were also searched, and subject matter experts consulted for additional references. Published government reports were included, but not unpublished manuscripts because they are not commonly available in the public domain.

Evidence Synthesis

Assessing the Quality and Summarizing the Body of Evidence on Effectiveness

Each study that met the inclusion criteria for candidate studies was read by two reviewers who used standardized criteria (www.thecommunityguide.org/about/methods.html) to assess the suitability of the study design and threats to validity. Uncertainties and disagreements between the reviewers were reconciled by consensus among team members. Classification of the designs of reviewed studies accords with the way in which study findings were used in the review and with the standards of the *Community Guide* review process[21]; they may differ from the classification reported in the original studies.

Each candidate study for this review was evaluated for quality of study design and execution. Studies with greatest design suitability were those in which outcome data on exposed and comparison populations were collected prospectively, such as panel (i.e., cohort) studies; studies with moderate design suitability were those in which data on exposed and comparison populations were collected retrospectively or in which there were multiple pre- or post-intervention measurements, but no concurrent

[a]Countries with high-income economies as defined by the World Bank are Andorra, Antigua and Barbuda, Aruba, Australia, Austria, The Bahamas, Bahrain, Barbados, Belgium, Bermuda, Brunei Darussalam, Canada, Cayman Islands, Channel Islands, Cyprus, Denmark, Estonia, Faeroe Islands, Finland, France, French Polynesia, Germany, Greece, Greenland, Guam, Hong Kong (China), Iceland, Ireland, Isle of Man, Israel, Italy, Japan, Republic of Korea, Kuwait, Liechtenstein, Luxembourg, Macao (China), Malta, Monaco, Netherlands, Netherlands Antilles, New Caledonia, New Zealand, Norway, Portugal, Puerto Rico, Qatar, San Marino, Saudi Arabia, Singapore, Slovenia, Spain, Sweden, Switzerland, Trinidad and Tobago, United Arab Emirates, United Kingdom, U.S., Virgin Islands (U.S.).

comparison population; and studies with least suitable designs were cross-sectional studies or those that had no separate comparison population and only a single pre- and post-measurement in the intervention population.

On the basis of the number of threats to validity—such as poor measurement of exposure or outcome, lack of control of potential confounders, or high attrition—studies were characterized as having good (≤1 threat to validity); fair (2–4 threats); or limited (≥5 threats) quality of execution. Studies with good or fair quality of execution and any level of design suitability (greatest, moderate, or least) qualified for the body of evidence; studies with limited quality of execution were excluded.

With dram shop liability jurisdiction as the unit of analysis, effect estimates were calculated as relative percentage change using the following formulas:

- For studies with before-and-after measurements and concurrent comparison groups:

$$\text{Effects Estimate} = [(I_{post}/C_{post})/(I_{pre}/C_{pre}) - 1] \times 100\,\%,$$

where:

I_{post} = last reported outcome rate in the intervention group after the intervention;

I_{pre} = last reported outcome rate in the intervention group before the intervention;

C_{post} = last reported outcome rate in the comparison group after the intervention;

C_{pre} = last reported outcome rate in the comparison group before the intervention.

- For studies with before-and-after measurements but no concurrent comparison:

$$\text{Effects Estimate} = [(I_{post}/I_{pre})/I_{pre}] \times 100\%.$$

When appropriate data were provided, CIs for effect estimates were calculated. When a body of evidence included three or more studies, medians and data range of values were reported.

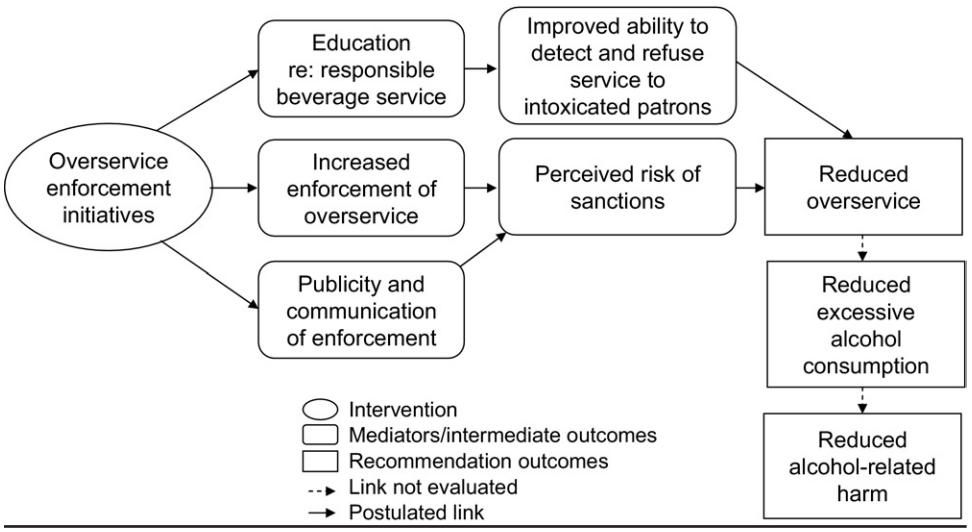

Figure 2. Analytic framework: enhanced enforcement of alcohol overservice initiatives

Intervention Effectiveness: Dram Shop Liability

The review included 11 studies[22,24-33] of the effectiveness of dram shop liability in preventing excessive alcohol consump-

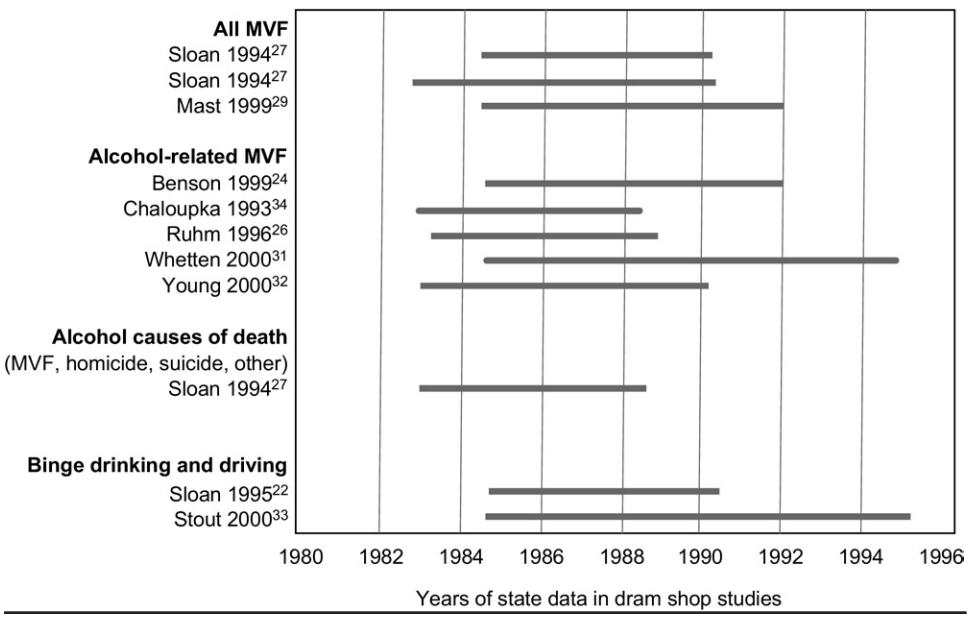

Figure 3. Overlap in time periods among dram shop studies indicating dependence among the data
MVF, motor vehicle fatalities

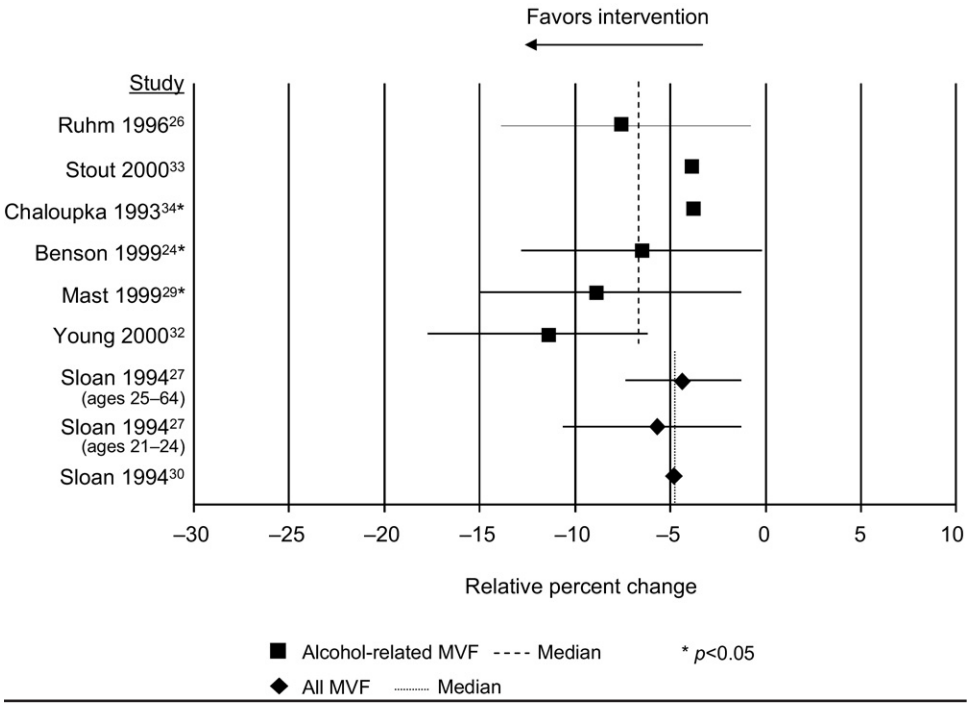

Figure 4. Relative percentage change in alcohol-related and all-cause motor vehicle fatalities associated with dram shop liability

tion and related harms. Nine[24-32] of these were of greatest design suitability and two[22,33] were of least suitable design. Five[24-28] were of good quality of execution and six[22,29-33] were of fair quality of execution.

All studies but one[28] were panel studies of U.S. states using econometric models to assess the effects of dram shop liability and other interventions on diverse outcomes. These studies covered overlapping time periods (Figure 3) and states, and thus are not entirely independent. However, the models in these studies included different covariates and assessed effects on different outcomes.

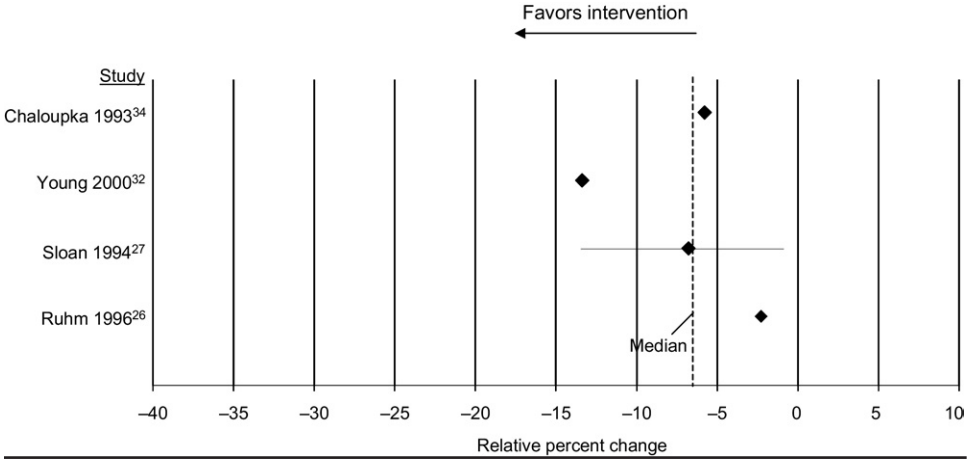

Figure 5. Relative percentage change in alcohol-involved motor vehicle fatalities associated with dram shop liability for underage drinkers

Six studies[24-26,29,32,33] that assessed the effects of dram shop liability on alcohol-related motor vehicle fatalities found a median reduction of 6.4% (range of values 3.7% to 11.3% reduction) associated with these policies (Figure 4). Two studies[27,30] that assessed all-cause motor vehicle fatalities (in which not all crashes were attributable to alcohol) found a median reduction of 4.8% (Figure 4). Those[26,27,32,34] that reported all-cause motor vehicle fatalities among underage drinkers all found reductions of between 2.2% and 13.0% (Figure 5). Only two studies[22,33] assessed changes in alcohol consumption (i.e., self-reported binge drinking) as an outcome; both found small, nonsignificant decreases (1.2% and 2.4%) associated with dram shop liability in states (data not shown in graphic).

One panel study[28] assessed the effects of two lawsuits brought against on-premises alcohol outlets in Texas in 1983 and 1984. These suits, filed by the families of people killed in alcohol-related motor vehicle crashes, were publicized in general public and alcohol-industry periodicals. The researchers used interrupted time-series models to assess the effects of these suits on single-vehicle nighttime crashes in Texas, compared with the 47 other contiguous U.S. states. The researchers found that the first suit was associated with a 6.6% decrease (95% CI=0.5%, 11.3%) in single-vehicle nighttime crashes, and the second suit was associated with an additional 5.3% decrease (95% CI=0.4%, 10.1%) in single-vehicle nighttime crashes (data not shown).

One study[27] reported reductions in rates of suicide, homicide, and alcohol-

related medical conditions; the last two findings were significant ($p<0.01$), the first was not ($p>0.10$).

Summary: Results of Dram Shop Liability Review

Eleven studies of dram shop liability consistently found that this intervention reduced motor vehicle crash deaths in general and alcohol-related crash deaths in particular. Strong evidence indicated that dram shop liability is an effective intervention for reducing alcohol-related harms, as indicated by reduced motor vehicle crashes. Two studies of binge drinking did not provide sufficient independent evidence on the effect of dram shop liability on excessive consumption.

Intervention Effectiveness: Enhanced Enforcement of Overservice Laws

Two studies assessed the effects of enhanced enforcement of overservice laws.[35,36] Both studies were of greatest design suitability and fair quality of execution. Both studies had pre–post designs, with concurrent comparisons. They provided information on two key components of enhanced enforcement initiatives: (1) owners and servers of establishments serving alcohol were made aware of enforcement efforts through media coverage, letters, presentations, and reports containing information about undercover visits; and (2) owners and servers were offered server training and educational materials on responsible beverage service.

One study[35] assessed an overservice initiative in Washtenaw County, Michigan. State Police Department enforcement was countywide, and was followed by after-visit reports notifying licensees visited by undercover police officers that enforcement was in progress. After 1 year, prevalence of service to pseudo-intoxicated pseudo-patrons in intervention settings decreased by 14.8% compared with control settings, and the percentage of driving under the influence (DUI) arrestees in the experimental county who reported having consumed their last drink in an intervention setting decreased by a relative 36.3% in the intervention sites.

The second study[36] assessed the impact of enhanced enforcement of overservice laws administered by the Washington State Liquor Control Board in bars and restaurants in Washington State, assessing service to pseudo-patrons and DUI associated with alcohol consumption in intervention and control outlets. Compared with control sites, alcohol sales to pseudo-intoxicated pseudo-patrons in intervention sites increased 82.6%, and the average number of monthly DUI arrests in which intervention establishments were identified as "place of last drink" decreased by 31.2% ($p>0.05$).

Summary of Results of Enhanced Enforcement Initiative Review

The only available two studies of enhanced enforcement of overservice laws included in this review differed substantially in design (i.e., sample size and analysis) and findings. All outcomes in the Michigan study[35] had favorable and significant findings, but the Washington study[36] had contrary results (i.e., an apparent increase in service to pseudo-intoxicated pseudo-patrons, but an apparent decrease in DUIs). The small number of studies and inconsistent findings provided an insufficient body of evidence to determine the effectiveness of enhanced enforcement of overservice laws on excessive alcohol consumption and related harms.

Potential Harms, Additional Benefits, and Barriers to Implementation

Although dram shop liability appears to have deterrent effects, litigation may be an expensive and inefficient method of achieving this outcome. Under dram shop liability, for legal actions to be brought against a manager or server in an on-premises establishment, there must have been both illegal beverage service (e.g., service to an intoxicated patron) and harm to someone as a result of this illegal service. In addition, an individual who experienced harms related to illegal beverage service (or a representative of that individual) must prove that illegal service took place, which may be difficult.

On the other hand, dram shop liability can foster an environment that encourages responsible server behavior, and thus encourages investment in server training and other primary prevention strategies. This intervention can also help to create a retail environment that makes responsible beverage service the norm and, thus, does not unfairly disadvantage responsible beverage servers.

Despite these challenges to implementation, dram shop liability may be useful because it focuses on a regulated environment which is thus amenable to control. Furthermore, on-premises alcohol outlets have been strongly associated with high-intensity binge drinking (i.e., a higher self-reported number of drinks per binge episode) and related risk behaviors, such as driving after binge drinking, furnishing a strong public health justification for targeting interventions to these settings.

One harm that may be posited with overservice enforcement is that underage drinkers and intoxicated patrons in on-premises facilities may move to uncontrolled settings to consume additional alcohol. The team found no evidence on this issue.

Applicability

Much of the research assessing the effectiveness of dram shop liability was conducted before the enactment of various

caps on the financial liability of servers and managers in dram shop cases in the late 1990s. These changes may have modified the effectiveness of this intervention, limiting its applicability to current circumstances. Some states have instituted statutes of limitation that require injured plaintiffs to sue within a specified time period. The standards of evidence required in dram shop liability cases have also grown more stringent, making it increasingly difficult to prove illegal beverage service. In addition, knowledge of and access to legal services vary greatly by SES, making it difficult for some segments of the population to obtain legal services for dram shop litigation.

Economic Efficiency

Dram Shop Liability

The systematic economic review did not identify any studies that examined the costs and benefits of dram shop liability. Thus an economic analysis was not possible for this review.

Overservice Law Enforcement

Although insufficient evidence to determine the effectiveness of enhanced enforcement of overservice law initiatives was found, the systematic economic review identified two analyses that estimated the costs of enhanced enforcement of overservice laws, and found substantial benefit. Both studies were based on the findings of the Michigan program described above.[35] This evidence is summarized now, in case evidence accrues in the future to support this intervention.

Levy and Miller[37] conducted a cost–benefit analysis and estimated that the combined police, supervisory, and miscellaneous costs for enhanced enforcement of overservice laws in Ann Arbor city and Washtenaw County was $84,296 in 2009 dollars. The estimated benefits of the program (in 2009 dollars) attributable to reduced tavern-related DUI cases alone were approximately $800,000 in medical cost savings, and about $6.1 million when additional savings were taken into account (e.g., reduced demand for emergency services, such as fire and police; travel delays for motorists who would have otherwise been involved in crashes; property damage; costs to employers caused by workplace disruption; productivity losses for employees; and administrative costs, including claims-processing and legal and court costs).

If pain and suffering and lost quality of life were added, the economic benefit of enhanced enforcement would increase to about $16.6 million. However, the estimated benefit of this intervention would decline to about $8 million if only averted external costs (i.e., costs to third parties) were included. In the best-case scenario, when all societal benefits from averted DUI crashes are properly accounted for, each dollar invested in the program returned more than $196 in benefits. It is important to note that this benefit–cost estimate is exclusively based on traffic-related injuries, and does not consider other household injuries (e.g., assault and domestic violence) resulting from excessive drinking. The benefits of overservice enforcement may be reduced if people who are refused a drink in one location resume drinking at another location and then drive or engage in other risky behavior.

McKnight et al.[35] extended the cost–benefit analysis of the Washtenaw County Service to Intoxicated Patrons program to the national level, using benefit estimates from Miller and Levy.[37] Assuming an estimated total cost of a nationwide law enforcement effort of $74.5 million per year and annual net savings of $21 billion from averted costs related to DUIs and crashes, they reported a benefit of $282 for each dollar invested in the program. (All dollar figures are adjusted to 2009 dollars based on the consumer price index.) Thus, studies indicate the large potential cost benefit of this intervention, were it found to be effective.

Research Gaps

As noted, many of the studies included in this review were conducted prior to the enactment in the late 1990s of various caps on financial liability of servers and managers in dram shop cases, in addition to statutes of limitation and increased legal evidence requirements. Further research is needed to assess what impact, if any, these limits on liability have had on the effectiveness of dram shop laws in reducing excessive alcohol consumption and related harms.

Additional studies are needed to assess how effective enhanced enforcement of overservice regulations is in reducing excessive alcohol consumption and related harms. It would be useful to ascertain barriers to effective enforcement. In addition, research is needed to assess the role of the media in publicizing enhanced enforcement and enhancing its effectiveness and the potential role of responsible beverage service training programs in reducing overservice and thus enhancing the effectiveness of enforcement. The latter is important as these multicomponent server intervention programs may prove beneficial in decreasing excessive alcohol consumption and related harms in on-premises retail alcohol settings. The potential cost savings to owners of on-premises retail alcohol outlets through the promotion of responsible beverage service will be useful in assessing economic benefits.

The signs of intoxication that a patron exhibits may be difficult for servers or law enforcement officials to identify. To help servers avoid engaging in illegal service, additional research is needed to improve methods for identifying patrons who are intoxicated, underage, or

both. Other methods for avoiding overservice can also be explored, such as counting drinks and spacing out the frequency of drink service through the use of food or nonalcoholic drinks after a predetermined threshold has been achieved.

Although enforcement of existing laws and regulations prohibiting service of alcohol to intoxicated patrons appears to be cost-beneficial based on the estimated findings from Washtenaw County, additional studies are needed for a more reliable estimate of the economic value of enforcement.

Finally, additional research is needed to assess the effectiveness of both dram shop liability and enhanced enforcement in achieving these broader societal impacts, but if further research corroborates these findings, dram shop liability and enhanced enforcement of overservice laws could provide many collateral benefits.

Discussion

This review assesses two law-based approaches to promoting responsible beverage service in on-premises retail alcohol settings, including bars and restaurants. Room and colleagues[38] have argued that "the general rule in such situations is that it is easier and more effective for the state to influence licensed occupational behavior than it is to influence the behavior of private customers." Evidence of the effectiveness of one of these approaches—dram shop liability—is strong. The effectiveness of this approach, however, may be diminished by restrictions on these laws by stringent monetary caps, evidentiary requirements, and statutes of limitations. The effects of these restrictions should be investigated.

No studies of the economic effects of dram shop liability were found. Nevertheless, given the association between drinking in on-premises retail alcohol outlets and high-intensity binge drinking, and the relationship between binge drinking and a variety of other health and social problems, including alcohol-impaired driving and interpersonal violence, the potential economic impact of promoting more responsible beverage service by holding managers and servers responsible for harms resulting from illegal beverage service could be substantial. The real benefit of maintaining strong dram shop liability, however, may result from creating a business environment that supports responsible beverage service at on-premises retail outlets without penalizing servers and mangers who strive to comply with liquor control laws. This would, in turn, help to reduce illegal beverage service and harms resulting from it, thus decreasing the likelihood that dram shop liability cases will need to be adjudicated by the courts. Furthermore, reduced prevalence of drunken and disorderly conduct in on-premises retail alcohol outlets may also reduce the cost of operations for owners, and thus offset the potential loss in sales that may result from the intervention.[37,39]

Effectiveness of the other approach assessed in this review—the enhanced enforcement of overservice regulations—could not be determined because there were too few studies and inconsistent findings. There are examples of intensive enforcement efforts among U.S. states. New Mexico has one of the strongest overservice enforcement programs. As of 2006, alcohol licensees in New Mexico are subject to license suspension for a first violation and to license revocation following three violations within 1 year. Presumptive evidence of overservice can be established by a blood alcohol level of 0.14 g/dL in patrons within 90 minutes of exiting a drinking establishment. In addition, the New Mexico Department of Public Safety has a "Mobile Strike Team" that investigates licensed establishments where overservice has been noted.

Awareness of such policies may increase the level of deterrence in the state. A National Highway Traffic Safety Administration report, "Laws Prohibiting Alcohol Sales to Intoxicated Persons,"[15] proposes a series of "best practices," including the use of presumptive evidence of a blood alcohol level of 0.14 g/dL in patrons exiting a drinking establishment, as in New Mexico; enactment of service to intoxicated patron legislation in all states; the collection of data for the monitoring of alcohol-related harms; and the training of law enforcement personnel in the enforcement of service to intoxicated patron rules. Such measures may assist in the development of more-effective procedures for the reduction of the harms associated with excessive alcohol consumption in the U.S.

SUBSTANCE ABUSE TREATMENT, PREVENTION, AND POLICY

RESEARCH Open Access

Chronic disease and recent addiction treatment utilization among alcohol and drug dependent adults

Sharon Reif[1*], Mary Jo Larson[1], Debbie M Cheng[2], Donald Allensworth-Davies[2], Jeffrey Samet[2,3,4] and Richard Saitz[2,3,4]

Abstract

Background: Chronic medical diseases require regular and longitudinal care and self-management for effective treatment. When chronic diseases include substance use disorders, care and treatment of both the medical and addiction disorders may affect access to care and the ability to focus on both conditions. The objective of this paper is to evaluate the association between the presence of chronic medical disease and recent addiction treatment utilization among adults with substance dependence.

Methods: Cross-sectional secondary data analysis of self-reported baseline data from alcohol and/or drug-dependent adults enrolled in a randomized clinical trial of a disease management program for substance dependence in primary care. The main independent variable was chronic medical disease status, categorized using the Katz Comorbidity Score as none, single condition of lower severity, or higher severity (multiple conditions or single higher severity condition), based on comorbidity scores determined from self-report. Asthma was also examined in secondary analyses. The primary outcome was any self-reported addiction treatment utilization (excluding detoxification) in the 3 months prior to study entry, including receipt of any addiction-focused counseling or addiction medication from any healthcare provider. Logistic regression models were adjusted for sociodemographics, type of substance dependence, recruitment site, current smoking, and recent anxiety severity.

Results: Of 563 subjects, 184 (33%) reported any chronic disease (20% low severity; 13% higher severity) and 111 (20%) reported asthma; 157 (28%) reported any addiction treatment utilization in the past 3 months. In multivariate regression analyses, no significant effect was detected for chronic disease on addiction treatment utilization (adjusted odds ratio [AOR] 0.88 lower severity vs. none, 95% confidence interval (CI): 0.60, 1.28; AOR 1.29 higher severity vs. none, 95% CI: 0.89, 1.88) nor for asthma.

Conclusions: In this cohort of alcohol and drug dependent persons, there was no significant effect of chronic medical disease on recent addiction treatment utilization. Chronic disease may not hinder or facilitate connection to addiction treatment.

Keywords: addiction, substance abuse, substance abuse, treatment, medical care, chronic disease

Introduction

Chronic medical diseases are long-lasting conditions, often progressive, and often controllable with continuing care and behavior change. In an era of increasing health care costs [1], chronic disease stands out as a major contributor [2] with alcohol and drug use disorders playing an exacerbating role [3-5]. To improve population health and reduce U.S. health care costs, particular attention must be paid to the role of chronic diseases, including medical, psychiatric, and substance use disorders.

Substance use disorders (SUDs) are prevalent in about 9% of the U.S. population, but only 10% of those individuals access addiction treatment [6]. Although medical needs were not explicitly mentioned in this household

Full list of author information is available at the end of the article

survey as a reason for not accessing addiction treatment [6], medical needs may interfere with other priorities. For example, chronic medical conditions could cause functional limitations that preclude access to other health care. Interference from pressing medical conditions may thus contribute to perceived unimportance of addiction treatment among the 94% of people [6] deemed in need but who reported they did not need it. To enhance care of both chronic medical diseases and addiction, it is important to better understand their relationships.

More than 40% of the U.S. population is estimated to have at least one chronic medical disease [2,7], with prevalence higher for women and increasing dramatically with age [7]. Chronic medical disease is related to 70% of all U.S. deaths [2], and accounts for more than 75% of health care costs [2] and high out of pocket health care spending [7]. Diabetes, hypertension, and high cholesterol comprise nearly a third of all chronic conditions [7], and just seven conditions account for about one-fourth of annual outpatient visits and hospital discharges [8].

Chronic disease may have unexpected consequences on healthcare utilization, potentially reducing treatment of unrelated disorders, perhaps due to less time available, complexity of navigating multiple problems at once, or a preference to focus on the most troublesome problem [9]. In practice, however, perhaps due to more frequent interaction with medical providers, mental disorders are more often detected among patients with chronic medical diseases than among other patients [10]. Physician awareness of a substance abuse problem also is more likely when the person has episodic or chronic medical illness, however SUDs remain undiagnosed by primary care physicians in nearly half of patients seeking addiction treatment [11].

It is well documented that SUDs cause or exacerbate certain medical conditions and increase their costs [3,12-16]. Incidence for many chronic medical diseases, including hypertension, diabetes, asthma, chronic liver disease, chronic obstructive pulmonary disease (COPD), pain, and stroke is elevated, and for some disorders more than doubled, among people with SUDs [17-20]. Many more conditions are worsened by, have their management impaired by, or are attributable to SUDs [21]. Chronic conditions are prevalent even in younger individuals with SUDs [22]. These findings highlight the importance of medical management as an essential element of addiction treatment [23] particularly in early recovery [24].

Several examples of this complex interplay are reported in the literature. Alcohol use disorders increased medical illness complexity in a primary care population, even after controlling for medical morbidity, initial primary care utilization, and current medical care utilization [25]. Alcohol use disorders also were related to inconsistent attendance and less complex services for the chronic medical disease, suggesting that medical care may be less accessible for the comorbid population, who may require an increased focus on the complexities of care [26]. Among patients receiving diabetes care in the Department of Veterans Affairs, those who also had SUDs or mental illness had more diabetes complications [27]. Although SUDs have been linked to higher utilization of primary, specialty, and emergency medical services [25], there are few studies of how presence of complex medical disorders affects addiction treatment utilization.

Chronic medical diseases require regular and longitudinal care and self-management for effective treatment [28-30]. When chronic diseases include SUDs, care and treatment of both the medical and addiction disorders may affect access to care and the ability to focus on both conditions. An integrated approach could lead to effective treatment for all conditions [29], yet little is known about how chronic medical disease affects addiction treatment utilization. Chronic disease could cause functional limitations that interfere with an individual's ability to access addiction treatment, or alternatively could increase interaction with the health care system and perhaps addiction treatment. Involvement in addiction treatment could lead to linkage with medical care and effective attention to a chronic medical problem. The objective of this paper is to evaluate the association between the presence of chronic medical disease and recent addiction treatment utilization among adults with substance dependence.

Methods

Data Source and Sample

Data are from baseline interviews with 563 alcohol and/or drug-dependent adults enrolled in the AHEAD (Addiction Health Evaluation And Disease management) study, a randomized controlled trial testing the effectiveness of a chronic disease management program for substance dependence in primary care.

Study recruitment occurred from a free-standing inpatient detoxification unit (74% of enrolled subjects), primary care clinics and the emergency department in the urban medical center where the study was located (10%) and the community by advertising on buses and in newspapers (16%); subjects were recruited between September 2006 and September 2008.

Adults were eligible if they had (1) a diagnosis of current alcohol or drug dependence as assessed by the Composite International Diagnostic Interview Short Form (CIDI-SF) [31]; (2) past 30 day drug use or heavy alcohol use (defined as ≥4 standard drinks for women,

≥5 for men at least twice; or >14 drinks per week for women, >21 drinks per week for men, in an average week in the past month); and (3) were willing to establish or continue primary medical care at the study location. Subjects were excluded if they could not provide contact information for tracking purposes; were not fluent in English or Spanish; had specific plans to leave the area that would preclude in-person research assessments; were pregnant; or had a Mini-Mental State Examination [32] score <21.

Trained research associates administered the standardized baseline research assessment and assured confidentiality. Data collected include sociodemographics, substance use and related problems, anxiety, depression, health questions, and medical and addiction service use. Subjects were compensated for their study participation after completing baseline study procedures.

The Institutional Review Board approved the study. Additional privacy protection was secured by a Certificate of Confidentiality issued by the Department of Health and Human Services.

Chronic Disease and Other Medical Condition Measures

Subjects were asked if a doctor had ever told them they had any of a series of medical conditions. A number of these conditions were included on a chronic disease comorbidity questionnaire validated by Katz et al. [33], which is a self-report version of the medical record-based Charlson Comorbidity Index [34]. The Katz questionnaire includes myocardial infarction, congestive heart failure, peripheral vascular, stroke or other cerebrovascular disease, COPD, ulcer disease, diabetes, renal, connective tissue disease, and other conditions (dementia, liver disease, leukemia, lymphoma, cancer, AIDS). Scoring replicates the Charlson Comorbidity Index, which empirically weighted severity by disease (e.g., cerebrovascular = 1, moderate or severe renal disease = 2, AIDS or metastatic solid tumor = 6), based on 1-year adjusted relative risk for mortality [34]. The comorbidity score is the weighted sum of the specified conditions.

The main independent variable, chronic disease status, is a 3-category variable which classified comorbidity scores as: none; only one condition of lowest severity (Katz = 1); or, more than one condition of lowest severity or one or more condition(s) of higher severity (Katz > 1). Asthma was considered in separate secondary analyses, as an example of a specific symptomatic condition, selected due to its high prevalence in the sample; it is also included in the Katz questionnaire, as part of COPD, with a weight of 1. Asthma is a common comorbidity among urban young to middle-age adults, reflecting the age range common for addiction, whereas other common chronic diseases such as heart disease are less common in young populations. Two other common chronic conditions in this population, hepatitis and hypertension, were prevalent but are often asymptomatic to the patient, and thus were not evaluated in the current analyses.

Additional secondary independent variables were used to evaluate whether broader health status significantly predicted addiction treatment utilization: the single item self-report health status from the SF-12 [35] (excellent/very good/good, fair/poor) and physical health-related functioning and quality of life as determined by the SF-12 Physical Component Score (PCS) (continuous 0-100 scale).

Addiction Treatment Utilization Measures

The primary outcome was any addiction treatment based on self-report, defined as any treatment for addiction (excluding detoxification) in the 3 months prior to study enrollment in any of the following: residential program for alcohol or drug treatment; outpatient full-day/partial hospital program; outpatient with a psychiatrist, other doctor, or other healthcare professional (e.g., counselor); or by taking medication to prevent drinking or drug use. Two secondary outcomes were the counts of outpatient addiction treatment days (at a full-day/partial hospital or with a psychiatrist, other doctor, or other healthcare professional including counselors) and nights in a residential program for alcohol or other drug treatment in the prior 3 months based on self-report at the baseline assessment. These measures were adapted from the COMBINE study Form 90 [36]. Self-report is known to be a reliable way of obtaining treatment utilization information among people with substance use disorders [37,38].

Covariates

Demographic variables included age, gender, and race/ethnicity. Current type of substance dependence is a 3-category variable indicating either alcohol dependence with heavy alcohol use in the past 30 days, any drug dependence with drug use in the past 30 days, or both. Alcohol and drug dependence were determined using the CIDI-SF alcohol and drug modules [31]; heavy alcohol use in the past month was indicated by 4 or more drinks per day or 15 or more drinks per average week for women, and 5 or more drinks per day or 22 or more drinks per week for men. The regression models included other variables that may affect addiction treatment utilization: recruitment from a detoxification program (versus from medical care or the community), criminal justice involvement (any arrest, probation, parole, pretrial release, diversion program or incarceration in the past 3 months), homeless (any time living in a shelter or on the streets in the past 3 months),

unemployed (usual pattern past 3 months), having health insurance (including Medicaid), current smoker, and anxiety in the past week (Beck Anxiety Index [39] scores: low = 0-21, moderate = 22-35, or high = 36 or higher).

Statistical Methods

Secondary data analysis of the AHEAD study baseline data was conducted. Descriptive statistics were obtained and Spearman correlations were used to evaluate potential collinearity between independent variables and covariates. No pair of variables included in the same regression model was highly correlated ($r > 0.40$). Multivariate regression models were used to evaluate the effect of presence of chronic disease on addiction treatment utilization, adjusting for covariates defined above.

The primary outcome of any addiction treatment was modeled using logistic regression, with odds ratios and 95% confidence intervals calculated. The distributions for outpatient addiction treatment days and residential nights, which are count variables, were skewed with many zeros and long tails, thus models assuming normality were inappropriate and overdispersed Poisson regression models were used [40]. The Pearson chi-square correction was used to account for overdispersion. The magnitudes of association between measures of chronic disease and utilization were quantified for the Poisson models using incidence rate ratios (IRRs) with 95% confidence intervals. IRR is interpreted as the ratio of the number of outpatient days (or residential nights) for the exposed group of interest (e.g., any chronic disease) versus the reference group (no chronic disease). The null value of no association for the IRR is equal to 1. An IRR >1 indicates that chronic disease is associated with more treatment utilization.

Multivariate models were fit separately for each dependent variable (any addiction treatment, outpatient days, and residential nights) and for each key independent variable (chronic disease, asthma, health status, and PCS). The primary analyses using the Katz score included 498 subjects with complete data on outcomes, the main independent variable, and covariates; secondary models included the same 498 subjects. Power calculations assumed that 27% of subjects without chronic disease utilized addiction treatment (based on the observed data), giving our study approximately 80% power to detect an odds ratio as small as 1.9 for those with one chronic disease of lowest severity and an odds ratio as small as 2.1 for those with one chronic disease of higher severity or multiple chronic diseases. Thus, power was sufficient for effects that were clinically meaningful. All analyses were conducted using two-sided tests and a significance level of 0.05, using SAS software (version 9.1; SAS Institute, Cary, NC).

Results

Baseline Characteristics

Of 2,018 potential subjects screened, 650 subjects were eligible, and 563 subjects were enrolled. Enrolled subjects were similar to unenrolled subjects in terms of gender, age and race/ethnicity. Baseline sociodemographic characteristics are noted in Table 1, as are prior healthcare and addiction treatment utilization.

Table 1 Baseline Characteristics (n = 563)

	n	%

Outpatient days	97	17
Residential nights	70	12

Addiction Treatment

At baseline, 28% of subjects had been in addiction treatment in the prior 3 months, excluding detoxification (Table 1). The 97 patients (17%) who had outpatient treatment in the prior 3 months attended a median of 5 days (interquartile range 3-13). The 70 patients (12%) with residential treatment in the past 3 months attended a median of 23 nights (interquartile range 8-45).

Chronic Disease, Physical Health and Other Medical Conditions

Overall, two thirds of subjects had no chronic disease, 20% had one chronic disease of lower severity, and 14% had one of higher severity or multiple diseases (Table 2). One third of subjects reported their health status to be only poor or fair. The mean Physical Comorbidity Score is 41.7 (SD = 8.4) (the general population norm is 50 [35]).

Subjects reported a wide range of medical conditions (Table 2). Hepatitis was reported by nearly one third of subjects, the most common single condition. Hypertension was reported by 21% of subjects and about 20% reported asthma. Ten to thirteen percent of subjects reported skin infections, pneumonia, anemia or seizures. Five to ten percent reported tachycardia, gastritis, diabetes, COPD, ulcer, or tuberculosis. Few (2-5%) reported rheumatoid arthritis, neuropathy, heart conditions, stroke, HIV, pancreatitis, cancer, poor kidney function or cirrhosis, and remaining conditions were even more rare.

Effect of Chronic Disease on Addiction Treatment Utilization

In multivariate regression analyses (Table 3), no significant effect was detected for the main independent variable of chronic disease status on the odds of attending addiction treatment (adjusted odds ratio [AOR] 0.88 for lower severity vs. no chronic disease, 95% confidence interval (CI): 0.60, 1.28; AOR 1.29 for higher severity vs. no chronic disease, 95% CI: 0.89, 1.88). Similarly, no significant effect of chronic disease status was detected on number of outpatient days or residential nights.

For the primary outcome of any addiction treatment utilization (Model 1), being black was a negative factor, and having health insurance and severe anxiety were positively associated with any addiction treatment. Being female and having severe anxiety were positively associated with number of outpatient days, and recruitment from a detoxification facility was a negative factor (Model 2). Being black was a negative factor for residential nights (Model 3).

Similar results were found for the secondary independent variables of asthma and PCS, with neither significantly associated with any of the addiction treatment measures. Fair or poor health status was negatively associated with any addiction treatment and with outpatient addiction treatment, but not with residential treatment. Table 4 summarizes the results for each of the secondary independent variables (from separate regression models) on each of the outcome variables.

Discussion

Despite the potential for interference or facilitation of chronic medical disease on utilization of addiction care, no statistically significant effect was found for chronic disease status on addiction treatment utilization in the prior 3 months, in this cohort of alcohol and drug dependent persons, controlling for sociodemographics, type of substance dependence, recruitment site, current

Table 4 Summary of Other Secondary Multivariate Regression Models, with alternate key independent variables (N = 498)

	Model 1 Any Addiction Treatment	Model 2 Outpatient Days	Model 3 Residential Nights
Key Independent Variable	**AOR (95% CI)**	**IRR (95% CI)**	**IRR (95% CI)**
Asthma	1.05 (0.74, 1.49)	1.03 (0.52, 2.03)	1.03 (0.50, 2.12)
Self-reported health status			
Excellent/Very Good/Good	Referent	Referent	Referent
Fair/Poor	0.67 (0.48, 0.94)*	0.40 (0.20, 0.80)**	0.61 (0.31, 1.21)

Model 1 used logistic regression; Models 2 and 3 used Poisson regression. Models duplicate those in Table 3 (controlling for age, gender, race, substance dependence, recruitment from detox, criminal justice involvement, homeless, unemployed, health insurance, smoker, anxiety), solely replacing the chronic disease variable with the secondary variables above.

*p < .05 **p < .01; Wald chi-square tests, df = 1

smoking, and severity of recent anxiety. Nor was addiction treatment associated with asthma or physical function and quality of life. These findings held for any addiction treatment and for quantity of treatment services received. Only perceived health status, which is a subjective measure, was associated with less addiction treatment utilization. It is encouraging to note that chronic disease itself may not be a barrier to addiction treatment.

On the other hand, it also appears that chronic medical disease did not increase addiction treatment participation in this cohort. People with chronic disease are often connected to the medical treatment system, but the acute focus of episodic care may not extend to providing assistance or motivation for these patients to access addiction treatment. This may be a missed opportunity for medical providers to encourage their patients to seek addiction treatment given that the self-reported perception of health status was frequently only fair or poor. The lack of a significant positive association between chronic disease and addiction treatment utilization suggests that facilitated access to addiction care is not routinely occurring. Such "reachable moments" [41] for the individual with both chronic disease and addiction are perhaps most likely when formalized linkages between primary care and addiction treatment exist or if the primary care doctor is willing to address addiction with the patient [18,42]. One way to increase these reachable moments is to encourage screening, brief intervention, and referral to treatment approaches in the primary care setting. Opportunities for referral to addiction treatment should increase as the number of medical visits increases. An integrated, longitudinal approach to managing both chronic medical disease and substance dependence is likely to be most beneficial [13,43,44].

It is worthwhile to note that no chronic diseases were reported by two thirds of this sample of substance dependent individuals, somewhat better than an estimate of 53% with no chronic conditions in a comparable population 10 years earlier [22]. The lower estimate here may be due to recruitment beyond detoxification settings; subjects recruited from the community may be less medically ill than those in detoxification facilities. Most of the chronic diseases noted here had prevalence within the range of national and state estimates [45,46]. The asthma prevalence here appears slightly higher than the state average, but this likely reflects the higher rates often found in inner city and African-American populations [47] and the high prevalence of current smoking in this sample. The below average Physical Comorbidity Score in this population is comparable to similar populations 10-15 years earlier [22,48].

Although we did not detect an association between chronic medical variables and treatment utilization, several other variables were significantly related to treatment utilization, including several sociodemographic variables. Health insurance was positively associated with any addiction treatment utilization, demonstrating an expected increase in access to treatment, but did not reach significance for the count variables. Recruitment from detoxification was negatively associated with outpatient days, highlighting the severity of addiction treatment needs for this group, and the expected lack of treatment preceding detoxification entry. Psychiatric comorbidity (e.g., anxiety) was positively associated with addiction treatment utilization reflecting other findings in the literature [49], although this past-week measure was collected for most individuals soon after detoxification, so may reflect short-term anxiety symptoms rather than a chronic disorder.

The lack of findings concerning our primary hypothesis may simply be the reflection of a complex relationship between chronic disease and addiction, with many competing forces. Several opposing effects from chronic disease may have occurred, which could collectively show little or no effect on addiction treatment utilization. First, individuals with chronic disease may be functionally less able to access and participate in addiction treatment, reducing the likelihood of treatment utilization. If physical function were an important barrier, we should have seen some effect from the PCS, which did not occur, but it might be important to consider specific functional limitations. By considering asthma separately, thus removing the variability across conditions, we might have highlighted the functional effects, but that also did not occur. It is also possible that the severity of addiction, as indicated by most individuals in the sample recruited from detoxification, overshadowed any functional limitations as they sought treatment; a desire to focus on the most pressing problem has been highlighted in some literature [9]. Second, for a variety of reasons, addiction treatment facilities may be less likely to accept individuals with medical conditions, who may require medications or have more acute medical needs. This study could not address that question. Third, chronic disease may interfere with the quality of treatment participation; number of visits could be construed as a proxy for this, but if chronic disease affects self-care management this issue may go beyond what could be considered here. Fourth, 3 months is a relatively short time period, so may have masked any differences that would appear with longer history of treatment utilization. However, the focus here is on relative differences in utilization, so the 3 month period should have been sufficient to compare groups. Fifth, and alternatively, individuals with chronic disease may be more likely to access treatment due to their likely existing linkages with the healthcare system. A study of women with

trauma and mental or substance use disorders found that greater disability was associated with more outpatient counseling, but not residential, group counseling or peer treatment [50]. While referral from the healthcare system is not a common pathway to addiction treatment [51] the finding that physicians are more likely to know about substance abuse if the patient has an episodic or chronic medical condition [11] suggests that this pathway may be more likely for these patients.

The characteristics of the study sample may have tempered the potential relationships between chronic disease and addiction treatment utilization. In a relatively young sample such as this, chronic disease is less likely, and related problems are likely to be less severe than in an older population. However, addiction itself may increase such problems even in a young sample [22]. The subjects in this study are largely reflective of individuals in addiction treatment, and these results should apply to similar cohorts. Relatively few individuals in this sample had severe chronic disease or multiple conditions, thus findings may be different in an analysis of only individuals with chronic disease. The implications of recruiting much of the sample during a detoxification stay should be considered, where individuals entering detoxification may be unlikely to have been in addiction treatment during a period of substance use severe enough to warrant detoxification. These findings also represent a sample from a single site, so may be less generalizable than recruitment from multiple sites.

A limitation is that the study may have been inadequately powered to detect differences of the observed magnitude. Power calculations estimated 80% power to detect an odds ratio as small as 2.1 for those with higher severity chronic disease, thus it is likely that the study was not adequately powered to detect the small observed magnitude of association of 1.3 (for higher severity). However, since the observed degree of association may still be clinically meaningful, the possibility that individuals with higher comorbidity are more likely to utilize addiction treatment should be further studied in a larger sample to see if a small but clinically important effect is detectable. But the effect of greater concern, interference with receiving addiction treatment due to a chronic disease, is unlikely based on our findings. Last, the current analysis relied on retrospective data from a sample of individuals, most of whom had recently completed detoxification. A prospective or qualitative study would be better able to track the likely causal issues related to chronic disease and addiction treatment access.

To our knowledge, this is the first analysis of the role of chronic disease in addiction treatment utilization. Current household studies on barriers to addiction treatment, such as SAMHSA's National Survey on Drug Use and Health (NSDUH), do not consider medical comorbidities, so are unable to shed light on these underlying questions. Further research in this area is warranted to better understand these complex issues. The individuals in this study were, by definition, willing to receive health care. Other populations may differ. Also, samples with a large number of individuals with chronic disease would allow a focus on more specific chronic diseases, such as diabetes or heart disease, and would allow a better consideration of other psychiatric comorbidity. In the meantime, we highlight the conclusion from these data that chronic disease is not a significant barrier to addiction treatment utilization. While we found no significant association between chronic medical disease and addiction treatment utilization, these issues are complicated and we suggest prospective and qualitative studies to further explore these complexities.

Acknowledgements

Preliminary results of this study were presented at the *Integrating Services & Research for Co-Occurring Conditions* conference, Bethesda, MD, March 2009, and the *Association for Medical Education and Research in Substance Abuse* conference, Bethesda MD, November 2009. Authors' contributions

All authors contributed to the design, interpretation of results, and the manuscript preparation and have approved the final manuscript. In addition, significant individual contributions are as follows. SR conceived of the study, designed the analytic plan, and led the writing, interpretation of results, and revisions of the manuscript. MJL contributed to the study scope, analytic plan, and interpretation of results. DMC provided statistical expertise, and contributed to the study scope, analytic plan, and interpretation of results. DA conducted the statistical analysis. RS and JS lead the parent study from which the data were obtained, brought expertise regarding the data and the study population, and contributed to the study scope, analytic plan, and interpretation of results.

Competing interests

The authors declare that they have no competing interests.

The Business Case for Quality Improvement
Oral Anticoagulation for Atrial Fibrillation

Adam J. Rose, MD, MSc, FACP; Dan R. Berlowitz, MD, MPH; Arlene S. Ash, PhD; Al Ozonoff, PhD; Elaine M. Hylek, MD, MPH; Jeremy D. Goldhaber-Fiebert, PhD

Background—The potential to save money within a short time frame provides a more compelling "business case" for quality improvement than merely demonstrating cost-effectiveness. Our objective was to demonstrate the potential for cost savings from improved control in patients anticoagulated for atrial fibrillation.

Methods and Results—Our population consisted of 67 077 Veterans Health Administration patients anticoagulated for atrial fibrillation between October 1, 2006, and September 30, 2008. We simulated the number of adverse events and their associated costs and utilities, both before and after various degrees of improvement in percent time in therapeutic range (TTR). The simulation had a 2-year time horizon, and costs were calculated from the perspective of the payer. In the base-case analysis, improving TTR by 5% prevented 1114 adverse events, including 662 deaths; it gained 863 quality-adjusted life-years and saved $15.9 million compared with the status quo, not accounting for the cost of the quality improvement program. Improving TTR by 10% prevented 2087 events, gained 1606 quality-adjusted life-years, and saved $29.7 million. In sensitivity analyses, costs were most sensitive to the estimated risk of stroke and the expected stroke reduction from improved TTR. Utilities were most sensitive to the estimated risk of death and the expected mortality benefit from improved TTR.

Conclusions—A quality improvement program to improve anticoagulation control probably would be cost-saving for the payer, even if it were only modestly effective in improving control and even without considering the value of improved health. This study demonstrates how to make a business case for a quality improvement initiative. **(*Circ Cardiovasc Qual Outcomes*. 2011;4:416-424.)**

Key Words: anticoagulants ■ atrial fibrillation ■ patient simulation ■ quality improvement

Atrial fibrillation (AF) is a common condition and a leading cause of ischemic stroke.[1,2] The benefit of long-term anticoagulation with warfarin to prevent ischemic stroke in patients with AF is well established.[3–6] However, the anticoagulation that is actually provided leaves much room for improvement.[7] Quality of anticoagulation can be measured by percent time in the therapeutic range (TTR).[8,9] Higher TTR has been linked with lower rates of ischemic stroke, major hemorrhage, and death.[10,11] Although improving TTR would have benefits, payers may be hesitant to invest the time, effort, and resources required for a quality improvement (QI) program. In particular, payers are generally less interested in questions of long-term cost-effectiveness, focusing instead on traditional business considerations of maximizing short-term profitability. Because the Veterans Health Administration (VA) is considering a QI program to increase TTR, we undertook to study whether a "business case" can be made for such a program, that is, whether it has the potential to save money in the short term.

We therefore used our Veterans AffaiRs Study to Improve Anticoagulation (VARIA) data base to identify 67 077 patients with AF receiving anticoagulation from the VA over a 2-year period. We simulated the number of adverse events that would be prevented in this population through improved TTR as well as the resulting cost savings and utility gains. We hypothesized that potential cost savings to the payer (the VA), mostly from preventing ischemic strokes, would constitute a compelling business case for this QI program.

Circ Cardiovasc Qual Outcomes **is available at http://circoutcomes.ahajournals.org** **DOI: 10.1161/CIRCOUTCOMES.111.960591**

WHAT IS KNOWN

- Improved control of oral anticoagulation could prevent many adverse events, which would improve patient health and could potentially produce cost savings for payers.
- Cost savings from adverse events averted could at least partly defray the costs of a quality improvement program to improve anticoagulation control.

WHAT THE STUDY ADDS

- Using data from a real cohort of >60 000 patients anticoagulated for atrial fibrillation in the Veterans Health Administration, we simulated the number of adverse events that might be prevented by slight, moderate, and large improvements in anticoagulation control.
- Even assuming a small improvement in control and even with other conservative assumptions, the short-term cost savings from averted events would likely be much larger than the historical cost of most quality improvement programs.
- Because improved anticoagulation control has the potential to produce short-term savings from the payer's perspective while improving patient health, pursuing this goal should be a top priority for the Veterans Health Administration and other systems of care.

Methods

Inclusion Criteria and Calculation of Percent Time in Range (TTR)

The data base for this study has been described previously.[9,12] VARIA included all patients deemed to be receiving oral anticoagulation therapy from the VA between October 1, 2006, and September 30, 2008, according to the criteria described below. The study was approved by the Institutional Review Board of the Bedford VA Medical Center.

There are 128 sites of care in the VA system. We included 100 of these sites and excluded the remaining 28 because their international normalized ratio (INR) values were not captured reliably in VA data bases. For the current study, we limited our data base to patients who were experienced users of warfarin, that is, who had used it for at least 6 months. We defined each patient's date of warfarin initiation as the first INR value >1.2 or the first outpatient warfarin fill, whichever came first. It would be extremely unusual for a patient to record an INR value >1.2 unless he or she had taken warfarin. We then stratified the sample into inception time (the first 6 months of warfarin therapy for each patient) and experienced time (any time thereafter).

We included INR tests within the VA when patients were "on warfarin": that is, when a patient was either (1) "in possession" of warfarin or (2) having INR tests every 42 days. We defined the period of warfarin possession as the duration of the most recent VA prescription for warfarin, plus 30 days. We calculated TTR using the Rosendaal method,[13] which uses linear interpolation to calculate the percentage of time during which the INR was between 2 and 3.[13]

Estimates of Adverse Event Risks and Their Relationship to Clinical Characteristics

We focused on 3 adverse events: ischemic stroke, major hemorrhage, and death. We relied on estimates from randomized, controlled trials and observational studies, published in English, that reported all of the following: the anticoagulation control achieved by patients receiving adjusted-dose warfarin; sufficient information to compute rates for at least 1 category of adverse events (ie, number of events and person-time of observation); and information on the proportion of patients with congestive heart failure, hypertension, age >75 years, diabetes mellitus, and prior stroke or transient ischemic attack.

We identified studies using the literature review conducted by the American College of Chest Physicians Guidelines Group in their most recent guidelines for stroke prevention in AF.[5] This review included all randomized and observational studies of patients receiving adjusted-dose warfarin for stroke prevention in AF from 1950 through 2008. We characterized patients' risk of adverse events using the CHADS2 score.[14] CHADS2 stands for Congestive heart failure, Hypertension, Age >75 years, Diabetes, and prior Stroke. Patients are assigned 1 point for each of the first 4 risk factors, and 2 points for prior stroke; scores vary from 0 to 6. CHADS2 scores are predictive of the risk of ischemic stroke[14] as well as major hemorrhage[15–17] and are widely used by clinicians and researchers to summarize stroke risk in AF.

The included studies are listed in Table 1. In total, 18 studies reported rates of ischemic stroke and major hemorrhage[18–35]; of those, 14 studies also reported all-cause mortality.[18–31] For each study, we computed the average CHADS2 score of the included patients.[14] We then used Poisson regression to model the annual rate of each adverse event type as a function of study average CHADS2 score. We assumed that these risks increase exponentially as the CHADS2 score increases, as was shown in the original CHADS2 study.[14] We used the CHADS2 score not only in its original sense (as a predictor of ischemic stroke risk) but also to predict the risk of other adverse events (ie, major hemorrhage and all-cause mortality). The supposition that patients with higher CHADS2 scores have higher rates of all-cause mortality is reasonable but has not been empirically demonstrated. When we subsequently used these models to predict the annual rate of events for individual patients, we substituted each patient's actual CHADS2 score for the study average CHADS2 score. The parameter estimates for these Poisson regressions are shown in Table 2. The pseudo R^2 values for meta-regressions of stroke, major hemorrhage, and death were 0.16, 0.19, and 0.19, respectively.

Estimates of the Effects of TTR on Adverse Event Risks

We then estimated the relationships between TTR and the rates of our 3 adverse events, using analysis from White et al.[11] Although White reported the relationship between TTR and outcomes using tertiles, we used additional information from another study that analyzed the same data sets[36] to produce a continuous plot for event rates as a function of TTR (Figure 1). To model the predicted event rates for each patient, we predicted each event rate for each patient based on his/her CHADS2 score. We then adjusted this rate on the basis of the patient's TTR.

Simulating the Adverse Events for the VA Population

We constructed a simulation model to predict the likelihood of each type of adverse event given current TTR levels (the "status quo") over a 2-year period and used it to explore how improvements in TTR levels would reduce adverse events. First, we predicted the 2-year event rates for each patient on the basis of his or her CHADS2 score and TTR level, as described above, then summed these event rates to describe the overall rate of any event occurring. We converted this summed rate to a daily probability assuming a constant hazard (exponential model). We then drew random numbers to determine whether any event had occurred each day, and, if yes, then of what type. We assumed that 16% of major hemorrhages are intracranial, as per O'Brien et al.[37] We right-censored patients who did not have an event within the 2-year analysis window. We repeated the simulation 1000 times to generate 95% confidence intervals.

Table 1. Randomized Trials and Observational Studies Included in Our Meta-Regression

DM indicates diabetes mellitus; HTN, hypertension; CVA, cerebrovascular accident; TIA, transient ischemic attack; and CHF, congestive heart failure.

Patient characteristics are given in percentages, and rates are given in events per 100 patient-years.

*For some studies, the average age was reported along with the standard deviation, but the proportion of patients age >75 years was not directly reported. For these studies, proportion with age ≥75 years was estimated by assuming that age was normally distributed.

Simulating the Benefits of Improvements in TTR for the VA Population

At this point, each patient was defined by 2 parameters that determined his risk of adverse events: CHADS2 score and TTR. We then altered the status quo by assuming that a QI program had increased TTR, ranging from a 2.5% absolute improvement in TTR to a 20% absolute improvement. Our estimate for the approximate magnitude of this change is based on a meta-analysis, which showed that dedicated anticoagulation clinics achieve a TTR 8.9% higher than management by individual clinicians.[7] It is reasonable to expect that an intervention to improve VA anticoagulation clinics could improve TTR by a similar margin. We assumed that all patients in the data set would have an equal improvement in TTR. Some patients began with a very high TTR at baseline; if the incremental improvement had exceeded a TTR of 100%, some of the postulated improvement was "lost."

Costs and Utilities

For cost and utility estimates, we relied on published literature (Table 3), especially a cost-effectiveness analysis published by O'Brien and Gage.[37] We calculated the cost savings and health benefits of different degrees of improvement in TTR, compared with the status quo (ie, baseline TTR), based on the number of events averted. We included costs for ongoing warfarin therapy and for adverse events that might be prevented by or caused by warfarin therapy. Costs were expressed in 2008 dollars and were inflation-adjusted when their original sources reported costs from other years.[38,39] Utilities were expressed in terms of quality-adjusted life-years (QALYs), a measure that combines longevity and morbidity.[39] These utilities were derived from a population of patients with AF who are similar to our study population in most respects. Given the short time horizon of the analysis (2 years), we report undiscounted costs and QALYs.

Sensitivity/Uncertainty Analyses

We performed 1-way sensitivity analyses on all inputs to the model, including the relationship between CHADS2 scores and event rates, the relationship between TTR and event rates, costs, and utilities. We also performed 2-way sensitivity analyses using pairs of variables with large effect sizes in the 1-way sensitivity analyses.

Although White and others have reported considerable mortality benefits from improved TTR,[11,40,41] we suspect that these are overestimates of the effect size. Although it is logical that deaths caused by ischemic stroke or major hemorrhage would be prevented, we suspect that these estimates are inflated by the inclusion of other causes of death that would not be prevented by improved anticoagulation control. The reason for this would be that sicker patients have lower TTR[12] and higher rates of all-cause mortality, some of which is unrelated to excessive or insufficient anticoagulation. Therefore, we ran an additional set of analyses under the extreme assumption that improved TTR has no impact on all-cause mortality—not because we think this is likely, but simply to explore the fullest possible impact of this input on our results.

Finally, we performed a probabilistic sensitivity analysis (via Monte Carlo simulation), simultaneously varying all of our parameters on the basis of their uncertainty distributions, described by their plausible ranges (Table 3) for 1000 iterations. For the probabilistic sensitivity analyses, we assumed beta distributions for utilities, triangular distributions for costs, and normal distributions for the

Table 2. Results of Poisson Meta-Regressions for Rates of Ischemic Stroke, Major Hemorrhage, and All-Cause Mortality, Based on CHADS2 Scores (Events Per Patient-Year)

	β	95% CI
Ischemic stroke: 18 studies; 393 events; 32 605 patient-years		
CHADS2 score	0.634	0.373 to 0.894
Study is an RCT	−0.165	−0.402 to 0.073
Constant	−5.482	−5.922 to −5.042
Major hemorrhage: 18 studies; 611 events; 32 605 patient-years		
CHADS2 score	0.379	0.175 to 0.584
Study is an RCT	0.151	−0.033 to 0.335
Constant	−4.746	−5.094 to −4.397
All-cause mortality: 14 studies, 601 events, 15 024 patient-years		
CHADS2 score	0.380	0.228 to 0.532
Constant	−3.973	−4.292 to −3.653

RCT indicates randomized, controlled trial.

Observational studies did not report on all-cause mortality; therefore, the variable for RCT was dropped.

relationships between CHADS2 or TTR and adverse event rates. All analyses were undertaken with Stata/SE 10.1 (StataCorp, College Station, TX). Drs Rose and Goldhaber-Fiebert had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

Results

Patients

Our population consisted of 67 077 patients anticoagulated for AF between October 1, 2006, and September 30, 2008 (Table 4). Patients were overwhelmingly male (99%), with a mean age of 72.7 years. Patients had considerable comorbid illness: 41% had diabetes, 37%, had heart failure, and 20% had prior stroke or transient ischemic attack. Many had high CHADS2 scores, indicating substantial risk for ischemic stroke and other adverse events. Anticoagulation control in the overall population was fair (mean TTR, 62.4%). Patients in the lowest tertile had TTR <55.6%; those in the highest tertile had TTR >73.4%.

Simulation of Improved Control and Impact on Adverse Events

In the status quo analysis, we simulated adverse events for all 67 077 patients according to their actual observed TTR (Table 5). During the 2-year study, 23.1% of patients (95% confidence interval [CI], 22.8 to 23.4) had any adverse event. Improving TTR by 2.5% averted 584 adverse events (95% CI, 302 to 883). These included 96 ischemic strokes (95% CI, −74 to 258), 136 major hemorrhages (95% CI, −24 to 289), and 352 deaths (95% CI, 126 to 584). Improving TTR by 5% averted 1114 adverse events (95% CI, 825 to 1389). These included 183 ischemic strokes (95% CI, 8 to 346), 269 major hemorrhages (95% CI, 118 to 416), and 662 deaths (95% CI, 435 to 869). Larger improvements in TTR were associated with even greater benefits.

Costs and Utilities/Sensitivity Analyses

Cost savings and utility gains from different levels of TTR improvement are shown in Table 5. Increasing TTR by 5% saved $15.9 million (95% CI, 3.2 to 28.4) and gained 863 QALYs (95% CI, 575 to 1154). Larger improvements in TTR had progressively greater benefits in terms of cost savings and utility gained. We also found that a QI program for oral anticoagulation is very likely to be cost-effective, although the cost of the program and its effectiveness in improving TTR cannot be known in advance. For example, if the QI program achieved a 5% improvement in TTR (a modest result), the program could cost as much as $59 million to implement and still achieve cost-effectiveness at the traditional $50 000/QALY threshold given our 2-year time horizon.

One-way sensitivity analyses are summarized in the online-only Data Supplement Appendix. Varying the cost

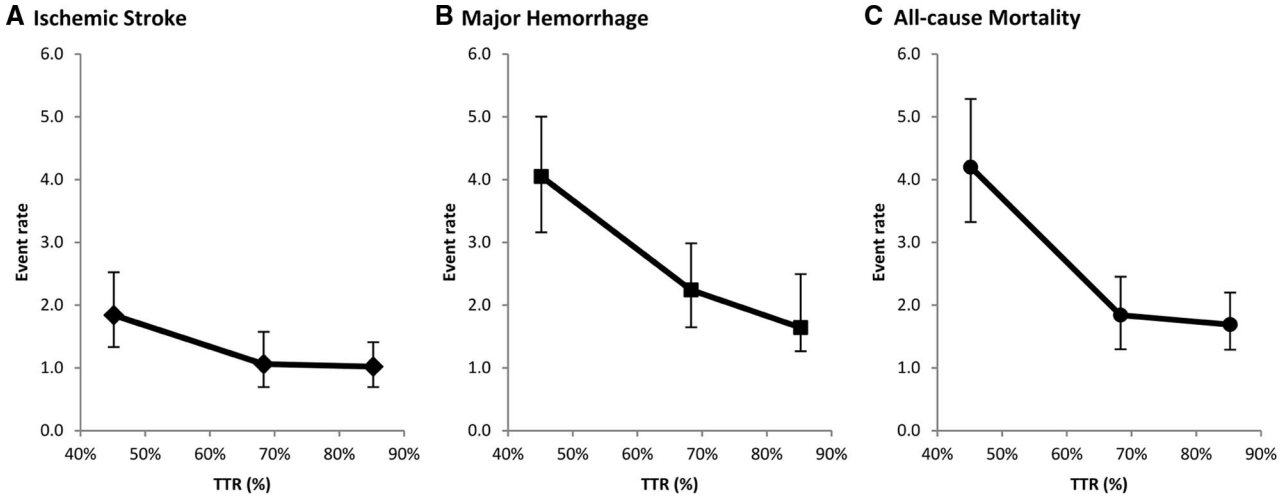

Figure 1. A, Interpolated relationships between TTR level and rates of ischemic stroke; **B**, major hemorrhage, and **C**, all-cause mortality. Rates are given in events per 100 patient-years.

Table 3. Cost and Utility Estimates (and Ranges) for Various Health Events and Health States Related to AF and Anticoagulation

Health Event or Health State	Estimate	Range
Costs		
Warfarin, 1 y	$210	$70–$400
Anticoagulation monitoring, 1 y; 17.4 visits/y	$520	$100–$1000
One-time cost of ischemic stroke		
Moderate-severe sequelae	$14 100	$7000–$30 000
Minor sequelae	$8700	$4000–$17 000
No sequelae	$7100	$4000–$14 000
Monthly (long-term) cost of ischemic stroke		
Moderate-severe sequelae	$5100	$2500–$10 000
Minor sequelae	$2300	$1000–$5000
One-time cost of ICH	$36 600	$17 000–$70 000
Monthly (long-term) cost of ICH	$5400	$2500–$10 000
One-time cost of non-ICH major hemorrhage	$4200	$2000–$7000
Utilities		
Healthy, using warfarin	0.987	0.953–1.0
Neurologic event with sequelae		
Moderate-severe sequelae (including ICH)	0.39	0.2–0.6
Minor sequelae	0.75	0.6–0.9
Major hemorrhage other than ICH	0.80	0.6–0.9

ICH indicates intracranial hemorrhage.

Costs are given in 2008 dollars. Utilities are given in QALYs and are reported per patient per year. One QALY is a full year of life in perfect health; a state of death is worth 0 QALYs, and a year of life with less than perfect health is valued as stated in the table. A major hemorrhage other than ICH causes the listed decrement in utility for only 1 month after the acute event, whereas strokes with sequelae cause the listed decrement in utility until the end of the study.

inputs did not meaningfully alter our results, with the possible exception of the monthly cost of an ischemic stroke with moderate-severe sequelae (example: increasing TTR by 5% saved between $12.2 to $22.7 million, depending on this one input). Varying the utility inputs did not meaningfully alter our results regarding expected utility gains. Varying the relationships between CHADS2 scores and events, or between TTR improvement and events, had the greatest impact on results. Gradients for ischemic stroke had the greatest impact on cost savings: For example, the savings from improving TTR by 5% varied from $8.3 to $35.3 million, depending on the relationship with CHADS2 and from $4.8 to $26.7 million, depending on the relationship with TTR. Gradients for death had the greatest impact on utility gains; for example, the gains from improving TTR by 5% varied from 532 to 1378 QALYs, depending on the relationship with CHADS2 and from 338 to 1230 QALYs, depending on the relationship with TTR. In the most extreme version of this sensitivity analysis, we assumed that changes in TTR had no impact on the risk of death. Predictably, this greatly reduced utility gains; for example, improving TTR by 5% gained 863 QALYs under the base case scenario and only 44 QALYs under this alternative scenario. Cost savings were largely unaffected by this maneuver, leaving the business case for quality improvement intact.

We also performed 2-way sensitivity analyses among the 3 variables with the largest impact on cost in the 1-way sensitivity analyses, including the relationship between CHADS2 score and stroke risk, the relationship between TTR and stroke risk, and the monthly cost of caring for a patient with moderate-severe stroke sequelae. In general, only extreme changes in these inputs had a sizeable impact on the overall cost savings. For example, the combined relationship between TTR, CHADS2, and stroke risk reduced estimated cost savings by >33% only if either improving TTR had no effect on stroke risk regardless of the relationship between CHADS2 and stroke risk or else if both improving TTR and higher CHADS2 scores had little effect on stroke risk.

Probabilistic sensitivity analyses confirmed that improving TTR is likely to result in benefit, although the exact size of the benefit might vary (Figure 2). For example, improving TTR by 5% was 76% likely to result in a savings of ≥$10 million and 97% likely to result in a utility gain of ≥500 QALYs. Of note, a very small improvement in TTR (2.5%) failed to save money approximately 6% of the time. Therefore, to ensure a high probability of being cost saving, a QI program would need to improve TTR by ≥3%.

Discussion

Improving the quality of oral anticoagulation for patients with AF can avert adverse events including ischemic stroke, major hemorrhage, and death.[11] We therefore simulated the effects of a program to improve anticoagulation control in the VA. In this population, even a modest improvement in TTR (5%)

Table 4. Baseline Sample Characteristics for 67 077 Patients Receiving Anticoagulation for AF in the VA

Variable	n (%)
Female sex	825 (1.2%)
Mean age, y (SD)	72.7 (9.6)
Race/ethnicity	
Non-Hispanic white	53 186 (79.3%)
Non-Hispanic black	3968 (5.9%)
Hispanic	1853 (2.8%)
Asian	226 (0.3%)
Native American	158 (0.2%)
Other/unknown	7686 (11.5%)
Comorbid conditions	
Coronary artery disease	36 052 (53.8%)
Diabetes	27 428 (40.9%)
Heart failure	24 974 (37.2%)
Hypertension	57 970 (86.4%)
Prior stroke or TIA	13 606 (20.3%)
CHADS2 risk score	
0	2256 (3.4%)
1	11 929 (17.8%)
2	21 604 (32.2%)
3	17 086 (25.5%)
4	8527 (12.7%)
5	4410 (6.6%)
6	1265 (1.9%)
Anticoagulation control	
Percent time in range (TTR), mean, SD	62.4% (21.5%)
Percent time in range (TTR), tertiles	<55.6%; 55.6%–73.4%, >73.4%

TIA indicates transient ischemic attack.

All patients had received anticoagulation for at least 6 months as of study inception.

would be expected to avert 1114 adverse events over 2 years, many of them fatal. We estimated that this change would result in a savings of $15.9 million and a gain of 863 QALYs over our 2-year study period. Even for a system as large as the VA, the cost of QI programs does not approach tens of millions of dollars. For example, the highly successful Translating Initiatives in Depression into Effective Solutions (TIDES) program has greatly improved management and outcomes for VA patients with depression.[42] The total cost of creating and implementing TIDES was recently estimated at $282 000.[43] Therefore, it seems likely that there is a compelling business case for our proposed QI initiative. Although our study is based on a VA population, its lesson would seem to apply to any integrated health care organization.

Anticoagulation therapy for AF is currently undergoing a major change, as dabigatran, the first serious competitor to warfarin, has recently received Food and Drug Administration approval. The RE-LY study showed that dabigatran is slightly superior to warfarin; for example, one would need to treat 357 patients with dabigatran (150 mg) to prevent 1 more ischemic stroke than warfarin would have prevented.[44] Although dabigatran is expected to improve patient convenience, it will be much more expensive than warfarin, even considering the cost of monitoring warfarin therapy.[45,46] It is likely that the small improvement in outcomes associated with dabigatran can be matched, or nearly matched, by a quality improvement program such as the one simulated here, but at a fraction of the cost. In other words, it may be easier to make a business case for QI in anticoagulation than for dabigatran. Our group plans to examine this issue.

We may have underestimated the benefits of improved TTR because of several of our assumptions. First, we only examined the impact of improved TTR for patients anticoagulated for AF because this is the condition for which we best understand the relationship between TTR and outcomes.[11] However, only about half of all patients receiving anticoagulation in the VA have AF,[12] and patients anticoagulated for other indications also achieve superior outcomes with improved control.[47,48] Any program to improve TTR would benefit these patients as well, though the magnitude of cost savings or cost effectiveness remains to be determined.

Second, given the available trial-based data on effectiveness,[18–35] we limited our study to a 2-year time horizon. However, preventing events such as ischemic stroke or major hemorrhage often provides cost and utility benefits for more than 2 years, another source of underestimated benefit. A third conservative feature of this study is that we censored patients after a first adverse event because this is how study outcomes are generally reported.[18–35] However, patients can have several adverse events, leading to additional costs. A fourth assumption is that we did not consider transient

Table 5. Simulated Adverse Events, Costs, and Utilities Over a 2-Year Period for the Entire Population of VA Patients With AF (n=67 077)

Scenario	Ischemic Strokes (95% CI)	Major Hemorrhages (95% CI)	Deaths (95% CI)	Total Events (95% CI)	Cost, $ Millions (95% CI)	Utility, QALYs (95% CI)
Status Quo	3872 (3749–3994)	3318 (3218–3429)	8285 (8109–8449)	15 475 (15 275–15 676)	368 (358–377)	121 685 (121 472–121 888)
Change in TTR	Estimated Adverse Events Averted, Costs Saved, or QALYs Added by Improving TTR					
+2.5%	96 (−74 to 258)	136 (−24 to 289)	352 (126–584)	584 (302, 883)	8.1 (−4.0–20.9)	458 (161–748)
+5%	183 (8–346)	269 (118–416)	663 (435–869)	1115 (825–1389)	15.9 (3.2–28.4)	863 (575–1154)
+7.5%	259 (91–421)	396 (251–548)	964 (722–1194)	1619 (1315–1912)	22.9 (10.9–35.2)	1255 (962–1528)
+10%	332 (171–499)	523 (377–685)	1233 (1000–1457)	2088 (1811–2364)	29.7 (16.7–41.7)	1606 (1338–1900)
+15%	454 (280–623)	755 (607–910)	1711 (1480–1931)	2920 (2630–3200)	41.3 (28.9–54.3)	2224 (1970–2224)
+20%	557 (394–720)	965 (826–1120)	2092 (1857–2307)	3614 (3320–3882)	51.5 (39.5–63.7)	2721 (2430–2983)

95% CIs are calculated by bootstrapping with 1000 iterations. Utilities are given in QALYs. Some of the estimates of benefit from the smallest TTR improvement that we modeled (2.5%) cannot be distinguished from zero at the 95% confidence level.

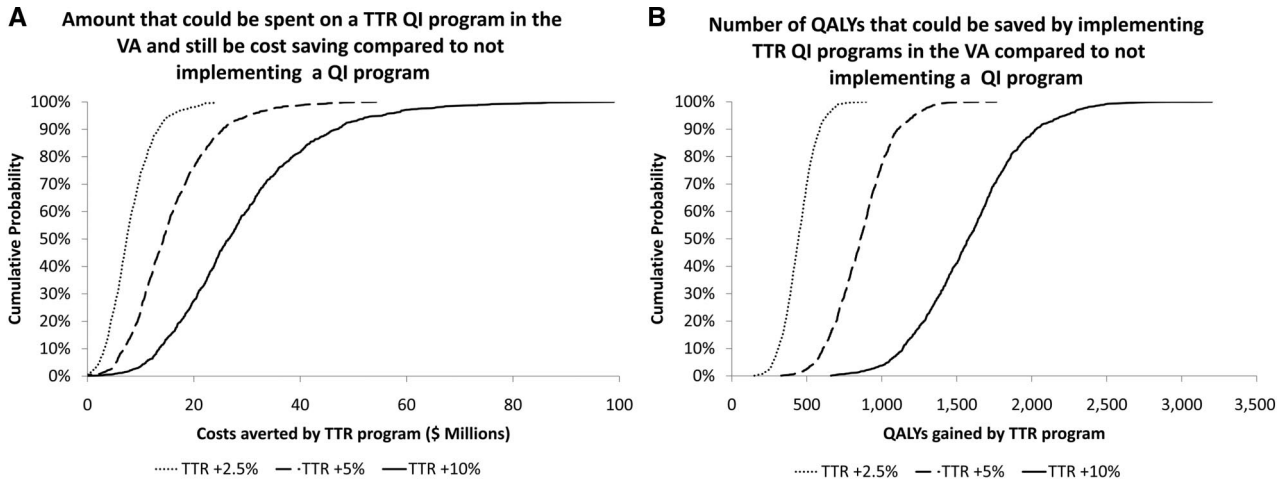

Figure 2. Distribution of outcomes from probabilistic sensitivity analyses, which varied all model inputs over their plausible ranges for 1000 iterations. These plots show the cumulative probability that (**A**) QI program for TTR would save a particular amount of money or (**B**) gain a particular number of QALYs.

ischemic attacks or minor hemorrhages because most trials do not report these events. Improved TTR should reduce the rates of these events as well. Finally, we did not consider the fact that improved TTR is likely not only to reduce the number of adverse events but also the severity of the events that are not prevented. We did not consider these effects because we lacked solid estimates for effect sizes, but their omission would also tend to underestimate the benefits of improved TTR.

This study has important strengths. First, as mentioned above, a number of underlying assumptions suggest that we have, if anything, underestimated the benefits of improved TTR. Second, we used a large data base of VA patients about which we have relatively complete data, especially regarding their CHADS2 risk for ischemic stroke. This allowed us to perform a detailed patient-level simulation to examine the impact of different degrees of TTR improvement in this population. Finally, much is known about the relationship between anticoagulation control and outcomes in AF, which is why we chose to focus on this condition in particular.

However, our study also has limitations. First, patient comorbidities were assessed using ICD-9 scores, which can be inaccurate. However, the CHADS2 scores that we ascribed to our population are well within the realm of what has been reported previously.[18–35] Second, we used CHADS2 not only as it was originally intended that is, as a risk score for ischemic stroke,[14] but also as a risk score for major hemorrhage and all-cause mortality; however, some literature supports using CHADS2 as a risk score for major hemorrhage.[15–17] When we used CHADS2 to risk-stratify for mortality, we used it as an all-purpose composite comorbidity score, similar to others that have been used in many prior studies.[49] This was necessary in large part because most of our source studies only reported these comorbidities.[18–35] Third, VA cost data are somewhat unique in that the VA does not usually bill for services. Therefore, we chose to use Medicare cost estimates for our study[37] to enhance generalizability to most settings. Fourth, our utility estimates are derived from a general population[37] rather than a VA population, and we did not include the inherent disutilities of comorbid conditions, old age, and ill health. This omission somewhat overstates benefits, although the extent of this is limited by our 2-year time horizon. Fifth, our estimates for event rates by CHADS2 score were derived from meta-analysis at the study level; however, in our data set we applied these coefficients at the individual patient level. To the extent that components of the CHADS2 score are correlated within individuals, our study-level analysis may in fact underestimate the risk of events with increasing CHADS2 scores at the individual level.

In conclusion, we modeled the possible benefits of a program to improve anticoagulation control for patients with AF in a large, integrated health care system. We found that such a program would be cost-saving even if it had only a minimal impact on control and even if it were considerably more expensive to implement than most QI programs have historically been. Our results suggest that the VA and other integrated healthcare systems should strongly consider implementing such a program. It is unusual to have an opportunity to save money while improving patient outcomes; this study describes such an opportunity.

Sources of Funding

This study was supported by a United States Department of Veterans Affairs, Health Services Research and Development Service, Career Development Award CDA-08-017 to Dr Rose. The sponsor had no role in the design and conduct of the study; the collection, management, analysis, and interpretation of the data; or the preparation, review, and approval of the manuscript.

Sensitivity analyses for TTR gradients are for the segment joining poor to moderate TTR; the segment between moderate and good TTR is less important (because it is very shallow) and is therefore not considered here. Trends are not always monotonic across categories because in some cases, the variability inherent in the random number simulation exceeds the differences between categories.

Effects of Daily Adherence to Antihypertensive Medication on Blood Pressure Control

Adam J. Rose, MD, MSc;[1,2] Mark E. Glickman, PhD;[1,3] Meredith M. D'Amore, MPH;[2] Michelle B. Orner, MPH;[1] Dan Berlowitz, MD, MPH;[1,2,3] Nancy R. Kressin, PhD[1,2,4]

From the Center for Health Quality, Outcomes, and Economics Research, Bedford VA Medical Center, Bedford;[1] the Department of Medicine, Section of General Internal Medicine, Boston University School of Medicine, Boston;[2] the Department of Health Policy and Management, Boston University School of Public Health, Boston;[3] and the VA Boston Health Care System, Boston,[4] MA

Clinicians are often uncertain about how to manage elevated blood pressure (BP) when a patient reports that he/she has recently missed several doses of antihypertensive medications. While we know that better adherence can improve BP during several months, the magnitude of this relationship in the short term is poorly understood. The authors examined this issue using a group of patients who monitored adherence using a Medication Events Monitoring System (MEMS) cap and had BP measurements in the course of routine clinical practice. BP readings were compared following 7 days of excellent adherence (100%) or poor adherence (<60%), omitting BP values following intermediate adherence. Using several different methods, BP following 7 days of excellent adherence was between 12/7 mm Hg and 15/8 mm Hg lower than after 7 days of poor adherence. Clinicians can use this effect size to calibrate their impressions of what the BP might have been with improved adherence. *J Clin Hypertens (Greenwich).* 2011;13:416–421. ©2011 Wiley Periodicals, Inc.

Treatment adherence is an important determinant of blood pressure (BP) control.[1,2] In usual clinical practice, treatment adherence can vary over time. While many studies have categorized patients as "adherent" and "nonadherent,"[2–5] most patients have periods of better and worse adherence that do not fit into such dichotomized categories.[6–10] Clinicians are commonly informed by a patient that his or her adherence has been less than perfect during the past week because the patient ran out of medication, forgot, or was confused, or for other reasons. It is unclear how clinicians should interpret BP values obtained after the patient has reported a period of relatively poor adherence because there are few available estimates of the expected impact on BP. It would therefore be useful to estimate the impact of poor adherence on BP during a short period.

There are at least 3 kinds of previous studies that might shed some light on the impact of a brief period of poor adherence on BP, but each has shortcomings. Most medications, particularly at the time they are being considered for approval, are evaluated compared with placebo. This provides some information about the effect of a single medication under controlled circumstances. However, the applicability to clinical practice is limited because real-life regimens usually contain more than 1 drug, and real-life nonadherence is usually partial rather than complete.[6–10] There are a few studies in which patients are instructed to stop their antihypertensive medications abruptly in order to compare the rebound effects of different medication classes during 7 days.[11] While such a study can provide valuable physiologic data, it also simplifies regimens down to only 1 drug and does not mirror real-world patterns of nonadherence. Finally, there are large retrospective database studies in which adherence is usually characterized using pharmacy fill data[3–5] or patient self-report.[1,2,12] Such studies have often shown that so-called nonadherent patients have worse BP control than adherent patients. Shortcomings of such designs include the unspecified time relationship between adherence behavior and BP measurements, as well as the oversimplification inherent in dividing patients using a binary adherence measure (adherent vs nonadherent).[10,13]

Recently, we have had another tool for measuring adherence: the Medication Event Monitoring System [MEMS] caps (Aardex Group, Ltd, Sion, Switzerland). A MEMS cap records each bottle opening, allowing clinicians and researchers access to extremely detailed data regarding persistence with therapy and timeliness of dosing.[6–10,14–17] The availability of detailed adherence data from MEMS caps provides an opportunity to better characterize the effect on BP of a brief period of poor adherence in a real-world setting. We therefore examined data from a study on hypertension in which patients used MEMS caps to monitor adherence. We sought to characterize the precise relationship between a 7-day period of poor adherence to antihypertensive therapy and the resultant change in BP.

METHODS

Data

The data for our analyses were obtained from the pre-intervention period of a randomized trial that

Manuscript received: July 28, 2010; **Revised:** November 22, 2010; **Accepted:** November 23, 2010
DOI: 10.1111/j.1751-7176.2011.00427.x

examined the effects of a provider-patient communication skill-building intervention on adherence to antihypertensive medication therapy and BP control (clinicaltrials.gov identifier: NCT00201149). Patients were enrolled from 7 outpatient primary care clinics at Boston Medical Center, an inner-city safety-net hospital affiliated with the Boston University School of Medicine. The study was approved by the institutional review board of Boston University Medical Center.

Patients were recruited from August 2004 through June 2006 if they were of white or black race, aged at least 21 years, and had an outpatient diagnosis of hypertension on at least 3 separate occasions prior to enrollment. Based on initial screening, patients were ineligible for the study if they already used a medication dispenser (as this might invalidate adherence data collection), were cognitively impaired, were of an ethnicity/race other than white or black, were unable to speak English, were not prescribed antihypertensive medication, were already participating in another hypertension study, or refused to participate.

Among 869 patients enrolled in the study who received dispensers with MEMS caps to monitor adherence to antihypertensive medication, 689 returned them. Our current study focuses on medication-taking behavior during the 90 days after the first opening of the MEMS cap. Rather than giving a patient multiple MEMS caps for all agents in their hypertension regimen, we gave one MEMS cap to each patient to correspond with one of their antihypertensive medications, asking them to use the MEMS cap for the most frequently taken medication. We characterized the medication-taking behavior of each patient using only this one medication, the ''index medication.'' A similar strategy has been pursued in prior studies using MEMS caps to characterize adherence to a multidrug regimen, which have found that adherence to an index medication generally correlates with adherence to the entire regimen.[10,16,17]

We imposed additional restrictions to increase the homogeneity of the analytic sample. During the first 90 days after issuance of the MEMS cap, a patient needed at least 2 clinic visits with BP readings to be part of our final sample. Ensuring multiple BP readings per patient reduced the potential for confounding effects of adherence and characteristics specific to a patient. This reduced the sample to 249 patients. We then excluded 35 patients taking regimens of $\geq$2 doses per day, one patient whose index medication changed during the first 90 days, and 3 others whose dose frequency for the index medication changed from twice to once daily during the first 90 days. This resulted in 210 patients who were taking regimens of 1 dose per day for the first 90 days of the study. Furthermore, if a patient opened his/her MEMS cap more than twice per day during $\geq$10% of the monitored period, then the patient was excluded because of suspicion that the patient did not understand the MEMS cap and was not using it correctly. This resulted in a final study sample of 200 patients.

Independent Variable: Adherence to Therapy

We characterized adherence to antihypertensive therapy using MEMS caps. These devices use a microchip to record all bottle openings. Good adherence as measured by MEMS caps has been linked to improvements in numerous clinical outcomes,[7,8,14,15] including hypertension control.[16,17] In the current study, clinicians were not given feedback about their patients' adherence as measured by MEMS caps.

The MEMS cap data for this sample were cleaned in the following manner. For nonmonitored periods (eg, hospitalizations), the number of MEMS cap openings were treated as missing. A patient was considered adherent on days in which the MEMS cap was recorded to have been opened exactly once or twice and was considered nonadherent if the MEMS cap was not opened. On days where the MEMS cap was opened more than twice, the number of openings was considered missing data due to the extra uncertainty in the reason for the multiple openings.

Dependent Variable: Clinical BP Measurements

BP was taken for each patient at irregular intervals, as part of routine clinical care. BPs could be taken using manual or electronic devices by clinical staff including physicians, nurses, and medical assistants and were recorded in the electronic medical record. If multiple readings were taken on a single day, the values were averaged for our study. We separately examined systolic BP (SBP) and diastolic BP (DBP) as outcomes.

Control Variables

We recorded sex, self-reported race (white vs black), and age at study inception. Using both *International Classification of Diseases, Ninth Revision* codes and problem lists from the electronic medical record, we noted whether the patients had the following comorbid conditions, all of which could impact BP, the use of antihypertensive medications, or the perceived urgency of controlling hypertension: cerebrovascular disease, congestive heart failure, chronic kidney disease, coronary artery disease, diabetes mellitus, hyperlipidemia, obesity (body mass index $>$30 kg/m^2), and peripheral vascular disease.

Patient Adherence Example

An example of the relationship between MEMS cap openings and BP measurements can be seen for one of the patients in our study (Figure). The horizontal axis counts the number of days since the patient entered the study, and the vertical axis counts the number of MEMS cap openings on each day displayed as black dots. For this patient, 3 clinic visits occurred in which BP readings were taken, with the days represented by the vertical lines and the SBP and DBP indicated by diamonds on the lines. The 7 days preceding the BP

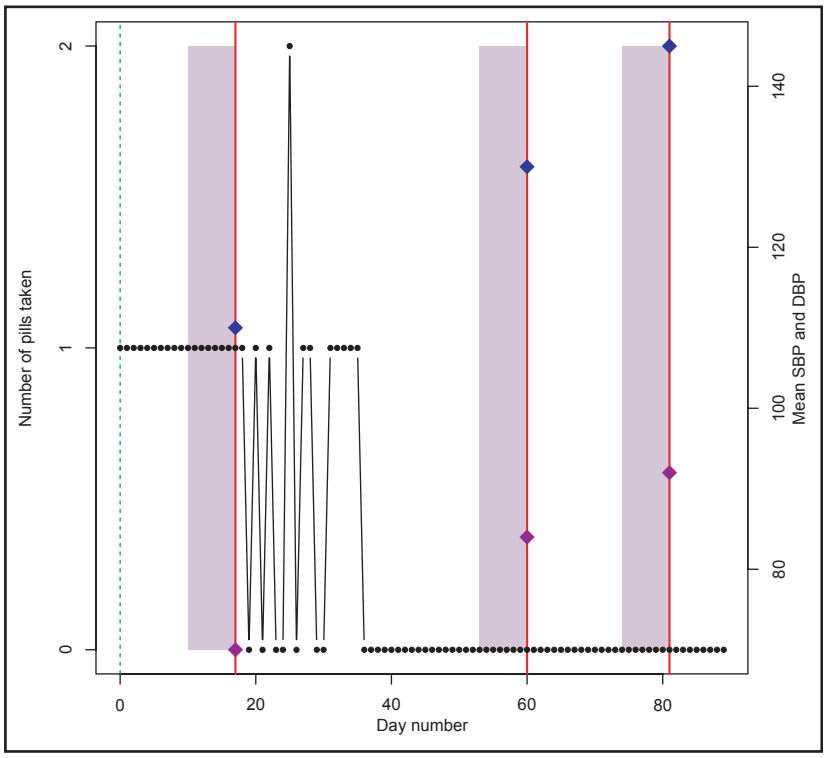

FIGURE. Example patient profile. The number of pills taken on each day of the study for a selected patient. The 3 vertical lines indicate clinic visit days on which blood pressure readings were taken, and the diamonds on each line denote the systolic blood pressure (SBP) and diastolic blood pressure (DBP) at the visit (labeled on the right). The shaded rectangular areas mark off 7 days prior to each clinic visit.

visits are shaded. In the 7-day period preceding the first visit, the patient had excellent adherence (1 pill per day), and the BP reading was 110/70 mm Hg. For the subsequent two visits, the adherence was at 0% for the 7-day period preceding the BP readings, and the corresponding BP measurements were 130/84 mm Hg on the first visit and 145/92 mm/Hg on the second visit. This example provides an informal basis for the statistical analyses we apply to these data.

Statistical Analysis

Two distinct approaches were taken to assess the effects of adherence on BP. The first approach treated each BP reading as a separate outcome and used adherence during the preceding 7 days to predict BP. For these analyses, we used the full analytic sample of 200 patients. The second approach restricted the sample to patients who had $\geq$2 BP readings, one of which was preceded by excellent adherence and one of which was preceded by poor adherence. With the first approach, we analyzed a larger sample and adjusted for between-patient differences through the control and health factors. In the second approach, every patient served as his/her own control and it was not necessary to control for patient-specific covariates. In both cases, recent adherence prior to a BP reading was determined based on the percentage of days in which the patient opened the MEMS cap. Days in which MEMS cap openings were missing were not counted in the adherence calculation. Adherence was considered poor if adherence was <60% and excellent if adherence was 100%. BP readings preceded by a 7-day period with intermediate adherence (between 60% and 100%) were removed from this analysis to provide a more precise estimate of the two ends of the scale, which resulted in a sample size decrease to 178. All models were separately fit to predict SBP and DBP.

In our first analytic approach, adherence was computed for the 7 days prior to each BP reading. BP readings were excluded if they occurred within the first 7 days of a patient's entry to the study. Random effects least-squares regressions were fit to the resulting data. BP (SBP and DBP) were regressed on an excellent/poor adherence indicator, along with sex, race, age (in years, categorized into 0–59, 60–69, 70–79, and 80+), and comorbid conditions, with a normally distributed mean-zero random effect per unique patient. In this way, we compared BPs following periods of excellent vs poor adherence while controlling for measured patient characteristics and patient identity as a random effect.

Our second approach focused exclusively on 14 patients who had at least one period each of poor and excellent adherence within the 90-day study window.

Other medication, %	12	8	14
Total number of medications, mean (SD)	2.3 (1.0)	2.4 (1.1)	2.8 (1.3)

Abbreviations: ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure; SD, standard deviation. [a]$P<.05$. Significant differences at the .05 level were found between the 178 patients in analysis 1 and the 691 (869–178) distinct patients in the full sample for sex, presence of diabetes, presence of coronary artery disease, and first DBP measurement. A significant difference at the .05 level was found between the 14 patients in analysis 2 and the 164 (distinct) patients in analysis 1 for only first DBP measurement.

TABLE II. Models for Effect of Excellent vs Poor Adherence Based on 178 Patients

	Systolic Blood Pressure	Diastolic Blood Pressure
Intercept	137.55 (3.70)	89.98 (2.13)
Excellent adherence	−11.60 (2.79)[a]	−7.67 (1.61)[a]
Men	2.36 (2.61)	1.85 (1.51)
White	−2.69 (2.39)	−1.99 (1.38)
Age <60 y	Reference	Reference
Age 60–69 y	2.96 (2.66)	−3.44 (1.53)[b]
Age 70–79 y	6.37 (3.32)	−4.98 (1.92)[b]
Age 80+ y	13.47 (6.76)[b]	−10.15 (3.91)[b]
Hyperlipidemia	1.42 (2.37)	−2.39 (1.37)
Diabetes	−2.69 (2.61)	−4.15 (1.51)[b]
Peripheral vascular disease	−6.67 (4.70)	−4.20 (2.72)
Renal insufficiency	0.24 (5.12)	1.20 (2.96)
Coronary artery disease	1.06 (3.26)	−2.01 (1.88)
Congestive heart failure	2.76 (5.19)	2.24 (3.00)
Cerebrovascular disease	13.77 (5.85)[b]	0.30 (3.38)
Obese	2.35 (2.47)	1.57 (1.43)

Values are expressed as coefficient estimates (standard errors). [a]$P<.001$. [b]$P<.05$.

The analyses consisted of random effects least-squares regressions in which SBP and DBP were regressed on binary indicators of excellent vs poor adherence 7 days prior to the reading, with normally distributed mean-zero patient-specific random effects. The random effects models were fit using the ''lme'' function in the statistics software package R (R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

As shown in Table I, the full cohort of 869 patients were 35% male, 43% white, and aged between 25 to 86 years with a mean age of 59.4 years (standard deviation=11.4 years). We recorded the first BP reading taken after enrollment. For 781 of the full cohort of 869 patients, this corresponded to BP taken on the day of enrollment. The average initial post-enrollment SBP and DBP were 133.6 mm Hg and 80.4 mm Hg, respectively, and 45% of the cohort had an initial BP >140/90 mm Hg. The most commonly used medication classes were angiotensin-converting enzyme inhibitors/angiotensin receptor blockers and diuretics. The average patient received 2.3 medications at baseline. For analysis 1, we studied only BP readings preceded by a 7-day period of poor (<60%) or excellent (100%) adherence, eliminating BP values preceded by a period of intermediate adherence. The sample for analysis 1 consisted of 178 patients. The characteristics of this sample were similar to the full cohort, except that the analysis 1 sample contained a significantly ($P<.05$) smaller fraction of men (29% compared with 35%), had a significantly higher proportion with diabetes (40% compared with 33%), and had a significantly higher proportion with coronary artery disease (19% compared with 13%). The average DBP was significantly lower for the analysis 1 sample compared with the full cohort (78.7 compared with 80.4).

Analysis 1 included a total of 357 BP readings for 178 unique patients. For 7-day periods with poor adherence, the average adherence rate was 34%, with a standard deviation of 22%. Table II summarizes the main results for analysis 1. Controlling for demographics and comorbid conditions, BP readings following periods of excellent adherence were lower than those following periods of poor adherence (SBP −11.6 mm Hg, DBP −7.7 mm Hg; $P<.001$ for both).

In analysis 2, 14 patients had at least 1 BP value preceded by a period of poor adherence (<60%) and at least 1 BP value preceded by a period of excellent adherence (100%). These 14 patients contributed a total of 36 observations. During the 90-day study

window, 8 of the patients had excellent adherence always followed by poor adherence, 5 had poor adherence always followed by excellent adherence, and 1 patient had both poor and excellent adherence following each other. For 7-day periods with poor adherence, the average adherence rate was 33%, with a standard deviation of 24%, nearly identical to the results based on the larger sample in analysis 1. The analysis 2 group appeared to have a higher burden of comorbidity than the analysis 1 group and higher initial BP values. However, except for a higher initial DBP in the analysis 2 group, these differences were not statistically significant. Accounting for patient random effects, mean BP following excellent adherence was 130.6/78.1 mm Hg, compared with 145.5/85.2 mm Hg following poor adherence, a difference of 14.9/7.1 mm Hg ($P<.05$ both for SBP and DBP).

In both analyses, we examined alternative window periods prior to BP readings (vs the base case definition of 7 days), and different definitions of excellent and poor adherence (vs the base case definitions of 100% and <60%). In general, the results were similar. Extending the window length excluded a larger number of patients in the excellent and poor adherence groups, and decreasing the window length resulted in somewhat less powerful effects of adherence on BP. Increasing the percent threshold for poor adherence (eg, to 80%) attenuated the effect of poor adherence on BP.

DISCUSSION

In this study, we estimated the effect size of adherence on BP control. By focusing on 7-day periods characterized by excellent (100%) or poor (<60%) adherence, we were able to show that the difference between these two is approximately 12/8 mm Hg or 15/7 mm Hg, in our first and second analyses, respectively. Our second analysis, although limited to only 14 patients, allowed each patient to serve as his or her own control. The effect size we found is robust to the method of analysis. It was similar whether we included a large number of patients and controlled for several potential confounding factors or whether we included only patients for whom both poor and excellent adherence periods were observed. These results, therefore, provide a methodologically robust estimate regarding the extent of the impact of poor adherence on BP control during a 7-day period.

Our findings have utility for clinicians who treat hypertension. Patients often arrive at a visit not having taken their medication for 1 or more days, and may communicate this fact to the clinician. We have previously shown that an impression that a patient is nonadherent is often associated with a decision not to intensify the antihypertensive regimen.[18] This relatively common occurrence (ie, admission of suboptimal adherence leading to a decision not to intensify) is likely a major contributor to clinical inertia, which, in turn, is a major barrier to improved BP control.[18–21] In another study, we have shown that, contrary to what many clinicians might expect, therapy intensification improves BP to a similar extent in patients with suboptimal adherence compared with those with optimal adherence.[22] We have therefore suggested that clinicians not dismiss the idea of intensifying therapy in a patient who is known or suspected to have suboptimal adherence.[22]

The present study adds to this line of reasoning by providing an estimate of the extent of BP elevation that can be expected after a 7-day period of poor adherence in a real-life setting. While our previous study suggested that intensification can be considered in patients with suboptimal adherence,[22] the current study suggests that intensification may be indicated when the SBP is elevated by >15 mm Hg or the DBP by >8 mm Hg. Blaming this extent of BP elevation on nonadherence may not make sense in light of the present study.

Previous efforts to estimate the effect size of nonadherence on BP have been limited by assessing both adherence and BP control in less-than-optimal ways (binary measures of control, binary measures of adherence, unclear timing between the two). In a seminal study, Morisky and colleagues[2] developed a 4-item scale to measure self-reported nonadherence and then demonstrated the criterion validity of that measure. In that study, 75% of patients deemed adherent by the scale had controlled BP at 5-year follow-up, compared with 47% of patients deemed nonadherent by the scale. In another well-known study, the authors used automated pharmacy fills data to assess adherence and again found that nonadherence during a 30-day period was a risk factor for uncontrolled BP.[3] In contrast, our study quantifies the effect size of adherence in terms of mm Hg rather than limited to a binary outcome of controlled/uncontrolled, and does so during a 7-day period. Previous studies have shown that it may not be sufficient to characterize patients as adherent or nonadherent, because patients may have periods of excellent adherence interspersed with "drug holidays," or periods during which the medication is intentionally omitted for several days.[10,23–25] Because long-term adherence is not a binary concept, it is important to understand the impact of short-term adherence on the outcome of interest rather than simply labeling some patients as nonadherent and then demonstrating that they have inferior BP control.

LIMITATIONS

While the results of our study are compelling, we do acknowledge some important limitations. First, and most importantly, we cannot establish causal effects of nonadherence from our observational data. While we controlled for important determinants of BP in our analyses, unobserved confounders could have played a role in our results. Second, we used a carefully selected subset of patients who recorded periods of excellent or poor adherence, and for the second analysis, patients

who recorded at least one of each. Not only did this sample selection necessarily limit our sample size, but it arguably could impact generalizability, although the group comparisons in Table I did not reveal large differences in the variables we measured. Still, by limiting our study to patients who had multiple BP measurements in 90 days, we may have selected for a sicker group of patients, specifically those who were more likely to have comorbidities such as diabetes and coronary heart disease. In addition, the second analysis was restricted to patients who had periods of both excellent and poor adherence, so that by design this particular sample had more erratic behavior than the general hypertensive population. However, because the estimated effect sizes from the two analyses were consistent, this concern may not be a serious one. Further, the consistent results between the two analyses greatly enhances validity because using each patient as his or her own control is arguably the gold standard for controlling for confounding due to patient-specific factors. A third limitation is that we tracked adherence using the index medication, ie, the medication whose bottle had a MEMS cap. However, most of these patients were taking other medications as well, which were not monitored by MEMS caps. This is a usual practice in adherence research,[10,17] and previous studies have shown that adherence to an index medication matches well with adherence to other medications in the regimen. Furthermore, there is no accepted method available for harmonizing the results of multiple simultaneous MEMS caps. Fourth, this study relied on actual BP measurements from clinical practice, rather than obtaining BP measurements through a standardized research protocol. While this feature of the study may enhance generalizability to real-world settings, it may also compromise the reliability of our BP data. Finally, our study enrolled patients from a single medical center, an inner-city safety-net hospital with a high proportion of minority and immigrant patients. This also may impact generalizability.

CONCLUSIONS

This study provides a fairly precise estimate of the effect of adherence on BP control in the short term: 7 days of poor adherence (<60%) increases BP by approximately 12 mm Hg to 15/7–8 mm Hg compared with 7 days of excellent adherence. Patients who admit to substantial nonadherence may nevertheless benefit from intensification of the antihypertensive regimen if their BP is elevated by more than this amount.

Prompt Repeat Testing After Out-of-Range INR Values
A Quality Indicator for Anticoagulation Care

Adam J. Rose, MD, MSc, FACP; Elaine M. Hylek, MD, MPH; Dan R. Berlowitz, MD, MPH; Arlene S. Ash, PhD; Joel I. Reisman, AB; Al Ozonoff, PhD

Background—Improved control of oral anticoagulation reduces adverse events. A program of quality measurement is needed for oral anticoagulation. The interval until the next test after an out-of-range International Normalized Ratio (INR) value (the "follow-up interval") could serve as a process of care measure.

Methods and Results—We studied 104 451 patients cared for by 100 anticoagulation clinics in the Veterans Health Administration (VA). For each site, we computed the average follow-up interval after low (≤1.5) or high (≥4.0) INR. Our outcome was each site's average anticoagulation control, measured by percent time in therapeutic range (TTR); 59 837 patients (57%) contributed to the low INR analysis, 37 697 (36%) contributed to the high INR analysis, and all patients contributed to the dependent variable (mean site TTR). After a low INR, site mean follow-up interval ranged from 10 to 24 days. Longer follow-up intervals were associated with worse site-level control (1.04% lower for each additional day, $P<0.001$). After a high INR, site mean follow-up interval ranged from 6 to 18 days, with longer follow-up intervals associated with worse site-level control (1.12% lower for each additional day, $P<0.001$). These relationships were somewhat attenuated but still highly statistically significant when the proportion of INR values in-range was used as the dependent variable rather than TTR.

Conclusions—Prompt repeat testing after out-of-range INR values is associated with better anticoagulation control at the site level and could be an important part of a quality improvement effort for oral anticoagulation. **(*Circ Cardiovasc Qual Outcomes*. 2011;4:276-282.)**

Key Words: anticoagulants ■ quality of health care ■ ambulatory care ■ medication therapy management ■ warfarin

Although anticoagulation therapy with warfarin is potentially life-saving, it is also potentially dangerous. Warfarin has an extremely narrow therapeutic window, and fluctuations in the degree of anticoagulation can be difficult to anticipate or prevent.[1] Meticulous control of anticoagulation, as measured by percent time in therapeutic range (TTR), has been shown to reduce the rate of adverse events in patients receiving anticoagulation, both at the level of the individual patient[2–5] and at the site of care level.[6,7] However, anticoagulation control is often suboptimal, leaving much room for improvement.[8,9] Before we can improve the quality of anticoagulation care, we must be able to measure it. Therefore, we are in need of a program of quality measurement and quality improvement in the management of oral anticoagulation. Our group has proposed an outcome measure (anticoagulation control, as measured by risk-adjusted TTR)[10] and has used it to profile 100 sites of care in the Veterans Health Administration (VA).[11]

TTR is an intermediate outcome measure that has been linked to definitive outcomes including stroke, venous thromboembolism, and major hemorrhage. Although outcome measures can be an excellent way to measure quality of care, they do not provide a prescription for action. Process measures are attractive in this regard because they do provide a prescription for action and because process can be measured at each clinical encounter.[12,13] One attractive process measure for oral anticoagulation would be promptness of repeat testing after an out-of-range International Normalized Ratio (INR) value. Although both high and low INR values have been linked to patient harm,[14–18] clinical guidelines do not give specific advice about the optimal follow-up interval after a high or low INR value.[1,19] This is probably because there have been no studies of this important issue.

We therefore used a database of 100 sites of care and over 100 000 unique patients in the VA to address 2 questions. First, do sites of care differ regarding the interval until the

next INR test after a low (≤1.5) or a high (≥4.0) INR value? Second, how do these differences relate to site-level performance, as defined by risk-adjusted TTR? By demonstrating both significant variations in practice and their relationship with intermediate outcomes of care, we sought to find support for promptness of follow-up after an out-of-range INR value as a process measure for oral anticoagulation care.

WHAT IS KNOWN

- Episodes of excessive or insufficient anticoagulation increase the risks of bleeding and thromboembolism, respectively.
- There have been no previous studies regarding the ideal follow-up interval after a high (≥4) or low (≤1.5) International Normalized Ratio (INR) value.
- In the absence of empirical evidence, clinical guidelines make no specific recommendations regarding follow-up after an out-of-range INR value.

WHAT THE STUDY ADDS

- In our study, the mean interval until the next INR test after a high or low INR varied widely among 100 sites of care in an integrated health care system (from 6 to 18 days after a high INR and from 10 to 24 days after a low INR).
- Sites with shorter mean follow-up intervals had better anticoagulation control. Risk-adjusted site mean percent time in range was approximately 1% lower for each additional day of the follow-up interval after either a high or low INR.
- Follow-up within 1 week after a high or low INR appears to be ideal, based on our results; this has the potential to serve both as a performance measure and as a putative standard of care.

Methods

Data

The database for this study has also been described elsewhere.[8,11] The Veterans AffaiRs Study to Improve Anticoagulation (VARIA) included all patients deemed to be receiving oral anticoagulation therapy (OAT) from the VA between October 1, 2006, to September 30, 2008, based on the criteria described below. The study was approved by the Institutional Review Board of the Bedford VA Medical Center.

Patients

We included all patients who received warfarin from the VA during the 2-year study period (ie, at least 30 days' worth dispensed by the pharmacy) and who had at least 2 valid intervals for calculating percent TTR.[20] For this purpose, a valid interval consists of 2 INR values separated by 56 days or less, without an intervening hospitalization, as in the original study by Rosendaal et al.[20]

We excluded patients whose primary indication to receive warfarin was valvular heart disease. Many such patients have a target INR range of 2.5 to 3.5 rather than the more standard 2 to 3, but it is not possible to determine with certainty which patients have the higher target range. Without specific knowledge of the target range, we cannot calculate TTR. We also excluded patients who only recorded INR values 1.2 and lower, reasoning that most such patients received INR tests for reasons unrelated to warfarin management (eg, frequent emergency department visits).

Laboratory Values and Calculation of Percent TTR

We included INR values within the VA system that were obtained while patients were "on warfarin," that is, when a patient was either (1) in possession of warfarin or (2) having INR tests at least every 42 days. This choice of a 42-day interval is based on previous work by Go et al[21] as well as the current American College of Cardiology/American Heart Association/European Society of Cardiology guidelines for the maximum allowable follow-up interval for patients anticoagulated for atrial fibrillation.[22] We defined the period of warfarin possession as the duration of the most recent VA prescription for warfarin, plus 30 days. We excluded INR tests measured while the patient was hospitalized within the VA system. Patients who are hospitalized may receive temporary parenteral anticoagulation (eg, with heparin) or no anticoagulation; therefore out-of-range INR values while hospitalized may be intentional and do not necessarily reflect poor quality of care. For this study, we also excluded patient INR data from the first 6 months of therapy with warfarin (the "inception period"). We have previously shown that TTR is lower during the inception period,[8,11,23] and decisions regarding the follow-up interval may also differ during this period.

We calculated TTR using the Rosendaal method,[20] which uses linear interpolation to assign an INR value to each day between successive observed INR values. Gaps of 56 days or more between INR values are not interpolated. After interpolation, the percentage of time during which the interpolated INR values lie between 2.0 and 3.0 (from 0% to 100%) is calculated.[20]

Sites of Care

We included 100 VA sites of care, each of which includes a hospital, an outpatient care center, and several outlying community-based clinics. Each site has a specialized anticoagulation clinic, which is usually run by clinical pharmacists under the supervision of a medical director.[24] Therefore, essentially all patients whose anticoagulation is managed in the VA are treated by specialized anticoagulation clinics. Most patients only visited one site of care, and their INR data were assigned to that site. If a patient visited more than 1 site (3% of patients), we partitioned their data by site.

Risk Adjustment Model

We have previously described the derivation and validation of our risk adjustment model for TTR.[8] We considered many potential variables that we thought were likely to affect TTR, including demographics, area-level poverty, driving distance to care, physical health conditions, mental health conditions, number of medications, and number of hospitalizations. Most variables were retained within the model, with the exception of several comorbid conditions that did not have appreciable effect sizes. The model was derived and validated according to customary procedures, which included considerations of maximizing predictive ability, clinical credibility, and ease of use and understanding.[8] This patient-level risk adjustment model for TTR has an R^2 of 13.3% when used with this dataset.[11] Table 1 contains all the variables that were retained in the final model.

Dependent Variables: Site-Level Anticoagulation Control

For our dependent variable, we used 2 separate measures of site-level anticoagulation control. Our main dependent variable was mean site risk-adjusted TTR. We calculated risk-adjusted TTR for each patient who received anticoagulation management at our 100 sites of care, whether or not they recorded any out-of-range INR values. This is because we wanted to measure the results achieved by each site for all of its patients, as a measure of overall quality of care. Site risk-adjusted TTR was calculated using the following procedure. First, for each patient, we calculated the observed TTR ("O") and applied the risk adjustment model to calculate the expected TTR

Table 1. Baseline Sample Characteristics for the Overall Sample and Subsets of the Sample

Variable	Overall Sample (n=104 451)*	Low INR Sample (n=59 837)*	High INR Sample (n=37 697)*
Female sex	1.9%	2.2%	2.3%
Median age (IQR)	72 (62–79)	72 (61–79)	72 (61–79)
Race/ethnicity

INR indicates International Normalized Ratio; IQR, interquartile range.

Baseline sample characteristics are for the overall sample, which was used to calculate site performance (ie, risk-adjusted percent time in range), and for subsets of the sample, which were used to characterize follow-up intervals after low or high INR values.

*All patients were included in the overall sample, which was used to measure site performance (percent time in range). The subset of patients with at least 1 low INR value (≤1.5) was included in the low INR sample, and the subset of patients with at least 1 high INR value (≥4.0) was included in the high INR sample. These groups are not mutually exclusive.

†Patients whose main indication for anticoagulation was valvular heart disease or prosthetic heart valve were excluded from this study.

("E"). Then, an observed minus expected (O-E) score was calculated for each patient. The mean O for each site constituted its unadjusted TTR, whereas the mean O-E score for each site constituted its risk-adjusted TTR. A full explanation of how we calculated risk-adjusted TTR, as well as a comparison between adjusted and unadjusted TTR, can be found in our earlier reports.[8,11]

One possible criticism of using TTR as the outcome for this study is that TTR will necessarily reward sites for following up sooner after an out-of-range value, even if the date on which the patient's control improved was in fact the same, and all that changed was the promptness of measurement. We therefore examined the extent to which our results depended on this mathematical truism. We substituted site-level proportion of INR values in range for risk-adjusted TTR as an alternate dependent variable and reran our main analyses. This allowed us to determine whether we still saw the same effect even without the measurement property related to the calculation of TTR.

Independent Variable: Site Mean Interval Until Next INR Test

We characterized each site regarding the mean interval until the next test after an out-of-range INR value (the "follow-up interval"). We divided out-of-range INR values into 2 categories: ≤1.5 ("low") and

≥4.0 ("high"). Both high and low INR values have clearly been linked to patient harm[1,14–18] and should be addressed promptly to bring the patient back within the therapeutic range. In addition, we examined follow-up intervals after INR values that are only slightly out of range: "slightly low" (1.6 to 1.9) and "slightly high" (3.1 to 3.9). The evidence regarding harm from such values is less robust, so we wanted to characterize the extent to which sites are responding more promptly to the more extreme values. In addition, we wanted to explore the effect of the management of slightly out-of-range INR values on site-level TTR.

We located all patients who had at least 1 high or low INR value (the "index value") followed by another INR within 56 days without intervening hospitalizations. For an out-of-range INR value, another INR is expected soon after; therefore, the following INR could be recorded as soon as the next day. If the patient was hospitalized between the index INR and the next value, we looked back to the next possible index value instead, because hospitalization also counts as prompt follow-up of the aberrant value. When a patient had multiple qualifying episodes of a high or low INR, we selected the last such episode, so that each patient was sampled no more than once for high and/or once for low. We also reran our analyses after selecting the first such episode or a random episode of high or low INR; the results did not change appreciably (data not shown). We averaged values from individual patients to calculate mean values for each site. We followed similar procedures to characterize each site regarding its response to slightly low (1.6 to 1.9) and slightly high (3.1 to 3.9) INR values.

Statistical Analyses

We examined the baseline characteristics of patients in our source population as well as the characteristics of patients who were included in the subsamples to analyze follow-up intervals after a high or low INR value. We characterized each site by a mean follow-up interval after a low INR (≤1.5), after a high INR (≥4.0), and after an INR value that was slightly low (1.6 to 1.9) or slightly high (3.1 to 3.9). We modeled the site-level relationships between follow-up intervals and risk-adjusted TTR using simple correlation, linear regression, and ANOVA with the Tukey honestly significant differences test (after grouping sites into quintiles by follow-up intervals). We repeated these analyses using our alternate dependent variable (proportion of INR values in range by site). All analyses were conducted using SAS, version 9.1 (SAS Corporation). Dr Rose had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Results

Patients

We studied 104 451 unique patients who received anticoagulation during the experienced period (ie, >6 months' experience with anticoagulation). Baseline characteristics for the source population are described in Table 1. The sample was mostly male (98%) and had a median age of 72 years. Most patients (64%) were anticoagulated for atrial fibrillation, with the remainder anticoagulated for venous thromboembolism (27%) or other indications (9%; eg, mural thrombus, cardiomyopathy, pulmonary hypertension, etc). The population had a substantial burden of comorbidity. For example, 40% had diabetes mellitus, 33% had heart failure, 14% had chronic kidney disease, and 7% were newly diagnosed with (nonskin) cancer during the study period. The burden of mental illness and substance abuse was also considerable: 22% had major depression, 9% had a diagnosis of alcohol abuse, and 5% had dementia.

In general, differences between the source population and the samples used to study high and low INR were slight. Some characteristics that we have previously linked to lower patient-level TTR (such as cancer, alcohol abuse, and substance abuse) were slightly more common among the high and low INR samples; these differences attained statistical significance due to the large study size (for example, $P<0.001$ for these 3 variables). Mean TTR for the source population was 61%, compared with 54% in the high and low INR groups, respectively ($P<0.001$ for both comparisons).

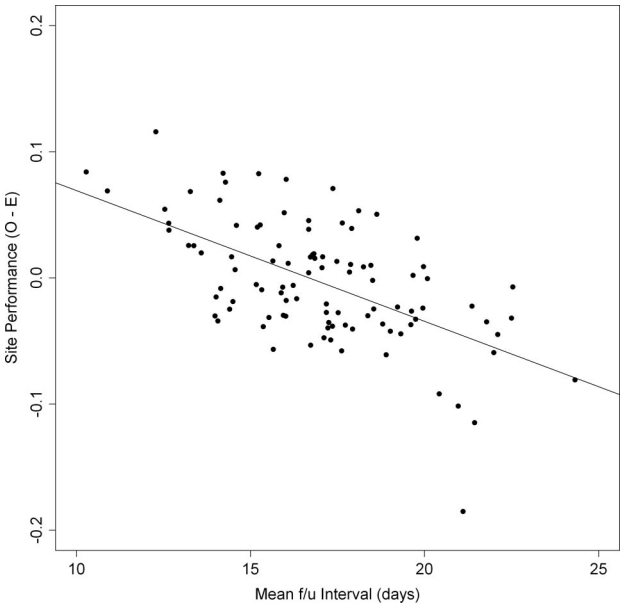

Figure 1. Correlation between mean site-level follow-up (f/u) interval after a low International Normalized Ratio value (≤1.5) and site-level performance, as measured by risk-adjusted percent time in range (n=100 sites). For the line of correlation, $r=-0.59$ ($P<0.001$), indicating that shorter follow-up intervals are associated with better site-level performance. O-E indicates observed minus expected score.

Relationship Between Follow-Up Intervals and Site-Level Anticoagulation Control

There were 100 sites of care in the database. Site mean TTR ranged from 41% to 72% and site risk-adjusted performance (site O-E score) ranged from 19% below to 12% above expected. Performance was above expected at 46 sites and below expected at 54 sites; the median site O-E score was 0.6% below expected. Sites differed widely regarding mean follow-up intervals. After a low INR (≤1.5), site mean follow-up intervals ranged from 10 to 24 days (Figure 1). After a high INR (≥4.0), site mean follow-up intervals ranged from 6 to 18 days (Figure 2). Site mean follow-up intervals after slightly low and slightly high INR ranged from 12 to 32 and from 13 to 31 days, respectively (data not shown). Generally, the sites that pursued prompter follow-up after low INR also pursued prompter follow-up after high INR. For example, the correlation between site-level mean follow-up interval after low and high INR values was 0.72.

With regard to follow-up after a low INR (≤1.5), shorter site-level intervals correlated with improved site-level performance as measured by risk-adjusted TTR (Figure 1; $r=-0.59$, $P<0.001$). This result was unchanged when unadjusted site-level TTR was used as the outcome ($r=-0.59$). With regard to follow-up after a high INR (≥4.0), shorter

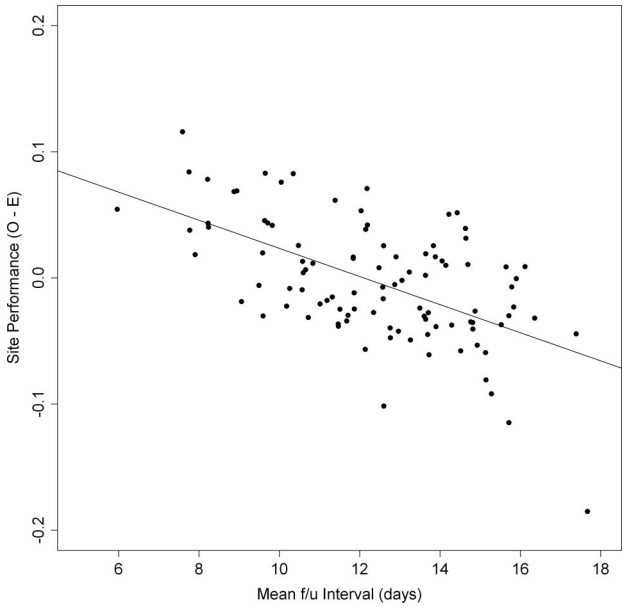

Figure 2. Correlation between mean site-level follow-up (f/u) interval after a high International Normalized Ratio value (≥4.0) and site-level performance, as measured by risk-adjusted percent time in range (n=100 sites). For the line of correlation, $r=-0.57$ ($P<0.001$), indicating that shorter follow-up intervals are associated with better site-level performance. O-E indicates observed minus expected score.

site-level intervals correlated with improved site-level performance as measured by risk-adjusted TTR (Figure 2; $r=-0.57$, $P<0.001$). This result was unchanged when unadjusted site-level TTR was used as the outcome ($r=-0.57$).

We further examined the strength of these relationships. For each additional day of mean site-level follow-up interval after a low INR, site-level risk-adjusted TTR was 1.04% lower (95% confidence interval, 0.75 to 1.32%; $P<0.001$). We found similar results when we used a cutoff of ≤1.3 to define a low INR value (data not shown). For each additional day of mean site-level follow-up interval after a high INR, site performance was 1.12% lower (95% confidence interval, 0.80 to 1.43%; $P<0.001$). We found similar results when we used a cutoff of ≥5.0 to define a high INR value (data not shown).

We repeated these analyses in subpopulations defined by indication for anticoagulation, namely patients anticoagulated for atrial fibrillation (64% of the sample) and patients anticoagulated for venous thromboembolism (27% of the sample). The main findings of the study did not change. For example, for each additional day after a low INR value, site-level risk-adjusted TTR was 1.00% lower among atrial fibrillation patients, 1.01% lower among venous thromboembolism patients, and 1.04% lower among all patients ($P<0.001$ for all 3 findings).

We also divided sites into quintiles (20 sites per group), based on the intervals after a low or high INR value. Site performance was generally best in the quintile with the shortest follow-up and worst in the quintile with the longest follow-up (Table 2), although differences among the middle 3 quintiles were small and not statistically significant.

Table 2. Quintiles of Site Follow-Up Intervals Compared With Site Performance as Measured by Risk-Adjusted Percent Time in Therapeutic Range

Quintiles of Follow-Up Interval After Index INR Value	Mean Follow-Up Interval (SD)	Mean O-E	*P* Value, ANOVA
After low INR (≤1.5)			$P<0.001$
Shortest follow-up (a)	13.4 (1.2)	3.24%	
Short (b)	15.6 (0.5)	0.77%	
Moderate (c)	16.9 (0.3)	−0.41%	
Long (d)	18.2 (0.5)	−0.76%	
Longest (e)	20.9 (1.3)	−4.49%	
After high INR (≥4.0)			$P<0.001$
Shortest follow-up (a)	8.8 (1.1)	4.20%	
Short (b)	11.1 (0.5)	−0.16%	
Moderate (c)	12.5 (0.4)	−0.62%	
Long (d)	14.0 (0.4)	−0.73%	
Longest (e)	15.6 (0.8)	−4.35%	

INR indicates International Normalized Ratio.

There are 20 sites in each quintile (total n=100 sites).

Site performance is measured by the observed minus expected (O-E) score. For each 1% increase in this score, the site performed 1% better than expected according to the risk-adjustment model.

Tukey honestly significant differences test revealed that the following groups were statistically indistinguishable at the corrected 0.05 level of significance: for low INR: a–b, b–d, and e; for high INR: a, b–d, and e.

We also examined the correlation between follow-up after mildly out-of-range INR values and site risk-adjusted TTR. These correlations were slightly less than for more pronounced deviations from the target range, but were still considerable (Table 3). For slightly low values (1.6 to 1.9), the correlation was −0.53 ($P<0.001$), compared with −0.59 for low values (≤1.5). For slightly high values (3.1 to 3.9), the correlation was −0.45 ($P<0.001$), compared with −0.57 for high values (≥4.0).

Sensitivity Analysis: Substituting Proportion of INR Values in Range for Percent Time in Range

As discussed in the methods, we substituted the proportion of INR values in range at each site for the site O-E score (ie, risk-adjusted TTR) as our dependent variable. As shown in

Table 3. Correlation Between Mean Site Follow-Up Intervals After Out-of-Range INR Values and 2 Measures of Site-Level Anticoagulation Control

	Risk-Adjusted Percent Time in Range		Proportion of INR Values in Range	
Index INR Value	*r*	*P*	*r*	*P*
≤1.5 (very low)	−0.587	<0.001	−0.415	<0.001
1.6–1.9 (somewhat low)	−0.529	<0.001	−0.286	0.004
3.1–3.9 (somewhat high)	−0.454	<0.001	−0.281	0.005
≥4.0 (very high)	−0.575	<0.001	−0.407	<0.001

INR indicates International Normalized Ratio.

Values are risk-adjusted percent time in range and proportion of INR values in range (n=100 sites).

Table 3, substitution of proportion of INR values in range lessened the magnitude of these correlations, but they were still present and statistically significant. Effect sizes decreased much more with regard to follow-up after mildly out-of-range INR values than severely out-of-range values. For example, the correlation for follow-up after low INR (≤1.5) decreased from −0.59 to −0.42 and the correlation for follow-up after slightly low INR (1.6 to 1.9) decreased from −0.53 to −0.29.

Discussion

Improving the quality of care in oral anticoagulation has the potential to save thousands of lives per year in the United States as well as preventing numerous nonfatal events that nevertheless lead to hospitalization or institutionalization.[2–7,10] To improve quality of care in oral anticoagulation, we need valid quality measures. In particular, process measures may be useful because they can provide a ready prescription for action and remediation.[10] In this study, we found that sites vary considerably with regard to promptness of repeat testing after an out-of-range INR value and that prompter repeat testing after out-of-range INR values (a process measure) is associated with improved site-level anticoagulation control (an intermediate outcome of care). This relationship was true both with and without risk adjustment for patient characteristics and both with and without linear interpolation between adjacent INR values.

Despite being part of an integrated health system, the 100 sites that we studied had a wide range of practice in this regard, possibly due to the relative lack of evidence and clear guideline recommendations. For example, after a high INR (≥4.0), site mean follow-up intervals ranged from 6 to 18 days. These variations had important consequences for anticoagulation control: Based on our regression models, a site with an average 6-day interval after a high INR would be expected to have a mean TTR 13% higher than a site with an average 18-day interval. This is a very large difference in anticoagulation control and one that has been linked to considerable differences in rates of adverse events.[2–7] It is likely that clinicians practicing at each site arrive at a consensus about the ideal follow-up interval in certain situations, whether by written policy or unwritten common practice. These site-level tendencies can presumably be changed, and our results suggest that prompter follow-up could improve TTR considerably for most of the sites in our study.

In addition to its implications for quality measurement, our study also has implications for clinical practice guidelines in anticoagulation care. Our results suggest that anticoagulation control could be improved considerably by following up within 7 days after a high (≥4.0) or low (≤1.5) INR value and within 14 days after a mildly high (3.1 to 3.9) or mildly low (1.6 to 1.9) INR value. If all VA patients had been treated in this manner during our study, our results suggest that the VA might have recorded an overall TTR between 5% to 10% higher, a difference that has been associated with meaningful improvements in the rates of outcomes such as stroke, venous thromboembolism, major hemorrhage, and mortality.[2–7]

This study has several strengths. We used a large and powerful database, rich in clinical detail. We used 2 measures of anticoagulation control, both a simple one (proportion of values in range) and one that is the result of much development by our group and represents the state of the art in quality measurement for oral anticoagulation (risk-adjusted TTR).[8,10,11] The consistency of our findings suggests that they are not attributable only to the measures used but represent a real and important finding that means exactly what one would think it means.

However, several limitations should be noted. First, we measured average follow-up intervals at the site level rather than at the level of the individual patient or the individual instance. Sites of care probably determine these follow-up intervals through written or unwritten policies, which can and should be changed to improve performance. However, follow-up for individual patients is dependent on many clinical considerations and is inherently variable. Therefore, we believe that it would be ill advised to attempt to measure quality of care for individual patients using these measures—although this issue could certainly be examined empirically. Second, we measured the actual interval that elapsed between INR values but did not measure the interval that the clinician requested. To some extent, nonadherence to recommendations on the part of the patient might have played a role in the correlation between longer follow-up intervals and poor control. However, our main outcome measure was risk-adjusted for the patient population at each site, which should have controlled for many of the patient-level factors that contribute to poor compliance and poor control. Third, this study only included patients with a target INR range of 2 to 3. Therefore, these results may not be generalizable to patients with other target ranges (most often 2.5 to 3.5). Finally, VA patients are mostly male and have a high burden of comorbidity. However, it is unclear how this fact would have altered the basic relationships that we showed between follow-up intervals and site-level anticoagulation control.

In summary, we found that there is a wide range of practice regarding the interval until a repeat test after out-of-range and mildly out-of-range INR values. Longer follow-up intervals were associated with worse anticoagulation control. We believe that we have truly identified a quality measure for oral anticoagulation care. Our study suggests that optimizing follow-up intervals after out-of-range INR values could greatly improve anticoagulation control and prevent thousands of fatal or morbid adverse events each year.

Risk-Adjusted Percent Time in Therapeutic Range as a Quality Indicator for Outpatient Oral Anticoagulation

Results of the Veterans Affairs Study To Improve Anticoagulation (VARIA)

Adam J. Rose, MD, MSc; Elaine M. Hylek, MD, MPH; Al Ozonoff, PhD; Arlene S. Ash, PhD; Joel I. Reisman, AB; Dan R. Berlowitz, MD, MPH

Background—Oral anticoagulation is safer and more effective when patients receive high-quality care. However, there have been no prior efforts to measure quality of oral anticoagulation care or to risk adjust it to ensure credible comparisons. Our objective was to profile site performance in the Veterans Health Administration (VA) using risk-adjusted percent time in therapeutic range (TTR).

Methods and Results—We included 124 551 patients who received outpatient oral anticoagulation from 100 VA sites of care for indications other than valvular heart disease from October 1, 2006, to September 30, 2008. We calculated TTR for each patient and mean TTR for each site of care. Expected TTR was calculated for each patient and each site based on the variables in the risk adjustment model, which included demographics, comorbid conditions, medications, and hospitalizations. Mean TTR for the entire sample was 58%. Site-observed TTR varied from 38% to 69% or from poor to excellent. Site-expected TTR varied from 54% to 62%. Site risk-adjusted performance ranged from 18% below expected to 12% above expected. Risk adjustment did not alter performance rankings for many sites, but for other sites, it made an important difference. For example, the site ranked 27th of 100 before risk adjustment was one of the best (risk-adjusted rank, 7). Risk-adjusted site rankings were consistent from year to year (correlation between years, 0.89).

Conclusions—Risk-adjusted TTR can be used to profile the quality of outpatient oral anticoagulation in a large, integrated health system. This measure can serve as the basis for quality measurement and quality improvement efforts. **(*Circ Cardiovasc Qual Outcomes*. 2011;4:22-29.)**

Key Words: anticoagulants ■ quality of health care ■ ambulatory care ■ risk adjustment ■ patients ■ safety

Oral anticoagulation is a highly effective but potentially dangerous therapy.[1,2] The level of anticoagulation control is a critical determinant of benefit from warfarin[3–7]; indeed, patients with atrial fibrillation may not benefit from anticoagulation unless they achieve a certain level of control.[3] However, warfarin management is difficult, and achieving good control requires much effort and skill on the part of both the patient and the clinician.[1] Because many patients do not achieve excellent control,[8] there is great potential to improve outcomes for patients by improving quality of care in oral anticoagulation.[9] To improve quality of care, we first must be able to measure it.[10,11] Previous efforts to measure quality of care in oral anticoagulation therapy have focused disproportionately on the failure to provide anticoagulation to as many ideal candidates as possible.[12] However, receipt of anticoagulation is only a first step toward improving outcomes; we also need to measure the quality of oral anticoagulation management to ensure that the benefits of anticoagulation are maximized and the harms minimized.[9]

An ideal quality indicator for outpatient oral anticoagulation would have several characteristics: it would be easy to abstract, calculate, and understand; it would vary among providers or sites of care; improvement would be possible; and there would be strong evidence linking it to important outcomes, such as stroke, venous thromboembolism, and major hemorrhage. Percent time in therapeutic range (TTR) has many of these characteristics. It can be calculated from automated data, it can be improved,[8] and it has been linked to important outcomes.[3–7] Although it might be possible to consider using definitive outcomes themselves as quality indicators, reliance on these rare events would preclude quality measurement at all but the largest sites of care.[9,13]

Circ Cardiovasc Qual Outcomes **is available at http://circoutcomes.ahajournals.org** **DOI: 10.1161/CIRCOUTCOMES.110.957738**

One reason why TTR has not been used previously as a quality indicator may be the absence of a risk adjustment model for TTR. Risk adjustment can enhance the credibility of performance comparisons between providers or sites by ensuring that sites are being compared regarding quality of care rather than regarding merely differences in case mix.[14] Risk adjustment can increase the acceptance of quality measures by poorly performing sites who might otherwise protest that their performance is poor because their patients are sicker. Our group recently has derived and validated a risk adjustment model for TTR that should allow for fair site-site comparisons on this quality indicator.[15] In deriving and validating our model, we confirmed the widely held belief that some patients are indeed much harder to keep within the target range than others, suggesting that risk adjusting TTR is necessary.

We therefore set out to address 3 related questions, using a database of 100 anticoagulation clinics and >100 000 patients from the Veterans Health Administration (VA). First, does mean TTR differ among sites of care? Unless meaningful differences exist, profiling is unlikely to spur quality improvement. Second, does risk adjusting TTR meaningfully alter site rankings? Risk adjustment may enhance credibility,[14] but it requires effort, so it is important to know whether it matters. Finally, would risk-adjusted site rankings be relatively constant from year to year, suggesting that risk-adjusted TTR is measuring quality of care (a stable attribute of a site) rather than measuring mere statistical variation? Our overarching objective was to examine the suitability of risk-adjusted TTR as a potential quality indicator.

WHAT IS KNOWN

- The safety and effectiveness of oral anticoagulation can be improved by better control, (ie, more time in therapeutic range [TTR]).
- Although oral anticoagulation is prescribed for millions of patients each year, there has been no organized approach to measuring or improving the quality of oral anticoagulation.

WHAT THE STUDY ADDS

- We used clinic-level risk-adjusted TTR to profile the performance of 100 anticoagulation clinics in an integrated system of care (the Veterans Health Administration).
- We propose the use of risk-adjusted TTR as a quality indicator to measure and track the quality of oral anticoagulation in the Veterans Health Administration and other integrated health systems.
- Quality measurement in oral anticoagulation is a necessary prerequisite to quality improvement, which holds the promise of preventing adverse events due to inadequate or excessive anticoagulation.

Methods

Patients

The database for this study also has been described elsewhere.[15] The VA is the largest integrated health system in the United States, and for many years, has collected comprehensive data regarding the care delivered to its patients, including inpatient care, outpatient care, and pharmacy records. The Veterans Affairs Study to Improve Anticoagulation included all patients deemed to be receiving oral anticoagulation therapy from the VA between October 1, 2006, and September 30, 2008, based on the criteria described later. The study was approved by the Institutional Review Board of the Bedford VA Medical Center.

A flowchart of study inclusion criteria is shown in Figure 1. We included all patients who received warfarin from the VA during the 2-year study period (ie, at least 30 days' worth dispensed by the pharmacy) and who had at least 2 valid intervals for calculating TTR.[16] For this purpose, a valid interval consists of 2 international normalized ratio (INR) values separated by ≤56 days without an intervening hospitalization.

There were 2 levels of exclusions: individual patients and entire sites of care. On the patient level, we excluded patients whose primary indication to receive warfarin was valvular heart disease. Many such patients have a target INR range of 2.5 to 3.5 rather than the more standard 2 to 3, but it is not possible to determine with certainty which patients have the higher target range. Without specific knowledge of the target range, we cannot calculate TTR. We also excluded patients whose only recorded INR values were ≤1.2, reasoning that most such patients received INR tests for reasons unrelated to warfarin management (eg, frequent emergency department visits).

Sites of Care

There are 128 sites of care within the VA, each of which includes a hospital, an outpatient care center, and several outlying community-based clinics. Each site has a specialized anticoagulation clinic, which usually is run by clinical pharmacists under the supervision of a medical director.[17] Therefore, essentially all patients whose anticoagulation is managed in the VA are managed by specialized anticoagulation clinics. Self-testing devices are not covered by the VA; therefore, few patients have or use them.

We excluded 28 sites from our study and several months of data from an additional 14 sites because our data-checking procedures revealed possible problems with data completeness at those sites. The problem with data completeness relates to the laboratory data only. Although accurate data are collected about which laboratory tests are drawn (because something akin to a billing code is generated), the data regarding laboratory results must be checked carefully. Specifically, the name given to each laboratory test by the local facility is not uniform throughout the system, and these names may change unexpectedly; after this happens, there may be a period of several months where the local laboratory results are not captured by the national database until the name change is noted. We identified which sites had this issue by dividing the data into 3-month periods; problematic sites had few or no INR results in certain periods, whereas the number of INR tests drawn remained constant over time. In contrast, there were 86 sites that had complete data for the entire 2-year study period and 14 sites that began to have complete data during the period (usually early in the study) and continued to have it through to the end. Thus, 28 sites were excluded because of incomplete data, and 14 sites were partially included. The 14 partially included sites performed similarly to the 86 sites with complete data, suggesting that they differed only in data collection rather than in performance (results not shown). Most patients only visited 1 site of care, and their INR data were assigned to that site. If a patient visited >1 site (3% of patients), we partitioned his or her data by site.

Laboratory Values and Calculation of TTR

We included INR values within the VA system when patients were on warfarin, that is, when a patient was either (1) in possession of warfarin or (2) having INR tests at least every 42 days. We defined the period of warfarin possession as the duration of the most recent VA prescription for warfarin plus 30 days. Because patients may be instructed to take half-doses of warfarin, we recognize that going >30 days beyond the end of a prescription does not necessarily

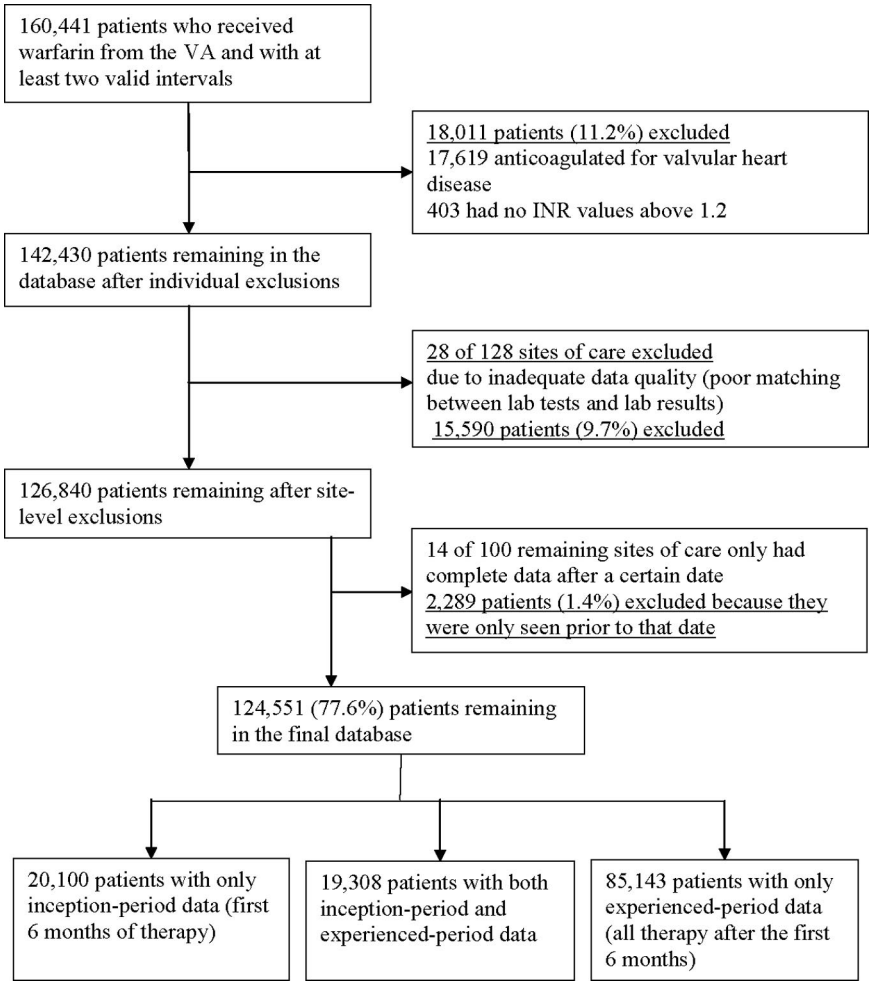

Figure 1. Flowchart of included and excluded patients.

indicate that warfarin therapy has stopped. Therefore, we also allowed a consistent pattern of INR measurements (ie, every 42 days or fewer) to indicate that a patient was still being managed. A similar approach was used to define time on warfarin in a previous study.[18]

We excluded INR tests measured while the patient was hospitalized within the VA system. Patients who are hospitalized may receive temporary parenteral anticoagulation (eg, with heparin) or no anticoagulation, so out-of-range INR values while hospitalized may be intentional and do not necessarily reflect poor quality of care.

We calculated TTR using the Rosendaal method,[16] which uses linear interpolation to assign an INR value to each day between successive observed INR values. Gaps of ≥56 days between INR values are not interpolated. After interpolation, the percentage of time during which the interpolated INR values lie between 2.0 and 3.0 (from 0% to 100%) is calculated.[16]

Risk Adjustment Model

We have previously described the derivation and validation of our risk adjustment model for TTR.[15] We considered many potential variables that we believed were likely to affect TTR, including demographics, area-level poverty, driving distance to care, physical health conditions, mental health conditions, number of medications, and number of hospitalizations. Most variables were retained within the model, with the exception of several comorbid conditions that did not have appreciable effect sizes. The model was derived and validated according to customary procedures, which included considerations of maximizing predictive ability, clinical credibility, and ease of use and understanding.[15] The Table contains all the variables that were retained in the final model.

Inception and Experienced Management of Warfarin

We calculated TTR and built separate risk adjustment models for 2 time periods—the first 6 months of therapy (inception period) and all care after 6 months (experienced period)—because these 2 periods are qualitatively different with regard to anticoagulation management. We defined each patient's date of warfarin inception, looking back as far as October 1, 2005. Inception was defined as the first INR value >1.2 or the first outpatient warfarin fill, whichever came first. It would be extremely unusual for a patient to record an INR value >1.2 unless he or she had taken warfarin. We then divided the sample into inception time (the first 6 months of warfarin therapy for each patient) and experienced time (any time thereafter). A single patient might contribute only to the inception data set (if he or she had <6 months of therapy), only to the experienced data set (if he or she began warfarin >6 months before the inception of our study), or both. Coefficients for the 2 models differed substantially,[15] confirming that the 2 periods should be risk adjusted separately.

Statistical Analyses

First, we calculated TTR for each patient during the inception and experienced periods. We then calculated a mean observed TTR (O) for each site and period. We applied our risk adjustment models to calculate the expected (E) TTR first for each patient and then for each site on the basis of the patient population at that site. We then calculated an observed minus expected (O-E) score for each site for the 2-year study period. Each site had 2 O-E scores: 1 for inception management and 1 for experienced management. Site O-E scores for the 2 time periods were highly correlated, so we combined them into

Table. Baseline Sample Characteristics for the Overall Sample, the Inception Cohort (ie, First 6 Months of Anticoagulation Therapy), and the Experienced Cohort (All Management Thereafter)

Variable	Overall Sample (n=124 551)	Inception Cohort (n=39 408)	Experienced Cohort (n=104 451)
Female sex	2589 (2.1)	1046 (2.7)	1983 (1.9)

*Patients whose main indication for anticoagulation was valvular heart disease or prosthetic heart valve were excluded from this study.

a single O-E score for each site, weighting by the number of patients in each period.

A site was considered a high or low outlier performer if its combined O-E score deviated from 0 by ≥5% and if the O-E score differed from 0 at the 0.01 level of significance (using *Z* scores). We used the 0.01 level of significance as opposed to the traditional 0.05 to address issues of multiple testing. A 5% absolute difference in TTR has been cited by other studies as constituting a meaningful difference in performance and is probably the agreed-on standard for a clinically important difference.[19]

We also investigated whether empirical Bayesian methods would change determinations of outlier status.[20] This technique has been shown to alter results regarding outlier status, particularly when sample sizes are small.[21] Typically, empirical Bayesian estimation shrinks estimates for the observed site mean TTR toward the overall mean, and fewer sites are outliers when analyzed by such methods. However, we observed almost no shrinkage presumably because of the large sample sizes even at the smaller sites of care. Therefore, we concluded that Bayesian methods were not necessary for this situation and relied on *Z* scores to determine outliers.

We compared site rankings before and after risk adjustment to determine its effect. We calculated the proportion of the variance in TTR that was explained by patient characteristics, site-level variability, and both together. We also divided the study period in half (ie, fiscal year 2007 [FY07] versus FY08) to evaluate the stability of site O-E scores and rankings between the 2 years. Analyses were conducted using SAS version 9.1 and R version 2.8 statistical software. Dr Rose had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Results

Patient Population

We studied 124 551 unique patients who received anticoagulation from 100 sites of care (Figure 1). Baseline characteristics for the sample are described in the Table. The sample was mostly men (98%) with an average age of 72 years. Most (62%) patients were anticoagulated for atrial fibrillation, with the remainder anticoagulated for venous thromboembolism (29%) or other indications (9%) (eg, mural thrombus, cardiomyopathy, pulmonary hypertension). The population had a substantial burden of comorbidity, for example, 39% had diabetes, 31% had heart failure, 14% had chronic kidney disease, and 7% had received a new diagnosis of (nonskin) cancer during the study period. The burden of mental illness and substance abuse also was considerable: 22% had major depression, 10% had received a diagnosis of alcohol abuse, and 5% had dementia. As would be expected with a population of sicker patients, they received many medications (median of 8), and 28% were hospitalized at least once during the 2-year study period.

Site Performance

The median number of patients per site was 1584 (range, 103 to 5103; interquartile range, 1043 to 2345). Mean site-expected TTR during inception was based on patient population at each site and varied from 44% to 50%. Mean site-expected TTR during the experienced period varied from 58% to 65%. We examined case mix at the 5 sites with the lowest predicted TTR (difficult case mix) and the 5 sites with the highest predicted TTR (easy case mix). The difficult sites treated more minority patients and more patients living in high-poverty zip codes. Patients at the difficult sites had higher rates of almost every comorbid condition that is associated with lower TTR in our database,[15] often several-fold higher. Finally, patients at the difficult sites received more medications and were more likely to be hospitalized. In short, there was no single factor that explained these differences in case mix; all the variables appeared to play a role. These between-site differences in case mix will be addressed more fully in a separate article.

During the inception period, the mean observed TTR was 48%; site mean observed TTR varied from 30% to 59% during inception. Site O-E scores for inception, which measured the difference between observed and expected TTR, ranged from −17% to +13%. Of the 100 sites of care, during the inception period, there were 12 high outliers, indicating performance at least 5% better than expected and O-E different from 0 at the 0.01 level of significance. There were 12 low outliers, indicating performance at least 5% worse than expected and O-E different from 0 at the 0.01 level of significance. During the experienced period, the mean observed TTR was 61%; site mean observed TTR varied from 41% to 72%. Site O-E scores for the experienced period ranged from −19% to +12%. Of the 100 sites of care, during the experienced period, there were 14 high outliers and 10 low outliers.

The correlation between site O-E scores for the inception and experienced periods was high (r=0.89; P<0.001) (Figure 2), suggesting that they measure a similar construct and may be combined. Mean combined TTR for the entire sample was 58%, and sites varied from 38% to 69%. Site-expected TTR ranged from 54% to 62%, and O-E scores ranged from −18% to +12%. Of the 100 sites of care, there were 13 high outliers and 10 low outliers. The 100 sites of care in our study are shown in Figure 3; a tabular form of these results appears in the online-only data supplement. The overall performance of our risk adjustment model was as follows: Patient-level characteristics alone explained 13.3% of the variability in TTR, site-level variability alone explained 2.9%, and both together explained 15.9%.

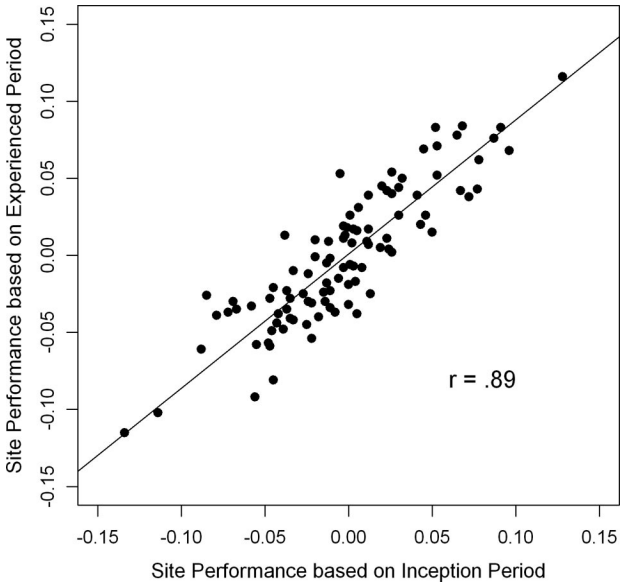

Figure 2. Comparison of site performance between the inception period (first 6 months of therapy) and the experienced period (all therapy thereafter). Performance is measured by the O-E score, which compares the TTR achieved by each site to the TTR that would be expected based on its patient population. Possible O-E scores range from −1 to +1, with positive scores indicating better-than-expected performance. Performance in the 2 periods was highly correlated (r=0.89; P<0.001).

Risk adjustment changed site rankings only slightly; there was a high degree of correlation between site rankings before and after risk adjustment (r=0.93; P<0.001). However, risk adjustment made an important difference for several sites of care. For example, site FC was ranked 27th of 100 before risk adjustment (observed TTR, 60.6%, or 2.7% above average). However, site FC had a challenging patient population (expected TTR, 53.5%, or 4.4% below average). Therefore, after risk adjustment, site FC was revealed to be one of the best performers (O-E, +7.0%; adjusted rank, 7th) as well as a high outlier. In contrast, site GI was ranked 95th before risk adjustment (observed TTR, 50.2%, or 7.7% below average) and would have been a low outlier using a definition based on unadjusted results. However, this site also had a challenging patient population (expected TTR, 53.9%, or 4% below average); although the risk-adjusted performance was poor (O-E, −3.7%; adjusted rank, 80th), it did not meet our definition for an outlier site. Not all sites were helped by risk adjustment, of course; for some sites, it invited a harsher view of their performance in light of their relatively easy case mix.

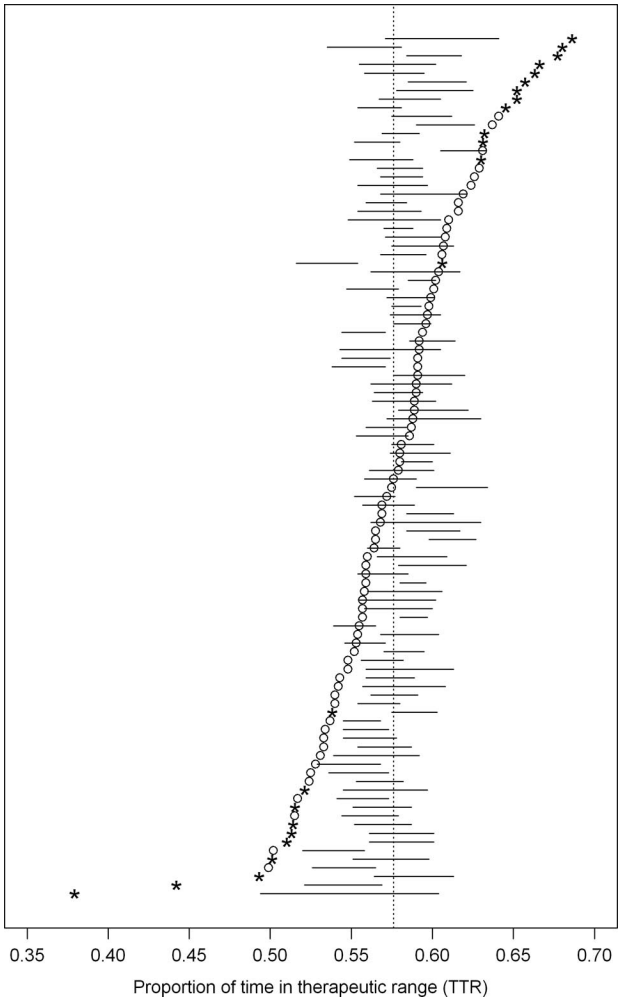

Figure 3. Overall site performance as measured by observed mean site TTR minus expected mean site TTR. The vertical line indicates the overall mean TTR (≈58% time in range). Each horizontal bar indicates the 99% CI around a site's expected mean TTR, whereas each ○ indicates the observed mean site TTR. For outlier sites (observed TTR differs from expected by ≥5%), the ○ is replaced by an *.

For example, site JC was ranked 79th before risk adjustment (observed TTR, 53.8%, or 4.1% below average), but because of its relatively easy case mix (expected TTR, 58.9%), the site was an outlier (O-E, −5.0%; adjusted rank, 92nd).

Stability of Rankings Between Years

We also divided our study period in half and compared the 2 years to each other. Most (62%) patients had INR values in both years, but 18% were only followed in FY07 and 20% only in FY08. We examined the stability of site performance between the 2 years. There was a high correlation between site performance in FY07 and FY08 both by O-E score and by risk-adjusted site rankings (r=0.89 and 0.88, respectively; P<0.001 for both) (Figure 4). Additionally, outliers were relatively consistent between years. For example, of the 9 high outliers in FY07 (year 1 of the study), 8 sites were also high outliers in FY08, whereas of the 8 sites that were low outliers in FY07, 6 were also low outliers in FY08.

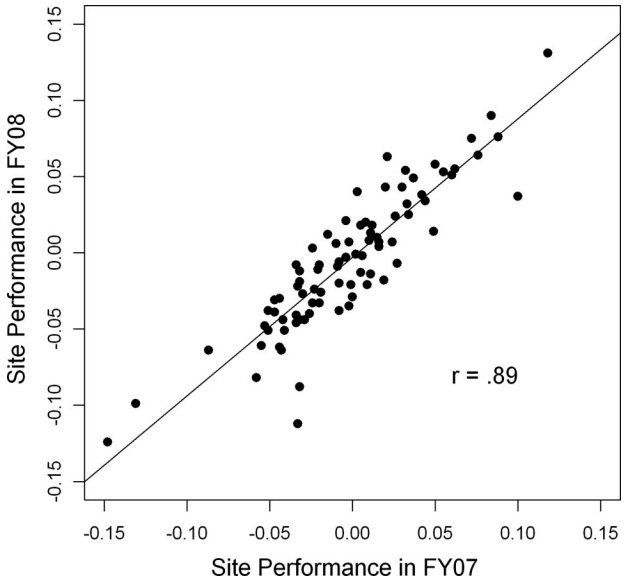

Figure 4. Comparison of site performance between FY07 and FY08. Performance is measured by the O-E score, which compares the TTR achieved by each site to the TTR that would be expected based on its patient population. Possible O-E scores range from −1 to +1, with positive scores indicating better-than-expected performance. Performance in the 2 years was highly correlated (r=0.89; P<0.001).

Discussion

In this study, we demonstrate that risk-adjusted TTR can be used as a quality indicator for oral anticoagulation care. Within the VA system, risk-adjusted TTR varies widely, with some sites performing as much as 18% below or 12% above expected. Risk-adjusted TTR is feasible to measure and is relatively consistent from year to year, suggesting that it is measuring an aspect of quality of care that is stable over time. This measure could be used by the VA or other integrated systems of care to profile annual performance and serve as an aid and impetus for quality improvement.

Risk adjustment is important for enhancing the credibility of site profiling; without risk adjustment, sites could claim that their poor performance was solely because of their case mix.[14] However, we found that the range of case mix was much smaller than the range of observed performance and that sites with very difficult or very easy patient populations were found equally among the best- and worst-performing sites (Figure 3), suggesting that although case mix varies among VA sites, the quality of oral anticoagulation care delivered to those patients varies even more widely.

We observed wide variations in performance within the VA system, from very-low TTR (38%) to very high (69%). However, after risk adjustment, site-site differences only accounted for 2.9% of the variability in TTR. Although this finding may sound like a small proportion of variability to explain, it is actually quite similar to the findings of previous studies. For example, using a population of patients with diabetes, Hofer et al[13] found that after risk adjustment, ≤4% (and as little as 1%) of the variability in hospitalization rates, visit rates, laboratory utilization rates, and glycemic control was attributable to differences between physicians. In discussing this result, these authors suggested that standardizing

processes of care among providers may not suffice to produce the quality improvement we seek; it may also be necessary to improve process of care on a system level. We therefore plan to use the present study as a basis on which to build a comprehensive program of quality measurement and quality improvement in anticoagulation care.[9] Our goal would be to improve the mean TTR in the VA to at least 70% (from the current 58%). Achieving this goal will require a focus on system-level approaches to improve processes of care. For example, our group[22] has shown that more judicious decisions regarding when to change the dose of warfarin can improve TTR considerably. Addressing this and other processes of care in a systematic way could greatly improve TTR in the VA; however, continually measuring risk-adjusted TTR will be a precondition to any program of quality improvement.[9]

Future studies also could expand this work outside the VA setting. A system of quality measurement, such as the one described in this article, would be relatively easy to implement in any integrated health system with a well-developed electronic medical record. However, the majority of patients are cared for in smaller community practices, not integrated health systems. The benefits of quality measurement could be extended to even more patients by incorporating risk-adjusted TTR into existing, commercially available anticoagulation management software, allowing sites to not only track their performance, but also potentially compare it to other sites after adjustment for case mix.

This study has important strengths, including the fact that we profiled performance among 100 sites of care within the nation's largest integrated healthcare system. In addition, the careful construction of the risk adjustment model and the considerable detail contained within its predictor variables improve our confidence that we have adjusted for case mix and that the residual variability in site performance is attributable to the quality of care.

As with any study, we acknowledge limitations. Our risk adjustment model did not include some factors that contribute to variability in TTR, especially diet and adherence to therapy. However, it could also be argued that dietary variation and medication nonadherence potentially are remediable, so adjusting for these factors could erase an important opportunity for sites to improve TTR. Second, our analyses combined patients with different indications for therapy, especially atrial fibrillation and venous thromboembolism. Although our risk adjustment model included a variable for indication, we were concerned that these groups might be too different to be combined in 1 model. To address this concern, we ran our analyses separately for patients with each indication; site performance by O-E scores did not change appreciably. Third, because of uncertainty regarding the target INR range, our study did not include patients anticoagulated for valvular heart disease, including prosthetic heart valves. However, we have every reason to expect that sites that provide superior care for patients with other indications for therapy also would provide superior care for patients with valvular heart disease. Fourth, because of strict requirements for completeness of data, we were unable to profile performance at some sites of care. Fifth, it is likely that some of the patients in our inception cohort had previously received warfarin outside the VA. If these patients were excluded from the inception cohort, we might have observed lower inception TTR; however, this is unlikely to affect site-site comparisons. Finally, although we examined TTR as a quality indicator, other summary measures of INR control might be used. For example, proportion of INR values in range could allow for more-frequent feedback about performance than TTR, which can only be calculated over a several-month period. Monthly proportion of values in range could therefore be used to provide real-time performance feedback, enhancing quality improvement efforts. In the future, we plan to compare TTR with other measures.

In summary, this article establishes that risk-adjusted TTR can be used to profile anticoagulation care in a large integrated healthcare system. Patients deserve to receive the very best care, particularly when the stakes are as high as they are with warfarin, but our report demonstrates that some patients are receiving much better care than others. It is time to shine the light of performance measurement on oral anticoagulation care.

O = Observed TTR; E = Expected TTR; O-E = Observed Minus Expected TTR

An outlier is a site whose observed TTR differs from its expected TTR by at least 5% and for which the difference is significant at the 0.01 level.

Relevance of Current Guidelines for Organizing an Anticoagulation Clinic

Adam J. Rose, MD, MSc; Elaine M. Hylek, MD, MPH; Al Ozonoff, PhD; Arlene S. Ash, PhD; Joel I. Reisman, AB; Patricia P. Callahan, RPh; Margaret M. Gordon, PharmD; and Dan R. Berlowitz, MD, MPH

Objective: To describe variations in the structure of anticoagulation clinic (ACC) care within the Veterans Health Administration (VA) and to identify structures of care that are associated with better site-level anticoagulation control.

Study Design: Questionnaire correlated with automated clinical data.

Methods: We characterized 90 VA ACCs using a questionnaire administered by the VA Central Office. Site descriptors included staffing levels, provider training, visit modalities, quality improvement programs, documentation, and care coordination. Patient outcomes were measured by site mean risk-adjusted percentage time in therapeutic range, a measure of anticoagulation control over time. Our study was powered to detect a 3% difference in risk-adjusted percentage time in therapeutic range, a small-to-moderate effect size, between sites with and without a certain characteristic.

Results: We observed considerable variation in the structure of ACC care. For example, 48 sites had fewer than 400 patients per provider, 25 sites had 400 to 599 patients per provider, and 17 sites had 600 patients or more per provider. However, none of the site characteristics measured were significantly related to anticoagulation control.

Conclusions: We found substantial variation in guideline-targeted organizational and management features of ACC care within the VA. However, no single feature was associated with better anticoagulation control. Current guidelines for organizing an ACC may have limited relevance for improving patient outcomes.

(Am J Manag Care. 2011;17(4):284-289)

For author information and disclosures, see end of text.

Millions of patients receive oral anticoagulation therapy to treat or prevent thromboembolic disease.[1] While effective management of warfarin sodium therapy is not easy, better anticoagulation control can improve outcomes and reduce adverse events.[2] Indeed, a growing body of literature has shown that patients whose care is managed in dedicated anticoagulation clinics (ACCs) have better outcomes than those managed in usual care.[3-6] Clinical guidelines[1,7] recommend that all ACCs should have certain features, including quality improvement programs, adequate documentation of care, sufficient training for providers, and a ratio of patients to providers of less than 400:1. However, there is little evidence as to which, if any, of these features contribute to the improved outcomes seen with ACC care.

Although oral anticoagulation therapy has been used for more than 5 decades, quality measurement has had little penetration into this field.[2] Our group recently undertook the first systematic effort to profile risk-adjusted anticoagulation control in an integrated health system. Within the Veterans Health Administration (VA), a system in which essentially all anticoagulation therapy is managed in an ACC, the mean percentage time in therapeutic range (TTR) varied widely among sites,[8] with some sites performing more than 10% better or worse than would be expected based on the risk-adjustment model. Variations of this magnitude are associated with important differences in rates of stroke, venous thromboembolism, and major hemorrhage.[9-13] To help all sites in the VA improve their performance, it is necessary to understand the site-level correlates of better or worse anticoagulation control.

Therefore, this study had the following 2 objectives: first, to describe differences in the organization and management of ACCs within the VA, and second, to assess whether these differences help explain site-level differences in anticoagulation control. We measured site characteristics using a survey of VA ACCs that examined structural features that seem likely to affect anticoagulation control, including staffing ratios, provider training protocols, and the existence of quality improvement programs.[1,7] We hypothesized that these variables would be associated with anticoagulation control. In this study, either a positive finding or a negative finding would be useful because it can help determine whether

enforcing conformity to any specific feature is likely to improve anticoagulation care and control in the VA.

Take-Away Points

Dedicated anticoagulation clinics (ACCs) improve anticoagulation control and patient outcomes.

- Clinical guidelines recommend that ACCs should have certain features, but these recommendations are based on expert opinion rather than on empirical evidence of benefit.
- In our study, 90 ACCs in an integrated system of care differed widely in their organization and management; however, none of these differences were consistently related to ACC performance as measured by anticoagulation control, an important intermediate outcome of anticoagulation care.
- Current guidelines for organizing and managing an ACC may have limited relevance for improving outcomes.

METHODS

Data

The data for this study have been described elsewhere. The Veterans Affairs Study to Improve Anticoagulation[8,14] included all patients who received oral anticoagulation therapy from the VA between October 1, 2006, and September 30, 2008. The study was approved by the institutional review board of the Bedford VA Medical Center, Bedford, Massachusetts.

We included international normalized ratio (INR) values when patients were "on warfarin" (ie, when a patient was in possession of warfarin or was having INR tests performed at least every 42 days). We defined the period of warfarin possession as the duration of the most recent VA prescription for warfarin, plus 30 days. We calculated percentage TTR using the method by Rosendaal et al,[15] which assigns an INR value to each day by linear interpolation between successively observed INR values. Gaps of 56 days or more between INR values are not interpolated. The patient's TTR equals the percentage of days for which the interpolated INR values lie between 2.0 and 3.0 (from 0%-100%).

Independent Variables of Site-Level Characteristics

There are 128 sites of care within the VA, each of which includes a hospital, an outpatient care center, and several outlying community-based clinics. Each site has a specialized ACC, which is usually run by clinical pharmacists under the supervision of a medical director.[16] Therefore, essentially all anticoagulation care within the VA is delivered within specialized ACCs. In October 2006, VA Pharmacy Benefits Management surveyed all 128 VA sites of care for the organization and management of their ACCs. Topics included visit modalities (face to face, telephone, and mail), quality improvement programs, clinic staffing, provider training, documentation, and care coordination (the verbatim text of the questionnaire is given in the eAppendix [available at **www.ajmc.com**]). We abstracted our independent variables from the responses to the questionnaire.

Dependent Variable of Risk-Adjusted Anticoagulation Control

Site mean TTR was adjusted for case mix using a model that incorporates patient demographics, comorbid conditions that have an adverse effect on TTR, and general measures of comorbidity, including the number of medications and the number of hospitalizations. The derivation and validation of this model, which achieved an R^2 of 13.3%, has been described previously.[8,14] The model was used to calculate the expected mean TTR for each site ("E") based on patient characteristics. The expected mean TTR was compared with the observed mean TTR for each site ("O"). Therefore, each site's performance was characterized by an O minus E ("O − E") score, our measure of risk-adjusted TTR (RA-TTR).

Statistical Analysis and Power

We began by first calculating the mean observed TTR and the mean expected TTR for each site of care and then computing an O − E score for each site. We compared O − E scores between sites with and without various organizational characteristics using unpaired *t* test and compared O − E scores for multilevel variables using analysis of variance. We did not adjust for multiple comparisons. With regard to statistical power, for a characteristic present at half of the sites, *t* test would have 80% power to detect a 3% difference in the O − E score (a small-to-moderate effect size). Analyses were performed using commercially available statistical software (SAS version 9.1; SAS Institute, Cary, North Carolina).

RESULTS

Study Sample

Of 128 sites in the VA, 28 were excluded because their data were insufficiently complete to fully assess TTR. Of the remaining 100 sites, 5 did not respond to the questionnaire. Five other sites included more than 1 ACC, and the responses we received indicated that practices at the multiple ACCs of these 5 sites were not uniform. However, the dependent variable (RA-TTR) was assessed at the level of the overall site. Because we were unable to match our data for structure and outcomes, we excluded these 5 sites as well. This left 90 sites with complete data on structure and outcomes of care. The mean (SD) number of patients managed at each site was 1244 (799). The site mean TTR ranged from 38% to 69% (median,

58%). Site O − E scores ranged from −17% (ie, 17% below the expected value) to 12%.

Structure of Care and Relationship With Performance

We observed considerable variation in structure of care (Table 1). About half of the sites (n = 50) conducted most of their visits face to face; at other sites, most care was provided by telephone or mail. Most sites (n = 59) had some sort of quality improvement program, although only 7 sites used formal plan-do-check-act cycles. Most sites (n = 77) had some sort of support; 43 sites had clerical support. About half of the sites (n = 41) had a formal protocol for training new clinic providers. Many sites (n = 48) adhered to the recommended staffing ratio of less than 400 patients per provider (Table 2), although 17 sites had 600 or more patients per provider. Sites differed markedly for the perceived likelihood of being informed about a new drug-drug interaction.

Despite these differences in structure of care, we found no statistically significant predictors of site-level performance. A finding of marginal statistical significance was that 8 sites that did not allow telephone follow-up visits had almost 3% worse TTR (P = .10). There was also a hint, although not statistically significant, that sites with fewer than 500 patients under management might have worse control (performance difference, −1.6%).

Sensitivity Analyses

We performed sensitivity analyses by altering the format of the dependent variable. To ensure that our risk-adjustment model was not obscuring relationships between structure and outcomes, we also examined the same independent variables

as predictors of the mean unadjusted TTR by site, with similar results (data not shown). We also tried categorizing site O − E scores into the top quintile, bottom quintile, and all others and repeated our analyses; the results were unchanged (data not shown).

We also performed sensitivity analyses by altering the format of the independent variables. For example, we varied the cutoffs for what constituted a small site of care or for what constituted adequate staffing levels; the results were unchanged. Finally, we created a combination quality score by assigning a point for each putative quality indicator that a site fulfilled, to examine whether these factors predicted performance better in the aggregate than individually. For example, a site might receive 1 point for having a dedicated program to train providers, 1 point for having fewer than 400 patients per provider, and 1 point for using a computerized system for documentation and patient tracking. We examined several different versions of this combination quality score, including various measures and assigning them variable relative weights, but none of these combination scores predicted site RA-TTR.

DISCUSSION

We examined site-level organizational factors (structure of care) as potential predictors of outpatient oral anticoagulation control (outcomes of care).[17] Although our hypotheses were supported by consensus guidelines,[1,7] the site-level characteristics that we studied were not associated with anticoagulation control. Many studies relating structure and processes of care have been performed within the VA among sample sizes similar to that of this study. One such study[18] found that organizational culture and commitment to continuous quality improvement were not associated with better processes of care for depression. However, most other studies have found associations between various aspects of organizational culture and processes of care, including rates of cancer screening[19-22] and recommended processes of care for heart failure,[23] chronic lung disease,[24] and diabetes mellitus.[25] In the diabetes study, the authors also found associations between organizational culture and intermediate outcomes of diabetes care,[25] a relationship more directly comparable to our examination of structure and intermediate outcomes. However, unlike these previous studies, we directly measured structural aspects of care within the ACC itself, which we expected to more directly affect anticoagulation control. Therefore, our null findings are all the more surprising; furthermore, they suggest the need to rethink quality improvement guidelines in anticoagulation care. For example, while some VA sites seem to emphasize face-to-face visits, this may not always be an efficient use of resources for the patient or for the provider, as telephone-based or mail-based care seemed to achieve similar results in this and other studies.[26,27]

Our study results do not suggest, nor do we believe, that efforts to improve the quality of oral anticoagulation therapy are futile. In fact, our group plans to implement a program to improve anticoagulation control in the VA, as we believe that this is feasible and important. Rather, our study findings suggest that we must look beyond the limited measures examined

herein to find the true determinants of high-quality oral anticoagulation care. Which aspects of structure of care did this study not measure and what might be fitting targets for future studies? We did not directly investigate how warfarin dosages are managed or which dosing protocols or computerized dosing aids are used. A rich literature shows that computer-aided dosing of warfarin[28-33] or simply judicious dosing in the absence of computerized support[34] can improve anticoagulation control. Our study was adequately powered to detect a 3% difference in RA-TTR, which is modest. By comparison, using a computerized dosing algorithm improves TTR by approximately 10% over usual care,[30] and more judicious dosing without computer assistance could improve TTR by approximately 6%.[34] It seems likely that aspects of structure or process of care that relate to actual warfarin dosage management would help explain the wide variations in ACC performance within the VA. Also, more detailed assessments of ACCs through site visits and staff interviews might identify differences between high-performing and low-performing clinics.[35]

This study has considerable strengths. We used measures of structure of care that are supported by prominent guidelines[1,7] and evaluated structure within the ACC itself rather than in the organizational culture of the entire medical center. In addition, our outcome measure (RA-TTR) has been carefully developed[8,14] and represents the state of the art in measuring intermediate outcomes of anticoagulation care.[2] This study also has limitations. Responses to the survey were by self-report, and it is possible that some responses (eg, the number of providers) were not fully accurate. Also, as already discussed, this survey instrument may not have collected enough detailed information to adequately characterize some aspects of structure, such as the nature rather than the mere existence of a quality improvement program. Finally, while our risk-adjustment model for TTR controlled for multiple measures of comorbidity and achieved a high R^2, it did not include data on adherence. However, part of the influence of good management may be expressed through improved adherence; adjusting for adherence could adjust away such an effect. Therefore, adherence arguably does not belong in the risk-adjustment model.

In summary, our data suggest that high-quality anticoagulation care can be provided across a wide array of structures of care. A dedicated ACC is a necessary first step for improving the quality of oral anticoagulation care.[3-6] However, within the structure of an ACC, further quality improvement efforts should focus on aspects of care that have been shown to affect anticoagulation control, such as the judicious dosing of warfarin.[34] A program of quality improvement based solely on the measures studied herein may not have the desired effect on outcomes.

ANTITHROMBOTIC THERAPY

Reexamining the Recommended Follow-up Interval After Obtaining an In-Range International Normalized Ratio Value

Results from the Veterans Affairs Study to Improve Anticoagulation

Adam J. Rose, MD; Al Ozonoff, PhD; Dan R. Berlowitz, MD, MPH; Arlene S. Ash, PhD; Joel I. Reisman, AB; and Elaine M. Hylek, MD, MPH

Background: **Patients receiving oral anticoagulation therapy should be tested often enough to optimize control, but excessive testing increases burden and cost. We examined the relationship between follow-up intervals after obtaining an in-range (2.0-3.0) international normalized ratio (INR) and anticoagulation control.**

Methods: **We studied 104,451 patients who were receiving anticoagulation therapy from 100 anticoagulation clinics in the US Veterans Health Administration. Most patients (98,877) had at least one in-range INR followed by another INR within 56 days. For each such patient, we selected the last in-range INR and characterized the interval between this index value and the next INR. The independent variable was the site mean follow-up interval after obtaining an in-range INR. The dependent variable was the site mean risk-adjusted percentage of time in the therapeutic range (TTR).**

Results: **The site mean follow-up interval varied from 25 to 38 days. As the site mean follow-up interval became longer, the risk-adjusted TTR was worse (−0.51% per day, $P = .004$). This relationship persisted when the index value was the first consecutive in-range INR (−0.63%, $P < .001$) or the second (−0.58%, $P < .001$), but not the third or greater (−0.12%, $P = .46$).**

Conclusions: **Sites varied widely regarding follow-up intervals after obtaining an in-range INR (25-38 days). Shorter intervals were generally associated with better anticoagulation control, but after obtaining a third consecutive in-range value, this relationship was greatly attenuated and no longer statistically significant. Our results suggest that a maximum interval of 28 days after obtaining the first or second in-range value and consideration of a longer interval after obtaining the third or greater consecutive in-range value may be appropriate.**

CHEST 2011; 140(2):359–365

Abbreviations: E = expected percentage of time in the therapeutic range; INR = international normalized ratio; IQR = interquartile range; O = observed percentage of time in the therapeutic range; OAT = oral anticoagulation therapy; TTR = percentage of time in the therapeutic range; VA = Veterans Health Administration

Oral anticoagulation therapy (OAT) is used to treat or prevent thromboembolic disease for millions of patients.[1-6] Although OAT has been used for decades,[7] many aspects of this therapy are governed by tradition rather than evidence, including the maximum allowable follow-up interval. It is important to follow patients often enough to achieve good control, because better control is associated with improved outcomes.[8-12] However, we should not follow patients more often than necessary, because extra testing is costly and burdensome for patients and the medical system. In the absence of evidence, guideline committees have recommended different maximum follow-up intervals. The American College of Chest Physicians recommends a maximum interval of 28 days for all patients.[1] The American College of Cardiology/American Heart Association/European Society of Cardiology guideline

For editorial comment see page 281

allows up to 42 days when good control has been achieved for the patient.[2] The British Society of Haematology allows up to 90 days when good control has been achieved.[13] Underlying these divergent recommendations is a disagreement about whether frequent testing will capture important changes in the international normalized ratio (INR) or merely capture random noise and allow more possibilities for unwise and excessive dose adjustments.[14]

If more frequent testing were found to be unnecessary for a subset of patients with stable control, then increasing the follow-up interval for these patients would save money and reduce patient burden. We, therefore, set out to examine the impact of follow-up intervals after obtaining an in-range INR value (2.0-3.0) upon anticoagulation control for patients. Because patient-level follow-up intervals can be endogenously related to anticoagulation control (that is, these variables can exert a mutual influence on each other),[15,16] we studied follow-up intervals at the level of the site of care. We will show that this approach successfully addressed the problem of endogeneity. Our objective was to find empirical support for one or more of the existing guideline recommendations for the maximum follow-up interval.

Materials and Methods

Data

The database for this study has been described in detail.[17,18] The Veterans Affairs Study to Improve Anticoagulation (VARIA) included all patients who were deemed to be receiving OAT from the Veterans Health Administration (VA) between October 1, 2006, and September 30, 2008, according to the criteria described in the next sections. The study was approved by the institutional review board of the Bedford VA Medical Center.

Manuscript received October 23, 2010; revision accepted January 14, 2011.

Sites of Care

We studied 100 VA sites of care, each of which has a specialized anticoagulation clinic run by clinical pharmacists under the supervision of a medical director.[19] For this study, we excluded INR values from the first 6 months of therapy with warfarin (the inception period). We have previously shown that the percentage of time in the therapeutic range (TTR) is lower during the inception period,[16-18] and follow-up intervals are justifiably shorter during this period.

Dependent Variable: Site Risk-Adjusted TTR

Our dependent variable was mean site risk-adjusted for the TTR, a measure of anticoagulation control over time. We calculated the TTR using the Rosendaal method, which uses linear interpolation to assign an INR value to each day between successive observed INR values.[20] Gaps of >56 days between INR values are not interpolated. After interpolation, the percentage of time during which the interpolated INR values are between 2.0 and 3.0 is calculated.[20] We calculated the risk-adjusted TTR for all patients, including the small subset that did not record an in-range INR value.

We included INR values obtained when patients were given warfarin, that is, when a patient was either in possession of warfarin or having INR tests at least every 42 days. We defined the period of warfarin possession as the duration of the most recent VA prescription for warfarin plus 30 days. We excluded INR tests measured while the patient was hospitalized within the VA system. We also excluded patients whose primary indication to receive warfarin was valvular heart disease or the use of a prosthetic heart valve. Many such patients have a target INR range of 2.5 to 3.5 rather than the more standard 2.0 to 3.0, but it is not possible to determine with certainty which patients have the higher target range. Without specific knowledge of the target range, we cannot calculate the TTR.

Our risk adjustment model for the TTR, which controls for patient-level risk factors for poor TTR, has been described previously.[17,18] Site risk-adjusted TTR was calculated using the following procedure. First, for each patient, we calculated the observed TTR (O) and applied the risk-adjustment model to calculate the expected TTR (E). Then, an observed minus expected (O − E) score was calculated for each patient. The mean O − E score for each site constituted its risk-adjusted TTR.

Independent Variables: Site Mean Follow-up Intervals

We located all patients who had at least one in-range INR value (2.0-3.0) followed by a second INR value 14 to 56 days later, without an intervening hospitalization. We judged that obtaining a follow-up INR value within <2 weeks was unlikely to represent usual treatment and was more likely related to an event such as an emergency visit or an outpatient procedure. We excluded intervals >56 days because they could not be interpolated for the calculation of the TTR.[20] To examine the impact of these decisions, we also reran our main analyses using different qualifying intervals, including 1 to 56 days, 14 to 90 days, and 1 to 90 days; our main results did not change.

When a patient had multiple qualifying episodes, we arbitrarily selected the last such episode, so that each patient was sampled no more than once. We examined the number of days between the index INR (ie, the in-range value) and the following INR. We averaged values from individual patients to calculate a mean value for each site. We also looked backward from each index INR value to see whether the INR immediately before it was also in range, and, if so, also looked at the INR before that. Thus, we divided patients into three mutually exclusive groups based on whether

the index INR value was the first, second, or third consecutive in-range value. We stratified the sample on these three categories and calculated the mean follow-up interval within each stratum. Thus, for each site, we calculated the mean follow-up interval after obtaining a single in-range INR value, two consecutive INR values, and three consecutive INR values.

Statistical Analyses

We examined the baseline characteristics of the patients in our source population (all patients who received OAT) and our study sample (patients with at least one in-range value). We examined the relationship between follow-up intervals and risk-adjusted TTR at the level of the individual patient. We then examined this relationship at the site level, using both simple correlation and linear regression. Finally, we examined the differential effect on anticoagulation control of the mean site follow-up interval after obtaining one, two, or three consecutive in-range INR values. All analyses were conducted using SAS, version 9.1 (SAS Institute Inc; Cary, North Carolina).

Results

Patient Population and Anticoagulation Control

Baseline characteristics for the study patients are described in Table 1, and they were similar between the source population (104,451 patients who received OAT) and the study sample (98,877 patients with at least one in-range INR). The sample patients were mostly men (98%) and had a median age of 73 years. Patients had a substantial burden of comorbidity. For example, 40% had diabetes, 32% had heart failure, and 14% had chronic kidney disease. The burden of mental illness and substance abuse was considerable: 21% had major depression, 9% abused alcohol, and 5% had dementia. The mean TTR for the study sample was 63%.

There were 100 sites of care. The site mean TTR (O) ranged from 41% to 72%. The site expected TTR (E) ranged from 58% to 65%. The site risk-adjusted TTR (O − E) score ranged from 19% below to 12% above expected.

Follow-up Intervals

We characterized the follow-up intervals after stratifying by the index INR (ie, the INR value that preceded the interval). As would be expected, the follow-up intervals were longest when the index value was in range (Fig 1) and were uniform throughout that range. This confirmed our decision to treat all INR values within the target range (2.0-3.0) equally.

Patient-Level Analysis

The mean interval after obtaining an in-range INR was 29.8 days, and the mean TTR was 63%. For each additional day of the follow-up interval, the patient experienced a 0.35% higher TTR ($P < .001$) and a 0.25% higher TTR after adjustment for covariates ($P < .001$). The effect was therefore in the expected direction (ie, longer follow-up intervals were associated with improved control on the patient level).

Table 1—*Baseline Sample Characteristics for Source Population and Study Sample*

Characteristic	Source Population (N = 104,451)	Study Sample (n = 98,877)
Female sex	1.9	1.9
Median age (IQR)	72 (62-79)	73 (63-79)
Race/ethnicity		
Non-Hispanic white	77.2	77.5
Non-Hispanic black	8.5	8.1
Hispanic	2.8	2.8
Asian	0.3	0.3
Native American	0.3	0.3
Other/unknown	10.9	11.0
Median percentage of poverty in zip code of residence (IQR)	10.7 (6.6-15.9)	10.6 (6.5-15.8)
Median distance from nearest VA facility, miles (IQR)	7.8 (3.7-16.5)	7.8 (3.7-16.4)
Primary indication for warfarin[a]		
Atrial fibrillation	64.2	64.7
VTE	27.3	26.9
All others combined	8.5	8.4
Physical comorbid conditions		
Newly diagnosed cancer	6.8	6.6
Chronic kidney disease	14.2	13.9
Chronic liver disease	1.2	1.1
Chronic lung disease	29.4	29.0
Diabetes	40.1	39.9
Epilepsy	2.8	2.7
Heart failure	32.8	32.4
Hyperlipidemia	75.4	75.7
Hypertension	84.0	84.1
Mental comorbid conditions		
Alcohol abuse	9.3	8.9
Bipolar disorder	2.3	2.2
Dementia	5.3	5.2
Major depression	21.6	21.2
Nonalcohol substance abuse	4.0	3.7
Median number of medications (IQR)	8 (6-12)	8 (6-12)
Hospitalized at least once	26.2	25.3
Anticoagulation control		
TTR, mean (SD)	61.2 (21.9)	63.4 (19.8)

Data on the source population were used to calculate site performance (ie, risk-adjusted TTR), and data on the study sample were used to characterize the follow-up interval after obtaining an in-range (2.0-3.0) INR value. Data are presented as % unless otherwise indicated. INR = international normalized ratio; IQR = interquartile range; TTR = percentage of time in the therapeutic range; VA = Veterans Health Administration.

[a]Patients whose main indication for anticoagulation was valvular heart disease or the use of a prosthetic heart valve were excluded from this study.

Site-Level Analysis

There were 100 sites, with a median of 888 patients per site (interquartile range [IQR], 576-1,341). The mean site follow-up interval after obtaining an in-range

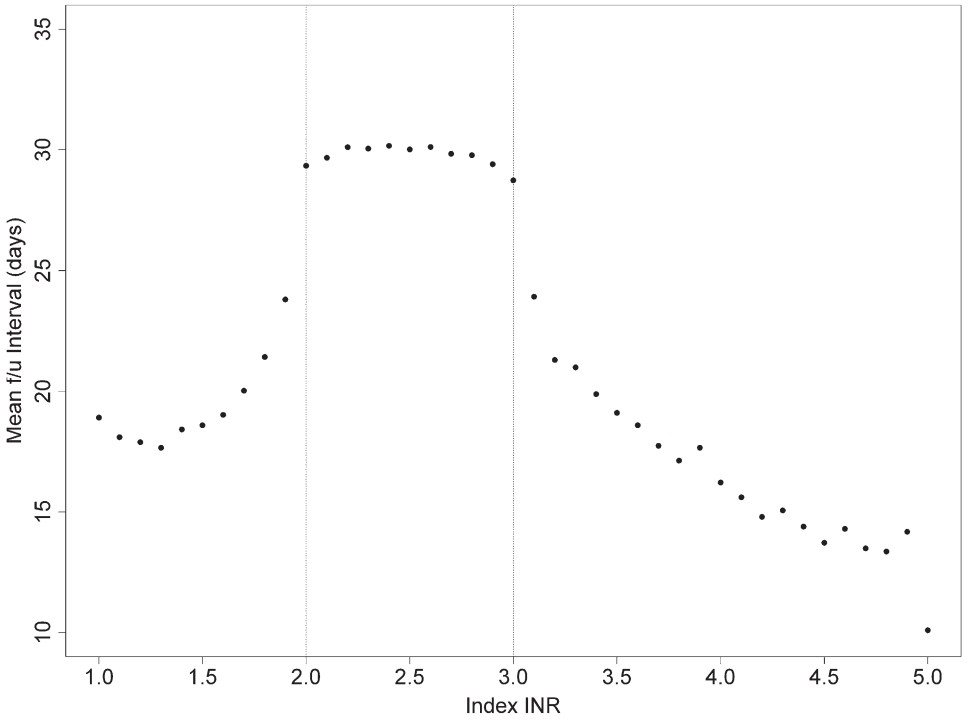

FIGURE 1. The interval (in days) between INR tests stratified by the index INR value (N = 104,451). Each patient contributes one interval (the patient's last in the database). All INR values ≥5.0 are combined into a single data point. f/u = follow-up; INR = international normalized ratio.

INR varied from 25 to 38 days (Fig 2). A longer mean follow-up interval after obtaining any in-range INR value was associated with worse performance, the opposite effect of that seen at the patient level (Fig 2; r = −0.28, $P = .004$). For each day of follow-up interval after obtaining an in-range INR, the site O−E score was 0.51% lower ($P = .004$) (Table 2).

We subdivided the index INR values into the first, second, or third consecutive in-range values. We found that 47% of the index values were preceded by an out-of-range value, while 23% were preceded by a single in-range value, and 31% were preceded by at least two consecutive in-range values (Table 2). The relationship between longer intervals and poorer site-level performance held for the interval after obtaining the first consecutive in-range value (−0.63%, $P < .001$) and the second consecutive in-range value (−0.58%, $P < .001$), but was greatly attenuated and no longer statistically significant after obtaining the third or greater consecutive in-range value (−0.12%, $P = .46$). Similar results were seen among patients aged >75 years and patients who received anticoagulation treatment for atrial fibrillation.

Discussion

In our study, 100 sites in an integrated health system varied considerably regarding the follow-up interval after obtaining an in-range (2.0-3.0) INR value. This variation likely reflects a lack of evidence and divergent practice guidelines.[1,2,13] We took advantage of these variations in practice to examine the relationship between follow-up intervals and anticoagulation control. We found that longer follow-up intervals predicted better anticoagulation control at the level of the individual patient but worse anticoagulation control at the level of site of care. This apparent paradox, which is what we expected to find, can be explained as follows.

Each site of care is managed by a group of clinicians who, whether by official policy or unofficial tradition, have arrived at a usual follow-up interval after obtaining an in-range INR. However, this usual interval may be lengthened or shortened depending on the clinician's suspicion that a particular patient will be in range at the next visit. Because these clinical impressions have some validity, longer follow-up intervals at the patient level predict better anticoagulation control.[16] However, by examining the mean follow-up intervals at the site level, we showed that when the site had a pattern of longer follow-up intervals, the intervals were actually associated with worse anticoagulation control.

In a previous study,[18] we showed that patients who receive anticoagulation treatment at VA facilities have a mean TTR of 58%; our goal is to improve this to approximately 70%. An improvement of this magnitude would be expected to improve patient outcomes

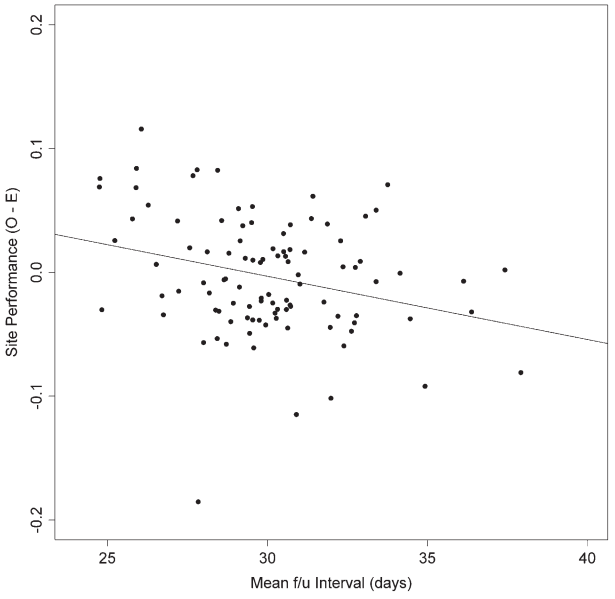

FIGURE 2. The correlation between the mean site-level follow-up interval after obtaining an in-range INR value (2.0-3.0) and the site-level performance as measured by the risk-adjusted percentage of time in the therapeutic range (TTR) (No. = 100 sites). For the regression line, r = −0.28 (P = .004), indicating that shorter follow-up intervals are associated with better site-level performance. O − E = observed TTR minus expected TTR. See Figure 1 legend for expansion of the other abbreviations.

considerably.[8-12] In the present study, the site mean follow-up intervals varied from 25 to 38 days. Because each additional day in the follow-up interval reduces the site-level TTR by 0.51%, this variation would be expected to account for a 6.6% difference in the TTR across the range of practice we observed. These results suggest that optimizing the follow-up intervals after obtaining in-range INR values could help achieve our goal of improving the TTR to 70%. Our main finding (that longer follow-up intervals were associated with poorer control) persisted when we limited our analysis to patients aged > 75 years and those who received anticoagulation treatment for atrial fibrillation. Given the particular importance of excellent control for improving outcomes in these groups,[2,5,8,12] they may benefit most from efforts to improve TTR by optimizing the follow-up interval.

In addition, we examined follow-up intervals after obtaining the first, second, or third or greater consecutive in-range INR value. The association between longer follow-up intervals and poorer performance was seen only after obtaining a first or second consecutive in-range value, but after obtaining a third or greater consecutive in-range value, it was greatly attenuated and no longer statistically significant. This provides an opportunity to explain our main findings in the context of divergent guideline recommendations. In general, this study lends support to the American College of Chest Physicians recommendation to limit follow-up intervals for many patients to 28 days,[1] because sites of care that pursued this strategy in our study had the best anticoagulation control (Fig 2). However, our results also suggest that for patients with extremely stable control, extending the follow-up interval beyond 28 days might be considered. Several previous studies have also supported the idea that some patients can safely extend their

Table 2—*Relationship Between Site Mean Follow-up Interval After Obtaining an In-Range INR (2.0-3.0) and Site Performance*

Index INR Value	Group, No. (%)	Mean Follow-up Interval, d (SD)	Effect on Site Performance, %	*P* Value
All patients				
All in-range values	98,877 (100)	29.8 (8.8)	−0.51	0.004
First consecutive in-range value	46,386 (47)	28.2 (9.2)	−0.63	< 0.001
Second consecutive in-range value	22,260 (23)	30.4 (8.3)	−0.58	< 0.001
Third or greater consecutive in-range value	30,231 (31)	31.9 (7.9)	−0.12	0.46
Patients aged > 75 y				
All in-range values	38,299 (100)	29.6 (8.5)	−0.48	0.007
First consecutive in-range value	17,356 (45)	28.0 (8.9)	−0.52	< 0.001
Second consecutive in-range value	8,598 (22)	30.1 (8.0)	−0.63	< 0.001
Third or greater consecutive in-range value	12,345 (32)	31.6 (7.6)	−0.21	0.18
Patients who received anticoagulation treatment for atrial fibrillation				
All in-range values	63,978 (100)	30.0 (8.6)	−0.53	0.003
First consecutive in-range value	29,353 (46)	28.4 (9.1)	−0.60	< 0.001
Second consecutive in-range value	14,454 (23)	30.5 (8.2)	−0.59	< 0.001
Third or greater consecutive in-range value	20,171 (32)	32.0 (7.8)	−0.19	0.24

Data were measured by risk-adjusted TTR. The index (in-range) INR value was stratified by whether it was the first, second, or third or greater consecutive in-range value. Analyses were performed first using the entire dataset, followed by selected subsets (ie, patients aged > 75 years, patients with atrial fibrillation). The effect on site performance was determined in units of TTR per additional day of follow-up interval. For example, an effect size of −1.0 signifies a 1% decrease in the site mean TTR per additional day of follow-up interval. See Table 1 legend for expansion of abbreviations.

follow-up interval beyond 28 days.[16,21] Most notably, Witt et al[21] showed that patients with all of their INR values in range had lower rates of complications than the comparator patients, despite the fact that they also had fewer INR tests. Indeed, an ongoing randomized trial is comparing a 1-month follow-up interval with a 3-month follow-up interval for patients whose warfarin dose has been stable for at least 6 months,[22] a group likely to overlap considerably with patients who record three consecutive in-range values. If a longer follow-up interval is confirmed to be safe for such patients, this could save time and money for patients and the health-care system.

This study has important strengths. The database comprised over 100,000 patients and was rich in clinical detail. Our outcome measure (risk-adjusted TTR) is the product of extensive development[17,18] and represents the state of the art in quality measurement in OAT. We used innovative methods to avoid the problem of endogeneity in observational studies of follow-up intervals. However, our study also has limitations. As with any observational study, inferences about cause and effect must be interpreted with caution. A second limitation is that we measured the follow-up interval that was achieved, not necessarily the interval that the clinician requested. It is possible that some patients were followed up later than the clinician wanted and that this negatively impacted anticoagulation control. We addressed this by risk adjusting the risk for patient characteristics that impact anticoagulation control,[17] thereby equalizing this effect between sites. Furthermore, our finding that longer follow-up intervals are associated with better control on the patient level would also argue against this being an issue. A third limitation is that this study was limited to patients with a target INR of 2.0 to 3.0 and at least 6 months of experience with warfarin; our results may not apply to patients with different target ranges or those new to warfarin. Finally, our sample population was predominantly male and had a high degree of comorbidity. However, it is unclear how this would alter the basic relationships we demonstrated between follow-up intervals and anticoagulation control.

In summary, we found that 100 sites of care within an integrated health system (the VA) pursued widely divergent follow-up intervals after obtaining an in-range INR value. Longer follow-up intervals are associated with poorer anticoagulation control at the site level, except when three or more consecutive in-range values have been recorded for the patient. Our results support a 28-day maximum follow-up interval after obtaining one or two consecutive in-range values and consideration of a longer interval after obtaining a third or greater in-range value. Our study also suggests that reducing practice variation could contribute both to improved anticoagulation control and enhanced efficiency.

Incorporating Health Literacy into Larger Operational Environments

STEVEN R. RUSH

United Health Group Health Literacy Innovations Program, Minnetonka, Minnesota, USA

MICHAEL K. PAASCHE-ORLOW

Section of General Medicine, Department of Medicine, Boston University School of Medicine, Boston, Massachusetts, USA

In their article, *Health Literacy and Health Care Spending and Utilization in a Consumer-Driven Health Plan*, Hardie et al. examine health literacy and health care spending and utilization by linking responses to three health literacy screening questions to 2006 claims data of enrollees new to consumer-driven health plans. Focusing on emergency department and inpatient admission data, they were able to link costs for these services with self-reported ability to read and learn about medical conditions. They found that better health literacy was associated with fewer inpatient admissions, fewer emergency department visits, and lower total medical spending. Their data supports the notion that members with lower health literacy tended to access care with more advanced conditions and consequently required more services and more costly services. However, as they acknowledge, their analyses are limited by the absence of several parameters such as income. They also do not have data on the appropriateness of hospital or emergency department utilization. The opportunity to use existing data such as these is frequently compromised by missing data elements.

Several things about this project deserve comment. The article represents the collaboration between a health insurer and independent investigators and capitalizes on claims data. This is a welcome sign. Insurers and health plans have become increasingly aware of the need to provide accessible, understandable, and actionable communications to their consumers. Health plans, individually and in conjunction with America's Health Insurance Plans (AHIP), have begun working to incorporate the principles of clear health communication into their organizations (America's Health Insurance Plans, 2011). However, much progress is needed. Little has been done to transfer the findings of health literacy research into the larger operational

environment of health plans. Dissemination in these environments is driven by opportunity, leadership, policy, competition, and the bottom line. While the dominant TLA (three-letter acronym) in the research community is EBM (evidence-based medicine), in the health care industrial sector it is ROI (return-on-investment). The emerging Health Literacy research community can aspire to influence both. To do so will require the types of basic research called for by Johnson and colleagues in their Commentary in this issue, but it will also require research in cost effectiveness, organizational change, and implementation. As Allen et al. describe in their article in this issue, a lot of work is needed to establish the generalizability and sustainability of health literacy interventions. As much time as we spend striving to publish excellent articles we have to remember that the Journal Impact Factor is not the goal of research—it is the human impact factor that matters.

Second, Hardie et al. used the Chew questions to measure health literacy. By and large, subjective measures that have been validated against pyrite standard measures such as the REALM and TOFHLA represent a severe limitation and should be eschewed. After all, as Pleasant et al. write in their Commentary in this special issue, such measures are not based in any theory of health literacy, fail to measure all the domains of the underlying concepts, and have not been rigorously tested according to appropriate psychometric methods. And yet, these limited tools appear to be measuring something that is very important. In fact, as much as we agree with the motivation to significantly improve measurement in this field, the relevance of additional domains that would be included (e.g., navigation) will need to be empirically established. However crude, some research aims do not require more refined measures and many opportunities for valuable research and evaluation will be missed if we completely shun existing tools.

For the aim of showing that difficulty with forms is associated with higher costs, these screening questions were sufficient. But they do not provide adequate guidance for the subsequent question: What should be done? And even once a causal pathway is exposed and an intervention is designed and proven to be effective, further work is needed to transfer and maintain these interventions into larger operational settings. Greater collaboration between health literacy researchers and thought leaders and payers of health care is needed. Such collaboration could provide access to data, funding for research, and the levers to inform change within diverse parts of the health care system.

Consumers and their employers recognize the need for accessible, understandable, and actionable health and wellness communications. The paper by Hardie et al. helps show the business case; this will help influence insurers to get involved.

Purpose: The purpose of this study was to determine whether a belief in the AIDS origin conspiracy theory is related to likelihood or fear of participation in research studies. **Methods:** The Tuskegee Legacy Project Questionnaire was administered via random-digit-dialed telephone interview to black, white, and Hispanic participants in 4 cities in 1999 and 2000 (n = 1,133) and in 3 cities in 2003 (n = 1,162). **Results:** In 1999, 27.8% of blacks, 23.6% of Hispanics, and 8% of whites ($P \leq .001$) reported that it was "very or somewhat likely" that AIDS is "the result of a government plan to intentionally kill a certain group of people by genocide." In 2003, 34.1% of blacks, 21.9% of Hispanics, and 8.4% of whites ($P \leq .001$) reported the same. **Conclusions:** Whereas blacks and Hispanics were more than 3 times more likely than whites to believe in this AIDS origin conspiracy theory, holding this belief was not associated with a decreased likelihood of participation in, or increased fear of participation in, biomedical research. **Key words:** *AIDS, biomedical research, conspiracy theory, health disparities, HIV, research participation*

Despite the 1994 US government legislation that mandated inclusion of racial and ethnic minorities in all nationally funded biomedical research studies, minority groups remain underrepresented.[1] Reasons for this disparity that have been previously examined with varying results include fear of participation in biomedical research,[2,3] mistrust in doctors/scientists, mistrust in the US government,[4] perceived racism,[5] lack of awareness and/or knowledge of the availability of clinical trials,[3,6] and knowledge of past research abuses, including the US Public Health Service (USPHS)-Tuskegee Syphilis Study.[2,7–12]

An additional, underexplored potential explanation for the lack of participation in biomedical research by racial and ethnic minorities in the United States may be a belief in conspiracy theories, specifically regarding the origin of AIDS and the role of government in the HIV epidemic, which have been shown to be held by a substantial proportion of persons in these minority groups.[13] Although AIDS conspiracy beliefs have been shown to be associated with health-damaging behaviors, including inconsistent condom usage and greater numbers of sexual partners,[14,15] and despite persistent reported racial/ethnic disparity in biomedical research participation[4,16–18] and the documented popularity of conspiracy theories regarding the origins of AIDS in minority populations,[13–15,19–30] to date only one study has examined

the relationship between belief in conspiracy theories of the origin of AIDS and willingness to participate in biomedical research studies.[31] In this study, the relationship of misconceptions about HIV and HIV vaccines to willingness to participate in HIV vaccine research trials was investigated among a group of 220 community college students in Atlanta, Georgia. Racial minority students were more likely than white students to believe that "the AIDS epidemic was caused by a government conspiracy." Belief in this statement was unrelated to willingness to participate in research. However, it was unclear whether results varied by race/ethnicity. Also, belief in AIDS origin conspiracy was not analyzed separately from other "AIDS misconception" questions, but as part of a scale. It is uncertain to what extent the results of this previous study might be applicable to the broader question of willingness to participate in biomedical research studies in general, or to other populations, given the narrow sampling framework (ie, the inclusion of only white, African American, and Asian college students) and the lack of demographic information provided about the participants of this study (eg, age, socioeconomic status).

The goals of the present analyses were as follows: (1) to examine and compare the proportion of blacks, whites, and Hispanic participants in 2 large, multicity population-based cohorts who believe that the origin of AIDS is a government conspiracy ("AIDS origin conspiracy theory"); (2) to determine which demographic factors within each group are related to belief in AIDS origin conspiracy theory; and (3) to evaluate whether belief in AIDS origin conspiracy theory is related to an expressed fear of participation and/or a decreased likelihood of participation in biomedical research within each racial/ethnic group. We hypothesized that blacks and Hispanics would be more likely to report a belief in AIDS origin conspiracy theory, compared with non-Hispanic whites, and that believing in AIDS origin conspiracy would be related to fear of participation and likelihood of participation in biomedical research studies, regardless of racial/ethnic identification.

METHODS

The data for this report were obtained by the repeated use of the Tuskegee Legacy Project (TLP) Questionnaire administered in 2 separate random-digit-dialed (RDD) telephone surveys conducted in a rigorous and similar fashion in 1999 and 2000 in 4 US cities and in 2003 in 3 US cities. The 60-item, 25-minute-long TLP survey was developed via pilot studies conducted from 1994 to 1997 by a multidisciplinary, multi-university research team, and its design, including the rationale for the selection of questions and cities, has been described previously.[2] Questions were initially drawn from other studies, and the survey was extensively piloted with members of the target population and refined over time.[2] In late 1999 and early 2000, the TLP Questionnaire was administered by the Survey Research Unit of the University of Alabama to targeted populations of noninstitutionalized self-reported blacks, whites, or Hispanics (of either race) aged 18 years or older living in households with working telephones in Birmingham, Alabama; Tuskegee, Alabama; Hartford, Connecticut; and San Antonio, Texas. The RDD sample of households used a simple random sample in each of the cities and was partially screened for nonworking or business numbers. The goal was to achieve the completion of 25-minute telephone interviews with 900 adults in the following groups: (1) 300 blacks (100 in Hartford; 100 in Birmingham; 100 in Tuskegee); (2) 400 whites (100 in Hartford; 100 in Birmingham; 100 in Tuskegee; 100 in San Antonio); (3) 100 Hispanics of Puerto Rican descent (Hartford); and (4) 100 Hispanics of Mexican-American descent (San Antonio). The primary sampling unit for the calling area was the Central Office Code, the 3-digit telephone exchange used for local calling areas, that provided a concise area for geographic exposure and increased the likelihood of contacting "households" through RDD.

In 2003, the TLP Questionnaire was administered by ORC Macro, a US-based international opinion research corporation. The survey sample for this study was drawn from the total noninstitutionalized adult populations of persons over the age of 18 residing in telephone-equipped dwelling units in New York, New York; Baltimore, Maryland; and San Juan, Puerto Rico. Each of the 3 sites was sampled independently, with a target number of 900 completed interviews overall and the following specific race/ethnic groups targets within each city: 300 blacks (150 in New York City, 150 in Baltimore); 300 whites (150 in New York City, 150 in Baltimore), and 300 Hispanics (150 Puerto Rican

Hispanics in San Juan, 150 in New York City). The initial sample allocation across strata (within site) was based on expected yields computed using exchange incidence data. The yield of minority interviews by strata was monitored, and the mix of sample across race/ethnic strata in each replicate was adjusted, based on actual data.

Experienced, trained interviewers conducted the survey using full computer-assisted telephone interview (CATI) technology; they were supervised at all times and were randomly electronically monitored for both surveys. The 1999 and 2000 4-city TLP survey study was approved by the institutional review boards of the University of Connecticut and New York University; the 2003 3-city TLP survey study was approved by the institutional review board of New York University. Details regarding the administration of the 1999 and the 2003 TLP surveys, including rationale for selection of the cities, have been previously published.[2,8]

Measures

The TLP Questionnaire addresses a range of issues related to the recruitment of minorities into biomedical studies, specifically, whether minorities are more reluctant to participate in biomedical research studies and, if so, why. A question in the TLP specifically explored the belief that the US government created the human immunodeficiency virus in a laboratory in order to selectively kill a specific group of people ("How likely is it that AIDS is the result of a government plan to intentionally kill a certain group of people by genocide?"). This question occurred two-thirds of the way through the questionnaire (question 42 out of 60) and was prefaced with the statement, "AIDS has killed many people in the United States and throughout the world." Possible categorical responses to each question include "very likely," "somewhat likely," "don't know or not sure," "somewhat unlikely," or "very unlikely." We grouped persons who answered "very likely" or "somewhat likely" together and considered them to be "believers" in the statement and grouped those who responded "very unlikely" or "somewhat unlikely" together as "nonbelievers." In addition, although we examined the distribution by race/ethnicity and gender of those who answered "don't know or not sure," we excluded these persons from further analysis (by coding these respondents as "missing") because we considered them to be neither true believers nor true non-believers. However, because we considered arguments that this group might "act like" either believers or nonbelievers, we tested this assumption by grouping those who stated "don't know or not sure" first with the believers and then with the nonbelievers in order to analyze whether our recategorization appreciably changed the analysis outcome.

To measure 2 constructs, "likelihood of participation" and "fear of participation," 2 scales were created from multiple, related questions using standard psychometric analysis techniques. Both scales, the Likelihood of Participation (LOP) scale and the Guinea Pig Fear Factor (GPFF) scale, were standardized and measured on a continuous scale of 0 to 100, with a score of 0 indicating the lowest willingness to participate and the lowest fear of participation and 100 indicating the greatest willingness to participate and the greatest fear of participation in biomedical research studies. Details regarding the properties of these scales have been previously described.[2]

We calculated age using date of birth, and categorized age as 19 to 34 years old, 35 to 49 years old, or 50 years old or older. We classified education as less than high school graduate, high school alone or with some college, or college graduate and/or postgraduate degree. We categorized income as less than $20,000 a year, equal to or greater than $20,000 but less than $75,000 a year, or greater than or equal to $75,000. To acknowledge and account for cultural differences between the cities (ie, above and beyond simple demographic differences of respondents), the variable of "city" was included as a separate covariate in all multivariate analyses (Hartford, Birmingham, Tuskegee, or San Antonio for the survey conducted in 1999 and 2000 and New York, Baltimore, or San Juan in 2003).

Statistical Analysis

We analyzed each survey separately and then compared the findings of the 2 surveys. Because of the complex design of the 2003 3-city study, it was necessary to develop sampling weights for analysis of these data. Data from this survey were weighted separately in 3 stages, which yielded a

set of analytical weights that were included in the analysis of these survey data to avoid biased estimates. We compared these estimates with analyses without using weights and report whether these estimates changed the results substantially. We tested whether effects were modified by including interaction terms for race/ethnicity with age (older than 35 vs 35 or younger), gender, education, and income in our analysis.

We first examined, descriptively, demographic characteristics of the respondents in each survey by race/ethnic group (using analysis of variance [ANOVA] and chi-square tests) and then explored, for each survey, how the distribution of responses to the question "Is AIDS the result of a government plan to intentionally kill a certain group of people by genocide?" varied by race/ethnic category (white, black, Hispanic). We then evaluated, for each survey, whether a belief in this statement was related to age, gender, education, income, or geographic location within each racial/ethnic category, using Student *t* tests (for age) and chi-square or Fisher exact tests (for gender, education, income, and geographic location). We then conducted logistic regression analyses in which we included only those who responded "likely" (ie, "believers," very or somewhat) and "unlikely" (ie, "nonbelievers," very and somewhat) to examine whether the belief that "AIDS is the result of a government plan to intentionally kill a certain group of people by genocide" was related to race/ethnicity, controlling for differences between the race/ethnic groups in demographics when these variables were found to vary.

To compare the relationship between belief in AIDS origin conspiracy theory and fear of participation (as measured by the GPFF scale) and likelihood of participation (as measured by the LOP scale), we used linear regression to determine whether the dependent variables, GPFF and LOP, were related to the belief that "AIDS is the result of a government plan to intentionally kill a certain group of people by genocide" (dichotomized as yes/no) after first confirming that GPFF and LOP were normally distributed. For each racial/ethnic category, we created a full model with demographic factors (age, gender, education, income, and geographic location) as the independent variables and predictors of the 2 dependent variables, LOP and GPFF, setting the removal value at 0.10.

RESULTS

Study Sample

For both surveys, the original targeted enrollment goals were met or exceeded in each city with the exception of the Puerto Rican group in the 1999 and 2000 survey. Response rates were 70% for Birmingham, 65% for Tuskegee, 49% for Hartford, and 50% for San Antonio in 1999 and 2000, and 52% for San Juan, 51% for Baltimore, and 44% for New York City in 2003. Overall survey completion rates exceeded 90% in 1999 and 2000 and 82% in 2003. The overall final study sample for the 1999 and 2000 survey consisted of 353 blacks, 623 whites, and 157 Hispanics (116 Mexican and 41 Puerto Rican participants were grouped together as Hispanics; total n = 1,133), and the 2003 survey included 356 blacks, 493 whites, and 313 Puerto Rican Hispanics (total n = 1,162).

Demographic characteristics of the overall final study samples for each survey are shown in **Table 1**. Hispanic participants were younger than blacks and whites (ANOVA, $P \leq .001$) in each survey. In the 1999 survey, Hispanics were less likely to be men, compared with whites and blacks ($\chi^2_2 = 7.0$, $P = .03$); in the 2003 survey, there were no differences in gender distribution of the groups (in both the weighted and unweighted analysis). In both surveys, whites reported higher levels of education (1999: $\chi^2_4 = 65.6$, $P \leq .001$; 2003: $\chi^2_4 = 38.0$, $P \leq .001$) and higher incomes (1999: $\chi^2_4 = 80.7$, $P \leq .001$; 2003: $\chi^2_4 = 69.4$, $P \leq .001$) compared with blacks and Hispanics (both in the weighted and unweighted analyses).

Belief in AIDS Origin Conspiracy Theory

The distribution by race/ethnicity of responses in each survey to the question of whether AIDS was "the result of a government plan to intentionally kill a certain group of people by genocide" is shown in **Figure 1**. Patterns of responses by race/ethnic group to the AIDS origin conspiracy question were consistent across surveys. Compared with whites, in the 1999 survey, roughly 3 times as many blacks and Hispanics reported that it was "very or somewhat likely" that AIDS is "the result of a government plan to intentionally kill a certain group of people by genocide" (27.8% of blacks, 23.6% Hispanics vs 8% of whites; $\chi^2_4 = 80.6$, $P \leq .001$). In the 2003 survey, roughly 4 times as

Note: TLP = Tuskegee Legacy Project; NA = not applicable.

[a] Values may not add to 100% because of small amounts (<5%) of missing data.

many blacks and almost 3 times as many Hispanics compared with whites (34.1% of blacks, 21.9% of Hispanics vs 8.4% whites; $\chi^2_4 = 80.6$, $P \leq .001$) reported that it was "very or somewhat likely" that AIDS is "the result of a government plan to intentionally kill a certain group of people by genocide." In the 2003 survey weighted analysis, 4.1% of whites, 5.6% of Puerto Rican Hispanics, and 9.5% of blacks reported belief in AIDS origin conspiracy theory (Rao-Scott $\chi^2_4 = 61.3$, $P \leq .001$).

The proportion of persons who responded "don't know or not sure" to this question was greater in the 2003 TLP survey (range, 14.1% to 32.2%) compared with the 1999 TLP survey (range, 6.1% to 12.2%). However, we chose the more conservative analysis of excluding this group from further analyses in both surveys, because including this group in the group of "believers" or in the group of "nonbelievers" did not reveal consistent demographic or other patterns regarding this group of persons, and we hypothesized that those who responded "don't know/not sure" were not committed to either side (ie, believing or not believing in AIDS origin conspiracy theory).

When controlling for differences in age, gender, education, income, and geographic location, we found that, compared with whites, blacks and Hispanics were still much more likely to report belief in AIDS origin conspiracy theory (1999: blacks, adjusted odds ratio (OR) 3.1; 95% CI, 2.2–4.2; Hispanics adjusted OR 3.2; 95% CI, 1.9–5.3; 2003: blacks adjusted OR 7.4; 95% CI, 4.8–11.4; Hispanics

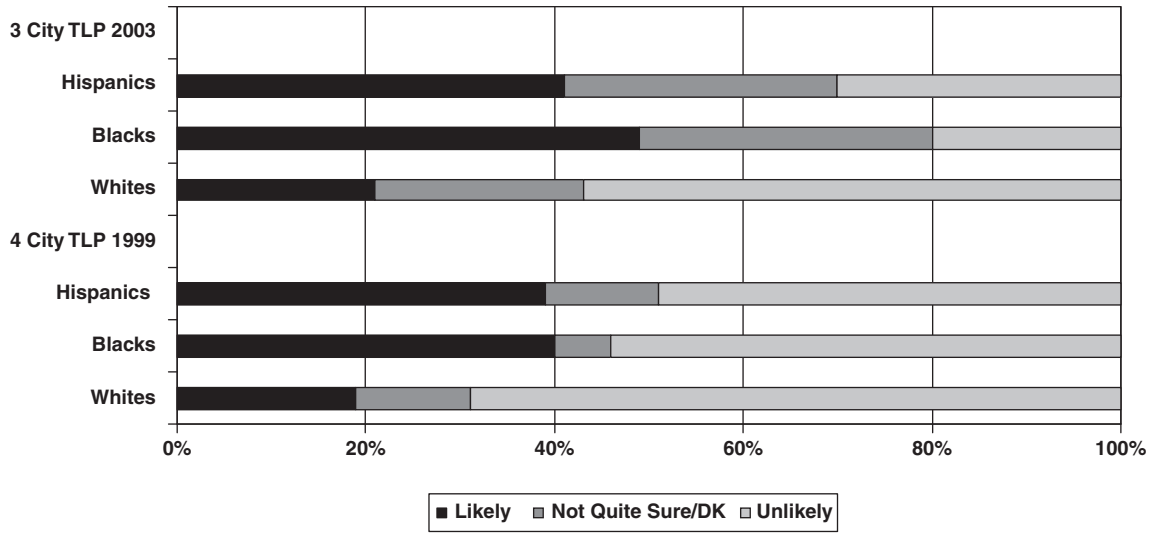

Figure 1. AIDS origin beliefs, by race/ethnicity, across 2 Tuskegee Legacy Project (TLP) Questionnaire surveys (1999 and 2003). DK = don't know.

adjusted OR 3.3; 95% CI, 1.9–5.7). We found no evidence of effect modification as no interaction terms were significant in our analysis.

Demographic Characteristics and Belief in Conspiracy Theory

The relationships between demographic factors (age, gender, education, income, and geographic location) and belief in AIDS origin conspiracy theory (based on response to the question on intentional killing and genocide) within each racial/ethnic group are shown in **Table 2**. Gender and age were not related to being a believer in any racial/ethnic subgroup in either survey. In general, lower education and lower income levels were related to a belief in AIDS origin conspiracy within each racial/ethnic group, with the exception of income in Hispanics and education in blacks in the 1999 survey. Geographic location was not related to being a believer in any racial/ethnic with the exception of Puerto Rican Hispanics in the 2003 survey, where those living in New York were more likely to express belief in AIDS origin conspiracy theory. These results were confirmed by the weighted analysis in the 2003 survey.

Relationship of Belief in AIDS Origin Conspiracy Theory, Likelihood of Participation, and Fear of Participation

We found no significant associations in whites, blacks, or Hispanics between belief in AIDS origin conspiracy theory and GPFF or LOP in either the 1999 or the 2003 TLP surveys (including the weighted analysis for the 2003 survey). We did identify a consistent relationship (ie, a significant association in both 1999 and 2003) between belief in AIDS origin conspiracy theory and an increased fear of participation in biomedical research (as measured by GPFF score) among whites when we adjusted for income and education (**Table 3**); this was confirmed by the weighted 2003 analysis. No consistent relationships were found within the black or Hispanic groups in adjusted analyses.

DISCUSSION

We found across 2 large surveys spaced 3 to 4 years apart that blacks and Hispanics were more likely than whites to report a belief in AIDS origin conspiracy theory. However, we found that for the racial/ethnic minority groups, holding such a belief was not associated with an expressed decreased likelihood of participation in, or an expressed increased fear of participation in,

biomedical research. The results of this investigation concur with many other reports that have demonstrated that AIDS conspiracy beliefs are more commonly held by blacks than by whites in the United States,[13–15,19–28,30] and they add to the growing literature that these beliefs are likely more common in other minority racial/ethnic groups, including Hispanics. A 1990 poll by *The New York Times* reported that 29% of blacks but only 13% of whites in New York City agreed with the statement "the virus which causes AIDS was deliberately created in a laboratory in order to infect Black people."[30] Herek reported that twice as many blacks as whites felt the government "is not telling the whole story about AIDS"[28] and reported that 5 times as many blacks as whites agreed with the statement "the government is using AIDS to kill off minority groups."[27] Thomas showed that anywhere from 15% to 35% of respondents agreed with the statement "I believe AIDS is a form of genocide against the Black race,"[29] and Goertzel reported that 31% of blacks in Philadelphia area believed that "the government deliberately spread the AIDS virus in the black community."[26] Klonoff reported that 26.5% of blacks agreed with the statement that "HIV/AIDS is a man-made virus that the federal government made to kill and wipe out Black people,"[24] and a group of studies by Bogart reported that 70% of blacks agreed with the statement "a lot of information about AIDS is being held back from the public," 50% with the statement that "HIV is a manmade virus," and 26% with the statement "AIDS is a form of genocide against African Americans."[14,15] More recent studies confirm that AIDS conspiracy beliefs continue to be persistent in the black community.[13,19–21,31] To date, only 4 studies measuring the prevalence of AIDS conspiracy theories have included data on Hispanics, the fastest growing minority group in the United States and one that is, like blacks, disproportionally affected by AIDS/HIV.[13,21–22,26] An attempt to identify barriers to participation in clinical trials among Hispanics is important, given the disparities in HIV rates by ethnicity and their underrepresentation in biomedical research, including HIV vaccine trials.[33] Our finding that

AIDS origin conspiracy theory belief is more common among Hispanics compared with whites concurs with 3 of these studies.[13,22,26]

We used the same methodology and the same wording in 1999 and 2000 and in 2003, and we found that results across the 2 surveys were similar, although the proportion of blacks reporting agreement with our AIDS conspiracy statement was slightly higher in the more recent survey (34.1% vs 27.8% in the earlier survey). We also found that a higher proportion of persons of any racial/ethnic category reported that they were "not quite sure" in 2003 compared with 1999 and 2000 and that the adjusted odds ratios for belief in AIDS origin conspiracy theories were twice as high for blacks as for whites in 2003 versus 1999. Differences in these rates may be related to the fact that the cities sampled were different or may be due to a true secular trend, which could be related to events occurring after the first but before the second survey (eg, the September 11th attacks of 2001) or to the government administration (ie, the election of George W. Bush following Bill Clinton's term as president). The latter may have caused some in the black community, who are statistically more likely to be members of the Democratic Party, to feel a greater disenfranchisement from the US government.

Although other surveys have found that conspiracy theory beliefs are more common in men, we failed to identify statistically significant gender differences within any racial/ethnic group. However, this study is likely to have limited power to identify differences between genders that were not

large. Regarding issues of education and income, our results concur with other reports that show that lower income and education are related to belief in AIDS origin conspiracy theory.[14,15] Because we adjusted for differences in education and income among the racial/ethnic groups, we are confident that the increase in belief in AIDS origin conspiracy theory is likely related to racial/ethnic categorization and not to differences in income, education, or other factors between groups.

To date, despite the fact that "minorities, overrepresented in the HIV epidemic are underrepresented in HIV clinical trials,"[34] only one other study has investigated whether belief in AIDS conspiracy theories is related to participation in biomedical research.[31] This investigation, which explored racial/ethnic differences in knowledge of and willingness to participate in HIV vaccine trials, was a cross-sectional survey of a convenience sample of 220 students attending a community college in Atlanta, Georgia. Students were asked a series of questions regarding beliefs of AIDS, including "the AIDS epidemic was caused by a government conspiracy." Willingness to participate in an HIV vaccine trial was measured by asking respondents the following question: "After a researcher told me the details of an HIV vaccine clinical trial, I would enroll in one." In that study, 25% of blacks versus 12% of whites stated that AIDS was caused by a government conspiracy; willingness to participate in an HIV vaccine clinical trial did not differ by race and was not associated with belief that AIDS was caused by a government conspiracy. Our survey results are remarkably similar despite the difference in sampling methods used. Even though we also identified a widespread belief that AIDS is "the result of a government plan to intentionally kill a certain group of people by genocide," the expressed likelihood of participation and fear of participation were not consistently associated with belief in AIDS origin conspiracy theory in blacks; in whites, only the expressed likelihood of participation was related to this belief. That earlier study, however, did not include Hispanics and included respondents drawn from a narrow segment of the population (community college students in a southern American city).

We found that among whites, the belief that AIDS is "the result of a government plan to intentionally kill a certain group of people by genocide" was directly related to fear of participation in biomedical research. Again, it is possible that because in each survey more participants were white, we had greater power to sense an effect of belief in AIDS origin conspiracy theory. The overall goal of the TLP, however, was to determine whether there is a greater reluctance to participate in biomedical studies among minorities as compared with whites and, if so, to explore the factors that might account for that observed difference. Attainment of this goal is critical to ensure that the findings from biomedical studies provide health data on the diverse populations of the United States, to assist biomedical researchers in achieving compliance with current 1994 National Institutes of Health (NIH) Guidelines for the Inclusion of Women and Minorities in Clinical Studies, and to provide empirical suggestions for intervention studies on enlisting minorities into biomedical studies including clinical trials.

Identification of barriers to recruitment of racial and ethnic minorities is an essential step in creating greater ethnic/racial balance in biomedical research studies. It appears that the belief that AIDS origin conspiracy theory is widely held among racial and ethnic minority groups, but this belief does not, according to our results, appear to be related to self-reported willingness to participate in biomedical research in these population subgroups. Indeed, we found such a relationship in whites but not in either of the 2 minority groups. Although this study had greater power to detect differences among whites because of a greater number of white participants in both the 1999 and the 2003 TLP surveys, differences in the GPFF and LOP scales among blacks and Hispanics were small and unlikely to be of clinical significance. Indeed, major advantages of this survey were its focus on comparisons among racial/ethnic groups and, along with its carefully worded and extensively tested questionnaire, its sampling methodology and large sample size.

As in any telephone survey, we are unable to make conclusions about persons who chose not to respond. It is possible that those who did not respond to our questionnaire were no different from those who responded. However, it is possible that response bias may have an effect on our absolute numbers, for example, the proportion in each group might have been lower or higher than reported. However, we believe it is unlikely that persons from various racial/ethnic groups would

have refused differentially to take part in the study, and therefore we believe the effect of nonresponse bias in the interpretation of the degree of differences across the groups is of only minor concern.

CONCLUSIONS

We found that blacks and Hispanics were more than 3 times as likely as whites to be believers in this AIDS origin conspiracy theory but that holding such a belief was not associated with a decreased likelihood of participation in, or increased fear of participation in, biomedical research.

Evidence-Based Medicine (EBM) serves at least two major communities – those teaching and studying evidence-based medicine (EBM) itself (and producing evidence), and those consuming evidence to improve patient care. Two recent developments of interest to both audiences are worth noting.

First, on 1 and 2 November, 2010, the *British Medical Journal (BMJ)* Evidence Centre and the Centre for Evidence-Based Medicine, Oxford University held an international conference ('evidence2010 Transforming Healthcare') in London. Although this was not a conference of a particular professional society nor was it an annual event (though it may be in the future), the conference was well-attended by a wide range of evidence producers and consumers from around the world. As a whole the participants had refreshing views about evidence-based medicine (EBM). They were neither 'for it' nor 'against it.' They understood that evidence-based medicine (EBM) was complex, has its place, has promised much and has delivered on much of that promise, but also faces many challenges, particularly in the area of how best to apply evidence in practice.

Many of the discussions were quite memorable, and I will mention only a few here (also see http://www.evidence2010.com). The editors of the *Lancet* and *BMJ* spoke, and debated, the future of medical publishing. One prediction was the greater accessibility of medical evidence, particularly online. That future, along with greater registration of clinical trials, will be welcome, because as was pointed out by another speaker, systematic reviews can be misleading when studies are done but never published. Victor Montori discussed the complicated work of being a patient with several chronic diseases and the challenges of applying evidence for specific diseases and interventions when caring for such patients. Although there was much discussion about how evidence is often not translated into practice, Bill Summerskill, when talking about a study that eventually leads to practice change, said "you may never actually be sure when that seed is planted and when it blossoms." That observation is one for implementation researchers to confirm and learn from. I cannot convey the genuine excitement that was evident among conference participants that they were taking part in an important event in the history of evidence-based medicine (EBM).

The other activity relevant for evidence-based medicine (EBM) as a field is the establishment of an international organisation called the International Society for Evidence-based Health Care. The mission is to develop and encourage research in evidence-based healthcare and to promote and provide professional and public education in the field. The society published its first newsletter (available at http://ebm.mcmaster.ca/), and it plans to hold meetings and disseminate evidence-based healthcare education via workshops and educational materials, and to promote research. It will no doubt be of interest to see how the society coalesces and finds its place in the world of professional societies.

To me, these developments indicate that despite, or perhaps because of the many challenges faced by evidence-based medicine (EBM) practitioners, teachers and researchers, evidence-based medicine (EBM) is alive, well and even thriving. I expect *EBM* (the journal) will continue to serve this community well, and I welcome input from you on how it can best do so.

Russia and human immunodeficiency virus—beyond crime and punishment

Russia faces formidable challenges in the second decade of its major human immunodeficiency virus (HIV) epidemic. Although Russian public health and medical responses are growing, they remain inadequate for the current crisis. HIV prevention lessons can be learnt by Russia from mistakes and innovations of the early epidemic in the United States, western Europe and Australia.

The human immunodeficiency virus (HIV) epidemic in Russia has been driven by injection drug use. The dire consequences of this epidemic in Russia reflect their public health and medical care approach to both HIV infection and drug users. Many of the mistakes that were made in the United States in the first two decades of the acquired immune deficiency syndrome (AIDS) epidemic with regard to HIV infection and drug users are being repeated in Russia at a comparable time-period in the disease's evolution in that country. Criticism has been leveled at Russia for its lack of adherence to the World Health Organization's recommendations for preventing HIV in drug users [1–3]. Two decades of additional experience with HIV among drug users in other countries may provide insight to advance successes and mitigate failures in Russia's second decade of the HIV epidemic.

Russia has approximately 1 million HIV-infected people among its 140 million population [4]. Eighty-three per cent have a history of injection drug use and most of the remainder are sexual partners of injection drug users (IDUs) [4]. The estimated HIV incidence rate among IDUs in St Petersburg is 14.1 per 100 person-years [5]. Simply stated, the HIV epidemic is not under control. Given that 1.8 million IDUs currently live in Russia [2], and that condom use by Russian drug users is not the norm [6], there is great risk for further expansion of the epidemic.

In the United States and Europe, the clinical syndrome that became known as AIDS resulting from HIV infection was spreading actively among IDUs during the late 1970s and early 1980s. It was not a problem in Russia at that time. HIV only began to spread among IDUs analogously in Russia in epidemic proportions two decades later, in the late 1990s and at beginning of the new millennium [7].

During the first two decades of the AIDS epidemic, mistakes were made in the United States and some other countries with regard to the public health and medical response; hence, HIV seroprevalence in IDUs was high, ranging from 22% to more than 50% [8]. Exceptions to this trend exist, most notably in Australia with an HIV seroprevalence rate among IDUs of 1% [9]. This is due largely to that country's aggressive adoption of harm reduction measures, such as syringe exchange and opioid agonist therapy (OAT) programs, as early as the mid-1980s. In the United States, distribution of clean needles and syringes to IDUs was shunned by government officials with disastrous consequences. Addiction treatment and OAT, essentially methadone, existed but were not actively expanded and improved in order to confront the epidemic directly (e.g. routine implementation of HIV testing within methadone programs was not instituted initially). More than a decade after the onset of the US/western European AIDS epidemic, while advancements were being achieved in elucidating viral etiology and developing effective antiretroviral medications, researchers reported that an infected person's entry into HIV care was commonly not occurring until the disease had become advanced [10,11]. Active efforts to engage HIV-infected people and, in particular, HIV-infected drug and alcohol users, were inadequate and not a high priority on the HIV activists or researchers' agenda.

Today in Russia, two of the most glaring policy mistakes from a public health perspective are the absence of OAT and the suboptimal distribution of clean needles and syringes [1]. Without a doubt, these measures have proved themselves immensely valuable in limiting the spread of infection even in the face of ongoing drug use. Needle availability from pharmacies in much of Russia is a step in the right direction, but insufficient to meet the needs of HIV prevention efforts.

One very positive dimension of HIV prevention among drug users in Russia is the comprehensive 'opt-out' strategy for HIV testing that has long existed in many spheres, particularly within the narcology treatment system [12]. Such a phenomenon differs sharply with the approach that existed in a comparable period in the United States, during which unawareness of HIV status was the major factor underlying the years of delay between HIV infection and entry into medical care [13].

Despite these testing policies, HIV-infected IDUs in Russia are not receiving care at acceptable rates. Although drug use accounts for more than 80% of Russian HIV infections, IDUs comprise fewer than half of those receiving HIV care [14]. In fact, Russia is among the countries with the lowest antiretroviral therapy (ART) coverage for those with advanced HIV [4].

One source of delay into medical care for those with HIV infection is the time between awareness of HIV infection and engaging with HIV medical care [15]. This is a poorly documented but suspected problem faced by many HIV-infected drug users in Russia in 2011. While IDUs face barriers to HIV care such as stigma, discrimination, addiction-related priorities, providers' pessimistic perceptions regarding adherence and unstable living situations [16,17], the problem is also structural. Although the HIV care system is evolving with introduction of narcologists into some AIDS treatment centers, coordination of narcology and HIV care remains unaddressed. Medical care in Russia is provided within silos of excellence with specific expertise. In a narcology hospital, addiction is addressed. In an infectious disease hospital, infections such as HIV and hepatitis B and C are treated. However, coordination of care between different physical sites of care is exceedingly limited, and yet patients who suffer from both maladies, addiction and HIV, are common in Russia. Those affected do not benefit from the expertise of providers of both disciplines giving coordinated medical care. Such fragmented systems of care have been shown to worsen access to HIV treatment [18]. It is time to actively facilitate thousands of infected Russian substance users into HIV care; with appropriate systems established, many could transition directly from narcology treatment.

Russia's long-standing excellent record of HIV testing is a bright light within the country's strategic plan to address HIV infection, but it is not sufficient. Innovative strategies need to be employed to engage individuals into the HIV care system. What will it take to engage HIV-infected drug users into care? Here, lessons from those countries with the unfortunate additional two decades of history addressing HIV among drug users could be informative.

Enhanced engagement of drug users into HIV care will be advanced by addressing five major challenges: reducing stigma towards drug users and the HIV-infected; developing protocols to facilitate transitions and coordination between HIV and narcology treatment systems; developing multiple points of entry for individuals into HIV and addiction care; expanding needle and syringe exchanges; and adopting OAT to treat opioid dependence with pharmacological agents. Engagement will enable efforts to achieve effective delivery of antiretroviral treatment to drug users. Engagement will also provide opportunities to mitigate sexual risk behaviors and its consequences among drug users, a high priority as the epidemic spreads from IDUs to the general Russian population [4]. Such efforts could focus on unsafe sex behaviors [19] and treatment of sexually transmitted diseases.

In the first two decades of the HIV epidemic in the United States, many missed opportunities to confront this disease effectively among drug users occurred. Bringing that experience to bear in a very different and yet not so different context holds opportunity to help transform the raging Russian HIV epidemic into one that employs the best strategies to engage reluctant patients in medical care and reduce the spread and consequences of this 21st-century Russian scourge.

The Impact of a Novel Computer-Based Decision Aid on Shared Decision Making for Colorectal Cancer Screening: A Randomized Trial

Paul C. Schroy III, MD, MPH, Karen Emmons, PhD, Ellen Peters, PhD, Julie T. Glick, MPH, Patricia A. Robinson, MEd, Maria A. Lydotes, BS, Shamini Mylvanaman, MPH, Stephen Evans, MPH, Christine Chaisson, MPH, Michael Pignone, MD, MPH, Marianne Prout, MD, MPH, Peter Davidson, MD, Timothy C. Heeren, PhD

Background. *Eliciting patients' preferences within a framework of shared decision making (SDM) has been advocated as a strategy for increasing colorectal cancer (CRC) screening adherence. Our objective was to assess the effectiveness of a novel decision aid on SDM in the primary care setting.* ***Methods.*** *An interactive, computer-based decision aid for CRC screening was developed and evaluated within the context of a randomized controlled trial. A total of 665 average-risk patients (mean age, 57 years; 60% female; 63% black, 6% Hispanic) were allocated to 1 of 2 intervention arms (decision aid alone, decision aid plus personalized risk assessment) or a control arm. The interventions were delivered just prior to a scheduled primary care visit. Outcome measures (patient preferences, knowledge, satisfaction with the decision-making process [SDMP], concordance between patient preference and test ordered, and intentions) were evaluated using prestudy/poststudy visit questionnaires and electronic scheduling.* ***Results.*** *Overall, 95% of patients in the intervention arms identified a preferred screening option based on values placed on individual test features. Mean cumulative knowledge, SDMP, and intention scores were significantly higher for both intervention groups compared with the control group. Concordance between patient preference and test ordered was 59%. Patients who preferred colonoscopy were more likely to have a test ordered than those who preferred an alternative option (83% v. 70%;* $P < 0.01$*). Intention scores were significantly higher when the test ordered reflected patient preferences.* ***Conclusions.*** *Our interactive computer-based decision aid facilitates SDM, but overall effectiveness is determined by the extent to which providers comply with patient preferences.* ***Key words:*** *preferences and quality of life; clinical prediction rules; risk stratification; decision aids; patient decision making; provider decision making; physician-patient communication; shared decision making.* ***(Med Decis Making 2011;31:93–107)***

DOI: 10.1177/0272989X10369007

Colorectal cancer (CRC) is the second leading cause of cancer-related death and the third most commonly diagnosed cancer among men and women in the United States. Screening has been shown to be a cost-effective strategy for reducing both CRC mortality and incidence[1] and is now widely endorsed by most authoritative groups.[2,3] Despite this endorsement, however, screening rates remain relatively low, partly due to poor patient acceptance and adherence. Data from the 2005 National Health Interview Survey suggest that while screening rates have improved, approximately 50% of eligible Americans have not had appropriate screening.[4]

Shared decision making (SDM) has been advocated as a potentially effective strategy for

increasing patient acceptance and adherence to CRC screening recommendations.[2,3] CRC screening is ideally suited for this approach given the availability of multiple strategies with distinct advantages and disadvantages, the lack of consensus regarding an optimal strategy, and historical ineffectiveness of the more traditional paternalistic approach in which providers assume full responsibility for the decision-making process. Further support is derived from studies that find that patients have distinct preferences for the different screening strategies,[5–18] that providers often misperceive patient preferences,[9] and that many patients support the SDM approach for CRC screening.[16]

SDM is an interactive process in which patients and their health care providers form a partnership to exchange information, clarify values, and negotiate a mutually agreeable medical decision.[19,20] Unfortunately, SDM has been difficult to implement into routine clinical practice in part due to lack of time, lack of clinician expertise, and lack of resources.[21] To circumvent several of these barriers, decision aids have been developed to facilitate informed decision making (IDM) outside of the clinical encounter.[22] IDM is a process in which patients receive sufficient information about the risks, benefits, limitations, alternatives, and uncertainties of a clinical condition or disease to make a value-concordant decision and participate in the decision-making process at a desired level.[23,24] Thus, it is not as collaborative with the provider as SDM but still includes a key element of patient empowerment. As with any decision aid, decision aids for CRC screening should provide, at a minimum, sufficient information about the pros and cons of the recommended options to enable users to identify a value-concordant preferred option.[25] Besides facilitating IDM, decision aids also have the potential to facilitate SDM by improving the quality and efficiency of the patient-provider encounter and by empowering users to participate in the decision-making process.[25] Alternatively, enabling patients to identify a preferred screening option outside of the clinical encounter could have a detrimental effect on the decision-making process in situations where patient and provider preferences differ by inducing decisional conflict and/or dissatisfaction with the provider recommendation.

Studies to date have clearly demonstrated that existing decision aids for CRC screening enable users to identify a preferred screening option,[6–9,12,13,15–18,26] reduce decisional conflict,[26] and increase interest in screening.[8,10,13,15] The extent to which decision aids facilitate effective SDM and increase adherence, which are of critical importance to the utility of such tools in clinical practice, however, is less well established. To address the former shortcoming, we report herein the interim results of a randomized controlled clinical trial aimed partly at evaluating the impact of a novel, interactive computer-based decision aid on relevant measures of SDM, including patient knowledge, patient preferences, satisfaction with the decision-making process, concordance between patient preference and test ordered, and screening intentions.

METHODS

Decision Aid Development, Format, and Usability Testing

Development of our decision aid was guided by constructs of the Ottawa Decision Support Framework.[27,28] The actual content of the tool was derived from systematic reviews of available evidence on the cost-effectiveness and attributes of the different screening strategies,[1,29,30] a systematic review of existing decision aids,[25] and expert opinion. We also conducted a series of focus groups of racially/ethnically diverse previously screened men (n = 7), previously screened women (n = 10), unscreened men (n = 5), and unscreened women (n = 9) recruited from a convenience sample of primary care patients seen at the target sites to determine key factors (e.g., knowledge, attitudes, beliefs, literacy, numeracy, etc.) that needed to be incorporated in the tool.

The prototype version of the decision aid was built using Web-based technology but initially formatted for DVD use on portable computer stations to provide maximum flexibility for use in the ambulatory care setting during the clinical trial. The decision aid uses an audiovisual and touch-screen format to simplify use for individuals with limited literacy and/or computer skills. It is comprised of a series of modules in which professional actors playing the role of a black, Hispanic female moderator and a white, non-Hispanic male physician convey relevant information via on-screen video, animation, and/or graphics. The modules (Figure 1) include 1) an introductory segment that briefly discusses the importance of screening, intended purpose of the tool, and instructions in its use; 2) an overview of the epidemiology of CRC, natural history, rationale for screening, benefits of screening, the availability of multiple screening options, and

the lack of consensus regarding a best screening method; 3) brief descriptions of the 5 recommended screening methods (fecal occult blood testing [FOBT], flexible sigmoidoscopy, the combination of FOBT plus flexible sigmoidoscopy, double-contrast barium enema, and colonoscopy) endorsed by the American Cancer Society, US Preventive Services Task Force, and GI Multi-Society Task Force on Colorectal Cancer at the time[2,3]; 4) audio and visual (i.e., traffic light graphic) comparisons of each screening method with respect to individual test-features including accuracy, inconvenience, discomfort, recommended frequency of testing, complications, and need (or lack thereof) for further diagnostic studies if the screening test result is positive; 5) a summary of the different test features for each screening strategy with optional links to more detailed information about the preparation or test itself, as well as vignettes from a racially diverse group of patients describing their experience with a particular test; 6) a decision-making module in which users are asked to identify a screening preference or lack thereof, using the discrete choice method, rank order test features influencing their selection, and assess whether out-of-pocket payments (if not covered) would alter their choice; and 7) a concluding segment in which the narrator encourages the user to discuss screening and their screening preferences with their doctor, acknowledging that the best CRC screening test is the test that gets done. Users can navigate forward or backward through the tool using either the touch screen or a mouse; they also have the option of repeating segments and printing out key information. Once developed, the tool was reviewed by the Massachusetts Department of Public Health's Colorectal Cancer Working Group for content validity and cultural sensitivity.

A modified version of the decision aid was also created, which includes the Web-based ''Your Disease Risk'' (YDR) CRC risk assessment tool (http://www.yourdiseaserisk.wustl.edu). The risk assessment tool was placed just after the introductory segment. The intent of the tool was to assess the extent to which personalized risk estimates influenced decision making. Based on the available literature at the time,[31] we postulated that personalized risk information might positively influence adherence among patients deemed to be at above-average risk.

Usability testing was performed prior to its implementation, in accordance with recommendations by Nielsen,[32,33] to assess ease of learning, efficiency of use, and user satisfaction. Based on observational data and feedback from 2 rounds of testing with 5 different users per test, the prototype was revised to enhance functionality and deemed ready for clinical use without further testing.

Study Design

A randomized controlled trial was initiated in April 2005 to evaluate the impact of our decision aid on SDM and patient adherence to CRC screening recommendations. Eligible patients were instructed to arrive 1 hour before a prearranged office visit with their primary care provider. After obtaining informed consent, patients were administered a pretest comprised of 28 close-ended questions that assessed knowledge, beliefs, attitudes, and behaviors related to CRC screening, as well as level of desire for participating in decision making related to CRC screening.[34] The pretest was administered by 1 of 3 trained research assistants in a private office located in one of the ambulatory care clinics at Boston Medical Center or the South Boston Community Health Center. After completing the pretest, patients were randomized to 1 of 2 intervention arms (decision aid plus YDR personalized risk assessment tool with feedback or decision aid alone) or a control arm after stratification by provider. Patients randomized to the control arm reviewed a modified version of ''9 Ways to Stay Healthy and Prevent Disease,'' previously posted on the Harvard Center for Cancer Prevention Web site, which discussed generic lifestyle changes other than screening for minimizing risk of preventable diseases. After completing the interactive computer session, patients then met with their providers to discuss screening and identify a preferred screening strategy. Providers received written notification in the form of a flyer hand delivered by the patient acknowledging that the patient was participating in the ''CRC decision aid'' study at the time of the visit to ensure that screening was discussed; no information was provided about preferences or factors influencing choice for patients in the intervention arm. Before leaving the clinic, subjects were administered a posttest, which assessed whether CRC screening was discussed, whether a screening strategy was chosen, patient satisfaction with the decision-making process, and screening intentions; the posttest also reassessed knowledge, beliefs, and attitudes related to CRC screening.

Setting

The study was conducted at 2 urban ambulatory care sites. The first, Boston Medical Center, is

Figure 1 Decision aid. Representative screens from the different segments of the tool including the introductory module (A); overview of colorectal cancer and colorectal screening (B); brief descriptions of each screening option (C); list of test features discussed (D); comparisons of screening options with respect to individual test features (E); summaries of attributes for each option with links to more detailed information about the preparation, procedure itself, and patient testimonials (F); and the decision-making module, where users are asked to identify a preferred option (G) and rank order test features influencing choice (H). One version of the tool also includes the ''Your Disease Risk'' risk assessment tool, which calculates personalized 10-year estimates for developing colorectal cancer (I).

a private, nonprofit academic medical center affiliated with the Boston University School of Medicine, which serves a mostly minority patient population (only 28% white, non-Hispanic). The second, the South Boston Community Health Center, is a community health center affiliated with Boston Medical Center, which serves a mostly white, non-Hispanic, low-income patient population. Both sites use the same electronic medical record system (Logician Centricity™, General Electric Company). The study protocols were approved by the Boston University Medical Campus Institutional Review Board, which was responsible for overseeing human studies research at both participating institutions.

Study Population and Recruitment Process

The study sample was comprised of average-risk patients under the care of one of the primary care providers at Boston Medical Center or the South Boston Community Health Center. Patients were deemed eligible if they were 50 to 75 years of age and had no

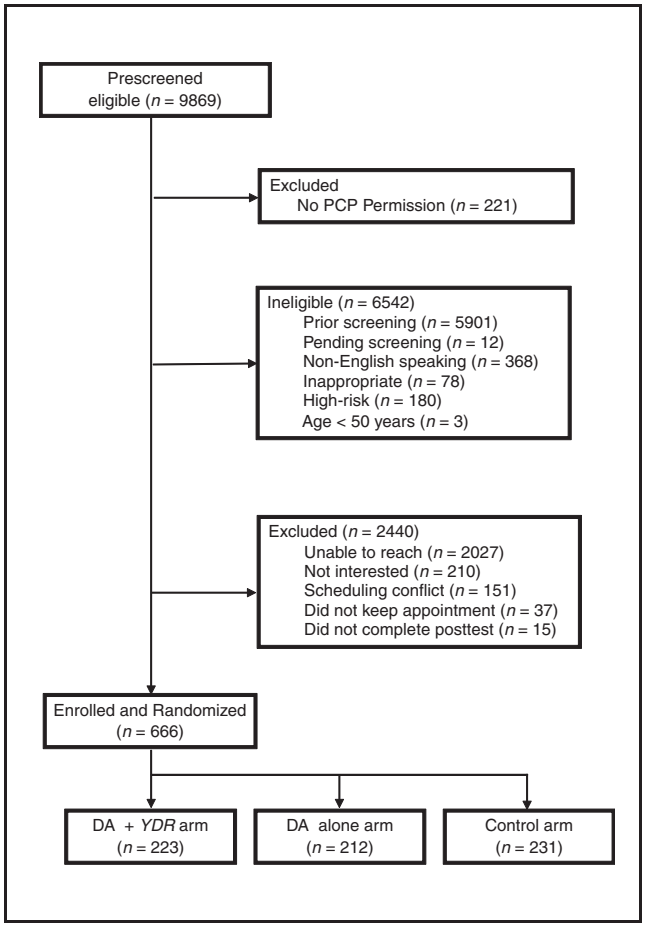

Figure 2 Study flow diagram. DA = decision aid; YDR = ''Your Disease Risk'' risk assessment tool.

prior structural CRC screening examinations. Potential subjects meeting any of the following criteria were excluded: 1) prior CRC screening by any method other than FOBT; 2) high-risk condition (personal history of colorectal cancer or polyps, family history of colorectal cancer or polyps involving one or more first-degree relatives, or chronic inflammatory bowel disease); 3) lack of fluency in written and spoken English; or 4) comorbidities that preclude CRC screening by any recommended method.

Three different recruitment strategies were used during the course of the study. The vast majority of patients ($N = 637$) were recruited using an investigator-initiated ''opt-out'' approach in which patients due for screening were identified from monthly audits of Boston Medical Center's electronic medical record 2 to 4 weeks prior to a scheduled office visit and contacted directly by telephone by one of the research assistants if deemed appropriate by the patient's primary care provider. Those expressing interest were provided with a brief overview of the study, evaluated for eligibility, and invited to participate using a passive informed consent process. Two other strategies, including a provider-initiated, ''opt-in'' electronic flagging approach ($N = 12$) and a provider-mediated, ''out-in'' letter approach ($N = 17$), were used initially but discontinued after 6 months due to low enrollment. As opposed to the ''opt-out'' investigator approach whereby potential subjects could decline to be recruited after being contacted by the research team without prior permission, the ''opt-in'' approach required that potential subjects grant permission to be contacted from the onset, and a nonresponse prohibited further communication. The relative cost-effectiveness of each of our approaches has recently been published.[35]

Provider Characteristics and Training

Fifty full-time primary care providers, including 47 board-certified general internists and 3 nurse practitioners, practicing at both Boston Medical Center and the South Boston Community Health Center participated in the study. A pretrial survey of 30 participating providers indicated that virtually all (97%) preferred a SDM approach when selecting an appropriate screening strategy for their patients. Pretrial seminars were conducted at both sites to educate providers about the current status of CRC screening, highlighting the recommendation for SDM, to provide an overview of the study design, and to elicit support. Because of provider turnover, brief annual meetings were also conducted to ensure that new providers were aware of the study, understood its design, and expressed a willingness to participate. The meetings also provided a venue for informing participating providers about the status of recruitment and addressing any logistical problems that they were experiencing related to the study. No formal training in SDM was undertaken.

Outcome Measures

The key outcome measures of interest for assessing the impact of our decision aid on SDM were patient knowledge, patient preferences, satisfaction with the decision-making process, screening

intentions, and test concordance (i.e., agreement between patient preference and test ordered).

Knowledge was assessed at baseline (pretest) and at the time of the exit survey (posttest) based on responses to a 12-item questionnaire (True/False/Don't know) that inquired about CRC risk factors, the rationale and goals of screening, and age at which screening should begin (see Appendix 1 for individual questions). The content was derived from key messages endorsed by the National Colorectal Cancer Roundtable[36] and the Massachusetts Department of Public Health[37] for public education. Cumulative knowledge scores (range, 0–12) were derived by summing correct responses to the 12 individual knowledge questions.

Patient preferences and factors influencing choice of options were obtained from response data captured electronically in the decision aid's decision-making module.

Patient satisfaction with the decision-making process was assessed on the posttest using the validated 12-item Satisfaction with the Decision-Making Process Scale (Appendix 2),[38] which has excellent reliability (Cronbach $\alpha = 0.85$) and discriminant validity. Five ordered response categories were used for each item. Each response was assigned a point score ranging from 1 for ''strongly disagree'' (or ''poor'') to 5 for ''strongly agree'' (or ''excellent''). A cumulative score was calculated based on the summed response scores for each item (maximum score = 60). Mean item substitution was used to impute missing data for patients answering between 8 and 11 items; patients answering fewer than 8 items were excluded from analysis.

Screening intentions were also assessed as part of the posttest. Subjects were asked how sure they were that they would schedule an appointment to get screened for CRC and how sure they were that they would complete the screening test they scheduled. An ordered 5-point response frame was used ranging from ''not at all sure'' to ''completely sure.''

Concordance between patient preferences and test ordered was assessed for the 2 intervention groups only because preferences were not elicited from the control group. Test ordered was ascertained from the ''Orders'' section of the electronic medical record. Concordance was defined as the percentage of patients who had their preferred screening test ordered.

Statistical Analyses

Based on crude estimates of baseline adherence, we calculated that a target sample of 825 patients provided 80% power of detecting a 54% versus 40% pair-wise difference in the percentage of patients completing a CRC screening, using a Bonferroni adjustment to overall α level of 0.05 to account for the 3-group study design.

As a check on randomization, the 3 study groups were compared on demographic characteristics, prior screening, and desired role in decision making through the χ^2 test of independence. The 3 study groups were also compared on cumulative pretest and posttest knowledge scores, satisfaction with the decision-making process (SDMP) scores, and intention scores through separate 1-factor analysis of covariance (ANCOVA); Bonferroni-adjusted multiple comparison procedure was used to investigate pair-wise differences following a significant 3-group comparison. ANCOVA was also used for subgroup analyses comparing SDMP scores across the 3 study groups after stratification by desired role in decision making (mostly patient, shared, and mostly provider). For the SDMP analyses, mean item substitution was used to impute missing data for patients who answered at least 8 items. To evaluate the possible bias of this approach, we employed multiple imputation analysis to generate 5 data sets using the expectation-maximization (EM) algorithm and found that the results agreed closely with those derived using mean item substitution. Differences between study groups on adjusted means from the ANCOVA are described through effect sizes (d) calculated as the difference in adjusted means divided by the pooled standard deviation estimate from the ANCOVA. Descriptive statistics were used to describe patient preferences for the 5 screening test options and factors influencing choice; associations between demographic characteristics and patient preferences (colonoscopy v. FOBT) were examined through a series of multiple logistic regressions. Test concordance, that is, the association between patient preference and test ordered, was examined through the χ^2 test of independence. Associations between test concordance and desired role in decision making were tested through the χ^2 test of independence, whereas associations between test concordance and both SDMP and intention scores were compared through the independent sample t tests. We controlled for study site (Boston Medical Center and South Boston Community Health Center) in the analyses of all outcome measures, using ANCOVA regression models for measurement outcomes and Cochran-Mantel-Haenszel analyses or logistic regression analyses for categorical outcomes. Data are expressed as mean [standard deviation], unless otherwise stated. P values less than 0.05 were deemed significant.

Table 1 Characteristics of Study Participants ($N = 666$)

Characteristic	DA + YCR ($n = 223$)	DA Alone ($n = 212$)	Control ($n = 231$)	P Value

RESULTS

Patient Characteristics

Of the 9648 patients identified as potentially eligible for screening (aged 50–75 years) for whom permission to contact was granted, 6542 (68%) were deemed ineligible (mostly due to prior screening), and 2440 (25%) were excluded. Reasons for exclusion were inability to contact ($n = 2027$), disinterest ($n = 210$), scheduling conflict ($n = 151$), failure to keep appointment ($n = 37$), or failure to complete posttest ($n = 15$) (Figure 2). The remaining 666 patients (62% of eligible subjects contacted) were enrolled and randomized to the decision aid plus ''Your Disease Risk'' (YDR) arm ($n = 223$), decision aid alone arm ($n = 212$), or control arm ($n = 231$).

As shown in Table 1, the 3 study arms were well balanced with respect to patient age, sex, race, ethnicity, education, prior FOBT, insurance status, and decision-making preference. Overall, the study group was predominantly less than 65 years of age, female, non-Hispanic, and black with at least a high school degree. Although most had some form of health care insurance, nearly two thirds were covered by Medicare, Medicaid, or the Massachusetts' ''free care'' program. Most had no prior experience with FOBT. Importantly, the majority preferred a patient-dominant (28%) or SDM approach (53%) for selecting a preferred CRC screening option.

Knowledge

Mean [standard deviation] cumulative pretest knowledge scores were comparable ($P = 0.91$) for the 3 groups (decision aid plus YDR, 7.6 [2.8]; decision aid alone, 7.7 [2.9]; control, 7.5 [2.7]). Cumulative posttest scores, however, were significantly higher

($P < 0.001$) for the 2 intervention groups (decision aid plus YDR, 10.7 [1.8]; decision aid alone, 10.9 [1.6]) compared with the control group (8.6 [2.7]), with differences corresponding to large effect sizes of $d = 1.15$ and $d = 1.27$ for the decision aid plus YDR group and decision aid alone group versus control, respectively. The mean increase in scores from pretest to posttest was also significant ($P < 0.001$) for both intervention groups (decision aid plus YDR, 3.0 [2.5]; decision aid alone, 3.2 [2.6]) but not the control group (0.8 [2.2]). There were no significant differences in cumulative posttest scores or change in scores between the 2 intervention groups.

Patient Preferences and Factors Influencing Choice

Screening test preferences for patients randomized to the 2 intervention arms are depicted in Table 2. Colonoscopy was preferred by a majority of patients (59%), followed by FOBT (26%), flexible sigmoidoscopy (5%), double-contrast barium enema (4%), and FOBT plus flexible sigmoidoscopy (3%); only 3% either declined testing or could not identify a preferred option. No significant differences were observed between the 2 intervention groups. Patients who chose colonoscopy were most likely to identify test accuracy (81%) as the most important feature influencing their choice; in contrast, patients who chose FOBT were most likely to identify concerns about discomfort (31%), inconvenience (23%), and bowel preparation (18%) as the most influential features. Logistic regression analysis found no significant independent associations between demographic factors (age, sex, race, ethnicity, education, insurance status, or study site) and preference for colonoscopy versus FOBT (data not shown).

Satisfaction with the Decision-Making Process (SDMP)

Overall, 636 subjects (96% overall) responded to ≥ 8 items of the SDMP scale and were included in the analysis; there were no significant differences in the percentage of patients answering all 12 items versus 8 to 11 items versus < 8 items (excluded) across the 3 study groups ($P = 0.31$). As shown in Table 3, mean SDMP scores were significantly higher for the 2 intervention arms compared to controls, with differences corresponding to moderate effect sizes of 0.53 and 0.61 for the decision aid plus YDR and decision aid alone groups versus control, respectively. Scores for the 2 intervention groups were comparable. Subgroup analysis found that satisfaction was also higher among intervention patients who preferred a shared or patient-dominant role in decision making; a similar trend was observed for patients who preferred a provider-dominant approach, but the differences between the intervention and control groups did not achieve statistical significance.

Table 3 Satisfaction with the Decision-Making Process (SDMP) Scores

	DA + YDR	DA Alone	Control	*P* Value
Overall	50.5 (6.2) *n* = 214	50.7 (6.2) *n* = 205	46.7 (7.9) (*n* =217)	<0.001[a]
Decision-making preference				
Mostly patient	49.4 (6.2) *n* = 58	50.2 (6.5) *n* = 50	46.0 (8.3) *n* = 66	0.01[a]
Shared	50.8 (6.4) *n* = 115	50.6 (6.3) *n* = 116	46.6 (7.9) *n* = 108	<0.001[a]
Mostly provider	51.4 (5.4) *n* = 41	51.5 (5.3) *n* = 39	49.0 (6.7) *n* = 43	0.06

Note: DA = decision aid; YDR = ''Your Disease Risk''. Data expressed as mean (standard deviation); maximum score = 60.
a. One-factor ANCOVA showed a significant difference in satisfaction between the 3 study groups, with pair-wise comparisons showing no significant differences between the 2 intervention groups and significantly lower satisfaction for those in the control group overall and after stratification by decision-making preference.

Intentions

Mean intention scores [standard deviation] were significantly higher ($P < 0.001$) for the 2 intervention groups (decision aid plus YDR, 4.3 [1.0]; decision aid alone, 4.4 [1.0]) compared to the control group (3.9 [1.4]) when asked ''How sure are you that you will schedule a colorectal cancer screening test?'' Mean intention scores were also significantly higher ($P < 0.001$) for the 2 intervention groups (both 4.3 [1.0]) compared to controls (3.9 [1.3]) when asked ''How sure are you that you will complete a colorectal cancer screening test?'' Differences in intention to schedule or complete a screening test for the 2 intervention groups versus control correspond to moderate effect sizes ranging between 0.36 and 0.44. Scores were comparable for the 2 intervention groups.

Concordance between Patient Preference and Test Ordered

Concordance between preference and test ordered is shown in Table 4. Among the 415 patients expressing a preference, 244 (59%) had their preferred test ordered, 79 (19%) had an alternate test ordered (colonoscopy, 85%; FOBT, 14%; flexible sigmoidoscopy, 1%), and 92 (22%) had no test ordered. For individual tests, concordance between patient preference and test ordered varied from 79% for colonoscopy to $\leq$30% for all other options. For the discordant group, virtually everyone (96%) who preferred a test other than colonoscopy had a colonoscopy ordered. Patients who preferred colonoscopy were more likely to have any test ordered than those who preferred a test other than colonoscopy (83% v. 70%; $P < 0.002$).

As shown in Table 5, there was no association between concordance and desired role in decision making, demonstrating that patients who preferred a patient-dominant or SDM style were no more likely to have a concordant test ordered than those who preferred a provider-dominant style. There was also no significant association between SDMP scores and concordance. Importantly, however, intention scores were significantly higher when there was concordance between patient preference and test ordered compared to when they differed. The positive associations between test concordance and screening intentions replicated significantly within the independent test preference groups (colonoscopy and ''other'').

Overall, patients in the intervention arms were more likely to have a test ordered than patients in the control arm (75% v. 68%; $P < 0.05$), regardless of whether there was concordance or discordance with test preference (data not shown). Colonoscopy (82%) was the most commonly ordered test for control patients with any test ordered, followed by FOBT (12%) and flexible sigmoidoscopy (1%), thus affirming a strong provider preference for colonoscopy.

DISCUSSION

Most authoritative groups, including the US Preventive Services Task Force, American Cancer Society, US Multi-Society Task Force on Colorectal Cancer, and American College of Radiology,[2,3] endorse a SDM approach when selecting an

Table 4 Concordance between Patient Preference and Test Ordered (Intervention Groups Only[a])

b. ''Same'' infers that at least 1 of the 2 preferred tests was ordered.

appropriate CRC screening strategy, but implementation into clinical practice encounters many barriers.[21] The purpose of this study was to assess the extent to which use of a novel CRC screening decision aid circumvents some of these barriers and facilitates effective SDM in the primary care setting. Like similar such studies,[6–9,12,13,15–18,26] our study finds that the tool enables users to identify a preferred screening option based on the relative value they place on individual test features. Our study also finds that while users are more knowledgeable, more satisfied with the decision-making process, and more intent to undergo screening than nonusers overall, screening intentions and test ordering are negatively influenced in situations where patient and provider preferences differ, regardless of a patient's desired role in decision making. Together, these observations suggest that the utility of our decision aid for promoting effective SDM is dependent upon the extent to which providers are willing to comply with an informed patient's screening preferences. Importantly, however, screening intentions were still higher for discordant users than for nonusers, suggesting that use of the decision aid is nonetheless superior to nonuse.

A critical question that arises when interpreting these findings relates to whether our outcomes of interest are valid measures of effective SDM. As previously noted, SDM has been defined as a process in which both the patient and provider engage in information exchange, deliberation (value clarification), negotiation, and mutual decision making.[19,20] Accordingly, we opted to include patient knowledge, SDMP, concordance between patient preference and test ordered, and screening intentions as appropriate measures of SDM within the context of this conceptual framework.

The notion of information exchange implies that there was a reciprocal exchange of information between the patient and health care provider. Because the primary intent of our decision aid was to educate users about the rationale for screening and the pros and cons of the different screening options so as to make an informed choice about screening and test preference, our knowledge outcome is a more reliable measure of IDM than SDM. The finding that knowledge scores did not increase after the provider encounter for the control group, however, suggests that most providers failed to convey relevant information about the rationale for screening, risk factors, goals, and benefits when discussing CRC screening with their patients.

The SDMP outcome provides a useful measure of patient involvement in the decision-making process from the patient perspective. As with decision aids for other conditions,[25] our findings suggest that our tool also empowered users to participate in the decision-making process at a desired level, particularly those who preferred a shared or patient-dominant role in decision making. We speculate that our tool's format and inclusion of specific messages encouraging patients to take a proactive role in the decision-making process provided meaningful guidance in deliberation and/or communication.

Our concordance and intention outcomes are arguably the most relevant measures of ''effective'' SDM. Concordance provides a measure of the extent to which providers are willing to respect patient autonomy in the decision-making process and comply with patient preferences when selecting an appropriate screening test. Intention provides a measure of the degree to which the patient is committed to the chosen course of action and, in the case of SDM, provides perspective on the extent to which the final decision reflects successful negotiation and mutual agreement. Intention is also a powerful predictor of CRC screening adherence.[39,40] In this study, we found that concordance was high for colonoscopy but relatively low for the other options, suggesting that providers were much more likely to

Table 5 Association between Test Concordance and Desired Role in Decision-Making Preference, Satisfaction with Decision-Making Process, and Screening Intentions (Intervention Groups Only)

	Test Concordance[a]		
Outcome	**Same**	**Different**	***P* Value**
Desired role in decision making, *n* (%)			0.9[d]
Mostly patient	60 (75)	20 (25)	
Shared	138 (75)	45 (25)	
Mostly doctor	45 (75)	15 (25)	
SDMP score[b]	51.3 (6.4)	49.4 (5.8)	0.20[e]
	n = 241	*n* = 75	
Intention[c]			
Schedule test	4.6 (0.7)	4.2 (1.1)	<0.001[e]
	n = 241	*n* = 75	
Complete test	4.6 (0.7)	4.2 (1.1)	< 0.001[e]
	n = 243	*n* = 74	

Note: SDMP = satisfaction with the decision-making process.
a. Agreement between patient preference and test ordered.
b. Mean cumulative scores (standard deviation); maximum = 60.
c. Mean scores standard deviation, where 5 = ''very sure'' and 1 = ''very unsure.''
d. Cochran-Mantel-Haenszel χ^2 analyses controlling for site.
e. ANCOVA controlling for site.

comply with patient preferences that agreed with their own screening preferences. We also found that the likelihood of having the preferred test ordered was unaffected by the extent to which patients wished to engage in the decision-making process, suggesting that most providers either fail to assess their patients' desired level of participation or assume decisional authority, regardless of the preferred role. Perhaps most importantly, we found that when there was concordance between patient and provider preferences, patients had stronger screening intentions and a greater likelihood of having any screening test ordered compared to when patient and provider preferences differed. In the aggregate, these observations suggest that our decision aid facilitates effective SDM in settings where providers truly endorse a SDM approach and are willing to comply with patient preferences when selecting an appropriate screening test. In settings where providers feel compelled to endorse a single screening option, regardless of patients' desired level of participation in the decision-making process, use of the tool may compromise effectiveness, possibly due to enhanced decisional conflict and/or dissatisfaction with the process or decision itself.

One of the principal goals of both IDM and SDM for CRC screening is the elicitation of a value-concordant patient preference for one of the recommended screening tests. Our findings corroborate a body of evidence demonstrating that patients have distinct CRC screening test preferences that are influenced by the value they place on one or more test features.[5–18] As in our prior study,[16] we found that colonoscopy was preferred by a majority (59%) of intervention patients, most of whom identified test accuracy as the predominant reason for their selection; in contrast, most of the remaining patients (26%) preferred FOBT primarily because of concerns about discomfort, inconvenience, and bowel preparation. Both Hawley et al.[18] and Marshall et al.[17] also observed a dominant preference for colonoscopy compared to FOBT, flexible sigmoidoscopy, and barium enema. Although the surge in media campaigns promoting colonoscopy in recent years might explain this predilection for colonoscopy, a similar trend has not been reported in other recently published studies.[12–15] Differences in the study population, options discussed, framing, and methodologies used to elicit preferences may be important factors in accounting for these disparate results. Collectively, however, these findings support the rationale for eliciting patient preferences within the context of IDM and/or SDM.

Our study also provides new evidence suggesting that providers also have a dominant preference for colonoscopy. Using test ordered as a proxy for provider preference, we found that providers referred the majority (~82%) of control patients for colonoscopy and that providers were unlikely to order tests other than colonoscopy, regardless of patient preferences, for the 2 intervention groups. This predilection for colonoscopy mirrors national trends in

utilization[4] and may be explained by highly publicized studies affirming superior accuracy for detecting advanced neoplasia compared to other screening modalities,[41–44] expanded coverage by Medicare and many health insurers, and an increase in patient demand due to heightened public awareness efforts.[45] The extent to which liability concerns, sociodemographic factors, health care coverage, patient comorbidities, and/or lack of adequate systems for follow-up (as in the case of FOBT) influence provider recommendations when dealing with individual patients is less well defined. A reliable risk prediction model that could accurately stratify patients into different risk categories for the presence of advanced colorectal adenomas and cancer at screening colonoscopy would be invaluable in this regard because it would bestow providers with objective decisional support when considering patient preferences and thereby enhance the effectiveness of SDM. In the interim, however, the growing tendency to promote colonoscopy independent of patient preferences undermines the spirit of SDM and its potential effectiveness as a strategy for increasing CRC screening rates.

Our decision aid has several features that distinguish it from other currently available CRC screening decision aids. First, the tool employs culturally sensitive video narratives, simple graphics and animation to enhance its appropriateness, and acceptability and comprehensibility for use by a diverse target audience with variable literacy skills. Second, it provides an overview of CRC and CRC screening that incorporates key messages endorsed by the National Colorectal Cancer Roundtable to heighten awareness and entice interest in screening.[36] Third, one version also incorporates the YDR risk assessment tool to enable users to incorporate personalized risk estimates into their decision making. Of note, however, we observed no significant associations between personalized risk feedback and patient preferences or other outcomes of interest. We speculate that the lack of difference between the 2 intervention arms may be due to the offsetting effects of informing some patients in the YDR arm that they were at above-average risk and others below average risk. Alternatively, the lack of difference may also be due to the fact that the information was disregarded by many of those receiving personalized feedback, possibly because it was perceived to be incorrect.[46] Fourth, unlike more complex decision-making approaches, such as conjoint analysis[18] and analytic hierarchy analysis,[12,26] the tool employs descriptive attribute-based comparisons of the different screening tests, as well as option-based summaries, to enable users to identify a value-concordant preference. Fifth, it provides optional links to more detailed information about the preparation, test itself, and patient testimonials to ensure that users have as much information as desired to make an informed choice. Lastly, it provides users with a no-screening option and explores reasons for their decision. The major drawbacks of the tool in its current form are its length, if users opt to view all segments, and its linear arrangement. Enhancements that permit tailored navigation to fit the informational needs of users are required for optimal Internet dissemination.

Our study has several notable strengths. First, the study provides new insight into the utility of decision aids for facilitating SDM related to CRC screening by assessing the extent to which such tools enhance satisfaction with the decision-making process and the extent to which concordance between patient preferences and provider preferences influence screening intentions and test ordering. Second, the use of a randomized controlled study design, a large sample size, and a racially diverse study population enhances both the internal and external validity of its findings. Third, implementation of the decision aid as a point-of-contact intervention attests to the feasibility of use in the primary care setting. Finally, the inclusion of mostly unscreened patients minimizes potential confounding.

Our study also has several notable limitations. First, the lack of provider blinding might have negatively influenced the magnitude of the interventions' effect on several outcomes of interest, most notably satisfaction with the decision-making process. Second, no attempt was made to assess the quality of the patient-provider discussion. Even though SDMP was universally high (albeit higher in the intervention groups), recent data suggest that most patient-provider discussions related to CRC screening fail to incorporate key elements of IDM.[47–49] Third, no attempt was made to assess factors influencing provider preferences, as previously noted, nor provider satisfaction related to either the use of the decision aid or the decision-making process. Fourth, we failed to explore whether users experienced greater decisional conflict or uncertainty when their preferences differ from those of their provider. Fifth, we opted to exclude cost information in our tool when discussing attributes because of conflicting data regarding its impact on decision making in this setting[7,50,51] and because of

the complexity of presenting such information in a meaningful way given the variability in coverage under different health plans. Lastly, despite its obvious importance, we opted to exclude data on patient adherence in this interim analysis because of incomplete follow-up. Although extrapolation of our findings suggests that failure to comply with patient preferences may have negative consequences on screening behavior, it could be that providers who can effectively communicate their reasoning for recommending colonoscopy and facilitate its completion may be successful in getting their patients screened, regardless of their preferences. Existing data, however, would suggest that providers who focus on colonoscopy tend to adopt a more paternalistic approach with little exchange of information or attention to barriers.[52]

In conclusion, our study finds that our decision aid facilitates SDM related to CRC screening by enabling patients to identify a preferred screening option based on the values they place on individual test features and screening intentions. Although use of the tool also enhances SDMP, this empowerment may compromise the effectiveness of SDM in situations where patient and provider preferences differ. Future studies are needed to better understand factors that influence provider preferences and identify effective strategies for reconciling these differences. Pending a final analysis of our adherence data, our findings suggest that providers who utilize decision aids to facilitate SDM for CRC screening should be willing to comply with patient preferences when selecting an appropriate screening test in instances where the patient expresses a desire to participate in the decision-making process, the choice is informed, and there are no mitigating factors to warrant an alternate recommendation. Failure to do so undermines not only the spirit of patient-centered decision making but also the potential effectiveness of SDM as a strategy for increasing uptake of CRC screening.

APPENDIX 1
Knowledge Items*

1. CRC is the number 1 cause of cancer death among nonsmokers. [True]
2. Both men and women are at risk of getting CRC. [True]
3. People 50 years of age and older are more likely to get CRC than younger people. [True]
4. People of all racial and ethnic groups can get CRC. [True]
5. Most colorectal cancers develop from growths called polyps. [True]
6. Removing polyps can prevent CRC. [True]
7. You only have to worry about getting CRC if some one in your family has had it. [False]
8. You can have CRC and not have any symptoms. [True]
9. You can have colorectal polyps and not have any symptoms. [True]
10. The goals of screening are to find polyps and cancer before they cause symptoms. [True]
11. If found early, most colorectal cancers can be cured by surgery. [True]
12. You should begin screening for CRC at age 50. [True]

*Correct responses in brackets.

APPENDIX 2
Satisfaction with the Decision-Making Process Scale[36]

Response frame for questions 1–5:

1. Strongly disagree
2. Disagree
3. Not sure
4. Agree
5. Strongly agree
6. How would you rate the explanations of the screening tests for CRC?
7. How would you rate your doctor's interest in you and your choice of colorectal screening test?
8. How would you rate the reassurance and support offered to you by your doctor?
9. How would you rate the amount of time you had with your doctor?
10. How would you rate the amount of help you got with choosing a CRC screening test?

11. How would you rate the amount of information you got about CRC screening?
12. How would you rate the attention given to what you had to say about CRC screening?

Response frame for questions 6–12:

1 Excellent
2 Very good
3 Good
4 Fair
5 Poor

1. I got as much information as I wanted about colorectal cancer screening.
2. I am satisfied that I was adequately informed about the different tests available for colorectal cancer screening.
3. I had as much input as I wanted in choosing a test for colorectal cancer screening.
4. I am satisfied that my own opinion was important in deciding which colorectal screening test to order.
5. Looking back, I think I relied too much on the opinion of my doctors in deciding which colorectal screening test to order.

ABSTRACT. This study is the first investigation to explore the alcohol brand preferences of underage youth via a national survey. The authors conducted a pilot study of a new, Internet-based alcohol brand survey with 108 youth aged 16 to 20 years who were recruited from an existing panel and had consumed alcohol in the past month. The authors ascertained respondents' consumption of each of 380 alcohol brands during the past 30 days, including which brands of alcohol were consumed during heavy drinking episodes. The findings suggest that, despite the wide variety of alcohol brands consumed by older adolescents in this study, the volume of alcohol consumed is concentrated among a relatively small number of brands. Accurate measurements of alcohol brand preferences will enable important new research into the factors that influence youth drinking behavior. This study establishes the feasibility and validity of a new methodology to determine patterns of brand-specific alcohol consumption among underage drinkers.

KEYWORDS. Adolescents, alcohol, alcohol brands, alcohol use, youth

INTRODUCTION

Alcohol use among adolescents is a major public health problem (1–4). Excessive alcohol consumption contributes to approximately 4600 deaths and 275,000 years of potential life lost among underage youth annually in the United States (5). Adequate surveillance of youth alcohol use is essential to identify the causes of youth drinking in order to plan interventions to prevent its consequences. Although there have been several investigations that examined the types of alcoholic beverages consumed by adolescents (e.g., beer, liquor, wine) (6, 7), we are unaware of any previous studies that reported on the alcohol brands (e.g., Bud Light, Bacardi Silver) consumed by underage youth. This is a critical gap in the literature. Alcohol is marketed and consumed at the brand level, and without any idea of the brands that youth are drinking, it is impossible to develop a complete understanding of the factors—such as alcohol marketing—that influence their drinking behavior.

In 2003, the Institute of Medicine noted this serious flaw in the existing alcohol research literature and recommended the collection of alcohol brand preference data from underage drinkers (4). To date, however, there are no published national data on youth alcohol consumption at the brand level. This paper presents our efforts to fill this glaring deficiency by conducting a pilot study, which we believe is the first survey to comprehensively ascertain youth alcohol brand preferences using a national sample of drinking youth.

Elucidating the brand-specific patterns of alcohol consumption among underage youth would make 4 important contributions. First, identifying the brands popular among young drinkers would allow researchers to examine the relationship between brand-specific advertising exposure and brand-specific alcohol consumption, thus providing the strongest evidence to date regarding whether advertising influences youth drinking. Although previous studies have documented that underage youth are heavily and disproportionately exposed to alcohol advertising for a number of alcohol brands (8–10), without knowing whether youth are actually drinking these brands, we cannot determine whether the advertising is actually affecting their alcohol consumption.

Second, identifying the brands of alcohol that youth consume would greatly enhance our understanding of the factors that influence youth alcohol use. For example, identifying differences in alcohol brands consumed by different age groups and by youth with differing frequencies or intensity of alcohol use may provide insights into the factors that influence the progression of alcohol use behavior.

Third, ascertaining youth alcohol use by brand may result in a more accurate description of drinking behavior among youth. Previous research has established that greater specificity in asking about alcoholic beverage types results in higher self-reported consumption (11, 12). By extension, inquiring about specific alcohol brands could result in the most accurate assessment of youth alcohol consumption to date. In fact, Casswell et al. (13) found that asking subjects to report the brands of alcohol they consume was one of the key factors in their ability to account for 94% of per capita alcohol consumption (as measured by sales data), as compared with less than 60% in prior surveys (14, 15).

Fourth, identifying the patterns of alcohol brand consumption among youth will help establish the feasibility of including alcohol brand use questions on federal or national surveys. A number of national surveys assess cigarette brand preference, which is feasible because cigarette brand use is concentrated among a relatively small number of brands. If alcohol brand consumption is also concentrated among a relatively small number of brands, then assessments of youth alcohol brand preference in national or federal surveys would be highly feasible because only a limited number of brands would need to be listed.

In this paper, we report the results of a pilot study, which we believe is the first national survey dedicated to measuring alcohol brand preferences among underage youth. Although this pilot study has a relatively small sample size, these findings do provide the first national data on youth brand preferences. No previously published paper reports either brand-specific or type-specific alcohol consumption with the comprehensiveness of our survey.

METHODS

Background

A major reason for the absence of studies on alcohol brand use among youth is the lack of an established methodology to collect such data. There are hundreds of major alcohol brands so researchers have assumed that it would take too long to collect such data, making brand research costly and impracticable. Yet, by using a combination of carefully crafted skip patterns, piping questions (using responses from previous questions on brand use to elicit more detailed information on alcohol consumption patterns for the identified brands), and Internet forms that include lists of brands with check boxes, we developed a survey instrument that assesses alcohol brand preferences within a reasonable time frame.

This pilot study was designed to determine our ability to use a preexisting Internet panel to administer the survey to a national sample of underage youth and obtain a valid assessment of their alcohol consumption.

Design

To conduct our survey, we utilized a prerecruited Internet panel developed by Knowledge Networks, the only US company that maintains an Internet panel (the Knowledge Panel) that was created using a national probability sample. The company recruited households to its Knowledge Panel sample through a combination of random digit dialing (RDD) and address-based sampling (ABS), which involves probability sampling of addresses from the US Postal Service's Delivery Sequence File (16).

The Knowledge Networks Internet youth panel provides high survey completion rates because of the ongoing relationship between the youth and the panel staff. To ensure adequate representation of panelists across race/ethnicity, telephone numbers from phone banks with higher concentrations of blacks and Hispanics are oversampled. To ensure adequate participation across levels of socioeconomic status, subjects agreeing to participate in the panel who do not have Internet access are given WebTV and Internet access and training for free.

Previous research has validated the alcohol data derived from adults in the Knowledge Networks Internet panel. Heeren et al. (17) compared the results of an alcohol survey conducted through Knowledge Networks with results from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC). Estimates of current drinking were similar to those from NESARC, demonstrating that the Knowledge Networks panel is a less expensive, viable alternative to telephone and in-person surveys for assessing drinking behavior.

Sample

Knowledge Networks recruited 108 youth aged 16 to 20 from its existing Internet panel to participate in the study by sending an e-mail invitation. The invitation did not disclose that the survey was related to alcohol consumption. Those who agreed to participate were provided a secure link to access the study site.

The initial screening question asked respondents to report on how many days out of the past 30 they had consumed at least 1 drink of alcohol. A drink was defined as a 12-ounce can or bottle of beer; a 5-ounce glass of wine or champagne; an 8.5-ounce flavored malt beverage; an 8-ounce alcohol energy drink; a 12-ounce wine cooler; 8.5 ounces of malt liquor; 1.5 ounces of liquor (spirits or hard alcohol), whether in a mixed drink or as a shot; and 2.5 ounces of cordials or liqueurs, whether in a mixed drink, a coffee drink, or consumed on their own.

Respondents who had consumed at least 1 drink of alcohol in the past 30 days were provided with an online consent form, which described the details of the study, risks and benefits, and the procedures in place to protect the confidentiality of their responses. Participants who provided informed consent completed the Internet-based questionnaire, which ascertained the alcoholic beverage brands they consumed within the past 30 days. After completion of the survey, a $25 gift was credited to the panel member's account. The protocol was approved by the Institutional Review Board of the Boston University Medical Center. A Certificate of

Confidentiality was obtained from the National Institutes of Health to help protect the confidentiality of the panelists' responses.

Because this was a pilot study, with funding for surveys of only about 100 subjects, we used a consecutive sampling process, enrolling the first 100 adolescents who responded to the e-mail invitation and were found to be eligible after they completed the screening questionnaire. A total of 1028 e-mail invitations were sent out. It took just 1 week to recruit the desired sample. During that week, 360 respondents (35%) completed the screening questionnaire: 108 were qualified (i.e., had consumed at least 1 drink of alcohol in the past 30 days) and completed the survey. We exceeded the desired sample size of 100 because closing the survey does not throw out subjects who are already online.

Survey Instrument

The Internet-based survey instrument was developed to assess brand-specific alcohol consumption among underage youth. The list of assessed alcohol brands was generated using 2 main sources. The first source was the complete list of alcohol brands measured by GfK Mediamark Research & Intelligence (GfK MRI) in its Survey of the Adult Consumer, a written survey of a representative sample of approximately 10,000 US adults. GfK MRI's survey, which ascertains the prevalence of use of various consumer products, inquires about the past-6-month and past-7-day consumption of 90 beer brands and 81 wine brands and the past-6-month and past-30-day consumption of 17 flavored alcoholic beverage brands and 132 spirits brands.

The second source was a list generated by TNS Media Intelligence, which is an advertising industry standard source that monitors advertising occurrences and expenditures in more than 300 national periodicals. The survey instrument included every alcohol brand advertised in the magazines during any of the years 2001 to 2006, except for wine and champagne. Due to the extensive number of advertised wine and champagne brands, it was sufficient and more practical to include only brands advertised in 2006.

Alcoholic energy drinks are not included in the GfK MRI list. To identify these brands, we performed Internet searches and used an extensive list compiled by the National Association of Attorneys General as part of an ongoing investigation into the marketing of these beverages. Finally, we included all alcohol brands reported by participants in the preliminary pilot study that were not on our initial list.

The final survey instrument included 61 brands of beer, 81 brands of wine or champagne, 19 brands of flavored alcoholic beverages (including flavored malt beverages, alcopops, wine coolers, and malt liquor), 35 types of mixed drinks, 38 brands of alcoholic energy drinks, 14 brands of bourbon, 3 brands of brandy, 8 brands of cognac, 9 brands of gin, 19 brands of rum, 15 brands of scotch, 13 brands of tequila, 30 brands of vodka, 8 brands of whiskey, and 27 brands of cordials or liqueurs. In total, the instrument assessed 380 brands of alcoholic beverages. Brand extensions were ascertained as a single brand category if they are typically advertised together (e.g., Absolut flavored vodkas); they were ascertained separately if they are typically advertised separately (e.g., Budweiser, Bud Light).

For each category of alcohol, the respondents checked off which specific brands they had consumed during the past 30 days. If a specific brand was not listed, then respondents entered the name, giving as specific a name as possible. After identifying the brands they had consumed in the past 30 days, the respondents reported the number of days during the past 30 that they had consumed each brand and how many drinks of each brand they usually had on a day when they drank that brand.

Respondents also reported on how many days out of the past 30 they had consumed 5 or more drinks in a row (that is, within a couple of hours). Next, for each category of alcohol, they selected all of the brands, either alone or in combination, which they remembered drinking in the past 30 days on those occasions when they drank at that level.

Analysis

The 3 main data analysis questions were as follows: (1) Of underage youth (aged 16 to 20)

who consumed alcohol in the past 30 days, what proportion reported having consumed each type and each brand of alcohol? (2) Of underage youth who consumed 5 or more drinks in row, what proportion used each type and brand of alcohol during these drinking episodes? (3) What is the overall market share, by volume of alcohol consumed in the past month, for each alcohol brand?

The market share for each alcohol brand by volume consumed was calculated by dividing the total number of drinks consumed during the past 30 days for each brand by the total number of drinks of all brands consumed during the past 30 days. The number of drinks of a brand consumed during the past 30 days was estimated by multiplying the number of days that brand was consumed by the usual number of drinks for that brand on days when it was consumed.

Knowledge Networks applied statistical weighting adjustments to account for selection deviations and to render the sample representative of the underlying population. These weights accounted for the different selection probabilities associated with the RDD- and ABS-based samples, the oversampling of minority communities, nonresponse to panel recruitment, and panel attrition. Poststratification adjustments were based on demographic distributions from the Current Population Survey (CPS) conducted by the US Bureau of the Census.

Validation of Survey Findings

Because there has been no previously published survey of youth alcohol brand preferences, there is no true gold standard to which we can compare our findings. Instead, we can validate our findings against GfK MRI's Survey of the Adult Consumer, a written survey of a representative sample of approximately 10,000 US adults used to ascertain the prevalence of use of various consumer products, including past-30-day consumption of 132 spirits brands. Since GfK MRI defines adults as aged 18 years or older, their findings on types of alcohol used can be applied as a validity check on our own findings for the 18- to 20-year-olds in our Internet panel. We previously obtained data on past-30-day use of various types of liquor among 18- to 20-year-olds from the 2007 Survey of the American Consumer (18), and we used these data here to validate our survey findings.

RESULTS

Description of Sample

The sample was slightly overrepresentative of males (55.6%) and somewhat more representative of older adolescents (age 16: 13.9%; age 17: 19.4%; age 18: 15.7%; age 19: 29.6%; age 20: 21.3%). By race/ethnicity, 66.7% of respondents were non-Hispanic white, 22.2% were Hispanic, 8.3% were black, and 2.8% other race/ethnicity. The mean number of days in the past month on which alcohol was consumed was 4.9, and the median was 3. Approximately two thirds of the respondents (65.7%) reported drinking no more than an average of once per week. The proportion of respondents who consumed 5 or more drinks in a row during the past 30 days was 61.1%.

Feasibility of the Survey Methodology

It was feasible to administer the alcohol brand preference survey using Knowledge Networks' prerecruited Internet panel. We received 108 responses within 1 week, with only 1 e-mail solicitation and no follow-up messages to panelists who did not immediately respond. The median time it took for respondents to complete the survey was 16 minutes; 68.5% of respondents completed the survey in 20 minutes or less. Of 70 respondents who answered an open-ended question regarding whether they had any problems filling out the survey, 65 (92.8%) reported no problems at all. Only 1 respondent reported difficulty with the questions about alcohol brand preferences. That respondent commented that it was difficult to remember specific information about alcohol consumption that occurred 30 days ago. The other 4 respondents reported difficulty with questions related to drinking among relatives, which were not relevant to the present study.

Validation: Comparison of Pilot Survey with GfK MRI Data, 18 to 20 Years of Age

Estimates of beverage category preferences among the 18- to 20-year-old respondents in our study were similar to those from the GfK MRI national survey for most of the alcoholic beverage types (Table 1). The correlation between our estimates and those from GfK MRI was high ($r = .86, P = .0006$), and the correlation between prevalence rank was similarly high (Spearman's rho = .82, $P = .0021$). Overall, the mean absolute difference in prevalence of consumption by beverage category was 1.5%, whereas the mean relative difference was 29.2%.

Alcoholic Beverage Type Preferences of Underage Drinkers, 16 to 20 Years of Age

For our survey respondents, all underage drinkers aged 16 to 20 years, the 3 most popular alcoholic beverage types (based on prevalence of any consumption) were beer (consumed by 67.1%), flavored alcoholic beverages (51.9%), and vodka (43.9%) (Table 2). These were also the types most commonly consumed during episodes when respondents had 5 or more drinks in a row. As a proportion of total drinks consumed, beer accounted for 43.4% of the total alcohol consumed by these youth, followed by flavored alcoholic beverages at 16.5% and rum at 13.0%. The top 5 alcoholic beverage types (beer, flavored alcoholic beverages, rum, vodka, and whiskey) accounted for 90.4% of the total volume of alcohol consumed. All liquor types combined accounted for 55.4% of the total volume of alcohol consumed.

Alcohol Brand Preferences of Underage Drinkers, 16 to 20 Years of Age

Our survey identified 160 brands of alcohol that were consumed in the past 30 days by our sample of underage drinkers. The top 10 brands consisted of 3 beer brands (Bud Light, Budweiser, and Coors Light), 2 brands of flavored alcoholic beverages (Smirnoff Malt Beverages and Mike's Hard Lemonade, Hard Iced Tea, and malt cocktails), 2 brands of rum (Bacardi and Captain Morgan), 1 brand of vodka (Smirnoff), 1 brand of bourbon (Jack Daniels), and 1 brand of tequila (Jose Cuervo) (Table 3). Only 11 brands (the 10 listed previously plus Absolut Vodka) were consumed by 10% or more of the adolescent drinkers in our sample. The brands of alcohol used during episodes when respondents consumed 5 or more drinks in a row were similar to those consumed overall.

TABLE 1. Comparison of Prevalence of Past-30-Day Consumption of Wine and Liquor Types Among 18- to 20-Year-Olds—Knowledge Networks Pilot Study[a] versus GfK MRI Survey of the Adult Consumer[b]

Beverage type	Pilot study, % (rank)	GfK MRI, % (rank)
Vodka	14.6 (1)	10.4 (1)
Rum	8.5 (2)	9.1 (2)
Bourbon	7.1 (3)	5.0 (5)
Tequila	7.0 (4)	7.1 (3)
Whiskey	4.7 (5)	3.4 (9)
Wine	4.5 (6)	4.3 (7)
Cognac	3.4 (7)	4.6 (6)
Cordials or liqueurs	3.2 (8)	7.0 (4)
Gin	2.4 (9)	3.5 (8)
Brandy	1.7 (10)	2.7 (10)
Scotch	1.1 (11)	1.8 (11)

[a]Estimate of overall prevalence of consumption of that alcoholic beverage type in the past 30 days based on weighted responses of 18- to 20-year-old participants in the pilot study. Beer was not included in this validation study because there was no comparable assessment of beer consumption in the past 30 days in the GfK MRI study.

[b]Estimate of overall prevalence of consumption of that alcoholic beverage type in the past 30 days based on weighted responses of 18- to 20-year-old respondents in the 2007 GfK MRI Study of the Adult Consumer (18).

TABLE 2. Alcoholic Beverage Types by Percentage Used in Past 30 Days, Percentage Used When Consuming 5 or More Drinks in a Row, and Overall Market Share by Number of Drinks Consumed in Past 30 Days

	Any use in past 30 days[a] % (95% confidence interval) [*N*]	Use when consuming 5 or more drinks in a row, past 30 days[b] % (95% confidence interval) [*N*]	Market share[c] (%)
Beer	67.1% (54.8–79.4) [73]	69.7% (55.9–83.6) [44]	43.4%
Flavored alcoholic beverages[d]	51.9% (39.0–64.9) [52]	51.2% (35.0–67.5) [29]	16.5%
Vodka	43.9% (30.6–57.2) [40]	45.6% (29.0–62.3) [26]	9.4%
Rum	27.1% (16.8–37.4) [29]	26.6% (13.9–39.4) [19]	13.0%[e]
Tequila	20.2% (8.9–31.6) [19]	10.2% (2.5–17.8) [8]	1.1%
Bourbon	19.8% (7.9–31.7) [18]	25.2% (8.2–42.1) [12]	2.8%
Whiskey	14.6% (3.7–25.4) [9]	15.4% (0.0–30.8) [5]	8.1%[f]
Cordials/liqueurs	13.0% (5.9–20.1) [16]	10.9% (2.0–19.9) [6]	0.6%
Wine	12.3% (1.7–22.8) [10]	6.8% (0.0–13.5) [5]	1.2%
Alcoholic energy drinks	10.9% (4.3–17.4) [14]	5.9% (0.0–12.3) [4]	1.6%
Cognac	8.7% (1.6–15.7) [7]	9.2% (0.8–17.7) [5]	1.8%
Gin	7.5% (1.6–13.5) [7]	5.3% (0.0–11.9) [3]	0.3%
Scotch	5.6% (0.7–10.5) [7]	3.8% (0.0–9.1) [3]	0.1%
Brandy	5.5% (0.1–11.0) [4]	4.1% (0.0–10.0) [2]	0.1%

Note. N = Unweighted number of respondents reporting consumption of that alcohol type during past 30 days (second column) or reporting consumption of that alcohol type when having 5 or more drinks in a row during past 30 days (third column).

[a]Proportion of all respondents who reported drinking that alcoholic beverage type on 1 or more days during the past 30 days.

[b]Proportion of respondents consuming 5 or more drinks in a row who reported drinking that type of alcohol during these episodes. Proportion of respondents who reported drinking 5 or more drinks in a row was 61.1%.

[c]Includes flavored alcoholic beverages, alcopops, malternatives, and malt liquor.

[d]Proportion of total number of drinks of that alcoholic beverage type in the past 30 days among all respondents to the total number of drinks of all alcoholic beverage types in the past 30 days among all respondents.

[e]Market share for rum is higher than for vodka, despite lower prevalence of use, because average monthly number of drinks per respondent is higher (26.9 drinks per month average for rum; 14.1 drinks per month average for vodka).

[f]High market share may be an anomaly due to very high reported consumption of brand during episodes when respondent consumed 5 or more drinks in a row.

We assessed brand market shares by calculating the volume of each brand consumed during the past 30 days. The majority of alcohol consumed was accounted for by a small number of brands, despite the large total number of brands consumed (Table 4). Of the 160 brands consumed, the top 10 brands accounted for 64.7% of the alcohol consumed, the top 20 brands accounted for 80.6%, and the top 30 brands accounted for 88.4%. Only 5 alcohol brands had market shares of 5% or greater and just 21 brands had market shares of 1% or greater.

We found a small concentration of preferred brands within alcoholic beverage categories. For example, although respondents reported drinking 37 different beer brands, the top 5 beer brands (Bud Light, Budweiser, Busch, Coors Light, and Natural Ice) accounted for three fourths (74.9%) of the total volume of beer consumed. The top 10 beer brands accounted for 86.4% of the beer consumed. Similarly, although respondents reported drinking 7 different brands of rum, the top 2 brands (Bacardi and Captain Morgan) accounted for 95.5% of the rum consumed. For tequila, youth reported consuming 7 different brands, but the top 2 brands (Jose Cuervo and Patron) accounted for 87.0% of the tequila consumed. For vodka, there were 18 brands consumed, but the top 5 accounted for 79.6% of overall vodka consumption by volume. Six brands of bourbon were cited by respondents, but 1 brand (Jack Daniels) accounted for 85.5% of consumption by volume. For flavored alcoholic beverages/malt liquor, 19 brands were consumed, but the top 5 brands (Smirnoff Malt Beverages, Mike's, Steel Reserve, Bacardi Silver, and Seagram's Smooth Malt) accounted for 93.5% of consumption by volume.

TABLE 3. Top 10 Leading Alcohol Brands by Percentage Use in Past 30 Days and Percentage Use When Consuming 5 or More Drinks in a Row in Past 30 Days

Any use in past 30 days[a] % (95% confidence interval) [*N*]			Percentage use when consuming 5 or more drinks in a row, past 30 days[b] % (95% confidence interval) [*N*]		
Rank/brand	Type	Percentage use	Rank/brand	Type	Percentage use
1. Bud Light	Beer	33.7% (20.6–46.7) [33]	1. Smirnoff Malt Beverages	Flavored alcoholic beverage	25.6% (12.0–39.2) [15]
2. Smirnoff Malt Beverages	Flavored alcoholic beverage	26.2% (15.6–36.7) [27]	2. Jack Daniels	Bourbon	21.8% (4.8–38.9) [9]
3. Budweiser	Beer	22.6% (10.8–34.4) [18]	3. Bud Light	Beer	21.2% (8.1–34.3) [16]
4. Smirnoff Vodkas	Vodka	18.7% (7.8–29.6) [20]	4. Budweiser	Beer	16.9% (0.9–33.0) [5]
5. Jack Daniels	Bourbon	16.6% (4.9–28.3) [15]	5. Mike's	Flavored alcoholic beverage	14.8% (0.0–29.6) [7]
6. Coors Light	Beer	14.0% (6.9–21.1) [19]	6. Busch	Beer	14.2% (0.0–28.9) [7]
7. Mike's	Flavored alcoholic beverage	13.6% (3.3–23.9) [11]	7. Smirnoff Vodkas	Vodka	14.1% (4.8–23.5) [10]
8. Jose Cuervo	Tequila	13.2% (2.5–23.8) [11]	8. Captain Morgan Rums	Rum	12.8% (3.4–22.2) [9]
9. Bacardi Rums	Rum	12.6% (5.4–19.8) [15]	9. Natural Ice	Beer	12.2% (0.0–27.2) [4]
10. Captain Morgan Rums	Rum	11.7% (4.4–18.9) [13]	10. Bacardi Rums	Rums	11.7% (3.2–20.2) [9]

Note. N = Unweighted number of respondents reporting consumption of that alcohol brand during past 30 days (columns 1 to 3) or reporting consumption of that alcohol brand when having 5 or more drinks in a row during past 30 days (columns 4 to 6).

[a]Proportion of all respondents who reported drinking that alcohol brand on 1 or more days during the past 30 days.

[b]Proportion of respondents consuming 5 or more drinks in a row who reported drinking that brand of alcohol during these episodes. Proportion of respondents who reported consuming 5 or more drinks in a row was 61.1%.

TABLE 4. Top 10 Leading Alcohol Brands by Overall Market Share by Number of Drinks Consumed in Past 30 Days[a]

Rank/brand	Beverage type	Market share, % [*N*]
1. Bud Light	Beer	14.0 [33]
2. Captain Morgan Rums	Rum	10.8 [13]
3. Budweiser	Beer	8.7 [18]
4. Five Star Whiskey	Whiskey	7.8 [1][b]
5. Smirnoff Malt Beverages	Flavored alcoholic beverage	5.2 [27]
6. Mike's	Flavored alcoholic beverage	4.8 [11]
7. Busch	Beer	3.8 [7]
8. Coors Light	Beer	3.6 [19]
9. Steel Reserve	Flavored alcoholic beverage	3.6 [2][b]
10. Jack Daniels	Bourbon	2.4 [15]

Note. N = Unweighted number of respondents reporting consumption of that alcohol brand during past 30 days.
[a]Proportion of total number of drinks of that alcohol brand in the past 30 days among all respondents to the total number of drinks of all brands in the past 30 days among all respondents.
[b]High market share may be an anomaly due to very high reported consumption of brand during episodes when respondent consumed 5 or more drinks in a row.

DISCUSSION

This study has demonstrated the feasibility of comprehensively ascertaining brand-specific alcohol consumption among a national sample of underage youth using a prerecruited Internet panel. The high concordance between our results and estimates of type-specific alcoholic beverage consumption from the GfK MRI Survey of the Adult Consumer confirms the validity of our study methodology in ascertaining type-specific patterns of consumption among underage youth and therefore supports the use of this method for assessing brand-specific alcohol consumption. To the best of our knowledge, this paper is the first to comprehensively report youth alcohol brand consumption patterns among a national sample.

Although the GfK MRI Survey of the Adult Consumer does assess brand-specific alcohol consumption among a small subset of underage drinkers (those aged 18 to 20), it does not include persons below the age of 18 years and thus provides little information about alcohol consumption among the high school and junior high school populations. In addition, the GfK MRI results are not publicly available or publicly reported.

The present research is limited because of the pilot study's small sample size and the relatively low precision of our brand consumption prevalence estimates. Even so, the study results support several important conclusions about brand-specific alcohol consumption among underage youth. First, our findings provide preliminary evidence that, although the spectrum of alcohol brands consumed is wide, the volume of alcohol consumed by underage persons is concentrated in a rather small number of alcohol brands. The top 10 brands alone accounted for 64.7% of all alcoholic beverage drinks consumed by the survey respondents. Only 11 alcohol brands were consumed by 10% or more of respondents. By total volume consumed, fully 88.4% of the alcohol consumption reported by our sample could be accounted for by 30 alcohol brands. If confirmed in a larger sample, this apparent concentration of alcohol brand preferences suggests that it may be feasible for national surveys to ascertain youth alcohol brand preferences quickly and efficiently, something that was not previously thought possible.

Second, there is a small concentration of preferred brands within the alcoholic beverage categories that are widely popular among youth drinkers. For example, although respondents reported drinking 37 different beer brands, the top 5 beer brands (Bud Light, Budweiser, Busch, Coors Light, and Natural Ice) accounted for three fourths (74.9%) of the total volume of beer consumed. Similarly, the top 2 brands of rum accounted for 95.5% of the rum consumed, and

the top 2 brands of tequila accounted for 87.0% of the tequila consumed.

Third, we found that flavored alcoholic beverages are extremely popular among underage drinkers, with more than half reporting consumption of this type of alcoholic beverage during the past month. This is a striking finding, since this type of alcoholic beverage makes up only 2% of the total market (19). This finding demonstrates an important benefit of improved surveillance of the types and brands of alcohol consumed by underage youths: it may point attention to specific brands or beverage categories that are disproportionately popular among youth.

An advantage of this study was that unlike previous surveys, our methodology did not rely upon youth to accurately classify the types of alcoholic beverages that they consume. Our survey specifically assessed consumption of each of the 380 brands. We therefore believe that this method of ascertaining alcohol consumption patterns by type of alcohol may be the most accurate to date, and will enable more accurate studies of the total volume of alcohol consumed by youth drinkers (13).

The major limitation of this study is the small sample size, which resulted in wide confidence intervals around the point estimates for brand-specific alcohol consumption. Therefore, the specific estimates of brand-specific consumption should be interpreted with caution and viewed only as preliminary estimates. The estimates of market share should be interpreted even more cautiously, because they are affected by the imprecision around multiple brands. Despite these limitations, however, the study reveals that alcohol consumption among older adolescents is concentrated around a limited number of highly popular brands. Larger studies that allow these brands to be definitively identified and then examine youth exposure to advertising for these brands should be a priority, as this research would provide strong evidence as to whether alcohol advertising affects youth drinking behavior. The present study therefore supports the need for a large, national survey of youth alcohol brand preferences and suggests that such a study both is feasible and would provide valid alcohol consumption data.

Alcoholic Beverage Preferences and Associated Drinking Patterns and Risk Behaviors Among High School Youth

Michael B. Siegel, MD, MPH, Timothy S. Naimi, MD, MPH, Jennifer L. Cremeens, PhD, MSPH, David E. Nelson, MD, MPH

Background: Very little is known about the types of alcoholic beverages preferred by youth in the U.S. and the relationship between beverage preference and demographic and behavioral characteristics of these youth.

Purpose: To determine the type of alcoholic beverages consumed by adolescent drinkers and how it varies by drinking patterns.

Methods: In 2010, an analysis was performed using 2007 data from the Youth Risk Behavior Survey (YRBS) conducted among public school students in eight states that included a question on the type of alcohol usually consumed. Analysis was restricted to the 7723 youth who reported consuming at least one drink of alcohol in the past 30 days. Beverage type preferences were analyzed by demographic factors, drinking patterns, and other health-risk behaviors. Logistic regression analyses were conducted to examine the correlates of type-specific alcohol consumption.

Results: Liquor was the strongly preferred alcoholic beverage of choice (43.8%), followed by beer (19.2%) and malt beverages (17.4%), with a very low preference for wine (3.7%) or wine coolers (3.4%). A higher preference for liquor or beer was observed among older youth, among those with a riskier pattern of alcohol consumption (e.g., greater frequency of consumption, binge drinking, or drinking and driving), and among youth who engaged in other risk behaviors.

Conclusions: Riskier patterns of drinking and other health-risk behaviors are associated with an increased preference for hard liquor and beer. Improved surveillance of alcoholic beverage preferences among youth will enable a better understanding of the factors related to youth drinking, allowing the development of more effective interventions.

(Am J Prev Med 2011;40(4):419–426)

Introduction

Excessive alcohol consumption contributes to approximately 4600 deaths and 275,000 years of life lost among underage youth annually in the U.S.[1] Despite slight declines in the past decade, almost half of high school–aged youth report past-month alcohol consumption, mostly in the form of binge drinking,[2] and alcohol use among adolescents remains a major public health problem.[2–6] Little is known, however, about the specific types of alcoholic beverages that underage youths consume, how this beverage-specific profile differs by drinking pattern, or what factors predict the type of alcohol that youths consume.

Identifying the types of alcoholic beverages that youth consume would contribute toward a better understanding of the motivating factors underlying underage drinking behavior.[7] There is evidence that preferences for particular types of alcoholic beverages are associated with different drinking patterns.[7–19] Kuntsche et al., for example, have described wine as being consumed in moderation as a social habit, beer and spirits as most often being used to get drunk, and alcopops as occupying a middle ground.[7] Other studies have identified spirits consump-

tion to be related to a desire to feel the effects of alcohol quickly,[8,19] whereas beer consumption has been associated with risky drinking, including binge drinking, heavy episodic drinking, and drunk driving.[9,11–15]

Because numerous evidence-based prevention strategies, including excise tax policy and alcohol sales and marketing regulation, are beverage-specific,[10] understanding the specific types of alcoholic beverages consumed by young people could also inform the development of appropriate beverage-specific policy and practice interventions. In addition, understanding the relationship between the types of alcoholic beverages that youth prefer and the alcohol source, drinking location, context, and relationship with other health-risk behaviors would provide clues as to the factors that influence youth drinking behavior.

Although several studies have investigated adolescent consumption of various types of alcoholic beverages (e.g., wine, beer, spirits) in other countries,[7–9] there is a paucity of such data in the U.S. There have been only two published studies on type-specific alcoholic beverage consumption among adolescents in the U.S.[20,21] In one study,[20] Roeber et al. reported type-specific consumption of alcoholic beverages among 9th–12th-grade students in four states in 2005 based on the Youth Risk Behavior Survey (YRBS). In the second study,[21] Cremeens et al. used the same data set to examine the type of alcohol consumed and its relationship to binge drinking behavior. However, neither study assessed whether beverage choice was related to drinking context or other personal health-risk behaviors and neither reported the relationship between type-specific consumption and the location of drinking or the source of alcohol.

In this paper, data from the 2007 Youth Risk Behavior Survey in eight states were used to examine beverage-specific drinking patterns among U.S. adolescents. The purposes of the present study were to determine (1) the types of alcoholic beverages preferred by adolescents and how these beverage preferences differ among demographic groups and (2) how alcoholic beverage preferences differ by age, drinking patterns, and other health-risk behaviors.

Methods

Overview

Data were analyzed from the 2007 state Youth Risk Behavior Survey (YRBS), a school-based questionnaire survey of 9th–12th-grade students, in eight states: Arkansas, Florida, Georgia, Hawaii, New Mexico, North Dakota, Utah, and Vermont. Each of these states included an additional question in its 2007 survey that ascertained the type of alcoholic beverage usually consumed by respondents who reported drinking alcohol in the past 30 days.

Sampling

In 2007, these states conducted their survey using a two-stage cluster sample design in order to produce data representative of the state's public school students in Grades 9–12.[3] The first level of clustering was the school level. All public schools were included in the sampling frame. Schools were selected such that their probability of selection was proportional to their enrollment in Grades 9–12.[22] The second sampling frame consisted of classes within the chosen schools. All classes in a required subject or all classes meeting during a particular time period were included in the sampling frame. Equal probability sampling of classes was conducted and all students in selected classes were eligible to participate.

The student sample sizes for the eight states ranged from 1191 (Hawaii) to 8453 (Vermont), with a total sample size of 24,622 across the eight states. School response rates ranged from 76% (Arkansas) to 100% (Vermont), and student response rates ranged from 63% (Hawaii) to 89% (Georgia), resulting in overall response rates ranging from 60% to 82%.[3]

Analyses were restricted to respondents who had consumed at least one alcoholic beverage during the past 30 days (n=8694), which represented 37.8% of the total sample. After deleting respondents who failed to answer the question about alcoholic beverage type preference, the total sample size was 7723.

Data were weighted to represent each state's public school student population for Grades 9–12. Individual sample weights were applied to each record to adjust for student nonresponse and poststratification to the gender, race/ethnicity, and grade-level distribution in that state.

Measures

Alcohol beverage preference was assessed among current drinkers, who were defined as respondents who indicated having had at least one drink of alcohol on at least 1 day during the 30 days prior to survey administration. Alcoholic beverage type was assessed with the question *During the past 30 days, what type of alcohol did you usually drink?* The possible responses were *beer*; *liquor (such as vodka, rum, scotch, bourbon, or whiskey)*; *wine*; *wine coolers (such as Bartles and James or Seagrams)*; *malt beverages (such as Smirnoff Ice, Bacardi Silver, or Hard Lemonade)*; *some other type*; or *no usual type*.

Beverage type preferences were analyzed by state; age; grade; gender; race/ethnicity; frequency of binge drinking (defined as having five or more drinks of alcohol in a row during the past 30 days); frequency of drinking; and driving after drinking (defined as having driven a car shortly after drinking). Beverage type preferences also were analyzed in relation to the usual source of alcohol and the location where alcohol is usually consumed.

Alcohol beverage preferences were analyzed in relation to the following other health-risk behaviors: wearing a seat belt, riding in a car driven by someone who had been drinking alcohol, carrying a weapon, being in a physical fight, feeling helpless, considering suicide, current smoking, marijuana use, TV viewing, number of sexual partners, and unprotected sex. TV viewing was included as a potential correlate of alcoholic beverage type preference because it has been shown to be related to youth alcohol consumption, possibly because of alcohol marketing and the positive portrayal of drinking on TV.[23–25]

Analysis

Analyses were conducted in 2010 with SAS, version 9.1, using procedures that account for the complex survey design and that allowed weighting of the data to produce estimates that were representative of the state school student populations.[26] The analysis relied on a Taylor series variance estimation, which accounts for the clustering and stratification in the survey sampling design.[27]

Both state-specific and pooled analyses across all eight states were conducted. For pooled analyses, an additional weight was employed in order to account for the different student sample sizes in each state and for the differences in state populations in the age range of the sample. One weighting factor accounted for the sample size in each state in order to ensure that responses from each state had an equal influence on the estimation of pooled proportions. A second weighting factor accounted for the population of those aged 10–19 years in each state (based on 2007 age-specific population projections from the U.S. Census Bureau[28]) in order to ensure that states with larger populations had the proper proportionate influence on pooled estimates. By using these two weighting factors, pooled estimates were designed to be representative of the combined population of these eight states.

Logistic regression analyses were conducted to examine the correlates of type-specific alcohol consumption. The outcome variable in each regression was preference for a particular type of alcoholic beverage (i.e., liquor, beer, malt beverages, wine coolers, wine, and beer/liquor combined) compared to all other categories (including "other" and "no usual type"). The independent variables included age, gender, race/ethnicity, usual source of alcohol, usual location of drinking, frequency of drinking, and frequency of binge drinking. All independent variables were included in each model as the aim was to investigate the independent effect of each of these variables on alcoholic beverage type preferences. The other health behaviors were not included in these models in order to avoid multicollinearity, which could have invalidated the findings.

Results

In each state except North Dakota, liquor was the most prevalent type of alcohol usually consumed by 9th–12th-grade students in 2007 (median=43.7%, range=33.9%–45.8%; Appendix A, available online at www.ajpm-online.net). Beer was generally the second most prevalent type of alcohol consumed (median=22.7%, range=17.4%–35.9%), followed closely by malt beverages (median=16.4%, range=12.4%–22.4%). Wine and wine coolers were not reported as the usual alcoholic beverage consumed by more than 4.3% of the youth in any state.

For pooled state data, liquor was the strongly preferred alcoholic beverage of choice (43.8%), followed by beer (19.2%) and malt beverages (17.4%; Table 1). Boys were more likely to prefer liquor and beer, whereas girls were more likely to prefer malt beverages, wine coolers, and wine. Older age was associated with increasing preference for liquor and beer and decreasing preference for malt beverages and wine coolers. Black adolescents were much more likely to prefer malt beverages and much less likely to prefer beer compared with those of any other race or ethnicity.

A riskier pattern of alcohol consumption (both for frequency of drinking and of binge drinking) was associated with an increased preference for liquor and beer and a decreased preference for other beverages (Table 1). Driving after drinking was associated with increased beer consumption and decreased consumption of malt beverages, wine coolers, and wine. Preferences for alcoholic beverages type by usual source of alcohol and usual location of drinking tended to mirror the overall preference pattern in the sample.

The use of other drugs (cigarettes and marijuana) was associated with an increased preference for liquor and beer and a decreased preference for malt beverages, wine, and wine coolers (Table 2). In general, youth who engaged in other risk behaviors were more likely to usually consume liquor. For example, 48.4% of the youth who reported having been in a physical fight preferred liquor, compared to 40.0% of the youth who had not been in a physical fight. Nearly half (49.9%) of the youth who carried a weapon preferred liquor compared to 40.8% of the youth who did not carry a weapon.

In regression models, older adolescents were significantly more likely to report usually drinking beer (OR=1.60, 95% CI=1.002, 2.56, for youth aged ≥18 years compared to those aged 12–14 years), and significantly less likely to report usually drinking malt beverages or wine coolers (Appendix B, available online at ajpm-online.net). Girls were less likely to prefer beer and more likely to prefer malt beverages and wine coolers, as were black adolescents. Hispanic youth were more likely than white youth to prefer malt beverages, and less likely to prefer liquor or beer.

Usual source of alcohol was associated significantly with the type of alcohol usually consumed for only a few variables. Compared to youth whose usual source of alcohol was *other*, those whose usual source was buying alcohol in a store were more likely to usually drink beer (OR=1.81; 95% CI=1.14, 2.87). Youths whose usual source of alcohol was a bar or restaurant were less likely to usually drink wine coolers. Youths whose usual source of alcohol was to have someone buy alcohol for them were more likely to usually drink malt beverages.

Compared to youths whose usual location of drinking was *other*, youths whose usual drinking location was in the home were less likely to usually drink liquor (OR=0.46, 95% CI=0.29, 0.74). Those who usually drank alcohol in another person's home or in a public place were less likely to prefer liquor and more likely to prefer beer.

A high frequency of drinking was associated with a preference for liquor and a decreased preference for malt

Note: Weighted percentages of respondents in each stratum are shown in parentheses following the stratum label.
[a]The analysis is restricted to students who reported drinking at least one drink of alcohol on ≥1 days during the past 30 days; based on the question *During the past 30 days, what type of alcohol did you usually drink?*
[b]Data are from the Youth Risk Behavior Survey and are weighted to reflect student nonresponse and to provide estimates representative of the student populations of each state. Additional weighting factors were added to reflect the different sample sizes and student populations in each state. Data presented are representative of the overall student populations of all eight states combined.
[c]Data reflect the past 30 days. These variables were recoded to create three relatively similar sized groups, so that the SEs would not be large in any one group and to create categories based on our conceptualization of the meaning of low, medium, and high frequency of drinking and binge drinking. The original categories for frequency of drinking were 1 or 2 days, 3–5 days, 6–9 days, 10–19 days, 20–29 days, and all 30 days. The original categories for frequency of binge drinking were 0 days, 1 day, 2 days, 3–5 days, 6–9 days, 10–19 days, and ≥20 days.
[d]*Other* includes source of alcohol reported as *at a public event* or *other*.
[e]*Other* includes usual location of drinking reported as *at a public event*, *on school property*, or *in a car*; question not asked in Hawaii, North Dakota, or Vermont

beverages. There was a strong relationship between binge drinking and the usual type of alcohol consumed. Binge drinking was associated with a preference for liquor and a decreased preference for malt beverages, wine coolers, and wine.

Discussion

The present research advances the literature by providing the largest sample to date in which adolescent beverage preferences are measured. It is also the first population-based study to examine alcohol beverage preference among youth based on location of consumption, source of alcohol, and as a function of other health-risk behaviors. Liquor was the most popular beverage preference among almost half of youth drinkers, was almost twice as popular as the next most popular beverage category, was the beverage of choice in seven of eight states, and was the predominant beverage choice for virtually all demographic strata. Furthermore, liquor was disproportionately popular among those who were frequent drinkers or binge drinkers, and among those who reported a variety of other health-risk behaviors (e.g., drinking and driving, carrying a weapon, smoking, having multiple sexual partners or not using condoms).

Beer and malt-based flavored beverages (referred to as malt beverages in the current study) were the second and third most popular alcohol beverage choices among youth. Although beer was a slightly more popular beverage than malt beverages for those drinking more frequently, binge drinking, or drinking and driving, it was nonetheless surprising that malt beverages had a similar overall popularity as beer given the large advertising expenditures for beer relative to malt beverages.[29,30] Data from the Monitoring the Future Study demonstrates that the past-30-day prevalence of beer consumption, which was formerly the clear-cut alcoholic beverage of choice among youth, decreased from 47% to 34% between 1990 and 2008.[31] In many respects, beer and malt beverages are similar in that malt beverages are taxed like beer in most states, and are similar to beer in terms of their distribution patterns and sales venues. Viewed in this light, it may be that malt beverage split the portion of the youth alcohol market that formerly consisted of beer. On the other hand, many malt beverages are highly flavored, and therefore likely more appealing to youth tastes, particularly to those who are relatively new to alcohol consumption or who are female. Because the prevalence of alcohol consumption and binge drinking among girls has increased and is now similar to that of boys, this may partly account for gains for malt beverages compared with beer. Finally, malt beverages are often produced by liquor companies and may be used to build brand loyalty among those who may go on to drink liquor at a later stage in their drinking trajectories. Moreover, the marketing activity for liquor has increased dramatically in the past decade, particularly on cable TV and in media venues whose audiences are disproportionately youthful relative to the general population.[32]

An important finding of this paper is the pattern of a decreased preference for malt beverages and wine coolers

Table 2. Usual alcoholic beverage type[a] among 9th- to 12th-grade students by other health-risk behaviors—eight states combined,[b] % (SE)

(continued on next page)

among older adolescents, accompanied by an increased preference for liquor and beer. The same pattern—a preference for beer and liquor instead of malt beverages and wine coolers—was associated with more frequent and riskier drinking behavior and with other types of addictive behaviors (i.e., smoking and marijuana use). This finding has potential implications for prevention, as it suggests that interventions aimed at young adolescents who drink wine coolers and malt beverages might help avert this transition to more hard-core alcohol and the

Note: Weighted percentages of respondents in each stratum are shown in parentheses following the stratum label.
[a]The analysis is restricted to students who reported drinking at least one drink of alcohol on ≥1 days during the past 30 days; based on the question *During the past 30 days, what type of alcohol did you usually drink?*
[b]Data are from the Youth Risk Behavior Survey. Data are weighted to reflect student nonresponse and to provide estimates representative of the student populations of each state. Additional weighting factors were added to reflect the different sample sizes and student populations in each state. Data presented are representative of the overall student populations of all eight states combined.
[c]*How often do you wear a seat belt when riding in a car driven by someone else?*
[d]*During the past 30 days, how many times did you ride in a car or other vehicle driven by someone who had been drinking alcohol?*
[e]*During the past 30 days, how many times did you drive a car or other vehicle when you had been drinking alcohol?*
[f]*During the past 12 months, how many times were you in a physical fight?*
[g]*During the past 12 months, did you ever feel so sad or hopeless almost every day for two weeks or more in a row that you stopped doing some usual activities?*
[h]*During the past 12 months, did you ever seriously consider attempting suicide?*
[i]Current smokers were respondents who reported having smoked ≥1 day during the past 30 days.
[j]*During the past 30 days, how many times did you use marijuana?*
[k]*On an average school day, how many hours do you watch TV?*
[l]*During the past 3 months, with how many people did you have sexual intercourse?*; question not asked in Georgia or Utah
[m]*The last time you had sexual intercourse, did you or your partner use a condom?*; question not asked in Georgia or Utah

associated adoption of heavier and riskier drinking patterns.

This study is subject to several limitations. First, underage youth may under-report how much they drink, although there are no data to suggest that this would skew self-reports of which alcoholic beverages actually were consumed. Second, these data are representative of students from public high schools and not necessarily representative of those who do not attend school or those who attend alternative schools or private schools. Furthermore, the study was a population-based study of eight states and was therefore not nationally representative. Third, there may have been some misclassification with respect to which beverage types were consumed.

Improved surveillance for beverage and brand preferences among youth will enable better understanding of how these factors related to youth drinking, particularly when these data are combined with data about price, availability, and access-related factors experienced by youth who drink alcohol. This will be an important next step to designing and promulgating additional interventions to reduce youth drinking and its consequences.

The authors acknowledge Dr. Robert Brewer, head of the Alcohol Team at the CDC, who led efforts to improve the surveillance of type-specific alcohol use and helped conceptualize the analytic design for the paper. We also acknowledge the Youth Risk Behavior Survey coordinators in the eight states involved in this study: Dave Randall (Hawaii); Kathleen Courtney (Arkansas); Erika Edwards (Vermont); Dan Green, Jim Roeber, and Dr. Kristine Meurer (New Mexico); Jamie Weitz (Florida); Dr. Daphna Kanny (Georgia); Andrea Pena (North Dakota); and Frank Wojtech (Utah).

No financial disclosures were reported by the authors of this paper.

ARTICLE

Gender-Based Disparities in Infant and Child Mortality Based on Maternal Exposure to Spousal Violence

The Heavy Burden Borne by Indian Girls

Jay G. Silverman, PhD; Michele R. Decker, ScD, MPH; Debbie M. Cheng, PhD; Kathleen Wirth, ScM; Niranjan Saggurti, PhD; Heather L. McCauley, MS; Kathryn L. Falb, MPH; Balaiah Donta, PhD; Anita Raj, PhD

Objectives: To examine associations between intimate partner violence (IPV) against Indian women and risk of death among their infants and children, as well as related gender-based disparities.

Design: Analyses of nationally representative data to estimate adjusted hazard ratios (aHRs) and attributable risks for infant and child mortality based on child gender and on IPV against mothers.

Setting: India.

Participants: Women aged 15 to 49 years (n = 59 467) across all 29 Indian states participating in the Indian National Family Health Survey 3 provided information about 158 439 births and about infant and child mortality occurring during the 20 years before the survey.

Main Outcome Measures: Maternal IPV and infant and child (<5 years) mortality among boy vs girl children.

Results: Infant mortality was greater among infants whose mothers experienced IPV (79.2 of 1000 births) vs those whose mothers did not experience IPV (59.1 of 1000 births) (aHR, 1.09; 95% confidence interval [CI], 1.03-1.15); this effect was significant only for girls (1.15; 1.07-1.24; for boys, 1.04; 0.97-1.11). Child mortality was also greater among children whose mothers experienced IPV (103.6 of 1000 births) vs those whose mothers did not experience IPV (74.8 per 1000 births) (aHR, 1.10; 95% CI, 1.05-1.15); again, this effect was significant only for girls (1.14; 1.07-1.21; for boys, 1.05; 0.99-1.12). An estimated 58 021 infant girl deaths and 89 264 girl child deaths were related to spousal violence against wives annually, or approximately 1.2 million female infant deaths and 1.8 million girl deaths in India between December 1985 and August 2005.

Conclusion: Intimate partner violence against women should be considered an urgent priority within programs and policies aimed at maximizing survival of children in India, particularly those attempting to increase the survival of girls 5 years and younger.

APPROXIMATELY 10 MILLION children die across the globe each year before their fifth birthday.[1] One in 5 of these children (2.1 million) die in India.[1,2] Child mortality is a stubborn problem across South Asia. With more than 8% of live births estimated to end in death before age 5 years,[1,3] the region is failing to meet Millennium Development Goal 4 (reducing child mortality by two-thirds from 1990 to 2015).[1] As other regions in Asia have made greater strides toward this goal, South Asia's fraction of infant deaths has steadily risen, now estimated at approximately 80%.[1] With India alone contributing more than one-quarter of all births worldwide each year,[1] reductions in national infant and child mortality, even of a modest magnitude, are critical.

Multiple infant and child mortality risk factors have been well documented (eg, malnutrition, low birth weight, and infectious disease)[4-7]; however, less attention has been paid to the potential role of violence against mothers of infants and children. Violence from husbands has been implicated in child malnutrition,[8,9] low birth weight,[10,11] and infectious disease,[12] as well as direct violence against a child,[13] suggesting its role in mortality outcomes. Investigation into the role of intimate partner violence (IPV) in mortality outcomes is indicated in India given its high prevalence of spousal violence against wives (>1 in 3),[14,15] coupled with high rates of infant and child mortality.[1]

Gender disparity constitutes a critical yet understudied issue regarding Indian infant and child mortality. Differential mal-

treatment of girls vs boys has been discussed extensively,[1,7,16-18] and millions of girls have been described as "missing" in the population.[19] The high ratio of male births to female births in India[20] is thought to reflect sex-selective abortion and undocumented female infanticide and other female infant death.[5,16,19,21,22] These gender-based disparities extend to child mortality in India[23]; an estimated 70 of 1000 boys born will die before age 5 years, while this estimate is 13% higher for girls at 79 of 1000 born.[1] Notably, the pattern in India is the reverse of that found globally (ie, child survival is greater for girls in most other nations[24,25]).

To date, there has been little empirical assessment as to whether and to what extent spousal violence affects the likelihood of infant and child survival. Four district or community-based studies have explored this question to date, 2 studies[26,27] in rural districts of the Indian states of Uttar Pradesh and Tamil Nadu, 1 study[28] in a rural district in Bangladesh, and 1 case-control study[29] in Leon, Nicaragua. Results of 3 of these studies[26,27,29] using mothers as the unit of analysis indicate that a woman's history of violence from a male partner increases the likelihood of infant or child mortality. The single study[28] of community-based data that assessed the association of violence against mothers with the risk of child mortality at the child level rather than at the maternal level found no overall elevated risk of mortality conferred by such violence. A 2009 study[30] examined this relationship using Indian data and found evidence of an association, but the findings cannot be considered nationally representative because sample weights were not used; furthermore, the analyses were not stratified by child gender.

To advance the state of knowledge, this study used a large national data set weighted to provide a nationally representative sample of mothers' reports of infant and child deaths in India collected via the Indian National Family Health Survey 3 (NFHS-3) between November 2005 and August 2006. Analyses were conducted to (1) assess whether violence against mothers was related to elevated rates of infant and child (aged <5 years) mortality, (2) evaluate if such rates differed for girls vs boys, and (3) explore the extent to which recent national census statistics reflect such mortality rates and related gender-based disparities.

METHODS

DESIGN, SETTING, AND SAMPLE

From November 2005 to August 2006, the NFHS-3 was conducted in all 29 Indian states by the International Institute for Population Sciences and Macro International.[15] The NFHS, also referred to as the Demographic Health Survey in other national contexts, is conducted regularly in many developing countries to obtain population-based estimates of major health threats. This surveillance involves confidential questionnaires administered verbally in private locations within sampled households; surveys were bilingual within each state, with questions available in English and in the principal language of that Indian state. The nationally representative household-based sample for the NFHS-3 was created via a stratified multistage cluster strategy. Within each state, 2-stage (rural areas) and 3-stage (urban areas) procedures identified 3850 primary sampling units comprising 1 or more villages in rural areas and census enumeration blocks within wards in urban areas; primary sampling unit selection probability was proportional to population size. Within each primary sampling unit, household enumeration generated the sampling frame for systematic selection of households. Trained research assistants conducted household-based recruitment and obtained written informed consent immediately before survey data collection. Further details concerning the NFHS-3 procedures have been published previously.[15]

These procedures identified 131 596 eligible women in India aged 15 to 49 years, of whom 124 385 completed the survey (response rate, 94.5%).[15] Although the overall sampling strategy allowed for multiple female participants per household, a separate systematic procedure selected a single female participant to complete the IPV assessment. This assessment was conducted by female interviewers only when the privacy of the respondent was guaranteed.[31] All interview responses were kept strictly confidential and were not shared with other members of the household. This procedure was designed to maximize participant confidentiality in responding to sensitive items concerning violence victimization and to prevent risk to any individual based on subsequent discussion of the assessment among participating household members. Of 124 385 female survey participants, 84 268 (67.7%) were selected for the IPV module, and 83 703 of these (99.3%) completed the module. Each participant was asked to enumerate the births of their children, including gender, current age, and age at death if applicable. Among 83 703 women who completed the IPV assessment, 63 356 had given birth; these participants provided birth information about 187 351 children, which serve as the unit of analysis for the present investigation. The analytic sample was further restricted to births within the past 20 years (n=159 053) to maximize inferences to the current population while retaining statistical power. Six hundred fourteen births with incomplete data concerning violence exposure were excluded, resulting in a final sample size of 59 467 mothers and 158 439 births.

MEASURES

Maternal demographics, including age, parity, and education, were assessed via single self-reported items. A relative index of household wealth was calculated based on interviewer-observed assets (eg, ownership of consumer items), with resulting scores divided into quintiles (1 indicated the lowest level of household wealth; 5, the highest level of household wealth). The primary exposure, IPV, was assessed via self-report in accord with World Health Organization recommendations[32,33] and was based on the Revised Conflict Tactics Scale.[34] Lifetime IPV victimization was indicated by a positive answer to any of 8 items pertaining to whether their current husband had performed the following: "push you, shake you, or throw something at you"; "slap you"; "punch you with a fist or something harmful"; "kick, drag, or beat you up"; "try to choke or burn you on purpose"; "threaten or attack you with a knife, gun, or any other weapon"; "physically force you to have sexual intercourse with him even when you did not want to"; or "force you to perform any sexual acts that you did not want to." Items demonstrated adequate internal consistency reliability; Cronbach α was .76 for the sample. Infant and child mortality outcomes were assessed via participant enumeration of each live birth, including date of birth, current age, and age at death if applicable; consistent with international standards, infant mortality was defined as death before age 12 months, and child mortality was defined as death before age 60 months.

All data collection procedures were approved by the ORC Macro International Institutional Review Board. The Harvard School of Public Health Human Subjects Committee deemed secondary analyses exempt given the anonymous nature of the data.

Table 1. Demographic Characteristics of 59 467 Indian Women Giving Birth in the 20 Years (1985-2005) Before the Survey[a]

Variable	Total Sample, % (95% CI)	IPV Exposed, % (95% CI)[b]
Overall	**100**	34.1 (33.6-34.6)
Maternal age, y		
<25	18.5 (18.1-18.9)	34.4 (33.3-35.6)

Rural	68.1 (67.7-68.5)	36.8 (36.3-37.4)

Abbreviations: CI, confidence interval; IPV, intimate partner violence.
[a]The mean (SE) parity was 3.10 (0.01) for the total sample and 3.50 (0.02) for the IPV exposed ($P < .001$, Pearson product moment χ^2 test).
[b]Row percentages. *P* values (Pearson product moment χ^2 test) are .41 for maternal age and <.001 for highest level of education achieved, household wealth index, and dwelling.

STATISTICAL ANALYSIS

Prevalence estimates of maternal IPV victimization were calculated for the total sample of mothers (n=59 467). Differences in IPV prevalence based on demographics were assessed using the Wald χ^2 analysis; significance for all analyses was set at $P < .05$.

Infant and child mortality rates per 1000 live births were calculated for the total sample of births (n=158 439) and by gender overall and stratified based on maternal exposure to IPV. The vital statistics method was chosen for the analyses (ie, the proportion of deaths per live births) rather than derivation of mortality via calculation of component death rates, as is practiced by Macro International. Because both methods of mortality rate calculation are limited by several potentially false assumptions (eg, accurate reporting of exact month-level date of a child's death and linear changes in mortality), the vital statistics method was chosen because of its ability to describe the actual number of deaths per 1000 births. Time-to-event analysis using Cox proportional hazards models was conducted to evaluate the association of maternal exposure to IPV with infant and child mortality using person-months as the unit of time. Models were subsequently adjusted for maternal demographic covariates (maternal age, educational status, parity, rural dwelling, and household wealth index). Effect modification by gender was assessed by creating an interaction term of maternal exposure to IPV and child gender and by including it in the multivariate-adjusted Cox proportional hazards model. The interaction term was evaluated using the Wald χ^2 analysis. Finally, adjusted hazard ratios (aHRs) were used to calculate the population-attributable fraction (PAF) to estimate the fractions of all infant and child mortality cases that would not have occurred in the absence of maternal violence (overall and by child gender). The PAF was calculated using the following computation: $p_c([RR-1]/RR)$, where p_c represents the IPV prevalence among the cases, and *RR* indicates risk ratio.[35,36] To estimate the effect of IPV on infant and child mortality during the 20-year period (December 1985 to August 2005), the PAF was then multiplied by the corresponding annual numbers of infant and child births and deaths by gender that occurred during that period.[15,20,37-39]

All analyses were performed using commercially available statistical software (SAS version 10.0; SAS Institute, Cary, North Carolina); survey analysis procedures were used to accommodate the stratified cluster sampling design of the NFHS-3 and the potential for nonindependence of responses within primary sampling units. Analyses were weighted for nonresponse using the nationally representative women's IPV module weights.

RESULTS

IPV PREVALENCE AND ASSOCIATED DEMOGRAPHICS

More than 1 in 3 married Indian women who had given birth in the past 20 years (34.1%) reported having experienced IPV (**Table 1**). This estimate is slightly lower than the 40% prevalence reported for the overall NFHS-3 sample.[15]

INFANT AND CHILD MORTALITY BASED ON IPV EXPOSURE AND CHILD GENDER

Infant mortality was significantly greater among births to mothers experiencing spousal violence (79.2 of 1000 births) vs those who did not experience spousal violence (59.1 of 1000 births) (significance was based on nonoverlapping 95% confidence intervals [CIs]). The aHR for this effect (1.09; 95% CI, 1.03-1.15) indicates an estimated 9% increase in the risk of infant mortality based on maternal violence exposure (**Table 2**).

Analyses stratified by child gender demonstrated that this association was pronounced and significant only for girl infants. Among infant girls, maternal exposure to IPV conferred elevated risk for infant mortality (HR, 1.15; 95% CI, 1.07-1.24), while for infant boys it was nonsignificant (1.04; 0.97-1.11) .

Similarly, children younger than 5 years were significantly more likely to die if their mothers experienced spousal violence (103.6 vs 74.8 deaths per 1000 births) vs those whose mothers did not experience such violence (74.8 of 1000 births). In adjusted Cox proportional hazards regression models, maternal exposure to IPV significantly elevated the risk of child mortality by approximately 10% (aHR, 1.10; 95% CI, 1.05-1.15). Similar to results for infant mortality, analyses stratified by child gender demonstrated that the elevated mortality was borne primarily by girls, with their risk of death by age 5 years increased by 14% based on maternal exposure to IPV (aHR, 1.14; 95% CI, 1.07-1.21). Among boys, IPV was not associated with a significant increase in mortality risk (aHR, 1.05; 95% CI, 0.99-1.12).

In analyses containing an interaction term for child gender and maternal exposure to IPV, the Wald χ^2 analy-

[a] Calculated as the proportion of live births resulting in death multiplied by 1000.
[b] Adjusted for maternal age, education, parity, rural (vs urban) residence, and household wealth index.

sis indicated that the observed differences between girl and boy mortality were statistically significant. *P* values for the interaction terms were .02 for child mortality and .03 for infant mortality.

The PAF was calculated to estimate the potential effect of reducing IPV on rates of infant and child mortality (ie, the fraction of deaths that may be attributable to the direct or indirect effects of IPV); the PAF is estimated only for those effects found to be significant based on hazard ratios. The PAFs were 3.66% (95% CI, 1.22%-6.04%) for overall infant mortality and 6.07% (2.43%-9.58%) for infant girl mortality (Table 2). The PAFs were 3.98% (95% CI, 1.82%-6.10%) for overall child mortality and 5.77% (2.66%-8.79%) for female child mortality. These findings suggest that approximately 1 in 15 deaths of female infants and 1 in 16 deaths of female children could be prevented by eliminating IPV.

To estimate the numbers of infant deaths overall and infant girl deaths attributable to IPV each year across the period studied, as well as across the entire period, PAFs were multiplied by the number of annual infant deaths and infant girl deaths per UNICEF (United Nations International Children's Emergency Fund)[37] and World Health Organization[39] statistics for the midpoint of this interval (ie, 1995). Infant mortality statistics from 1995 closely mirror the means of those derived for 1990 and 2000 and for 1985 and 2005 by the Indian government,[31] indicating the validity of using 1995 mortality statistics in calculating the mean annual mortality (further details about the computations are available from the corresponding author). On the basis of these calculations,[38-40] spousal violence in India against wives may account for 72 617 infant deaths each year across the 20-year period from 1985 to 2005, with girls representing 58 021 of these annual deaths. Considered over the 20-year period under study, spousal violence against mothers is associated with an estimated 1 160 440 girl infant deaths. Using the same method of computation,[38-40] spousal violence in India may be related to approximately 119 480 child deaths each year from 1985 to 2005, with girls representing 89 264 of these annual deaths. Therefore, across the 2 decades studied, violence against mothers is associated with an estimated 1 785 280 female child deaths.

COMMENT

Infants and young children in India were found to suffer significantly greater risk of death in families in which mothers had experienced spousal violence from their husbands. Furthermore, the effect of such gender-based violence was profoundly gendered; infant girls and children bear a far greater share of the mortality burden associated with IPV. In contrast, IPV was not significantly associated with infant boys and child mortality in adjusted analyses. Even after considering the birth of fewer girls than boys in India, deaths of infant girls and young girls accounted for an estimated 80% of all infant deaths and 75% of all child deaths related to IPV, translating to approximately 58 021 infant girls and 89 264 young girls dying each year from 1985 to 2005, or 1.2 million infant girl deaths and 1.8 million girl deaths in India across the 20-year period studied herein.

Violence against mothers may contribute to infant and child mortality by various mechanisms. Evidence of a significant gender differential in this pattern suggests that these mechanisms disproportionately affect girls, likely reflecting the perceived relative lower value of girls vs boys in many Indian families and communities. Moreover, violence against wives may well be a marker for multiple other forms of gender-based maltreatment and neglect of girls (eg, provision of less food, reduced attention to infection prevention, and decreased investment in care for illness).

Because violence against wives is considered an expression of men's sense of entitlement to use violence to control women (including women's care of children),[33,41] it is reasonable to assume that this same belief system informs such men's treatment of their girls.[33,41] Men who perpetrate IPV may well see girls as less deserving of care, leading to inadequate provision of food, hygiene, and other preventive measures, as well as reluctance to invest in the treatment of girls in case of illness; thus, such men ensure that the resources of the family are directed to adult men and sons.[42] In the most extreme forms, violence or mistreatment toward infant girls may take the form of female infanticide.[33,42] Evidence of this gender-based disparity was recently described among a large Indian sample

in which socioeconomic status was associated with the provision of health care only for boys[43]; such effects may be magnified in abusive homes.

Moreover, although child abuse was not assessed herein, it may be that men who are violent against their wives also exhibit violence and mistreatment toward their children.[13] The relative low worth and social and economic costs traditionally associated with girls[44] may make such abuse more likely to extend to girls 5 years and younger.

Abused women may be less able to care for their children based on the emotional and physical sequelae of the violence they have experienced,[45] with such violence being particularly severe following the birth of a girl for the reasons aforementioned.[16,46] The incapacitation of a mother may affect male children to a lesser extent, as family members may be more likely to assist with boys in such cases.[28]

Violence has been found to affect the pregnancy-related health of women and to increase the likelihood of having a low-birth-weight infant.[10,11] However, this explanation does not account for the observed gender disparity in the association of IPV and mortality, as the sex of the child will most likely remain unknown until birth.

Several important limitations of the present study design should be considered in reviewing these findings. The cross-sectional nature of the investigation does not allow for conclusions regarding temporality. In other words, infant and child deaths may precede violence against Indian wives. However, it is unclear why violence would be more likely in cases of the death of a girl 5 years or younger. As discussed, IPV may well be a marker for other gender-related conditions that affect female mortality; to clarify the present findings, longitudinal study regarding a broad spectrum of gender-based maltreatment of women and its potential effects on female child mortality is necessary. Several potential mechanisms underpinning our results were unable to be formally evaluated; data were not collected about the cause of death, abuse of children, or nutritional and health status among children who had died. Such data are needed to better understand the associations identified. Based on the nature of our research question, the present sample was limited to women who were systematically selected for and completed the IPV assessment module. Despite the high participation rate in the IPV module (99.3%), it is possible that this subsample of female participants and, most important, the births they described were in some way nonrepresentative of the larger survey sample and the population. Finally, although child deaths are critical events in life, the reliability of women's recall of such events across the preceding 20 years is unknown.

In summary, the magnitude of the association of IPV perpetration by Indian men with child mortality, as well as the numbers of infants and children who may die based on this modifiable factor, is great; so too is the disproportionate burden borne by young Indian girls. A clear implication of the present findings is the urgent need for IPV against women to be considered an urgent priority within programs and policies aimed at maximizing survival of children in India, particularly those attempting to increase the survival of girls. Violence against mothers[2,29] and the associated gender-based mistreatment of female infants and children[2,23,24] may represent major barriers preventing India from reaching the Millennium Development Goal 4 of a two-thirds reduction in child mortality from 1990 levels by 2015.[1] Regardless of such targets and deadlines, violence against wives in India must be vigorously challenged. Even a modest reduction in the prevalence of IPV may prevent the deaths of tens of thousands of Indian infant girls and children. Such progress may be accomplished by interventions that address gender norms within the context of maternal, neonatal, and child health (eg, antenatal programs for men who are identified as perpetrating IPV).

Our finding that approximately 1 in 15 female infant deaths and 1 in 16 fermale child deaths may be prevented by eliminating IPV should lead to greater investment in changing discriminatory gender norms among Indian boys and men. Norms should be altered that lead to a broad range of physical and social hazards for women and girls, including gender-based violence and other maltreatment of wives, as well as the associated gendered increase in infant and child mortality suffered by girls born into such families.

Sex Trafficking and Initiation-Related Violence, Alcohol Use, and HIV Risk Among HIV-Infected Female Sex Workers in Mumbai, India

Jay G. Silverman,[1] Anita Raj,[1] Debbie M. Cheng,[2] Michele R. Decker,[5] Sharon Coleman,[3] Carly Bridden,[4] Manoj Pardeshi,[6] Niranjan Saggurti,[7] and Jeffrey H. Samet[4]

[1]Division of Global Public Health, Department of Medicine, University of California at San Diego School of Medicine, La Jolla, [2]Department of Biostatistics, [3]Data Coordinating Center, Boston University School of Public Health, and [4]Department of Medicine, Section of General Internal Medicine, Boston University School of Medicine/Boston Medical Center, Massachusetts, [5]Department of Population, Family and Reproductive Health, Johns Hopkins School of Public Health, Baltimore, Maryland; [6]Network of Maharashtra by People Living with HIV & AIDS, (NMP+), Pune, and [7]Population Council, New Delhi, India

Female sex workers (FSWs) are the group at greatest risk for human immunodeficiency virus (HIV) infection in India. Women and girls trafficked (ie, forced or coerced) into sex work are thought to be at even greater risk because of high exposure to violence and unprotected sex, particularly during the early months of sex work, that is, at initiation. Surveys were completed with HIV-infected FSWs (n = 211) recruited from an HIV-related service organization in Mumbai, India. Approximately 2 in 5 participants (41.7%) reported being forced or coerced into sex work. During the first month in sex work, such FSWs had higher odds of sexual violence (adjusted odds ratio [AOR], 3.1; 95% confidence interval [CI], 1.6–6.1), ≥7 clients per day (AOR, 3.3; 1.8–6.1), no use of condoms (AOR, 3.8, 2.1–7.1), and frequent alcohol use (AOR, 1.9; 1.0–3.4) than HIV-infected FSWs not entering involuntarily. Those trafficked into sex work were also at higher odds for alcohol use at first sex work episode (AOR, 2.2; 95% CI, 1.2–4.0). These results suggest that having been trafficked into sex work is prevalent among this population and that such FSWs may face high levels of sexual violence, alcohol use, and exposure to HIV infection in the first month of sex work. Findings call into question harm reduction approaches to HIV prevention that rely primarily on FSW autonomy.

There are currently 2.4 million persons in India living with human immunodeficiency virus (HIV) infection [1], with most having acquired the virus via heterosexual sex [2]. Female sex workers (FSWs) remain at greatest risk for HIV infection in India, with commercial sex involvement viewed as the primary means of transmission [1, 3]. The city of Mumbai is considered an epicenter for both sex work and HIV infection [4], with ≥10 000 FSWs and more HIV-related deaths than in any other location in India [5, 6].

Forced or coerced entry (ie, being "trafficked") into sex work is increasingly considered a marker for HIV risk among FSWs. However, although recent data from South Asia illustrate high HIV prevalence among former FSWs identified as having been trafficked [7, 8, 9], little is known of either the prevalence of this experience among general samples of FSWs, or how sexual risk may differ based on involuntary entry into sex work. A prominent explanation for why those trafficked into sex work are at greater risk for HIV infection is exposure to high levels of violence and related sexual risk during their involuntary initiation into prostitution [10]. Qualitative research among Indian and Nepali FSWs identified as trafficked indicates that violence in the period immediately after entry to sex work may involve high levels of sexual brutality, leading to vaginal injuries and significant blood loss, thus creating high

vulnerability to sexually transmitted infection [8]. Two previous quantitative studies have compared sexual violence at entry and HIV risk based on having been trafficked; both demonstrated that sexual violence at entry is more common among those trafficked into sex work (in one case, those entering at <18 years of age were also coded as having been trafficked) than among FSWs not reporting this experience [7, 11]. However, no quantitative studies have examined the initial period of sex work (ie, after entry) to identify the prevalence and qualities of sexual risk and violence during this first month of "normal" commercial sex exposure, nor has the phenomenon been examined among FSWs infected with HIV. Alcohol has also been implicated in HIV risk among FSWs in India [12]. Almost half (44%) of FSWs in India report drinking alcohol [13], and a recent study of HIV-infected FSWs found that the majority of those who do use alcohol are heavy and/or dependent drinkers [12]. The aforementioned qualitative study of violence and HIV risk among trafficked South Asian women indicates that alcohol may be used to "initiate" women and girls into sex work involuntarily with heavy voluntary alcohol use continuing as a means for them to cope with their lack of autonomy [8]. To date, no quantitative studies have integrated assessments of forced or coerced entry with assessments of alcohol use. To advance the state of knowledge regarding the mechanisms that may link HIV infection and involuntary entry to sex work, the current study assessed the prevalence of trafficking among HIV-infected FSWs in Mumbai, India, and examined whether such history is associated with differences in history of sexual violence, sexual risk, and alcohol use in the initial 30 days of sex work. Such data are critical for prioritizing and developing HIV interventions designed to reach individuals in the early stages of sex work and illuminating the consequences of forced and coerced entry to sex work. Furthermore, because exposure to violence has been linked both to lower likelihood of adherence to antiretroviral therapy and to higher current sexual risk among HIV-infected FSWs, [8] the current findings may also inform secondary prevention efforts to reduce both mortality and the likelihood of HIV transmission among this vulnerable population.

METHODS

HIV infected FSWs were recruited from the ASHA Center, a community-based organization in Mumbai, managed and run by a group of FSWs who provide support and linkage to HIV-related healthcare. A total of 326 FSWs were contacted for study recruitment, of whom 246 (75%) responded positively. Of these, 216 individuals met the study's eligibility criteria: ≥18 years old, HIV infected, and reporting both sex trade involvement in the past year and penile-vaginal or anal sex in the past 30 days. HIV infection was confirmed by medical records brought by the participants. Of those eligible for the study, 97.7% (211/216) were willing to participate and complete survey interviews. Participants received a 45-minute interviewer-administered survey in Hindi assessing demographics, alcohol use, sex risk behaviors, and health status. Instruments were developed in English, translated into Hindi, and then reviewed by a study investigator fluent in both languages. Participants were given 100 rupees ($2.50) as compensation for their time in this study. Study procedures were reviewed and approved by the institutional review boards of Boston University Medical Campus, the Harvard School of Public Health, NMP+, and the Indian Council of Medical Research.

Measures

Demographic data were collected based on items modified or taken from the Indian Demographic and Health Survey [14]. The assessment of being trafficked into sex work, the main independent variable, was developed for this study based on the authors' previous research with sex-trafficked women and girls in South Asia [9, 15]; participants were asked "How did you start having sex for money?" and directed to select the answer they felt best described "how you got you into this work." (The wording of assessments reflects the back-translation from Hindi to English.) Options included (a) I decided myself that this was a good way for me to earn money; (b) someone told me that I should do this business, and I felt I had no choice but to enter; (c) someone forced me to come and do this business; (d) someone tricked me into coming to do this business; (e) I accepted a job doing some other kind of work and was made to have sex for money; and (f) someone used some other means besides trickery or force to make me enter. Participants selecting c, d, e, or f were classified as having been trafficked.

To assess experiences of sexual violence in the first month after entry, participants were asked "During the first month that you were in sex work, how often did anyone use violence or force to make you have sex or have certain types of sex with male clients?" Response options were "never," "rarely," "sometimes," or "very often." Those responding "sometimes" or "very often" were classified as experiencing violence in the first month of sex work. This same response set was used for determining condom nonuse during this same period with the question "During the first month in sex work, how often were condoms used when you were having sex with male clients?" This response pattern was again used to assess frequent alcohol use during the first month of sex work with the question "In the first month that you were in sex work, how often did you use alcohol when engaging in sex work?" Those who reported using alcohol "very often" were classified as frequently using alcohol during this period. Client volume during this initial period of exposure to sex work was assessed by asking "During the first month that you were in sex work, approximately how many male clients did you have on a working day?" Possible responses included 1–2, 3–6, and ≥7;

Table 1. Demographic Characteristics of HIV-Infected Female Sex Workers in Mumbai, India, and Demographic Differences Based on Experiences of Being Trafficked Into Sex Work

Demographic characteristic	Female sex workers, % (No.)			P
	Total sample (n = 211)	Trafficked into sex work (n = 88)	Not trafficked into sex work (n = 123)	
Age, years[a]				.33

Duration in sex work, mean ± SD, years	12.8 ± 5.4	12.7 ± 5.4	12.8 ± 5.4	.86

Abbreviations: HIV, human immunodeficiency virus; SD, standard deviation.

[a] Median age was 30 years.

[b] Median income was 3000 rupees per month.

reports of ≥7 partners per day were classified as high client volume in the first month. Alcohol at first sex work episode was assessed by asking the yes-or-no question "The first time you had sex in exchange for money or gifts, were you drinking alcohol?"

Data Analysis

χ^2 analyses were used to assess whether demographics (all categorical variables) differed based on having been trafficked. Frequencies for being trafficked and for each of the 5 outcome variables (sexual violence, high client volume, nonuse of condoms and frequent alcohol use in first month of sex work, and alcohol use at first sex work episode) were calculated for the total sample. Associations between being trafficked and each outcome variable were assessed via logistic regression, first unadjusted and then adjusted for the following confounders: education, marital status, religion, income, and age at entry into sex work. To minimize the potential for collinearity, we assessed correlation between pairs of independent variables; no variables included in the same regression model were highly correlated (ie, $r > 0.40$). All analyses were performed using SAS software (version 9.1; SAS Institute) [16].

RESULTS

Approximately 2 in 5 (41.7%) HIV-infected FSWs reported being forced or coerced (ie, trafficked) into sex work. The most common perpetrators reported by such women were coworkers (25.0%), acquaintances (25.0%), strangers (18.2%), and family members (9.1%) (data not shown). Slightly more than half (50.2%) entered sex work before age 18 years. The most common places of origin among participating FSWs were

Table 2. Sex Trafficking and Experiences of Violence, Alcohol Use, and HIV Risk in the First Month of Sex Work as Reported by HIV-Infected Female Sex Workers (FSWs) in Mumbai, India (n = 211)

Variable	FSWs, % [95% CI] (No.)
Forced or coerced into sex work	41.7 [35–49] (88)
Sexual violence in first month of sex work	62.2 [56–69] (132)
≥7 clients per day in first month of sex work	35.9 [29–43] (75)
No client condom use during first month of sex work	50.7 [44–58] (107)
Used alcohol very often in first month of sex work	54.0 [47–61] (114)
Used alcohol at first sex work encounter	59.2 [52–66] (125)

Abbreviations: CI, confidence interval; HIV, human immunodeficiency virus.

Mumbai (6.2%), other parts of Maharashtra (9.0%), Karnataka (33.6%), Bangladesh (6.2%), and Nepal (20.4%). Neither age at entry nor other demographics differed significantly between those who reported being trafficked into sex work and those who did not (all $P > .05$) (Table 1). Violence and sexual risk exposures were highly prevalent during the first month in sex work. Sixty-two percent of HIV-infected FSWs reported sexual violence from male clients during the initial month after entry. The volume of male clients during the first month was high, with 35.9% reporting sex with ≥7 clients per day during this period. Slightly more than half (50.7%) of HIV-infected FSWs reported no use of condoms in their first month in sex work. Alcohol related risk was also prevalent; the majority of participants reported frequent alcohol use in the initial month after entry (54.0%) and alcohol use at first sex work episode (59.2%) (Table 2). In multivariate models, those reporting having been trafficked into sex work had significantly higher odds of sexual violence during their initial month in sex work (adjusted odds ratio [AOR] 3.1; 95% confidence interval [CI], 1.6–6.1), a high volume of male clients (AOR, 3.3; 95% CI, 1.8–6.1), and no use of condoms in this same time period (AOR, 3.8; 95% CI, 2.1–7.1). Participating HIV-infected FSWs who reported entering sex work involuntarily also had significantly higher odds of frequent alcohol use during their first month of sex work (AOR, 1.9; 95% CI, 1.0–3.4) and of alcohol use at their first sex work episode (AOR, 2.2; 95% CI, 1.2–4.0) (Table 3).

DISCUSSION

More than 2 in 5 HIV-infected FSWs in the current study reported that they did not enter commercial sex work of their own volition but were instead forced or coerced (ie, trafficked) into the sex trade. This prevalence estimate is slightly greater than what was found in the single other study of sex trafficking among a general sample of FSWs in South Asia (32%) [11]. This greater prevalence is probably due to the high prevalence of HIV infection in the current sample, given that this same earlier study found that being trafficked into sex work was more common among FSWs infected with HIV. Regional differences between Mumbai and West Bengal may also account for this difference. The first month of sex work was characterized by high levels of sexual violence and sexual risk, with almost 2 of 3 FSWs in the current sample reporting such exposure. Those FSWs who were trafficked into sex work had ~3 times the odds of sexual violence at the hands of male clients in the first month after entry, compared with those entering voluntarily. This finding is

Table 3. Associations Between Being Trafficked Into Sex Work and Experiences of Sexual Violence, Frequent Alcohol Use, and HIV Risk in the First Month of Sex Work Among HIV-Infected Female Sex Workers in Mumbai, India (n = 211)

	Female sex workers, % (No.)		OR (95% CI)	
Variable	Trafficked into sex work (n = 88)	Not trafficked into sex work (n = 123)	Crude	Adjusted[a]
Sexual violence in first month of sex work	75.0 (66)	53.7 (66)	2.6 (1.4–4.7)	3.1 (1.6–6.1)
≥7 clients/day in first month of sex work	51.2 (44)	25.2 (31)	3.1 (1.7–5.6)	3.3 (1.8–6.1)
No client condom use in first month of sex work	68.2 (60)	38.2 (47)	3.5 (2.0–6.2)	3.8 (2.1–7.1)
Used alcohol very often in first month of sex work	62.5 (55)	48.0 (59)	1.8 (1.04–1.2)	1.9 (1.0–3.4)
Alcohol use at first sex work episode	69.3 (61)	52.0 (64)	2.1 (1.2–3.7)	2.2 (1.2–4.0)

Abbreviations: CI, confidence interval; HIV, human immunodeficiency virus; OR, odds ratio.

[a] Adjusted ORs were adjusted for history of any formal education, marital status, religion, income, and age at entry into sex work.

consistent with findings of the aforementioned study of FSWs in West Bengal [11] and a similar study of FSWs in Thailand [7], but it provides increased specificity regarding proximity to the time of entry, in that the current assessment of sexual violence was limited to the first 30 days in sex work.

Expanding on previous work assessing links between involuntary entry and HIV risk, current findings indicate that those FSWs who reported being forced or coerced into sex work also experienced far greater early exposure to sexually transmitted infection. Such FSWs had 3 times the odds, compared with those who entered voluntarily, of having had sex with ≥7 partners a day in the first month in sex work, and ~4 times the odds of reporting no condom use by male clients in this same initial period. Alcohol also figured prominently in the early experiences of sex work for trafficked women and girls. Trafficked HIV-infected FSWs had approximately twice the odds of reporting both using alcohol "very often" during the first month in prostitution and using alcohol during their first commercial sex episode. These findings confirm previous qualitative work among trafficked FSWs that describes alcohol being forced on women and girls on entry in order to gain their compliance and voluntary regular use of alcohol subsequent to violent sexual initiation in an attempt to cope with ongoing sexual violence [8]. Relationships between trafficking and other substance use (particularly injection drug use, a major source of HIV infection) warrant further examination.

Most all HIV prevention programs targeting FSWs The high prevalence of trafficking and experiences of sexual violence as part of being forced to participate in sex work described by this sample is critical to recognize; the great majority of current descriptions of conditions of sex work, and HIV prevention programs targeting FSWs assume voluntary entry and autonomy regarding sex work practice [18]. However, the ~40% of women and girls who report being trafficked describe extremely high levels of exposure to HIV risk within the initial month of sex work. Thus, peer education and FSW collectivism (the dominant approaches for HIV prevention among FSWs) are not likely to be effective for a large portion of this population, given that experiences of coercion directly contradict the autonomy and control over sexual protection needed to implement condom use and gain support from fellow FSWs. Further, assuming autonomy may be gradually obtained by those forced or coerced into sex work, the early and intense exposure to infection may well lead them to contract HIV before being able to benefit from such programs. This contention is supported by previous work among trafficked FSWs in Mumbai and in Nepal that found rates of HIV infection between 30% and 60% after only short periods of sex work exposure [9, 15].

There are several limitations related to the design of the current study. Assessments were of experiences in the first month of sex work, leaving open the possibility of recall error. However, recent research indicates that recall for traumatic events is likely to be highly reliable, significantly more than for nontraumatic events [19]. The study surveyed a group of HIV-infected FSWs who were members of an HIV service network; it is possible that the experiences of this population do not reflect those of the larger population of HIV-infected FSWS, or FSWs generally. Finally, the current estimate of the prevalence of trafficking into sex work may be inflated given that being trafficked is associated with elevated risk for HIV infection and the HIV-infected nature of the current sample [11].

In sum, ~2 in 5 HIV-infected FSWs report being trafficked (ie, forced or coerced) into sex work. This experience is associated with increased risk of sexual violence, frequent alcohol use, and high levels of exposure to HIV during the first 30 days after entry. These findings call into question utility of conventional harm reduction approaches to HIV prevention that rely on the autonomy of FSWs. Development of interventions that assure FSW autonomy within the context of sex work should be prioritized. HIV prevention programs and policies should include substantial efforts to prevent the involuntary entry of women and girls into sex work.

Brief Report

Predictors of Thyroid Hormone Initiation in Older Adults: Results From the Cardiovascular Health Study

Background. Despite widespread use, there are no data on initiation of thyroid hormone use in older people. We report the prevalence of thyroid hormone use and predictors of thyroid hormone initiation in a population of older men and women.

Methods. Thyroid hormone medication data were collected annually from 1989 to 2006 in community-dwelling individuals aged 65 years and older enrolled in the Cardiovascular Health Study (N = 5,888). Associations of age, sex, race, body mass index, education, and coronary heart disease with initiation were evaluated using discrete-time survival analysis.

Results. In 1989–1990, 8.9% (95% confidence interval 8.1%–9.7%) of participants were taking a thyroid hormone preparation, increasing to 20.0% (95% confidence interval 8.2%–21.8%) over 16 years. The average initiation rate was 1% per year. The initiation rate was nonlinear with age, and those aged 85 years and older initiated thyroid hormone more than twice as frequently as those aged 65–69 years (hazard ratio = 2.34; 95% confidence interval 1.43–3.85). White women were more likely to initiate thyroid hormone than any other race and sex group. Higher body mass index was independently associated with higher risk for initiation (p = .002) as was greater education (p = .02) and prevalent coronary heart disease (p = .03).

Conclusions. Thyroid hormone use is common in older people. The indications and benefits of thyroid hormone use in older individuals with the highest rate of thyroid hormone initiation—the oldest old, overweight and obese individuals, and those with coronary heart disease—should be investigated.

Key Words: Thyroid hormone—Levothyroxine—Elderly population.

Received September 2, 2010; Accepted March 11, 2011

Decision Editor: Luigi Ferrucci, MD, PhD

HYPOTHYROIDISM is more common in the elderly population, and the classic signs and symptoms found in younger people are often not apparent (1), making this an attractive demographic for biochemical screening. In addition, screening identifies subclinical hypothyroidism, which is found in up to 15% of older people (2). Management of subclinical hypothyroidism is controversial, and expert panels have published guidelines for (3) and against (4) routine treatment of subclinical hypothyroidism. An increase in the use of routine thyroid-stimulating hormone (TSH) screening and recognition of overt and subclinical hypothyroidism would be anticipated to lead to rising use of thyroid hormone supplementation in the elderly population. To date, there have been no studies to determine if an increase in thyroid hormone use over time has occurred. We conducted an analysis of individuals taking thyroid hormone preparations who were enrolled in the Cardiovascular Health Study (CHS), a population-based study of community-dwelling individuals aged 65 years and older. We sought to describe trends in the prevalence of thyroid hormone use and predictors of thyroid hormone initiation in a population of elderly men and women.

Methods

These analyses are based on data from the CHS (5). The CHS is a population-based, longitudinal study in 5,888 adults 65 years and older. Enrollment of an original cohort of 5,201 adults at four U.S. sites occurred between May 1989 and June 1990, and an additional cohort of 687, predominantly African Americans, was enrolled in 1992–1993. The institutional review boards of all four sites and of the coordinating center at the University of Washington in Seattle approved the study. All participants gave informed consent.

Table 1. Characteristics of Cohort by Thyroid Medication Status at Baseline

	Thyroid Medication			
	Original Cohort		New Cohort	
Characteristic	No (n = 4737)	Yes (n = 464)	No (n = 643)	Yes (n = 44)

Male, *n* (%)	2,149 (45.4)	90 (19.4)‡	249 (38.7)	7 (15.9)†
Caucasian, *n* (%)	4,476 (94.5)	449 (96.8)*	0	0
High school graduate, *n* (%)	3,393 (71.8)	356 (77.1)*	359 (56.0)	31 (72.1)*
Income ≥$25,000, *n* (%)	1,946 (41.1)	194 (41.8)	137 (21.3)	10 (22.7)
Current smoker, *n* (%)	551 (11.6)	50 (10.8)	95 (14.8)	4 (9.3)
BMI, kg/m^2, mean (*SD*)	26.4 (4.5)	26.7 (4.9)	28.7 (5.6)	29.4 (6.4)
Good or excellent health, *n* (%)	3,643 (77.0)	336 (72.4)*	379 (59.2)	22 (50.0)
Diabetes mellitus, *n* (%)	714 (15.2)	74 (16.1)	153 (25.0)	12 (27.9)
Hypertension, *n* (%)	2,687 (56.8)	255 (55.0)	479 (74.5)	36 (81.8)
Coronary heart disease, *n* (%)	930 (19.6)	92 (19.8)	118 (18.4)	14 (31.8)*
Stroke, *n* (%)	181 (3.8)	18 (3.9)	47 (7.3)	3 (6.8)
Any ADL difficulty, *n* (%)	332 (7.0)	42 (9.1)	93 (14.5)	9 (20.5)

Notes: ADL = activities of daily living; BMI = body mass index.
*$p < .05$; †$p < .01$; ‡$p < .001$ for comparison by medication use within cohort.

Thyroid hormone medication use was assessed annually from Study Year 1 (1989–1990) through Study Year 10 (1998–1999) via medication bottle examination during annual study visits and from Study Years 11 to 17 (1999–2000 to 2005–2006) by annual surveillance phone calls. Body mass index (BMI) was calculated as kg/m^2 using objective measures. Diabetes mellitus was classified using the American Diabetes Association criteria (6). Coronary heart disease (CHD) was present if one of the following was reported and confirmed by adjudication: myocardial infarction, angina pectoris, or history of angioplasty or bypass surgery (7). Stroke diagnosis was also confirmed by adjudication.

Statistical Analysis

Study participants' baseline characteristics were summarized by study cohort, and participants taking a thyroid hormone preparation at baseline were compared with those who were not using a *t*-test or chi-square test as appropriate. The percentage taking thyroid hormone medication was calculated by year, overall and stratified by sex and race. Annual initiation rates were calculated after exclusion of 508 participants taking thyroid hormone at baseline. Time to initiation was defined as the number of years after baseline that thyroid medication use was first reported. Discrete-time survival analysis was used to evaluate associations of baseline age, sex, race, education, income, smoking, BMI, weight gain, self-reported health, fatigue, diabetes, hypertension, prevalent CHD, stroke, and difficulty in activities of daily living with initiation of use. Only statistically significant ($p < .05$) variables were retained in the final model. Age and BMI were modeled continuously, and results shown on both continuous and categorical scales, with p values for all variables derived from the continuous model. Participants were censored at the time of their last visit. All analyses were performed using STATA version 9 (Stata Corp., College Station, TX).

Results

The mean age was 72.8 years (range 65–100 years), 58% were women and 84% white. At baseline, thyroid hormone users were more likely to be women, Caucasian, and high school graduates than nonusers were (Table 1). They were less likely to self-report good or excellent health, which was statistically significant in the original cohort, and more likely to have CHD only in the minority cohort.

In 1989–1990, 8.9% (95% confidence interval [CI] 8.1%–9.7%) of participants were taking a thyroid hormone preparation, increasing to 20.0% (95% CI 18.2%–21.8%) over 16 years, by 2005–2006. More thyroid hormone use was seen in women than in men, with a greater proportion of users at each year between 1989 and 1990 and 2005 and 2006 (Figure 1), and a greater proportion of users in whites than in nonwhites. At initiation of the study, 12.9% (95% CI 11.7%–14.2%) of white women were taking thyroid hormone, increasing to 26.3% (95% CI 23.5%–29.0%) by 2005–2006. In nonwhite women, 7.6% (95% CI 3.6%–11.5%) were taking thyroid hormone at enrollment, increasing to 13.2% (95% CI 8.9%–17.5%) by 2005–2006. Despite the lower proportion of thyroid hormone use across all years, white and nonwhite men also demonstrated a trend of increasing thyroid hormone use over calendar time. Only 4.1% (95% CI 3.3%–5.0%) of white men and 1.9% (95% CI 0.01%–4.1%) of nonwhite men were taking a thyroid hormone preparation at baseline, increasing to 13.6% (95% CI 10.7%–16.6%) and 8.2% (95% CI 2.7%–13.6%), respectively, by the end of follow-up.

After excluding the 508 thyroid medication users at baseline, there was a rate of initiation of 0.6%–1.4% per year among nonusers, with a total of 498 people initiating thyroid hormone after baseline. The average rate of initiation was 1% per year and without a consistent linear trend with time. The average age at thyroid hormone initiation was 79.7 ± 6.4 years. However, the association with age

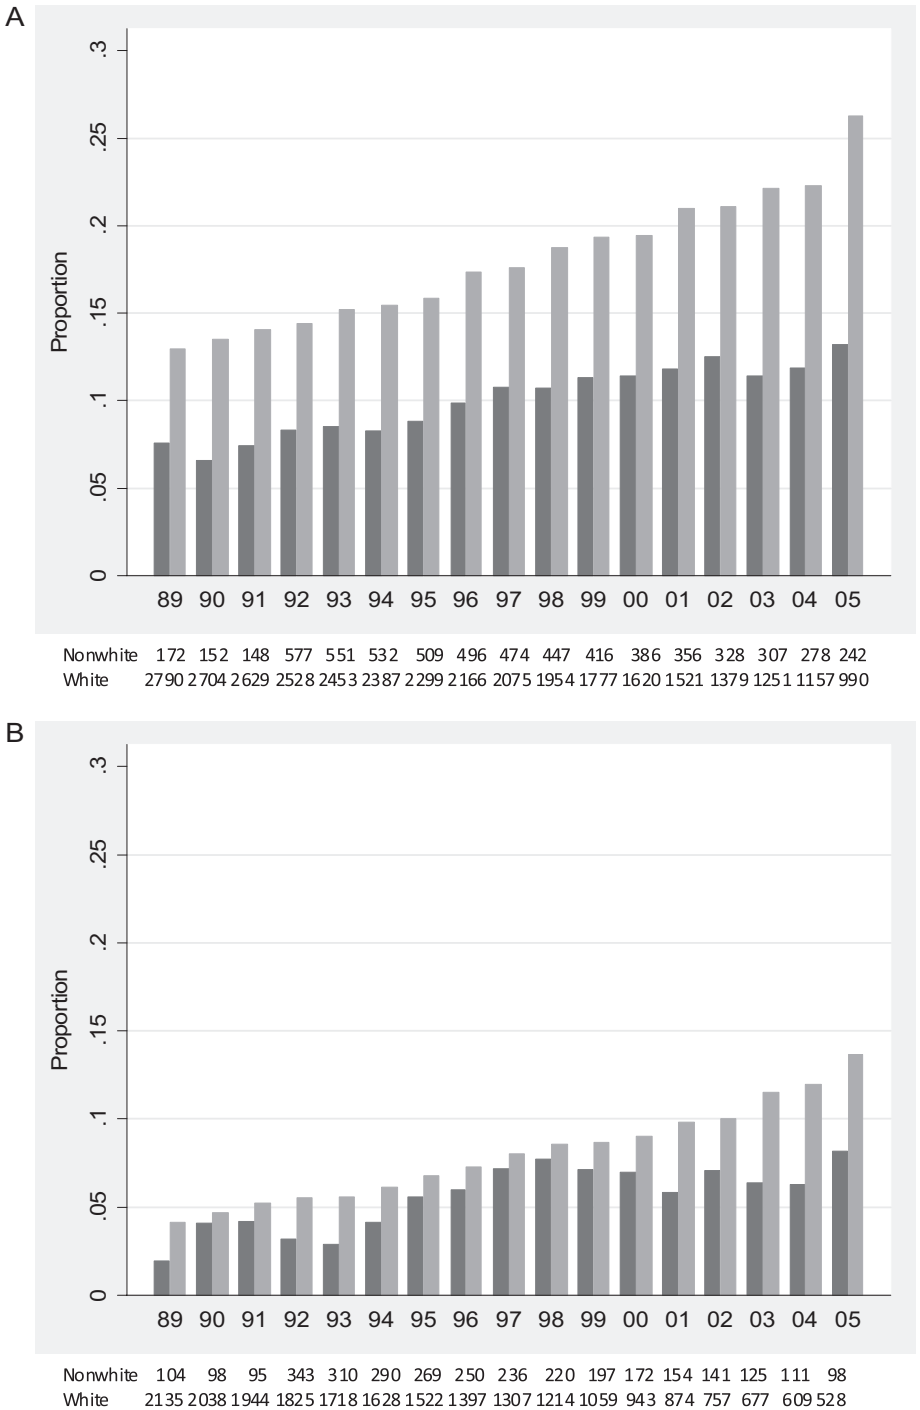

Figure 1. Proportion of participants taking thyroid hormone medication by calendar year: (A) white and nonwhite women and (B) white and nonwhite men. Black bars indicate nonwhites, gray bars whites.

was not linear, with a higher crude incidence rate, at 1.50% per year, in those aged 85 years and older at baseline than in the younger age groups, in which the crude incidence rate varied from 0.80% to 0.88% per year. In multivariable analyses (Table 2), those aged 85 years and older at baseline were more than twice as likely to initiate thyroid hormone (hazard ratio 2.34; 95% CI 1.43–3.85) than those aged 65–69 years. White women were more likely to initiate thyroid hormone than any other race and sex group (overall p value <.001), with no significant difference in rates of thyroid hormone initiation among white men, nonwhite women, and nonwhite men. Thyroid hormone initiation was higher in those whose BMI was above 25 kg/m^2 than below, achieving statistical significance for

Extremely obese (>40.0)	68	2.72	1.45–5.10	—
Education, y	—	1.03	1.00, 1.07	.022
CHD at baseline	988	1.31	1.04, 1.65	.028

Notes: BMI = body mass index; CHD = coronary heart disease.

*The *p* values shown are derived from a model in which each variable was modeled continuously. Results for age and BMI using categorical scales are also displayed.

the overweight (hazard ratio 1.26; 95% CI 1.03–1.54) and extremely obese (hazard ratio 2.72; 95% CI 1.45–5.10) groups. Initiation of thyroid hormone was also independently associated with more years of education ($p = .022$) and CHD at baseline ($p = .028$).

Conclusions

We found a high proportion of thyroid hormone users in our cohort of community-dwelling individuals aged 65 years and older, particularly among white women. Our study is the first to follow patients over an extended time frame, demonstrating a steady trend in thyroid hormone initiation. We also provide new demographic information about who initiates thyroid hormone, with age 85 years or older, being a white woman, more years of education, high BMI, and prevalent CHD independently predicting thyroid hormone initiation over our 16-year time frame of study.

Our study demonstrates a similar prevalence of thyroid hormone use by sex and race to that reported in the 70- to 79-year-olds enrolled in the Health, Aging, and Body Composition Study in 1997–1999 and to a white, community-dwelling population of women aged 65 years or older enrolled in the Study of Osteoporotic Fractures in 1986–1988, during each of these time frames (8,9). Hashimoto's thyroiditis is more common in women than in men, and thus, our finding of greater thyroid hormone use in women is not surprising and parallels this sex difference in indication for prescription of thyroid hormone. The differences we found in thyroid hormone use by sex and race correspond to reported findings of demographic differences in TSH distribution (10–13) and suggest that bias in screening practices by sex and race likely play a minor role. We also found a higher thyroid hormone initiation rate with increasing educational level and with CHD, which could suggest higher screening rates in more educated individuals and in those with cardiovascular disease.

We found that a BMI above normal is also associated with increased initiation of thyroid hormone preparations in this elderly cohort. A higher prevalence of subclinical hypothyroidism has been shown in obesity (14), and it is likely that individuals with concerns about their weight were more likely to have thyroid function testing performed and, in turn, to be prescribed thyroid hormone replacement. Interestingly, weight loss after bariatric surgery has been shown to reverse subclinical hypothyroidism in obese younger individuals (15). These data suggest that obesity depletes thyroid reserves, resulting in subclinical hypothyroidism, rather than the converse effect of mild thyroid dysfunction inducing weight gain.

Our most intriguing finding is a higher rate of thyroid hormone initiation among those aged 85 years or older that is independent of sex or race. Although it is possible that there is an increase in overt hypothyroidism in this age-group, the more likely explanation is prescription of thyroid hormone for treatment of subclinical hypothyroidism, which is present in 14.5% of the population of men and women aged 80 years and older (10). However, the benefits of thyroid hormone supplementation of subclinical hypothyroidism are unclear in this age-group. Data from the Leiden 85+ study show lower mortality in 85-year-old men and women with elevated TSH levels compared with their euthyroid counterparts and no difference in functional status (16). Offspring of nonagenarians tend to have higher TSH levels than their partners do, also suggesting a favorable effect of slower thyroid metabolism on longevity (17). A small study of nonagenarians showed no association between TSH level and mortality, although only 4% had elevated TSH levels (18). Furthermore, we have previously found in CHS that overreplacement with thyroid hormone is common in older people (19), and in Study of Osteoporotic Fractures, thyroid hormone use was independently associated with greater declines in lower extremity performance (20). Furthermore, we and others have previously found that overreplacement with thyroid hormone is common in older people (21,22), and others have shown adverse cardiac, skeletal, and cognitive effects in older people with low TSH levels (23–25). In aggregate, these data suggest the need to define a target TSH for thyroid hormone initiation, risk–benefit ratio of thyroid hormone replacement, and therapeutic goals that are specific to the 85 years and older age-group. This need is only highlighted by the fact that those aged 85 years and older are the fastest growing demographic group (26), and

a group in whom polypharmacy is a serious problem (27,28).

A major strength of this study is the use of a large, population-based cohort of older men and women to examine trends in thyroid hormone replacement over 16 years. Thyroid function testing was not performed in the CHS main study, and when it was performed using banked samples, results were never released to participants or their physicians. Thus, participation in CHS should not have influenced the prescribing patterns of participant's physicians. Limitations of our study include the lack of information on thyroid function testing prior to thyroid hormone initiation or the prescriber's indication for thyroid hormone prescription, and use of baseline covariates in the models. We were also unable to provide data after the 2005–2006 participant phone call.

Implications

Levothyroxine sodium was the fourth most commonly dispensed medication in the United States in 2008 (29). Mild TSH elevations increase in prevalence with increasing age, particularly in those aged 70 years or older (30). The management of subclinical hypothyroidism in the elderly population is controversial, with observational studies largely showing no harm in those with TSH levels lower than 10 mU/L (31,32) and no data from randomized clinical trials with clinical outcomes. Our data support the need to further investigate the threshold TSH level for thyroid hormone initiation and benefits of thyroid hormone use in the elderly population, particularly in the oldest old (aged 85 years and older), overweight and obese individuals, and those with CHD, who have the highest rates of thyroid hormone initiation.

Received January 2010; accepted for publication March 2010

SUMMARY. Approximately 3.2 million persons are chronically infected with the hepatitis C virus (HCV) in the U.S.; most are not aware of their infection. Our objectives were to examine HCV testing practices to determine which patient characteristics are associated with HCV testing and positivity, and to estimate the prevalence of HCV infection in a high-risk urban population. The study subjects were all patients included in the baseline phase of the Hepatitis C Assessment and Testing Project (HepCAT), a serial cross-sectional study of HCV screening strategies. We examined all patients with a clinic visit to Montefiore Medical Center from 1/1/08 to 2/29/08. Demographic information, laboratory data and ICD-9 diagnostic codes from 3/1/97–2/29/08 were extracted from the electronic medical record. Risk factors for HCV were defined based on birth date, ICD-9 codes and laboratory data. The prevalence of HCV infection was estimated assuming that untested subjects would test positive at the same rate as tested subjects, based on risk-factors. Of 9579 subjects examined, 3803 (39.7%) had been tested for HCV and 438 (11.5%) were positive. The overall prevalence of HCV infection was estimated to be 7.7%. Risk factors associated with being tested and anti-HCV positivity included: born in the high-prevalence birth-cohort (1945–64), substance abuse, HIV infection, alcohol abuse, diagnosis of cirrhosis, end-stage renal disease, and alanine transaminase elevation. In a high-risk urban population, a significant proportion of patients were tested for HCV and the prevalence of HCV infection was high. Physicians appear to use a risk-based screening strategy to identify HCV infection.

Keywords: hepatitis C, prevalence, screening.

INTRODUCTION

An estimated 3.2 million persons are chronically infected with the hepatitis C virus (HCV) in the U.S. [1], roughly three times as many as are infected with HIV [2]. HCV infection is thought to cause approximately 40% of chronic liver disease [3] and the majority of hepato-cellular carcinoma [4] Although the prevalence of anti-HCV is estimated at 1.6% in the U.S. [1], urban populations bear a disproportionate burden of infection and inner city prevalence has been reported as high as 8.3% [5]. Effective treatment for HCV infection is available [6–10], but the majority of those infected are not aware of their status [11–15]. Although testing for patients at high risk is recommended [3,9,10,16,17], optimal testing strategies have not been described [18]. To inform the discussion of testing strategies, we sought to examine the associations between patient characteristics and HCV testing practices among physicians, and estimate the prevalence of HCV infection in a high-risk urban population.

It has been suggested that routine testing for HCV is not efficient [17] or cost-effective [19,20]. Guidelines suggest testing patients with a history of transfusion or organ transplant prior to 1992, persons using injection drugs [3,9,16,17], those with HIV infection [3,9,10], those receiving hemodialysis [3,9,16,17], children of HCV-infected

Abbreviations: ALT, alanine transaminase; EMR, electronic medical record; HCV, hepatitis C virus; MMC, Montefiore Medical Center.

mothers, and persons with unexplained elevated alanine transaminase (ALT) levels [3,9,17]. In addition, it has been noted that prevalence of HCV infection is very high in patients with a history of alcohol abuse [21,22], sexually-transmitted diseases (STD) [23–25], and psychiatric disease [26–29]. It has also been noted that the majority of prevalent cases of HCV infection are found in patients born between 1945–1964 [1,30,31], and thus, being born in this high prevalence birth-cohort may be considered a risk factor for HCV infection.

It is unclear which of these potential risk factors physicians consider important when deciding which patients to test for HCV, and which testing strategies yield high rates of positivity. The objectives of this analysis were to examine the testing practices of physicians to determine which patient characteristics are associated with testing for HCV antibody and HCV infection, and to estimate the prevalence of HCV infection in a high-risk urban population. We hypothesized that many patient risk factors would be independently associated with HCV testing, and that the prevalence of HCV infection in this population would be significantly higher than the national prevalence.

METHODS

Study setting

The study was conducted at three community-based primary care (family medicine or internal medicine) clinics affiliated with Montefiore Medical Center (MMC), a university-affiliated teaching hospital. The three participating primary care clinics are large, urban clinics located in the Bronx, New York. Each year, 54 000 adults make over 150 000 primary care visits to the three clinics. The clinic sites are located in economically depressed areas of the Bronx and serve patients with high rates of poverty and substance use. Reported prevalence of HCV infection is higher in New York City [32] than the national estimate and the Bronx has a higher prevalence than NYC as a whole [33].

Study design

This study employed a cross-sectional design with retrospective electronic medical record (EMR) review to examine the associations between patient demographic and clinical characteristics, testing for anti-HCV, and anti-HCV positivity.

Study population

All study subjects were patients included in the baseline testing phase of the Hepatitis C Assessment and Testing Project (HepCAT), a serial cross-sectional intervention study investigating the optimal strategy to improve screening for HCV. A qualifying visit was defined as a primary care visit by patients 18 years and older to one of the three participating clinics between 1/1/08 to 2/29/08.

Data extraction

For research and quality improvement purposes, MMC maintains a data replicate of its computerized Clinical Information System containing patient demographics, outpatient visit records, hospital records, ICD-9 codes, prescriptions, and laboratory test results. From this replicate, we extracted demographic information associated with the qualifying clinic visit for each subject. In addition, we extracted clinical information dating back to March 1997, the year electronic records became available, including inpatient and outpatient ICD-9 diagnosis codes, prescription and inpatient medication records, and laboratory testing results. The Institutional Review Boards of Boston University Medical Center and MMC approved this study. Because the dataset contains only de-identified records, informed consent was not obtained from patients or physicians; instead, a Health Insurance Portability and Acountability Act-approved data use agreement [34,35] was signed by all participating investigators.

Outcome variables

For the current analysis, the primary outcomes were ''ever tested'' for HCV antibody and HCV antibody positivity. Ever tested for HCV was defined as an anti-hepatitis C virus antibody (anti-HCV) by ELISA performed from March 1997 through May 2008. HCV antibody positivity (indicating past or current HCV infection) was defined as a positive anti-HCV test from March 1997 through May 2008.

Independent variables/definitions

The major independent variables were demographic and clinical patient characteristics shown to be associated with HCV antibody positivity. Although a history of blood transfusion or organ transplant before 1992 is a known risk factor for HCV infection, the EMR had little data on these risks, so the analysis does not include them. In order to create clinically meaningful diagnosis groups, ICD-9 codes were classified using the Healthcare Cost and Utilization Project of the Agency for Healthcare Research and Quality system [36].

Age

For analysis, age was categorized into five distinct groups. In addition, age was dichotomized as within the high prevalence birth cohort (born from 1945 through 1964) defined by the Centers for Disease Control and Prevention (CDC) [1,30] *vs* not within the cohort.

Sex
Dichotomized as male and female.

Race/Ethnicity
For analysis, race/ethnicity was collapsed into four categories: non-Hispanic White, non-Hispanic Black or African American, Latino or Hispanic, and other/unknown.

Substance abuse
Substance abuse was coded as present if an ICD-9 code for substance abuse/dependence or a positive urine toxicology for amphetamines, barbiturates, cocaine, or methadone was recorded at any time from March 1997 through the qualifying visit date.

HIV
HIV was coded as present if an ICD-9 code for HIV infection or a positive antibody test confirmed by a Western blot was present at any time from March 1997 through the qualifying visit date.

Sexually transmitted disease
Sexually transmitted disease was coded as present if an ICD-9 code indicating gonorrhea or chlamydia or positive gonorrhea or chlamydia PCR probe was present at any time from March 1997 through the qualifying visit date.

Alcohol abuse
Alcohol abuse was coded as present if an ICD-9 code for alcohol dependence or alcohol-related liver disease, or a serum alcohol level ≥ 80 mg/dL was present at any time from March 1997 through the qualifying visit date.

Cirrhosis
Cirrhosis was coded as present if an ICD-9 code for cirrhosis was present at any time from March 1997 through the qualifying visit date.

End stage renal disease
Coded as present if an ICD-9 code for end-stage renal disease or procedure code for hemodialysis was present at any time from March 1997 through the clinic visit date.

Psychiatric disease
Coded as present if an ICD-9 code for affective disorder, anxiety disorder, schizophrenia, or psychosis was present at any time from March 1997 through the clinic visit date.

Alanine transaminase elevation
The highest ALT value reported from March 1997 through the clinic visit date for each subject was used. ALT was treated as a dichotomous variable: >40 U/L was defined as elevated (40 U/L is a commonly used upper limit of normal [37,38]).

Statistical analysis

Estimating the prevalence of hepatitis C virus infection
Although not all subjects were tested for HCV we estimated floor and ceiling values for the prevalence of HCV infection in our population. The floor estimation assumed that all untested subjects were negative. The ceiling estimation was calculated as follows: a predictive logistic regression model was constructed using the tested population to assign a probability of positivity based on co-morbidities associated with positivity. Assuming that untested subjects would test positive at the same rate as tested subjects based on risk profile, this predictive model was applied to the untested population to assign a probability of positivity in each untested subject. The sum of the untested subjects' probabilities was used to estimate the number of subjects who would have tested positive in the untested population.

Proportion tested/proportion positive
The proportion of patients tested for anti-HCV and the proportion of patients testing positive are reported. The proportions tested and positive were calculated for predefined age categories and demographic characteristics, presence or absence of pre-defined co-morbidities, and the presence or absence of ALT elevation.

To examine the relationship between subject age, and other demographic characteristics, co-morbidities and ALT levels, we calculated the proportion of subjects testing positive in each age category stratified by demographics, co-morbidities, and ALT categories.

To examine factors independently associated with HCV testing, a multivariate logistic regression model was constructed; factors eligible for the model included demographics (age, sex, race/ethnicity), high-risk co-morbidities (substance abuse, alcohol abuse, HIV, STD, cirrhosis, end-stage renal disease, psychiatric disease), and ALT elevation. The model was constructed in a forward stepwise fashion including each factor that maintained an independent association with anti-HCV testing (Wald statistic $P < 0.10$). A similar logistic regression model was constructed to examine factors independently associated with testing positive for anti-HCV.

STATA/IC software, version 10.0, (StataCorp, College Station, TX, USA) was used for all data management and statistical analysis.

RESULTS

Study population

Data on 9579 patients were examined. Demographic and clinical information for the study population are summarized in Table 1. The mean age was 48.6 years (range 18–101). The study population was predominantly female (72.4%) and predominantly Latino (51.3%) or African American

Continuous variables reported as mean ± standard deviation dichotomous variables reported as No. (%). *ICD-9 or positive urine toxicology. †ICD-9 for Etoh dependence or etoh liver disease or etoh level ≥ 80. ‡ICD-9 or positive antibody test or western blot. §STD, Sexually Transmitted Disease (not HIV): ICD-9 or Positive GC or Chlamydia PCR probe. ¶ICD-9 Code. **ESRD, End-Stage Renal Disease: ICD-9 code or procedure code for hemodialysis. ††ICD-9 for affective, anxiety, schizophrenia, or psychosis.

(31.7%). History of psychiatric disease was reported for 1550 (16.2%) subjects, 558 (5.8%) had a history of substance abuse, and 429 (4.5%) had a history of HIV.

Estimated prevalence

Anti-HCV prevalence among the 3803 (39.7%) persons in this sample tested in our medical systems was 11.5%. The floor estimate of HCV prevalence for the entire study population (assuming all untested subjects are negative) was 4.6%. The ceiling estimate of HCV prevalence (assuming untested subjects would test positive at the same rate as those tested, based on risk profile) was 7.7%.

Hepatitis C testing by age, high risk diagnosis, and alanine transaminase elevation

The proportion of patients tested for anti-HCV and the proportion testing positive stratified by demographics, high-risk co-morbidities, and ALT elevation are reported in Table 2. Several high risk co-morbidities were associated with a large proportion of subjects tested including substance abuse (78.1% tested, 43.8% positive), alcohol abuse (74.3% tested, 33.1% positive), HIV (87.4% tested, 34.4% positive), cirrhosis (89.7% tested, 51.7% positive), and end-stage renal disease (85.1% tested, 9.5% positive). A substantial proportion of subjects aged 18–29 years were tested (30.3%), but a small proportion of those tested positive (0.4%). Of subjects with any risk factor (in the high-prevalence birth cohort, any high-risk co-morbidity, or elevation of ALT), 48.6% were tested and 15.7% of those tested positive. Of subjects without any risk factor noted, 28.8% were tested, and of those, 3.0% were positive.

Multivariate analysis of testing

Bivariate and multivariate associations between factors and HCV testing are reported in Table 3. In multivariate analysis, each of the following factors was significantly independently associated with anti-HCV testing: born in high prevalence birth cohort; male sex; African-American race; Latino ethnicity; substance abuse; alcohol abuse; HIV; STD; cirrhosis; end-stage renal disease; psychiatric disease; and elevation of ALT.

Multivariate analysis of testing positive

Bivariate and multivariate associations between factors and testing positive for anti-HCV are reported in Table 4. In multivariate analysis each of the following factors was significantly independently associated with testing positive for anti-HCV: born in high prevalence birth cohort; male sex; substance abuse; HIV; cirrhosis; and elevation of ALT.

DISCUSSION

Testing practices in the three clinics evaluated in this study show that physicians test patients with known risk factors to identify HCV infection. The majority of patients with substance abuse (78.1%), alcohol abuse (74.3%), HIV (87.4%), cirrhosis (89.7%), end-stage renal disease (85.1%), ALT elevation (67.2%), or STDs (52.8%) were tested. In addition, a substantial proportion of patients with psychiatric diagnosis (49.7%) were tested. Each of these factors was independently associated with testing in multivariate analysis.

The majority of anti-HCV positive patients identified (73.3%) were born in the high prevalence birth-cohort. Being born in these years was also independently associated with HCV testing and anti-HCV positivity in multivariate analysis. Although testing all patients born in the high prevalence birth cohort may be warranted, evidence suggests that birth cohort-based testing alone would be a less than optimal strategy. First, our data suggest that birth cohort-based testing would fail to identify 26.7% of anti-HCV positive persons, which is similar to the unidentified proportions found when testing only in the birth cohort reported by O'Brien (25.4%) [31], Armstrong (34.4%) [1], and Alter (31.3%) [30]. Second, several factors were independently and strongly associated with positivity after

adjustment for birth-cohort status including substance abuse, HIV, cirrhosis, and ALT elevation. Lastly, in our study the risk-based screening strategy yielded high rates of anti-HCV positivity in all categories of risk in patients born outside the high-risk birth-cohort. These data suggest that current risk-based screening methods should be continued, and serious consideration should be given to expanding screening recommendations to include birth in the high-risk cohort. Birth cohort testing alone, however, is not recommended.

In this clinic population of an urban academic medical center, the conservative (floor) estimate of the prevalence of hepatitis C antibodies was 4.6%, almost three times the estimated national prevalence [1]. Our model designed to predict positivity in the untested population estimated a much higher overall prevalence, 7.7%, which is close to the prevalence of 8.3% reported in a similar population by McGinn [5]. Overall, 39.7% of subjects had been tested. Among those with identified risk (either born in the high prevalence birth-cohort, had a high-risk co-morbidity, or an elevated ALT level), 48.6% had been tested.

It is worth noting that the proportion tested was very high (28.8%) among patients with no identified risk (born outside the high prevalence birth-cohort, no high-risk co-morbidity, and no elevation of ALT) and that the rate of positivity in this group was substantial (3.0%), though less than those with identified risks. Whether a substantial proportion of these tested patients had risk factors not identified through the EMR is not clear. It is also possible that some patients without apparent risk were tested because patients or providers were responding to New York Department of Health efforts, begun in 2004, to raise Bronx community and provider awareness of HCV infection [39]. Because of the high underlying prevalence of HCV infection (between 4.6% and

7.7%) in this population, universal testing for high-risk urban populations may be more appropriate than the risk-based screening strategy.

This analysis has several important limitations. First, not all patients were tested for anti-HCV so the prevalence we report is an estimate based on risk profile. Second, we utilized an EMR for data collection so we were unable to capture all risks for HCV infection for each patient. Lastly, we did not take into account the temporal relationship between risk factors and HCV tests. It is possible, for example, that a substance abuse diagnosis might have been coded after a HCV test was ordered, and thus we cannot be sure that the diagnosis of substance abuse was present, or in the physician's mind, at the time of testing. Despite these limitations,

we were able to uncover a strong relationship between high-risk co-morbidities and physician testing behavior.

In conclusion, we found a very high estimated prevalence of HCV infection in a high-risk urban patient population with a high prevalence of risk factors. We found strong evidence that physicians are using a risk-based screening strategy to identify patients with HCV infection, using known risk factors and other conditions associated with HCV to guide testing. We also found evidence that screening recommendations should be expanded to include the high prevalence birth cohort.

Relationship between central and peripheral atherosclerosis and left ventricular dysfunction in a community population

Connie W Tsao[1], Philimon Gona[2,3], Carol Salton[1], Joanne M Murabito[3,4], Noriko Oyama[1,a], Peter G Danias[1], Christopher J O'Donnell[3,5], Warren J Manning[1,6] and Susan B Yeon[1]

Abstract

We aimed to determine the relationships between resting left ventricular (LV) wall motion abnormalities (WMAs), aortic plaque, and peripheral artery disease (PAD) in a community cohort. A total of 1726 Framingham Heart Study Offspring Cohort participants (806 males, 65 ± 9 years) underwent cardiovascular magnetic resonance with quantification of aortic plaque volume and assessment of regional left ventricular systolic function. Claudication, lower extremity revascularization, and ankle–brachial index (ABI) were recorded at the most contemporaneous examination visit. WMAs were associated with greater aortic plaque burden, decreased ABI, and claudication in age- and sex-adjusted analyses (all $p < 0.001$), which were not significant after adjustment for cardiovascular risk factors. In age- and sex-adjusted analyses, both the presence ($p < 0.001$) and volume of aortic plaque were associated with decreased ABI ($p < 0.001$). After multivariable adjustment, an ABI ≤ 0.9 or prior revascularization was associated with a threefold odds of aortic plaque ($p = 0.0083$). Plaque volume significantly increased with decreasing ABI in multivariable-adjusted analyses ($p < 0.0001$). In this free-living population, associations of WMAs with aortic plaque burden and clinical measures of PAD were attenuated after adjustment for coronary heart disease risk factors. Aortic plaque volume and ABI remained strongly negatively correlated after multivariable adjustment. Our findings suggest that the association between coronary heart disease and non-coronary atherosclerosis is explained by cardiovascular risk factors. Aortic atherosclerosis and PAD remain strongly associated after multivariable adjustment, suggesting shared mechanisms beyond those captured by traditional risk factors.

Keywords

aortic atherosclerosis; epidemiology; left ventricular wall motion abnormality; MRI; peripheral artery disease

Introduction

Central and peripheral artery disease (PAD) are manifestations of cardiovascular disease (CVD) that carry significant morbidity and mortality. In prospective, population-based studies, the presence and extent of atherosclerotic plaques in the carotid and femoral arteries are associated with increased CVD death.[1,2] Decreased ankle–brachial index (ABI) is associated with increased risk of congestive heart failure (CHF), coronary heart disease (CHD), and CVD death,[3,4] and confers increased morbidity and mortality for each category of the Framingham Risk score (FRS).[5] CVD risk increases with greater extent of atherosclerosis across multiple vascular territories.[6]

Myocardial ischemia and infarction resulting from CHD is a major cause of resting left ventricular (LV) wall motion abnormalities (WMAs). Echocardiographic resting WMAs correlate with significant angiographic coronary stenoses.[7] In participants with known CHD and LV dysfunction, the presence and severity of resting WMAs are associated with increased morbidity and mortality.[8,9] In subjects without overt CVD, WMAs may be a marker of silent CHD.[10]

Cardiovascular magnetic resonance (CMR) facilitates both qualitative and quantitative measures of LV systolic function, as well as aortic plaque burden. While the extent of polyvascular atherosclerotic disease has been reported,[6] there are few studies that examine the inter-relatedness of WMAs, aortic atherosclerosis, and PAD in an unselected population, particularly including subjects without prevalent CVD. As atherosclerosis has a prolonged subclinical course and correlates with future adverse CVD events,[3,4] early intervention may prevent the development of overt CVD or recurrent events, provided that similar mechanisms produce atherosclerosis in different vascular beds. We hypothesized that measures of aortic and peripheral atherosclerosis would be associated both with WMAs and with each other in a free-living population.

Methods

Participants

Study participants included a subset of the 3539 participants attending Examination 7 (1998–2001) of the Framingham Heart Study (FHS) Offspring Cohort, which has been described previously.[11] At evaluation every 3–4 years, beginning with Examination 1 (1971–1975), participants underwent routine medical history and physical exam, anthropometry, and assessment of CVD risk factors. For the CMR substudy, a random sampling strategy was used to recruit from strata of sex, decade age, and quintile of the FRS.[12] Participants were excluded if they were not in sinus rhythm, had a contraindication to CMR (e.g. pacemaker), or did not live in a state contiguous with Massachusetts. CMR scanning (2002–2006) was incomplete in 32 participants (claustrophobia, $n = 13$; scanner dysfunction, $n = 7$; metallic devices, $n = 10$; miscellaneous, $n = 2$). A total of 1726 participants (aged 65 ± 9 years, 806 men) completed CMR with analyzable images. ABI data were available in 1678 of these participants. The study was approved by the institutional review boards of both the Boston University Medical Center and the Beth Israel Deaconess Medical Center. All participants provided written informed consent.

CMR imaging

Supine CMR imaging was performed using a 1.5 T CMR scanner (Gyroscan NT; Philips Medical Systems, Best, The Netherlands) with a five-element commercial cardiac array coil for radio frequency signal reception. Following localizing scans to determine the position and orientation of the heart within the thorax, end-expiratory breath-hold, ECG-gated cine steady-state free precession images were acquired in two-chamber, four-chamber, and contiguous short axis orientations (temporal resolution 39 ms, repetition time = R-R interval, echo time 9 ms, flip angle 30 degrees, field of view 400 mm, matrix size 208 × 256, slice thickness 10 mm, gap = 0).

Aortic plaque imaging included 36 transverse slices from the aortic arch to the aortoiliac bifurcation using a free-breathing, ECG-gated, fat-suppressed, black blood T2-weighted turbo spin-echo sequence[13] with 5-mm slice thickness and an in-plane spatial resolution of 1.03 × 0.64 mm (10-mm and 5-mm slice gaps for thoracic and abdominal aorta, respectively).

Image analysis of LV function and aortic plaque

Cine-CMR image analysis was performed using dedicated software (EasyVision 5.1; Philips Medical Systems) by a single observer (C.S.) blinded to all clinical data. LV wall motion was analyzed according to a 17-segment model.[14] WMAs noted by the observer were confirmed by two additional reviewers blinded to all clinical data (C.T., S.Y). The global and regional wall motion score was computed using a five-point scale (1 = normal, 2 = hypokinetic, 3 = akinetic, 4 = dyskinetic, 5 = aneurysm), with the normal sum of all segments scoring 17. The wall motion score index (WMSI) was calculated as the total wall motion score divided by the number of segments, with a WMSI ≥ 19/17 (WMSI > 1.12, WMA) considered abnormal (≥ 2 contiguous hypokinetic segments, and/or one akinetic or dyskinetic segment).[10] Quantitative measures of LV systolic function and mass (LVM) were obtained by manually tracing epicardial and endocardial LV borders at end-diastole and end-systole, as previously described.[11] LV end-diastolic volume (EDV) and end-systolic volume (ESV) were computed using the summation of discs method. The LV ejection fraction (LVEF) was computed by (EDV – ESV)/EDV. The LVM was determined by summing myocardial volume and multiplying by myocardial density (1.05 g/ml). The LVM was indexed to body surface area (BSA). The LVM index (LVMI), relative wall thickness (RWT), LVM/LVEDV, and LVEF were tabulated.

CMR images were analyzed with commercial software (MASS v 6.1; QT-MEDIS, NL, Leiden, The Netherlands) for descending thoracic and abdominal aortic atherosclerotic plaque by a single expert reviewer (N.O.) blinded to all clinical data.[13] Images analyzed were perpendicular to the aorta with > 50% of the inner circumference of the aortic wall visualized. Atherosclerotic plaque was defined as luminal protrusions of ≥ 1 mm in radial thickness[13] that were visually distinguished from the minimal residual blood signal of each plaque. By visually tracing the plaque border, the cross-sectional area of plaque was measured, and total plaque volume was calculated. Inter- and intra-reader replicate measurements were made to determine reproducibility.[13]

Clinical variables and assessment of PAD

Participants underwent routine physical examination, anthropometry, and laboratory assessment of CVD risk factors at Examination 7 (1998–2001). Resting systolic (SBP) and diastolic blood pressure (DBP) were measured in the right arm seated position. Plasma glucose, and total and high-density lipoprotein cholesterol were measured on morning samples after an 8-hour fast. Hypertension was defined as SBP ≥ 140 mmHg or DBP ≥ 90 mmHg or use of

WMA, wall motion abnormalities; BMI, body mass index; HDL, high-density lipoprotein; FRS, Framingham Coronary Risk Score; CHD, myocardial infarction, angina pectoris, or coronary insufficiency; CHF, congestive heart failure; CMR, cardiovascular magnetic resonance; WMSI, wall motion score index; LVMI, left ventricular mass index; LVEDV, left ventricular end-diastolic volume; LVEF, left ventricular ejection fraction; IQR, interquartile range; PAD, peripheral artery disease; ABI, ankle–brachial index.
WMA = WMSI > 1.12; Obesity = BMI > 30; Dyslipidemia = total cholesterol ≥ 200 mg/dl or on lipid-lowering therapy; Tobacco = any smoking during Examinations 1–7.
[a]PAD data available in $n = 1671$.

antihypertensive medications. Dyslipidemia was defined as a total cholesterol ≥ 200 mg/dl or the use of lipid-lowering therapy. Diabetes mellitus was defined as fasting glucose ≥ 126 mg/dl or the use of insulin or oral hypoglycemic medications. A history of CHD (defined as recognized or unrecognized myocardial infarction [with diagnostic electrocardiography], angina, or coronary insufficiency) and CHF (identified by clinical signs and symptoms) were determined by physician end-point review.[12]

The presence of intermittent claudication at any clinic examination visit was defined by a physician-administered questionnaire, in which participants reported exertional leg discomfort related to degree of walking that was relieved with rest, verified by an endpoint review panel of three investigators.[15] Ankle–brachial SBP measurements, repeated twice, were obtained by trained technicians using a standard protocol at Examination 7 (average 4.4 years from CMR study).[15] ABI was calculated for each leg as the ratio of average SBP in the ankle divided by average SBP in the higher arm. The lower of the two ABIs calculated for each lower extremity was used for analysis. If ABI was missing for one lower extremity, data were used from the other extremity. A reported history of lower extremity revascularization, including percutaneous angioplasty, placement of stent, or vascular bypass surgery, was recorded and validated by medical record review. Three categories of ABI were defined: ABI ≤ 0.9 or history of lower extremity revascularization (significant PAD); 0.91 ≤ ABI ≤ 1.0; and 1.0 < ABI ≤ 1.4. Participants with ABI > 1.4 were excluded ($n = 7$) as these values may represent medial arterial calcification with associated increased mortality.[16] This exclusion resulted in $n = 1671$ participants with ABI data for analysis.

Statistical analysis

Participants were categorized by the presence or the absence of a WMA. Plaque volume was natural log-transformed due to a non-normal distribution and reported as median (interquartile range). Descriptive statistics for all covariates are presented as percentages or means ± SD. Differences in characteristics between the groups with and without WMAs were evaluated using two-sample t-tests and analysis of

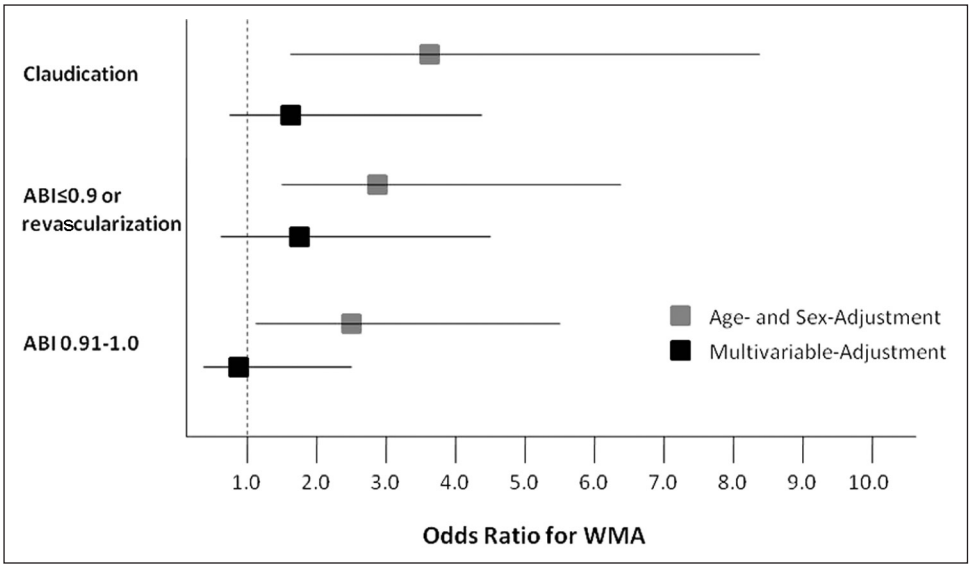

Figure 1. Odds of a WMA associated with peripheral artery disease (PAD). Boxes represent odds ratio for a WMA; lines represent 95% CI. Claudication, ABI ≤ 0.9 or revascularization, and ABI 0.91–1.0 were associated with increased odds of a WMA in age- and sex-adjusted analyses. These associations were attenuated after multivariable adjustment.

covariance (ANCOVA) for continuous variables, and the chi-squared test and logistic regression for binary variables. Age- and sex-adjusted and multivariable-adjusted ANCOVA and logistic regression models were constructed to assess the association of aortic plaque, natural log-transformed plaque volume, claudication, and ABI (as both continuous and categorical variables, using ABI > 1.0 to ≤ 1.4 as the referent group) with the presence or absence of a WMA. Odds ratios and 95% confidence intervals were calculated for the association of categorical variables with WMAs. Covariates in the multivariable model were determined at Examination 7: age, sex, BMI, tobacco pack-years, SBP, total cholesterol/high-density lipoprotein (HDL) ratio, and histories of hypertension treatment, dyslipidemia treatment, and diabetes mellitus. Similar models were generated to assess the relationship of aortic plaque to ABI severity. An age- and sex-adjusted Pearson correlation coefficient was used to determine the linear association between the presence and quantity of aortic plaque with ABI. All analyses were performed with SAS 8.0 (SAS Institute, Cary, NC, USA). A two-sided p-value < 0.05 was considered statistically significant.

Results

The demographics and characteristics of the study sample are shown in Table 1. WMAs were present in 106 (6%) of the total population. Compared to participants without a WMA, those with WMAs had a greater prevalence of all cardiovascular risk factors, particularly male sex, diabetes, and hypertension, and a greater prevalence of CHD or CHF (all $p < 0.001$). However, 53% of participants with WMAs had no history of CHD or CHF. Participants with WMAs also had greater LVMI and LVEDV, and lower LVEF (all $p < 0.0001$).

The prevalence of aortic plaque and raw measures of clinical PAD are presented in Table 1. Aortic plaque was present in 48% of the cohort. The majority of participants with aortic plaque (93%) had normal LV wall motion. Plaque volume was greater in participants with WMAs compared to those with normal wall motion ($p < 0.001$). This difference persisted after age- and sex-adjustment ($p = 0.001$) but was attenuated after multivariable adjustment ($p = 0.22$).

Participants with WMAs had a greater prevalence of both claudication and decreased ABI. Claudication was associated with a nearly fourfold odds of having a WMA in age- and sex-adjusted analyses (OR 3.78, 95% CI 1.68–8.52, $p = 0.001$); this association was attenuated after multivariable adjustment (OR 1.69, 95% CI 0.66–4.37, $p = 0.276$). Mean ABI was not significantly lower in participants with a WMA in multivariable adjusted analyses (mean ± SD: 1.11 ± 0.15 vs 1.14 ± 0.10, $p = 0.12$). ABI ≤ 0.9 or revascularization were present in 42 (2.5%) participants, ABI 0.91–1.0 was present in 76 (4.5%) participants, and ABI > 1.0–1.4 was present in 1553 (92.9%) participants. There was a significant increase in the proportion of participants with WMAs across decreasing levels of ABI (5.5% among ABI > 1.0 to 1.4, 10.5% among ABI 0.91–1.0, and 19.0% among ABI ≤ 0.9 or revascularization, $p < 0.001$ for linear trend). In age- and sex-adjusted analyses, ABI ≤ 0.9 or revascularization was associated with a nearly threefold risk of WMA (OR 2.94, 95% CI 1.28–6.76, $p = 0.01$) and ABI 0.91–1.0 was associated with an elevated risk for WMAs (OR 2.58, 95% CI 1.13–5.84, $p = 0.02$) compared to ABI > 1.0 and ≤ 1.4. However, the association between ABI level and WMA was not significant after multivariable adjustment (OR for WMA 1.9, 95% CI 0.78–4.40, $p = 0.843$, for ABI ≤ 0.9 or revascularization; OR for WMA 0.90, 95% CI 0.32–2.52, $p = 0.163$, for ABI 0.91–1.0) (Figure 1).

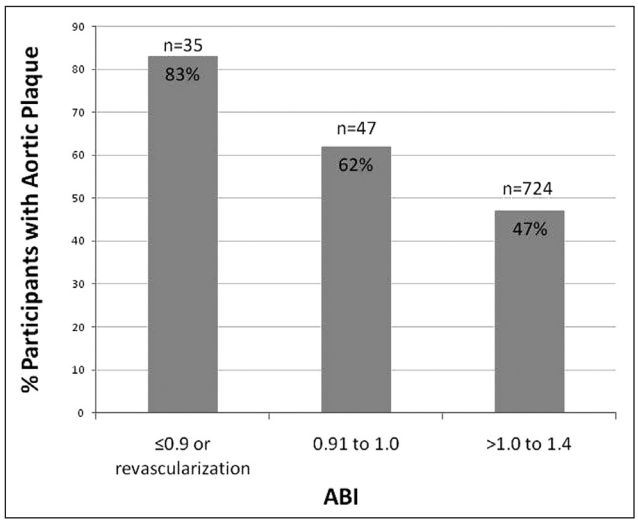

Figure 2. Relationship of aortic plaque prevalence with ABI groups. The prevalence of aortic plaque increased with decreasing ABI group ($p < 0.001$).

Aortic plaque and ABI were inversely associated. In participants with aortic plaque, ABI was significantly lower compared to those without plaque (ABI = 1.12 ± 0.11 vs 1.15 ± 0.09, $p < 0.0001$). The prevalence of aortic plaque increased with decreasing ABI category (Figure 2). ABI ≤ 0.9 or a history of revascularization was associated with fivefold increase in the odds of aortic plaque in age- and sex-adjusted analyses (OR 4.99, 95% CI 2.184–11.414, $p = 0.0014$) and a threefold increase in the odds after multivariable adjustment (OR 3.23, 95% CI 1.35–7.73, $p = 0.0083$). Likewise, median aortic plaque burden also increased with decreasing ABI group, from 0 cm^3 (IQR 0.0–0.39 cm^3) among ABI > 1.0 to 1.4, to 0.34 cm^3 (IQR 0.0–1.49 cm^3) among ABI 0.91–1.0, to 2.2 cm^3 (IQR 0.23–4.10 cm^3) among ABI ≤ 0.9 or with a history of revascularization. This relationship was significant in age- and sex-adjusted analyses (Spearman $r = –0.28$, $p = 0.001$), and persisted after multivariable adjustment ($p < 0.0001$).

Discussion

To our knowledge, this is the first population-based study to evaluate the relationship of LV WMAs, a likely surrogate for CHD, with both aortic and peripheral atherosclerosis. Notably, a significant proportion of participants with WMAs were free of prevalent CHD or CHF. While LV WMAs may result from non-ischemic etiologies, underlying CHD is a common etiology in middle-aged populations in developed countries.[17,18] The associations between extent of aortic plaque and clinical PAD with LV WMAs seen in age- and sex-adjusted analyses were not significant after multivariable adjustment. However, aortic plaque and ABI remained strongly inversely correlated after adjustment for CHD risk factors. While those with ABI data represented a smaller group, exclusion of these participants did not change the results of the prevalence and mean values of risk factors with the exception of obesity, whose lower prevalence was similar among participants with and without WMAs.

In our community-based population, CMR evidence of aortic plaque was common. Though many participants without WMAs had aortic plaque, this group had a lower overall plaque volume. The high prevalence of aortic plaque in both groups with and without WMAs is consistent with the high prevalence of CVD risk factors, notably hypertension, history of tobacco use, and dyslipidemia throughout the population. The association of increased plaque volume in participants with WMAs was attenuated in multivariable analysis, suggesting that these mechanisms of atherosclerosis in the aorta and coronary arteries have in common traditional CVD risk factors including obesity, smoking, diabetes, hypertension, and dyslipidemia. However, our results are consistent with transesophageal echocardiographic data showing an association of aortic plaque thickness with CHD[19] and an increased incidence of CHD and CVD morbidity in those with aortic calcification.[20–23]

Significant clinical PAD was uncommon in our cohort (2.4% with ABI ≤ 0.9 or revascularization and only 2.3% with claudication), despite the prevalence of CVD risk factors. This is similar to the 2–4% prevalence of ABI ≤ 0.9 reported in an earlier, larger subset of the FHS Offspring Cohort,[15] in the Atherosclerosis Risk in Communities (ARIC) Study,[24] in the Multi-Ethnic Study of Atherosclerosis (MESA),[25] and in a large Italian population.[26] The 8–9% prevalence of significant PAD among those with a WMA was greater than those with normal LV wall motion. The fact that ABI and WMAs were associated in age- and sex-adjusted analyses but not upon multivariable adjustment in our study suggests that both ABI and WMAs may be influenced by traditional CVD risk factors. A similar relationship was seen between claudication and WMAs in multivariable analyses.

While attenuated in multivariable analyses, the association between PAD and WMAs is in agreement with findings from the Cardiovascular Health Study, which reported an association between ABI < 0.9 and echocardiographic segmental WMAs and in age- and sex-adjusted analyses.[27] Our results are also consistent with that between decreased ABI and both prevalence and incident development of CHD in the ARIC studies.[24,28] While an ABI ≤ 0.9 is used as the cut-off for significant PAD,[5] an ABI 0.91–1.0 may reflect an intermediate risk, as this group still had a nearly threefold odds of WMA in age- and sex-adjusted analyses. These results are consistent with reports of both an increased prevalence of CHD[15,24] and both cohort and meta-analysis studies, demonstrating a greater risk for cardiovascular events and mortality with progressive decreases in ABI.[5,29]

Other studies have found a relationship between coronary artery calcification (CAC), another surrogate for CHD, and PAD. In a subset of 1932 participants without cardiovascular risk factors in MESA, a low ABI (< 1.0) was associated with the presence of CAC.[30] In addition, in a cohort of 3479 participants with CHD, those with concomitant PAD had a greater volume of coronary atheroma and extent of CAC.[31] Our study may show a lack of association in adjusted analyses due to the limited number of participants with PAD or due to the indirectness of WMAs as a marker of coronary artery disease as compared to CAC.

In contrast, both the prevalence and burden of aortic plaque demonstrated a strong inverse relationship with groups of ABI independent of traditional CVD risk factors. The stronger association of measures of non-coronary atherosclerosis with each other than with WMAs could reflect that WMAs are the result of a clinical event which may not correlate with absolute degree of atherosclerosis. This is consistent with past angiographic evidence that often angiographic severity may result from lesser grade, rather than highly stenotic lesions.[32] Alternatively, factors promoting atherosclerosis in coronary as compared with non-coronary beds may have different mechanisms. Consistent with this possibility, members of the Reduction of Atherothrombosis for Continued Health (REACH) cohort with PAD had a markedly greater prevalence of polyvascular disease than did those with CAD (60% vs 25%, respectively).[6]

CMR is advantageous as it is not limited by acoustic windows, generates standard imaging planes, and defines wall motion at the apex with higher precision than echocardiography.[33] We were able to assess LV wall motion in 99% of all participants and complete aortic plaque analysis in 96% of participants. This technique has been well-validated in the assessment of LV function[34] and imaging atherosclerotic plaque.[13]

Limitations of this study include a relatively small number of participants with clinical PAD and WMAs, which may have limited the power to detect associations between PAD and WMAs. In addition, Examination 7 data and CMR data were not obtained concurrently. While there was an average of 4.4 years between Examination 7 and the CMR test, this time interval would be more likely to bias true associations towards the null. Furthermore, assessment of regional WMAs remains largely observer-dependent, though CMR allows superior endocardial border definition and thus excellent interobserver agreement.[35] While the majority of WMAs (94%) reflected regional rather than global LV dysfunction, 6% of WMAs were global. This minority of WMAs could represent non-ischemic cardiomyopathy with no significant coronary artery disease. Finally, the FHS Offspring Cohort is a predominantly middle-aged and older Caucasian population. Thus, our results may not be generalizable to other races or ethnicities or age groups.

In conclusion, in this community-based population, incidentally detected WMAs which likely reflect CHD were associated with measures of aortic and peripheral atherosclerosis in age- and sex-adjusted, but not multivariable-adjusted models. The prevalence and burden of aortic plaque were strongly and independently associated with peripheral artery disease in both age- and sex- and multivariable-adjusted analyses. WMAs and peripheral atherosclerosis share common CVD risk factors. However, aortic atherosclerosis and PAD remain strongly associated after multivariable adjustment, suggesting shared mechanisms beyond those captured by traditional risk factors. While screening for WMAs is not advocated in a CHD at-risk population, unsuspected WMAs may be identified during imaging. Further prospective studies are necessary to determine the clinical utility of detection of WMAs relative to other markers of CHD.

Disclosures

Chronic Pain and Hepatitis C Virus Infection in Opioid Dependent Injection Drug Users

Judith I. Tsui, MD, MPH
Debra S. Herman, PhD

Bradley J. Anderson, PhD
Michael D. Stein, MD

ABSTRACT. It is unknown whether infection with hepatitis C is a risk factor for pain among people who have used injection drugs. Multivariate regression was used to determine whether hepatitis C was associated with greater likelihood of reporting significant chronic pain and discomfort intolerance in a cohort of 97 injection drug users dependent on opioids. Study results suggest that participants with hepatitis C may be more likely to experience chronic pain (aOR = 1.98; 95% confidence interval = 0.76 to 5.12, $p = 0.16$). Furthermore, hepatitis C was found to be associated with a higher discomfort intolerance scale score, reflecting intolerance to physical discomfort ($\beta = 2.34$; 95% confidence interval = 0.06 to 4.62; $p = 0.04$). Hepatitis C may be a cause for chronic pain and discomfort intolerance that is overlooked among injection drug users dependent on opioids.

KEYWORDS. Hepatitis C virus, injection drug use, chronic pain, pain hypersensitivity

BACKGROUND

Chronic pain and substance use frequently coexist for reasons that are poorly understood. Individuals dependent on opioids appear particularly vulnerable to chronic pain and pain hypersensitivity. There is a high prevalence of chronic severe pain (37% to 61%) among individuals dependent on opioids who receive methadone maintenance,[1–3] and studies of individuals with human immunodeficiency virus (HIV) have found that those with a history of injection drug use report more pain than those with no injection drug use.[4–8] Furthermore, experimental pain studies have demonstrated lower pain thresholds among individuals dependent on opioids.[9–12]

Individuals who inject opioids are at a greater risk for hepatitis C infections.[13–16] In a large case series, hepatitis C was linked to painful conditions such as peripheral neuropathies and arthritis.[17] Furthermore, quality of life studies have observed greater bodily pain among hepatitis C positive patients than hepatitis C negative patients.[18] These studies suggest a high prevalence of painful conditions among

hepatitis C positive patients; however, support for this association has been limited by a lack of control patients or adjustment for important confounders, most notably substance use disorders.[19–21] Researchers have hypothesized that increased levels of inflammatory cytokines may provide a biologic link between hepatitis C and fibromyalgia,[22] but a large population-based study failed to support such an association.[23]

Although the clinical overlap of substance use, hepatitis C, and pain is commonly seen in medical settings, there has been little attention to hepatitis C as a direct etiology for pain. One study of veterans seeking addiction services found that hepatitis C seropositivity was associated with a three-fold increased risk for persistent pain.[24] Hepatitis C may be an underrecognized and potentially modifiable cause of pain for patients with substance use. This study was undertaken to examine whether reported infection with hepatitis C was associated with chronic pain and discomfort intolerance in a sample of injection drug users dependent on opioids who exhibited symptoms of depression.

METHODS

Study Sample and Design

This cross-sectional study used baseline data from participants in a randomized, double-blind, placebo-controlled trial to determine whether treatment for symptoms of depression increases treatment retention among patients dependent on opioids initiating office-based buprenorphine treatment. Study inclusion criteria included age between 18 and 65, a *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) diagnosis of opioid dependence, a score on the Modified Hamilton Depression Revised Scale[25] greater than 14, the absence of significant suicidal ideation, willingness and ability to complete a 3-month treatment with buprenorphine, no history of severe mental illness (bipolar disorder, schizophrenia, schizo-affective disorder, or paranoid disorder), no currently prescribed psychotropic or antidepressant medications or medications that could cause depression (including interferons), and the ability to complete the study assessment in English. Between November 2006 and May 2009, 932 individuals were screened by telephone, and of those, 394 callers appeared eligible for the study and were invited for an in-person screening visit. Of the 226 who attended this visit, 147 fully met criteria and agreed to enroll in the parent study. This study restricted analyses to 97 participants who were current or former injection drug users (i.e., reported ever injecting drugs as assessed by an HIV-risk screening instrument).[26]

Pain Outcomes

Pain severity was assessed through the use of the Visual Analogue Scale, a rating scale that allows participants to mark their pain on a 100-mm line that ranges from "no pain" to "worst pain imaginable" and translates their pain to a point value between 0 and 100.[27] Pain interference was assessed using the mean of the 7-item subscale from the Brief Pain Inventory (BPI) short form.[28] The subscale measures pain interference in different domains such as sleep, work, and relationships, rating each item from "0" (pain does not interfere) to "10" (pain completely interferes). The primary outcome was significant chronic pain, which was defined as pain that was of at least moderate in intensity (Visual Analogue Scale score $\geq$40) or caused at least moderate interference (Brief Pain Inventory interference score $\geq$5) and which had been present for at least 6 months. This definition was modified from that used in a study by Rosenblum et al.[3] The secondary outcome of interest was discomfort intolerance, which was measured using the Discomfort Intolerance Scale (DIS).[29] It is a 5-item scale designed to measure the construct of discomfort intolerance, which is defined as the individual's perception of his or her ability to tolerate uncomfortable sensations. The scale is comprised of 5 questions (sample questions: "I am more sensitive to feeling physical discomfort compared to most people" and "I take extreme measures to avoid feeling physically uncomfortable") that have a range of seven possible responses (0 = *Not at all like me* to 6 = *Extremely like me*). Responses were analyzed as a total summed score, with higher

responses indicating a lower tolerance for physical discomfort. Additional analyses used data on the reported location of pain participants had in the previous week, which included headache, abdominal pain, back pain, joint pain, or muscle pain.

Predictors

The primary predictor of interest was chronic hepatitis C infection defined as a positive response to the question: "Do you have hepatitis C virus (hepatitis C)?" Additional covariates were age, sex, race (White vs. non-White), severe depression (score greater than 28 on the Beck Depression Inventory II[30]), and report of starting opioids for pain. Covariates were selected on the basis of face validity (demographics) or known associations with pain (depression).[31] In addition, models were adjusted for self-report of starting opioids for pain because individuals with preexisting pain might use prescription opioids preferentially over injecting heroin, and thus be less likely to be hepatitis C positive. Initiation of opioids for pain was defined as positive response to the question: "Do you believe that you started using your primary opiate of addiction to relieve physical pain?"

Statistical Analysis

Analyses were performed using baseline study data. We examined differences in demographic and clinical variables between participants with and without reported hepatitis C using t tests and chi-squared tests. Multivariate logistic and linear regression were performed to determine the adjusted relative odds for significant chronic pain and the mean difference in DIS score associated with being infected with hepatitis C, respectively. Given the small sample size, a stepwise backward selection strategy was used to select a final parsimonious model using a p value < 0.2 or a $>10\%$ change in the hepatitis C coefficient as criteria for retention of covariates. Finally, prevalence of specific pain locations or types (i.e., headache, abdominal pain, back pain, joint pain, and muscle pain) were compared using chi-square tests. All statistical analyses were conducted using Stata version 10.0 (StatCorp, College Station, TX).

RESULTS

Of the 97 participants, 37 (38%) reported that they were infected with hepatitis C; none reported being infected with HIV. Participants with hepatitis C were slightly older than those who were not infected with hepatitis C (mean age = 42 vs. 37 years, respectively, $p < 0.01$), otherwise there were no statistically significant differences between the two groups in the distribution of other variables (Table 1). The prevalence of significant chronic pain was 33% in the study cohort. A higher prevalence of significant chronic pain was observed among individuals who self-reported being hepatitis C positive (14 of 37; 38%) compared to those who were hepatitis C negative (18 or 60; 30%), although this difference did not reach statistical significance ($p = 0.43$). The mean DIS score was higher (indicating greater discomfort intolerance) among hepatitis C positive individuals

than hepatitis C negative individuals (19 vs. 16, repectively; $p = 0.05$). After adjusting for other covariates, participants with hepatitis C appeared to have a nearly two-fold increased risk for significant chronic pain, although results did not reach statistical significance at the $p < 0.05$ level (Table 2). Participants with hepatitis C scored significantly higher on the DIS scale, indicating a greater intolerance to discomfort (Table 3). Among those who endorsed chronic pain, there were no statistically significant differences at the $p < 0.05$ level between reported hepatitis C positive and negative participants in the prevalence of pain in the following locations: headache (29% vs. 17%, respectively, $p = 0.42$), abdominal pain (14% vs. 0%, respectively, $p = 0.10$), back pain (64% vs. 61%, respectively, $p = 0.85$), joint pain (50% vs. 56%, respectively, $p = 0.76$), and muscle pain (36% vs. 28%, respectively, $p = 0.63$).

DISCUSSION

Among a cohort of injection drug users dependent on opioids, we observed that reported hepatitis C infection was associated with intolerance for discomfort. In addition, there was a moderately strong (albeit non-significant) association between hepatitis C and significant chronic pain. Although patients with hepatitis C have been observed to have a high prevalence of painful conditions,[20–22] this is the first study to find an independent association between hepatitis C and pain in a cohort of injection drug use.

Hepatitis C may be associated with chronic pain in injection drug use through several different mechanisms. First, it may result in hepatic and non-hepatic complications that cause pain.[17] Our study observed the prevalence of pain to be higher in multiple domains (headache,

abdominal pain, and muscle pain) among participants with hepatitis C. Second, hepatitis C is associated with depression,[32] which is a strong risk factor for pain.[31] However, because the association between hepatitis C and chronic pain was observed even after adjustment for severe depression (and the sample itself was restricted to injection drug use with depressive symptoms), this appears not to be the sole mechanism. Finally, it is possible that hepatitis C may cause pain intolerance and hypersensitivity through a cytokine-mediated pathway.[22,24] Inflammatory cytokines such as Tumor Necrosis Factor-α (TNF-α) and interleukin-6 have recently been implicated in the pathogenesis of centrally mediated pain,[33,34] and patients with hepatitis C have been observed to have increased levels of these cytokines.[35–41] Our finding that participants with hepatitis C reported greater intolerance to physical discomfort may provide some indirect support for this hypothesis, although further experimental studies on pain tolerance thresholds are needed.

This study has major limitations, and results should be considered exploratory in nature. There was likely misclassification of our main predictor because hepatitis C status was based on self-report rather than hepatitis C antibody or viral load testing. Data from a prior research study suggest that self-report of hepatitis C has good specificity (88%) but low sensitivity (77%).[42] However, the relatively low hepatitis C prevalence among individuals with a history of injection drug use (38%) suggests that there was substantial underreporting. This misclassification, if non-differential with regards to pain, should bias to the null, which would give greater strength to our findings. However, it is also possible that patients with pain might be more routinely screened for hepatitis C (because of increased health service use), which could bias our results. Finally, the cross-sectional nature of this study precludes inferences on causality. It is possible that seeking pain relief could cause riskier injecting behaviors that led to hepatitis C infection rather than the opposite (i.e., hepatitis C leading to pain). However, we are not aware of any prior research suggesting an association between pain and riskier injecting behaviors.

This study provides preliminary results suggesting that hepatitis C is associated with chronic pain and intolerance to physical discomfort in injection drug users dependent on opioids. Although the findings of this study are preliminary, they have important implications for clinical practice because chronic hepatitis C may be an overlooked and potentially treatable cause for pain among current and former injection drug use. More research is needed to understand how chronic viral infections such as hepatitis C affect risk for chronic pain in substance users to inform future interventions.

ABSTRACT

Pain is common among opioid-dependent patients, yet pharmacologic strategies are limited. The aim of this study was to explore whether escitalopram, a selective serotonin reuptake inhibitor, was associated with reductions in pain. The study used longitudinal data from a randomized, controlled trial that evaluated the effects of escitalopram on treatment retention in patients with depressive symptoms who were initiating buprenorphine/naloxone for treatment of opioid dependence. Participants were randomized to receive escitalopram 10 mg or placebo daily. Changes in pain severity, pain interference, and depression were assessed at 1-, 2-, and 3-month visits with the visual analog scale, Brief Pain Inventory, and the Beck Depression Inventory II, respectively. Fixed-effects estimators for panel regression models were used to assess the effects of intervention on changes in outcomes over time. Additional models were estimated to explore whether the intervention effect was mediated by within-person changes in depression. In this sample of 147 adults, we found that participants randomized to escitalopram had significantly larger reductions on both pain severity ($b = -14.34$, $t = -2.66$, $P < .01$) and pain interference ($b = -1.20$, $t = -2.23$, $P < .05$) between baseline and follow-up. After adjusting for within-subject changes in depression, the estimated effects of escitalopram on pain severity and pain interference were virtually identical to the unadjusted effects. This study of opioid-dependent patients with depressive symptoms found that treatment with escitalopram was associated with clinically meaningful reductions in pain severity and pain interference during the first 3 months of therapy.

1. Introduction

Pain is common in opioid-dependent patients. Among methadone-treated patients, estimates of chronic pain prevalence range 37–61% [3,14,21]. Several hypothetical pathways may lead to the coexistence of pain and opioid dependence, including depression [2], comorbidities such as HIV [10] or hepatitis C virus [24], and opioid-induced hyperalgesia [8]. Management of pain in opioid-dependent patients is a clinical challenge given concerns for opioid abuse and misuse among individuals with prior substance use disorders [20]. Yet unresolved pain may be a risk factor for relapse among patients whose pain is not fully treated [15]. Some small studies have suggested that buprenorphine/naloxone may be associated with improved pain in opioid-dependent patients with chronic pain [5,16]. However, a study of opioid-dependent patients who were treated with methadone did not find overall changes in pain level at 1 year [13]. Alternative, nonopioid pharmacologic therapies are needed to address pain in opioid-dependent populations.

Antidepressants may constitute an appealing option for treating pain in opioid-dependent patients because of the frequent coexistence of depression in this population [22]. Systematic reviews and clinical guidelines support the use of antidepressants as pharmacotherapy for chronic pain conditions such as low back pain [7], fibromyalgia [27], and neuropathy [23], with the bulk of research to date being focused on use of tricyclic antidepressants and serotonin-norepinephrine reuptake inhibitors. The use of selective serotonin reuptake inhibitors (SSRIs) for chronic pain conditions has been less well studied. Escitalopram belongs to a class of newer SSRIs. It is the S-enantiomer of the SSRI citalopram that has been shown to be responsible for the drug's pharmacologic effect. Two small studies have reported escitalopram to be effective in treating pain in the setting of polyneuropathy [19] and low back pain [17]. No studies have evaluated the effects of escitalopram on pain in opioid-dependent populations.

We recently completed a clinical trial of escitalopram for the treatment of depressive symptoms to reduce treatment dropout in opioid-dependent persons initiating buprenorphine [26]. This secondary analysis was undertaken to examine the effects of escitalopram on pain severity and pain interference in that sample.

2. Methods

2.1. Study sample and design

This study used longitudinal data from a randomized, controlled trial that evaluated whether treatment with escitalopram increased treatment retention among opioid-dependent patients with depressive symptoms who were initiating buprenorphine/naloxone [26]. Participants were recruited through community advertising, physician referrals, and word of mouth. Study inclusion criteria included: age 18–65, DSM-IV diagnosis of opioid dependence, score on the Modified Hamilton Depression Revised Scale of >14 [18], absence of significant suicidal ideation, willingness and ability to complete a 3-month treatment with buprenorphine, no history of severe mental illness (bipolar disorder, schizophrenia, schizoaffective, or paranoid disorder), no currently prescribed medications for depression (participants were not excluded if they were receiving a tricyclic antidepressant for pain), and ability to complete the study assessment in English. The study was approved by the Rhode Island Hospital and Butler Hospital institutional review boards.

Between November 2006 and May 2009, a total of 932 individuals were screened by telephone, and of those, 394 callers seemed eligible for the study and were invited for an in-person screening visit. Of the 226 who attended this visit, 147 fully met the study criteria and agreed to enroll onto the parent study. Of these 147, a total of 72 were randomized to the intervention with escitalopram and 75 were randomized to placebo. In the intervention arm, 48 completed the week 12 study visit, and in the placebo arm, 42 completed the week 12 study visit. The reason for loss to follow-up was dropout from buprenorphine treatment.

Participants who enrolled onto the study completed a baseline interview that included questions on pain, and they were randomized to receive the study medication escitalopram 10 mg or placebo daily. Double-blinding regarding the medication group was maintained throughout the study period for all research staff; the off-site compounding pharmacist kept the key to the blind. Study medication and placebo were provided in identical capsule form. Approximately 5 days after beginning the study medication, participants returned to the research office for buprenorphine (buprenorphine/naloxone) induction. Dose adjustments were based on previous opioid use, craving, and reported symptoms. In general, buprenorphine doses ranging 12–24 mg/day were required for stabilization. At follow-up interviews at 1, 2, and 3 months after enrollment, participants were again asked about their pain.

2.2. Measures

The primary outcomes measured were pain severity and pain interference in the past week. Pain severity was measured with the visual analog scale (VAS) [6]. Participants were asked to rate their pain by placing a mark on a 100-mm nonhatched line that was marked as "No pain" at one end and "Pain as bad as you can imagine" on the other end. Pain interference was assessed with the mean of the 7-item subscale from the Brief Pain Inventory Short Form (BPI) [9]. This subscale measures pain interference in different domains such as sleep, work, and relationships, rating each item from 0 (pain does not interfere) to 10 (pain completely interferes). Other measures included age, sex, race/ethnicity, educational status, primary illicit opioid used, withdrawal pain (number of days experienced in the past week), and depressive symptoms. Depressive symptoms were measured with the Beck Depression Inventory II (BDI II) [4].

2.3. Analytical methods

Descriptive statistics are presented to summarize the characteristics of the study cohort; *t* tests and Pearson chi-square tests are presented to compare intervention arms on a range of background characteristics and indicators of study attrition. We used graphical methods to describe the pattern of pain severity and pain interference observed over time. We used the fixed-effects estimator [25] for panel regression models to statistically analyze change in pain over time and to assess the effects of intervention on change in these outcomes over time. The fixed-effects estimator uses only within-subject variability and effectively controls between subject heterogeneity on all time-invariant characteristics [1]. A potential limitation is that the effect of time constant between subject characteristics (eg, sex, ethnicity) on outcomes cannot be estimated. However, the fixed-effects estimator effectively controls for all unmeasured between subject differences that do not change over time [1]. All confidence interval estimates and tests of significance were based on the robust standard error estimators as implemented in Stata 10.1 [25]. The effect of time-invariant characteristics (treatment assignment) on change in the outcome over time can be estimated as the predictor by time interaction.

Our analysis proceeded in stages. We first estimated unconditional growth models to evaluate the change process. We used the likelihood-ratio difference in the chi-square test to compare the linear growth model to an unconstrained time model estimating separate parameters for each follow-up using 3 dummy variables. Examination of results suggested a more parsimonious parameterization in which time was represented by a single dummy variable coded 0 if baseline and 1 if follow-up. Conditional growth models that included the treatment by time interaction were specified to estimate the effects of intervention on change in pain severity and pain interference. Additional fixed-effects regression models were estimated to test the hypothesis that the effect of escitalopram on pain was mediated by within-person changes in depression.

3. Results

In our sample of 147 adults, participants averaged a mean ± standard deviation (SD) age of 37.5 ± 9.9 years, and most were men (76%) (Table 1). Most participants (80.1%) were non-Hispanic white, 4.9% were African American, 9.6% were Hispanic, and 5.5% were of other racial or ethnic origins. Ninety-three (63.7%) said heroin was their opiate of choice. The mean BDI II score at baseline was 29.4 ± 9.7. Most participants (85%) would be classified as having moderate to severe depression [4]. By means of the Structured Clinical Interview for DSM Disorders [12], 51% met the criteria for current major depression and 4% for dysthymia. Most (122, 83%) reported some pain in the past week, and of those with pain, 48% had pain that was chronic ($\geqslant$6 months). Among participants who reported pain, the most common sites were back pain (66%), joint pain (48%), and muscle pain (38%). Over 90% of participants were located for at least 1 follow-up, and there was no evidence of significant between-group differences with respect to attrition at any time point (Table 1). Intervention groups also did not differ significantly with respect to other background characteristics and pain. There was no evidence of systematic differences with respect to study attrition.

In the full cohort, mean VAS and BPI scores declined from baseline to 1 month and stayed relatively constant at months 2 and 3 (Fig. 1). Statistical comparisons of mean VAS and BPI scores across

VAS, mean ± SD	44.6 ± 31.8	54.1 ± 31.8	.08
BPI, mean ± SD	3.6 ± 3.0	4.5 ± 2.8	.06
Observed at:			
1 month, *n* (%)	64 (85.3%)	64 (88.9%)	.52
2 months, *n* (%)	51 (68.0%)	53 (73.6%)	.46
3 months, *n* (%)	48 (64.0%)	42 (58.3%)	.48
⩾1 Follow-up, *n* (%)	69 (92.0%)	69 (95.8%)	.33

the 1-, 2-, and 3-month follow-up visits were not significant (ie, $P > .10$) for all pairwise comparisons. Because differences in mean VAS and BPI scores across follow-up assessments were substantively small and not statistically significant, we also estimated a more parsimonious model constraining the outcome means to be equal across all follow-up assessments. Likelihood-ratio (LR) chi-square difference tests indicated that the more complex unconstrained time model did not fit the data significantly better than the simpler parameterization of time for either the VAS ($LR^2 = 1.41$, df = 2, $P = 0.50$) or BPI ($LR^2 = 3.54$, df = 2, $P = 0.17$); therefore, we used this parameterization for the subsequent analysis.

Table 2, Model 1, gives the results of fixed-effects regression estimating the effect of intervention on VAS and BPI at follow-up. The coefficient for time gives the estimated change in outcomes between baseline and follow-up in the placebo group among whom mean VAS and BPI scores decreased by 16.8 ($t = -4.50$, $P < .01$) and 1.15 ($t = -3.69$, $P < .01$) points, respectively, between baseline and follow-up. The "treatment by time" coefficient represents the effect of escitalopram relative to placebo. Compared to those receiving placebo, participants who were randomized to escitalopram had 14.34 ($t = -2.66$, $P < .01$) and 1.20 ($t = -2.23$, $P < .05$) larger mean reductions in VAS and BPI, respectively. Fig. 2 provides the expected follow-up mean VAS and BPI scores by treatment arm, as estimated by the fixed-effects model. Mean VAS scores a follow-up were estimated to be 32.1 (95% confidence interval [CI] 26.4–37.8) and 17.7 (95% CI 12.2–23.2) among those randomized to placebo and escitalopram, respectively. Predicted mean BPI scores were 2.53 (95% CI 1.96–3.10) for those receiving placebo and 1.33 (95% CI 0.79–1.87) in the escitalopram arm.

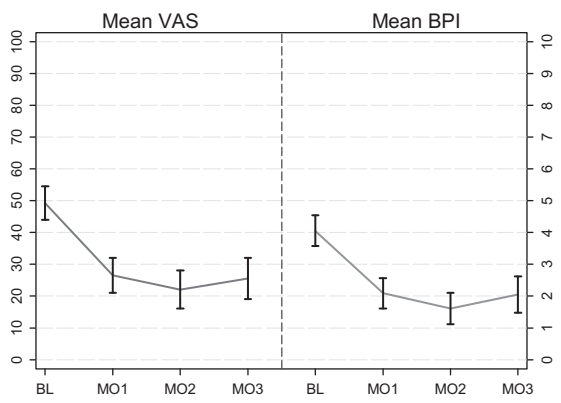

Fig. 1. Change in pain severity (VAS) and pain interference (BPI) from baseline to 3 months. Error bars denote 95% confidence interval estimates of the mean.

Because changes in depression represent a plausible mechanism through which the effect of escitalopram on pain may be mediated, we also estimated a model that included BDI II as a time-varying covariate (Table 2, Model 2). If changes in depression mediated the effect of escitalopram on pain, we would have expected that the effect of escitalopram on pain would be attenuated. We found no support for the mediation hypothesis. After adjusting for within-subject changes in depression, the estimated effect of escitalopram on pain severity ($b = -14.37$, $t = -2.69$, $P < .01$) and pain interference ($b = -1.20$, $t = -2.30$, $P < .05$) were virtually identical to the unadjusted effects reported in Model 1. However, within-subject change in BDI II was associated significantly with within-subject change in VAS pain severity ($t = 2.52$, $P < .05$) and BPI pain interference ($t = 4.25$, $P < .01$). A within-subject increase of 1 point on the BDI II was associated with a .55 point increase in mean VAS and a .09 point increase in mean BPI scores across time.

4. Discussion

This study of opioid-dependent patients with depressive symptoms found that treatment with escitalopram resulted in significantly decreased pain severity and interference over time. Adjusting for within-subject changes in depression scores did not affect the effects of escitalopram, suggesting the analgesic properties of escitalopram were independent of its antidepressant effects.

To our knowledge, this is the first study that demonstrates an association between the antidepressant escitalopram and improved general pain. A small randomized, controlled crossover

Table 2
Fixed-effects regression models estimating the effect of escitalopram on pain severity and pain interference, without (model 1) and with (model 2) adjustment for depression.

study of patients with painful peripheral neuropathy found that escitalopram was associated with significantly lower pain ratings, and that the treatment effect was concentrated among patients with hyperalgesia [19]. Another randomized, controlled trial compared treatment with escitalopram to duloxetine (which is approved by the US Food and Drug Administration for treatment of diabetic neuropathy, fibromyalgia, and chronic musculoskeletal pain) in patients with chronic low back pain, and found it to be equally efficacious for reducing pain [17]. Although our results demonstrated statistical significance, it is also important to assess clinical significance. In our study, the intervention escitalopram was associated with a 14-point decrease beyond what was observed with placebo, which reflects a 29% improvement from the baseline mean of 49. Recent consensus guidelines suggest that 10–20% and $\geqslant$30% decreases in numeric pain intensity represent minimally and moderately important changes in pain, respectively [11]. Therefore, our results suggest that escitalopram is associated with improvement in pain severity that exceeds minimal clinical importance. The same guidelines suggest that a change of 1 point of the BPI interference scale should be considered the threshold for clinically important change in pain interference. By means of this criterion, our results, which show a 1.2-point change associated with escitalopram, also suggest a clinically significant effect on pain interference.

The effects of escitalopram on pain in this study did not seem to depend on the drug's antidepressant effect. This was observed by adjusting for within-subject changes in depression in the second model. Depression scores did not differ significantly between the placebo and escitalopram over the course of the study (possibly related to the relatively low dose of escitalopram) [26]. This underscores the conclusion that the escitalopram's effect on reducing pain in this study was independent of the drug's antidepressant effect. However, the study also demonstrated that there were improvements in depressive symptoms over time in both placebo and intervention arms that were associated with reductions in pain. This reinforces the close relationship between pain and depression [2], which is relevant because depressive symptoms are highly prevalent in this population [22]. It is also of interest to note that pain decreased in the placebo group during the study period. This could be due to the placebo effect, the effects of buprenorphine, the resolution of withdrawal pain, or, most likely, some combination of all factors. Nonetheless, additional pain relief was observed in the escitalopram arm.

This study has numerous limitations and strengths. The study is based on secondary analysis of data; however, it makes use of a randomized, controlled study design with a blinded intervention. At baseline, the intervention group had slightly higher (though nonsignificant) mean VAS and BPI severity scores, but this should not influence the study's main findings, which focus on the effects of the intervention on change in VAS and BPI over time. The study had a relatively short follow-up time of 3 months. It is unknown whether reductions in pain associated with escitalopram are sustained beyond this period. The dose of escitalopram used in this study was relatively low (10 mg). It is possible that larger reductions in pain might have occurred with use of a higher dose. The study is focused on a relatively specific patient population, namely opioid-dependent patients with depressive symptoms initiating buprenorphine, which may limit the generalizability of the findings. However, there are studies that support escitalopram's effectiveness treating pain in non-opioid-dependent populations [19,17]. Furthermore, opioid-dependent patients are disproportionately affected by pain (yet are rarely included in clinical trials), and alternatives to narcotic medications are greatly needed for this population.

In summary, this study of opioid-dependent patients with depressive symptoms found that treatment with escitalopram was associated with a reduction in pain severity and pain interference during the first 3 months of buprenorphine therapy. Treatment with escitalopram was associated with a nearly 30% reduction in pain severity after 1 month compared to control, and its analgesic effect seemed to be independent from any antidepressant effect. More research is needed on the use of nonnarcotic medications such as SSRIs to treat pain in opioid-dependent populations.

Comparison of Diabetes Control Among Haitians, African Americans, and Non-Hispanic Whites in an Urban Safety-Net Hospital

VARSHA G. VIMALANANDA, MD, MPH[1]
JAMES L. ROSENZWEIG, MD[1]
HOWARD J. CABRAL, PHD, MPH[2]
MICHELE M. DAVID, MD, MPH, MBA[3]
KAREN E. LASSER, MD, MPH[4,5]

OBJECTIVE — To compare diabetes care and outcomes among Haitians, African Americans, and non-Hispanic whites.

RESEARCH DESIGN AND METHODS — We analyzed data from 715 Haitian, 1,472 African American, and 466 non-Hispanic white adults with diabetes using χ^2 testing and multiple logistic regression.

RESULTS — Haitians had a higher mean A1C than African Americans (8.2 ± 1.9 vs. 7.7 ± 2.0%) and non-Hispanic whites (7.5 ± 1.7%) (both $P < 0.0001$). There was no difference in completion of process measures. Haitians were more likely than non-Hispanic whites to have elevated LDL cholesterol or blood pressure. Macrovascular complications were fewer among Haitians than African Americans (adjusted odds ratio 0.35 [95% CI 0.23–0.55]), as were microvascular complications (0.56 [0.41–0.76]). Haitians also had fewer macrovascular (0.32 [0.20–0.50]) and microvascular (0.55 [0.39–0.79]) complications than non-Hispanic whites.

CONCLUSIONS — Haitians have worse glycemic control than African Americans or non-Hispanic whites. Future research and interventions to improve diabetes care should target Haitians as a distinct racial/ethnic group.

Diabetes Care 34:58–60, 2011

There are 531,000 black individuals of Haitian ancestry living in the U.S. (1). We identified no studies of diabetes care or outcomes in this population. Thus, it is unclear whether Haitians, like African Americans, have a higher mean A1C (2), receive less recommended testing (3), or have higher rates of retinopathy (4), nephropathy (5), or lower extremity amputations (6) than whites. We analyzed data from primary care clinics in the largest safety-net hospital in Massachusetts in order to compare diabetes care and outcomes among Haitians, African Americans, and non-Hispanic whites.

RESEARCH DESIGN AND METHODS

— We conducted an observational study of subjects with diabetes who received primary care at Boston Medical Center, an urban safety-net hospital with academic primary care practices. The Boston University Medical Center institutional review board approved the study protocol. We included individuals who had at least one primary care visit yearly between 1 August 2007 and 1 August 2009, were ≥20 years old, carried a diagnosis of diabetes by ICD-9-CM billing code 250.XX or by presence on the medical record problem list, and who self-identified as either Haitian, African American, or non-Hispanic white.

The percentage of patients with poor glycemic control (A1C >9%) (7) was our primary outcome measure. Process measures included yearly testing of A1C, LDL cholesterol, and urine microalbumin in patients without nephropathy (8). We ascertained diabetic complications by ICD-9-CM codes or presence on the problem list, although we defined nephropathy as an estimated glomerular filtration rate <60 ml/min, urinary albumin-to-creatinine ratio ≥30 mg/g, or a history of kidney transplant or dialysis.

We used SAS statistical software (version 9.1; SAS Institute, Cary, NC), performing cross-tabulations with χ^2 tests where appropriate and multiple logistic regression to analyze race/ethnicity as a predictor of outcomes. Each regression model included age, sex, language, insurance type, number of primary care visits over 2 years, and having at least one visit to an endocrinologist over 2 years. In models of complication risk, we also controlled for BMI, hypertension diagnosis, and having ever smoked. We assessed each model for interactions between race/ethnicity and either sex or higher health care utilization. A similar analysis was performed to compare English- and non-English–speaking Haitians.

RESULTS

— We identified 2,653 subjects, including 715 Haitians, 1,472 African Americans, and 466 non-Hispanic whites. Thirty-two percent of Haitians were English-speaking. Haitians were of similar mean age to African Americans (58.8 ± 12.0 vs. 57.8 ± 12.5 years) and non-Hispanic whites (59.8 ± 11.8 years), but had a lower mean BMI compared with both African Americans (30.8 ± 6.0 vs. 33.8 ± 8.0 kg/m^2, $P < 0.05$) and non-Hispanic whites (33.4 ± 8.0 kg/m^2, $P < 0.05$). A history of smoking was signifi-

**P* value for Haitians versus African Americans. †Adjusted odds ratio for Haitians versus African Americans. ‡Odds ratios adjusted for age, sex, language (English speaking/non-English speaking), and insurance type (Medicaid or Free Care, Medicare, private, and other insurance), number of primary care visits over 2 years, and having at least one endocrinologist visit over 2 years. Models for complications are additionally adjusted for BMI, diagnosis of hypertension, and ever having smoked. §*P* value for Haitians versus non-Hispanic whites. ‖Adjusted odds ratio for Haitians versus non-Hispanic whites. ¶This quality measure selected on the basis of clinical trials, which show a reduction in coronary heart disease events, stroke, and nephropathy with blood pressure <140/80 mmHg (9). #Macrovascular complications include coronary artery disease, congestive heart failure, ischemic stroke, peripheral vascular disease, and lower extremity ulcers. **Microvascular complications include retinopathy, nephropathy, and neuropathy. aOR, adjusted odds ratio; BP, blood pressure.

cantly less common among Haitians compared with African Americans (52 vs. 85%, $P < 0.05$) and non-Hispanic whites (77%, $P < 0.05$). Compared with African Americans, Haitians had lower health care utilization as measured by number of primary care visits over 2 years (9.2 ± 4.7 vs. 9.8 ± 5.9, $P < 0.05$) and the likelihood of having an endocrinologist visit (16 vs. 26%, $P < 0.05$).

The mean A1C was higher among Haitians than among African Americans (8.2 ± 1.9 vs. 7.7 ± 2.0%, $P < 0.0001$) and among non-Hispanic whites (7.5 ± 1.7%, $P < 0.0001$), and the higher risk of poor glycemic control among Haitians persisted after adjustment (Table 1). In the unadjusted analysis, Haitians had a higher risk of poor blood pressure control compared with both groups and a higher risk of poor LDL cholesterol control compared with non-Hispanic whites. After adjustment, these differences persisted in the comparison with non-Hispanic whites only. Rates of process measure completion were comparable across groups. The prevalence of retinopathy was similar across groups, but all other complications were less common among Haitians. Compared with African Americans, Haitians had lower adjusted odds ratios for macrovascular and microvascular complications (0.35 [95% CI 0.23–0.55] and 0.56 [0.41–0.76], respectively). These risks were also lower among Haitians than they were among non-Hispanic whites (0.32 [0.20–0.50] and 0.55 [0.39–0.79]). In the analysis of nephropathy alone, we found that Haitians fared better than both African Americans (0.56 [0.39–0.80]) and non-Hispanic whites (0.47 [0.31–0.70]). Creole- or French-speaking Haitians had better LDL cholesterol control than English-speaking Haitians, but in the adjusted analysis there were no differences in other outcomes. There were no significant interactions between ethnicity and either sex or health care utilization.

CONCLUSIONS — Haitians had similar rates of completed process measures but worse glycemic control compared with both African Americans and non-Hispanic whites in an urban safety-net hospital. The higher mean A1C among Haitians was evident in both the unadjusted and adjusted analyses, as were the worse lipid and blood pressure control among Haitians compared with non-Hispanic whites. Despite these findings, the rates of diagnosed and documented complications were lower in the Haitian group than in either comparison group.

We identified no other studies of diabetes care and outcomes in Haitians which with to compare these findings. Our results suggest that that worse glycemic control among Haitians may not be attributable to a language barrier or lower health care utilization. Patient-level factors, such as consumption of a traditional high-carbohydrate Haitian diet, or provider- and systems-level factors, such as limited cultural competency, may contribute to worse glycemic control among Haitians.

The finding of lower complication rates among Haitians is surprising in light of intermediate outcome measures that are worse than or similar to the comparison groups. One possible explanation is a shorter duration of diabetes among Haitians, but we cannot exclude detection bias or a higher loss to follow-up among this group. That nephropathy was also less common in Haitians is an interesting finding, because this complication was assessed primarily by results of lab testing and presence of serious complications and thus was less subject to underdiagnosis and underdocumentation.

Worse glycemic control is associated with higher risk of hypoglycemia and symptomatic hyperglycemia, and the frequency of complications among Haitians may worsen with increasing acculturation, obesity, and prevalence of diabetes. Future interventions to prevent diabetes-related morbidity and mortality and reduce health disparities should target Haitians and address the unique features of Haitian culture that may affect the course of diabetes care.

Assessing End-of-Life Preferences for Advanced Dementia in Rural Patients Using an Educational Video: A Randomized Controlled Trial

Angelo E. Volandes, M.D.,[1,2] Laurie Anne Ferguson, D.N.P., APRN,[3] Aretha D. Davis, J.D., MSIV,[2] Nathan C. Hull, MSIV,[4] Michael J. Green, M.D., M.S.,[4] Yuchiao Chang, Ph.D.,[1,2] Kristy Deep, M.D.,[5] and Michael K. Paasche-Orlow, M.D., M.A., M.P.H.[6]

Abstract

Objective: Few studies have evaluated the end-of-life preferences of elderly patients in rural communities and whether preferences are associated with level of health literacy.
Design: Randomized controlled trial of a goals-of-care video decision aid of advanced dementia.
Participants: Elderly subjects (65 years or older) at a primary care clinic in rural Louisiana.
Methods: Half of subjects heard a verbal description of advanced dementia and the goals of care; the other half heard the same verbal description and then viewed the video decision aid. End points were the preferred goal of care in advanced dementia: life-prolonging care (cardiopulmonary resuscitation [CPR], etc.), limited care (hospitalization but not CPR), or comfort care (symptom relief). The principal category for analysis was the difference in proportions of subjects preferring comfort care for each characteristic including randomization group and health literacy level.
Results: Seventy-six subjects were randomized to the verbal ($n = 43$) or video ($n = 33$) arms of the study. Among subjects receiving the verbal description of advanced dementia and the goals of care, 31 (72%) preferred comfort; 5 (12%) chose limited; and 7 (16%) desired life-prolonging. In the video group, 30 (91%) preferred comfort; 3 (9%) chose limited; and none desired life-prolonging ($\chi^2 = 6.3$, $df = 2$, $p = 0.047$). Factors associated with greater likelihood of opting for comfort included greater health literacy (unadjusted odds ratio [OR] 12.1; 95% confidence interval [CI], 2.4–62.6) and randomization to the video (unadjusted OR 3.9; 95% CI, 1.0–15.1).
Conclusion: Rural subjects with higher health literacy were more likely to want comfort care compared to those with lower levels of health literacy. Furthermore, subjects who viewed a video decision aid were more likely to opt for comfort compared to those who solely listened to a verbal description. These findings suggest that video can help elicit preferences and that interventions to empower such patients need to be designed in a manner that is sensitive to health literacy.

Introduction

Despite the fact that rural areas have a larger proportion of seniors over the age of 65 than do urban communities,[1] few studies have explored the end-of-life preferences of rural elderly patients.[2] Instead, the focus of research in end-of-life decision-making has centered around urban populations.[2,3] Nevertheless, given important differences between urban and rural populations, medical practitioners should not assume that taking care of rural patients at the end of life is no different from caring for urban patients at the end of life.[4] With the aging of rural populations, assessing the end-of-life preferences of rural elderly patients is critical for planning and providing palliative care and hospice services for diseases that

this underserved population is likely to confront. Furthermore, studying differences in rural–urban end-of-life care is vital for making palliative care services available to all patients regardless of geography.[5,6]

Variations in the use of end-of-life care services between the elderly in rural and urban settings are known to exist,[7,8] with rural populations tending to use fewer medical interventions at the end of life than those in urban settings.[9–13] Such variations may be attributed to a variety of factors including different access to medical services,[3,14–16] expectations of patients,[3] race,[17–25] and rural–urban cultural differences.[2,3,9] The role of culture is increasingly recognized as a vital interpretive lens through which end-of-life decision-making must be understood.[26–28] While much has been written about the impact of cultural differences on end-of-life preferences, there have been few studies focusing on the impact of rural–urban differences on this outcome.

Our own work studying end-of-life preferences of the elderly in urban settings suggests that health literacy affects preferences for medical treatment in the context of advanced dementia.[29,30] When tools such as video decision aids are used, which are known to surmount communication and health literacy barriers, patients are more informed about their end-of-life preferences. It is unclear, however, if rural patients respond to these videos in a similar manner. To the best of our knowledge, no prior studies on end-of-life decision-making have assessed the effects of health literacy in rural populations or the use of a video decision aid to better inform rural patients.

To address this question, we conducted a randomized controlled trial of a video decision aid of the goals of care in advanced dementia among a diverse group of elderly patients in a rural community. We hypothesized that rural subjects who viewed the video would be more likely to prefer comfort-oriented measures in advanced dementia, and that subjects' preferences for level of medical care would be associated with health literacy.

Methods

Participants

Subjects were recruited from a convenience sample of patients cared for at a primary care clinic located in rural Greensburg, Louisiana, a federally designated Health Professional Shortage Area. The clinic is reflective of the village of Greensburg, which is located in St. Helena Parish. According to the Census, half of residents are African American and the other half are white, more than 99% speak exclusively English in the home and 40% of residents have less than a high school education.[31] Poverty is a significant problem for St. Helena Parish. In 2003, the per capita personal income was $19,985 compared to the state average of $26,313 and the national average of $31,472. Geographic and technological barriers are significant problems for rural populations and in particular for this community. Residents have no access to public transportation and high-speed Internet service is sparse. According to the 2000 US Census, 14% of parish residents are without telephone service.[32]

Recruitment occurred between December 1, 2008 and January 30, 2010. All scheduled English-speaking patients 65 years or older were given a flier by the clinic staff outlining the study after registering for their clinic visit, which was scheduled as part of their usual care. At the end of the visit, patients were asked by clinic staff if they were interested in participating in the study. If they indicated interest, the patient was initially interviewed by the research team for eligibility. Eligibility criteria included: (1) ability to communicate in English; (2) ability to provide informed consent; and (3) not having moderate or severe cognitive impairment (i.e., score <7) based on the Short Portable Mental Status Questionnaire (SPMSQ).[33] The protocol was approved by the Institutional Review Board of the institution affiliated with the rural clinic and all subjects provided informed consent.

Design

After obtaining informed consent, all patients meeting the eligibility criteria were randomized into a control or intervention group. The control group listened to a verbal narrative describing advanced dementia and the goals of care in advanced dementia while the intervention group listened to the same verbal narrative followed by viewing a 6-minute video visually depicting a patient with advanced dementia and the goals of care. We used simple randomization based on a computer generated scheme. All data were collected in a quiet room in the clinic area by a trained member of the research team (L.A.F.), who followed a structured script. As we have described elsewhere,[29] the interviewer read aloud the verbal narrative describing advanced dementia and the goals of care. This description was based on the Functional Assessment Staging (FAST) stage 7a,[34] which is generally considered the threshold for advanced dementia. The narrative states that advanced dementia is an incurable illness of the brain caused by many years of Alzheimer's disease or a series of strokes; its salient features are the inability to communicate understandably with others; inability to walk without assistance; and inability to feed oneself.

We then outlined three levels of medical treatments and the goals associated with each level. The first level (life-prolonging care) aims to prolong life at any cost. It includes all medically indicated treatments. The second level (limited care) aims to maintain physical functioning. It includes treatments such as hospitalization, intravenous fluids, antibiotics, but excludes attempted cardiopulmonary resuscitation and treatments in the intensive care unit. The third level (comfort care) aims to maximize comfort and to relieve pain. It includes oxygen and analgesics but excludes intravenous therapies and hospitalization unless necessary to provide comfort. Subjects were asked which level they preferred in the event they developed advanced dementia. See Appendix A for the text of the verbal description. Participants randomized to the Intervention Group viewed the video decision aid on a portable computer after listening to the same verbal narrative. The 6-minute video depicts the principal features of advanced dementia and the goals of care as described in the narrative. The video presents an 80-year-old female patient with advanced dementia together with her two daughters in the nursing home setting. The patient fails to respond to their attempts at conversation (inability to communicate). The patient is next shown being pushed in a wheelchair (inability to ambulate). Lastly, the patient is hand-fed pureed food (inability to feed oneself). Video images then followed of the goals of care in advanced dementia. Life-prolonging care images included: an intensive care unit with a ventilated patient being tended to

by respiratory therapists; a simulated code with clinicians illustrating cardiopulmonary resuscitation (CPR) and intubation; and various intravenous medications including vasopressors administered through a venous catheter. Visual images to depict limited medical care included: a patient getting antibiotics via a peripheral intravenous catheter; scenes from a typical medical ward service; and a patient wearing a nasal cannula. The video depiction of comfort care included: a patient on home hospice care receiving pain medications; a patient with a nasal cannula comfortable on oxygen at home; and, a medical attendant assisting a patient with self-care. The goals-of-care segment of the video is narrated by an African American physician. All the patients depicted in the video are white. The development of the video followed a systematic approach and has been described in detail elsewhere.[29]

Data collection and other variables

All subjects were interviewed by one member of the research team (L.A.F.) who was not blinded to randomization group. Subjects were interviewed using structured questionnaires. The baseline structured interview (15 minutes) included sociodemographic data such as age, race, gender, educational status, and marital status, as well as health status. Race was self-reported. Health status was self-rated on a Likert scale as follows: excellent, very good, good, fair, or poor. Participants were also asked if they had a diagnosis of dementia and whether they had known a person with advanced dementia.

Immediately after receiving the verbal narrative alone or narrative plus video, a second structured in-person interview (15 minutes) was conducted that included the following components: preferences for goals of care (life-prolonging care, limited care, or comfort care); health literacy; and for the intervention group, comfort using the video decision aid.

Health literacy was assessed using the Rapid Estimate of Adult Literacy in Medicine tool (REALM).[35] This is a 2- to 3-minute English test of medically relevant vocabulary. The REALM is a validated test of word pronunciation and has been shown to correlate well with tests that evaluate a range of literacy skills.[35] As others have done, we defined three categories for health literacy based on the REALM scores: sixth grade and below (REALM score of 0–45); seventh to eighth grade (REALM score of 45–60); and ninth grade and above (REALM score of 61–66).[36,37]

For those participants randomized to the video intervention group, a four-point Likert scale was used to assess perceived value of the video by asking subjects whether they had a better understanding of the disease after viewing the video, and if they would recommend the video to others.

Statistical analysis

Data were analyzed based on the decision-making modality to which each subject was randomized. The primary outcome measure was preference for care in advanced dementia ("Imagine you have advanced dementia and became very ill and in need of medical treatment. What category of care would you want to have provided: life-prolonging care, limited care, or comfort care?") categorized as three options in each of our randomization groups.

All subject characteristics and outcomes were described using proportions for categorical variables and means

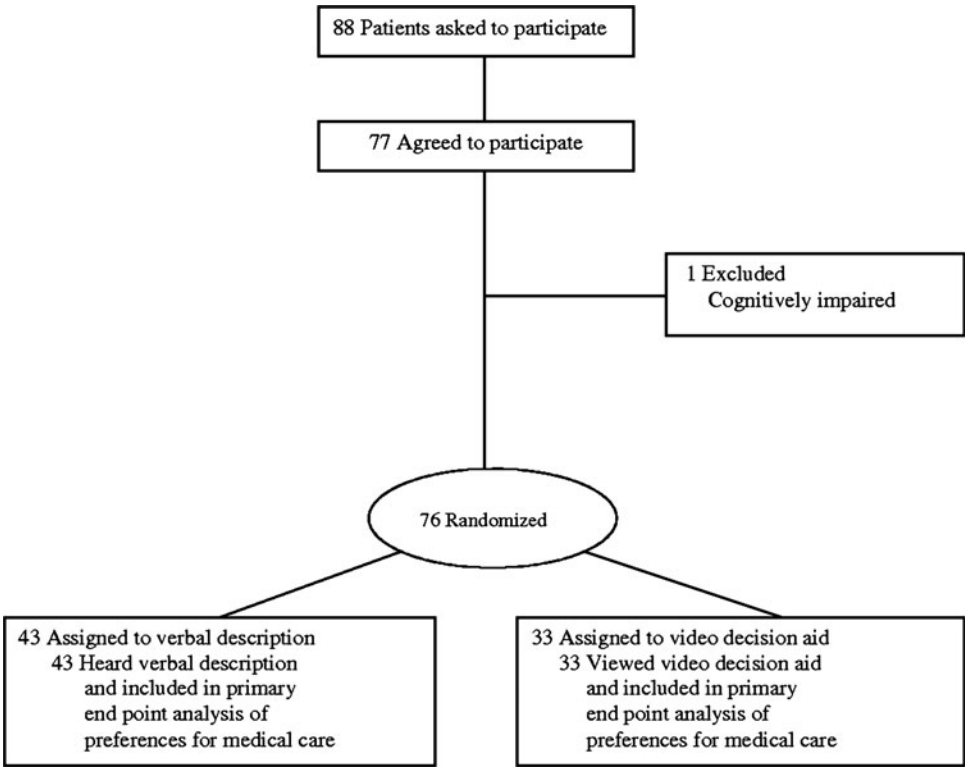

FIG. 1. Flow diagram.

(standard deviation, SD) for continuous variables. Outcomes with 95% confidence intervals (CI) were reported. Preferences for care (life-prolonging, limited, or comfort) were compared between the two groups using exact χ^2 tests.

The measure for the primary outcome analysis was the unadjusted difference in proportions of subjects preferring comfort care between the two study groups. Secondary analyses were conducted to identify factors associated with a preference for comfort care among all subjects. Bivariate analyses were conducted to determine the association between individual subject characteristics (age, gender, race, education, marital status, health status, personal history of dementia, previous relationship with a person with advanced dementia, health literacy, and randomization group) and a preference for comfort care utilizing the exact χ^2 tests. Unadjusted odds ratios (ORs) were calculated to summarize the effects of subject demographic characteristics on their preferences.

All reported p values were two-sided, with $p < 0.05$ considered statistically significant. Data were analyzed and the randomization table was prepared using SAS software, version 9.2 (SAS Institute In, Cary, NC).

Results

Study participants

A total of 88 eligible patients were approached for the study, of whom 77 (88%) agreed to be interviewed (Fig. 1). Patients who declined did not differ significantly from the recruited subjects in terms of age, gender, or race. The most common reason given for not participating was lack of interest. Of the 77 subjects recruited for the study, 1 was disqualified because her SPMSQ score was less than 7, resulting in a total of 76 study subjects. A total of 43 subjects were randomized to the control group, and 33 subjects were randomized to the video intervention group (Fig. 1). Baseline characteristics of the subjects are shown in Table 1. There were some baseline differences in the two groups including gender and marital status, but none that were statistically significant.

Outcomes

Among the 43 subjects receiving only the verbal narrative, 31 (72%) preferred comfort care, 5 (12%) chose limited care, and 7 (16%) desired life-prolonging care. Among the 33 subjects receiving the video decision aid after the verbal narrative, 30 (91%) chose comfort care, 3 (9%) chose limited care, and none desired life-prolonging care ($\chi^2 = 6.3$, $df = 2$; $p = 0.047$). Thus a significantly greater proportion of subjects in the intervention arm opted for comfort care (Fig. 2).

The unadjusted differences in proportions of subjects and odds ratios preferring comfort care as opposed to life-prolonging or limited care for each of the characteristics are listed in Table 2. Bivariate analyses revealed that factors associated with a greater likelihood to prefer comfort care among all subjects were: white race (OR 4.0; 95% CI, 1.1 to 13.9; $p = 0.041$), female (OR 3.6; 95% CI, 1.1–11.6; $p = 0.037$); randomization to the video arm (OR 3.9; 95% CI, 1.0–15.1, $p = 0.047$) and greater health literacy ($p = 0.003$). Subjects who had a health literacy level at or greater than ninth grade were more likely to have preferences for comfort care (OR 12.1; 95% CI, 2.4–62.6) compared to those with less than sixth grade level of health literacy.

The video decision support tool was highly acceptable to subjects in the intervention group: $n = 31$ of 33 (94%, 95% CI, 80–99) subjects found the video "very helpful" or "somewhat helpful," and 32 (97%, 95% CI, 84–100) said they would "definitely" or "probably" recommend the video to others. There were no adverse events in either group.

Comment

This study presents an assessment of end-of-life preferences for a group of elderly subjects from a rural community. When faced with the possibility of advanced dementia, subjects who viewed a video decision aid of advanced dementia and the goals of care were more likely to prefer comfort-oriented measures compared to patients who listened to a verbal narrative. Additionally, in unadjusted analysis, subjects were more likely to prefer a comfort-oriented approach if they had greater health literacy, were white, or were female. Finally, subjects who viewed the video found it to be very helpful, and stated that they would recommend it to other elderly patients.

To the best of our knowledge, this study represents the first randomized controlled trial looking at the end-of-life preferences of elderly patients in a rural community. Furthermore, it

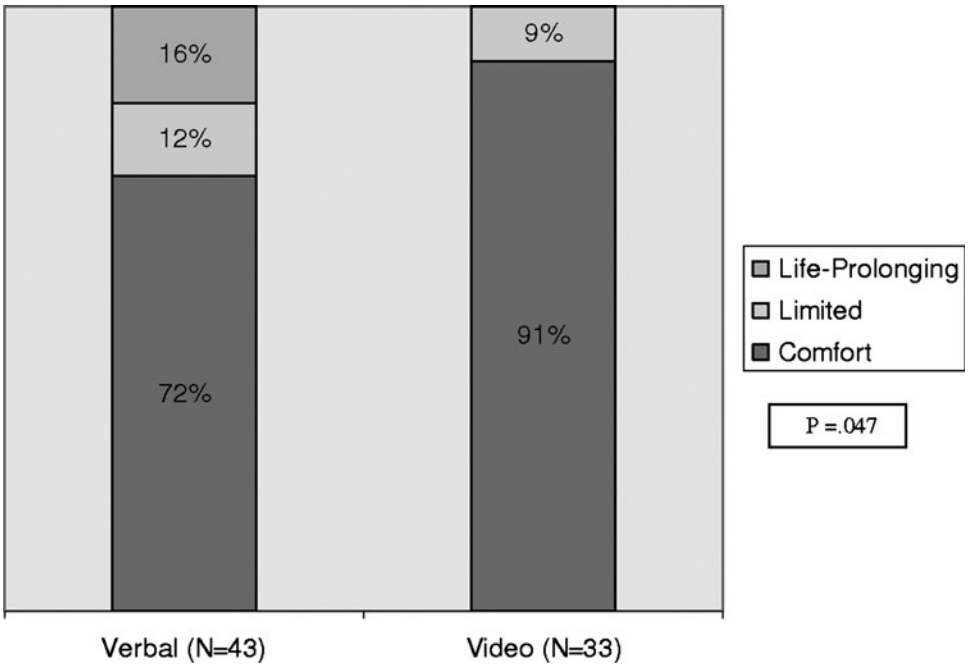

FIG. 2. Subjects' preferences for their goals of care in advanced dementia.

is the first study exploring the usefulness of a video to facilitate end-of-life discussions for elderly patients living in a rural area. Our findings are consistent with our previous investigations looking at the role of health literacy for elderly patients' preferences and the utility of a video decision aid depicting future health states to assist older subjects in expressing their preferences for end-of-life care if they were to develop advanced dementia.[29,30] The present work extends and builds upon these studies by demonstrating the role of health literacy in end-of-life preferences and the efficacy of video decision aids in end-of-life decision-making for patients in a rural setting.

Interestingly, our present study differed little from our previous randomized controlled trial of elderly subjects' preferences in an urban population.[29] While 68% of rural patients wanted comfort care in the verbal group of the present study, 64% of urban patients wanted comfort care in the verbal groups of a prior study. There was also little difference in preferences for comfort care between the video groups of the present study (91%) and our previous study (86%), although the present study included a longer video decision aid that depicted the goals of care in addition to a portrayal of advanced dementia.

In our study, white race also correlated with preferences for comfort care. This is consistent with prior studies looking at the role of race.[17–25] But this finding is limited by the fact that our study sample was not large enough to conduct multivariable analyses. Health literacy may confound the role of race. Our prior work also found an association for preferences for comfort care with white race, however, health literacy was a stronger predictor and explained the racial variance observed.[29,30] An additional association with preferring comfort care in this study was being female, which was not the case in our previous studies.[29,30]

Patients who live in rural settings are often medically underserved. Therefore, it is important to differentiate between the patients' true preferences and the type of fatalism that may be inculcated by the scarcity of medical resources. The fact that participants in our study had a similar pattern of end-of-life preferences as participants in our prior work conducted in urban settings does not exclude the possibility that improved accessibility to health services might not alter these patterns. Indeed, an appropriate critique of the current project is that we enrolled subjects at their primary care clinic, which means that our sample consists of people who already had access to health services. We did not evaluate the preferences of people outside the health setting. While this is a limitation of this study, these methods directly parallel those used in our prior projects and mimic the way we envision the video being used, i.e., in the context of a conversation with a health provider.

Additional limitations include that the interviewer collecting the data was not blinded to randomization assignment, which could have introduced bias. To minimize this potential bias, we used structured interviews and outcome measures, and a verbal script that was followed verbatim. Furthermore, prior randomized studies of interventions aimed at improving end-of-life decision-making have seldom been blinded because limiting the number of interviewers eases the burden of addressing difficult and often painful subject matter.[38–40] Second, this is a small study with a sample size of 76 subjects from one rural area in Louisiana. Thus, our findings may not be generalizable to other rural areas. We did not have the statistical power to perform additional logistic regression analyses disentangling the roles of health literacy, race and gender. Future larger studies may be of great use. Third, our video depicted white patients with an African American clinician as narrator. We did not test the robustness of our findings using other video clips that varied the features of the patient, such as race/ethnicity, gender, or clinical setting. It is possible that the race of patients or clinicians may be internalized differently for patients from different races.[41] Additional studies exploring other video clips that varied

Table 2. Univariate Analysis of the Likelihood of Choosing Comfort Care as the Primary Goal of Care

Characteristics	*Frequency in subjects choosing comfort care*	*Difference in % of subjects choosing comfort care (95% CI)*	*Univariate p Value*	*Odds ratio (95% CI)*
Age			1.0	
<80	47 (81%)			1 [Reference]
≥ 80	14 (78%)	−3% (−25% to 18%)		0.8 (0.2 to 3.0)
Gender, no. (%)			0.037	
Male	18 (67%)			1 [Reference]
Female	43 (88%)	−21% (−41% to 1%)		3.6 (1.1 to 11.6)
Education, no. (%)			1.0	
Less than college graduate	51 (80%)			1 [Reference]
College graduate or higher	10 (83%)	4% (−20% to 27%)		1.3 (0.2 to 6.5)
Marital status, no. (%)			1.0	
Not married	37 (80%)			1 [Reference]
Married	24 (80%)	0% (−19% to 18%)		1.0 (0.3 to 3.1)
Health status,[a] no. (%)			0.07	
Fair or poor	24 (92%)			1 [Reference]
Good or better	37 (74%)	−18% (−34% to −2%)		0.2 (0 to 1.1)
Diagnosis of dementia, no. (%)			1.0	
No	60 (80%)			
Yes	1 (100%)	20% (11% to 29%)		NA
Previous relationship with a person with advanced dementia, no. (%)			0.73	
No	50 (79%)			1 [Reference]
Yes	11 (84%)	5% (−17% to 27%)		1.4 (0.3 to 7.3)
Randomization, no. (%)			0.047	
Verbal	31 (72%)			1 [Reference]
Video	30 (91%)	19% (2% to 35%)		3.9 (1.0 to 15.1)
Health literacy,[b] no. (%)			0.003	
$\leq$ 6th grade	14 (58%)			1 [Reference]
7–8th grades	13 (82%)	23% (−5% to 50%)		3.1 (0.7 to 13.8)
$\geq$ 9th grade	34 (94%)	36% (15% to 57%)		12.1 (2.4–62.6)
Race, no. (%)			0.041	
Black or African American	25 (69%)			1 [Reference]
White	36 (90%)	21% (3% to 38%)		4.0 (1.1 to 13.9)

[a]Health status was one of the following: excellent, very good, good, fair, or poor.
[b]Health literacy assessed with the Rapid Estimate of Adult Literacy in Medicine (REALM).
CI, confidence interval; NA, not applicable.

features of the patients and clinician would be helpful. Finally, an emotional response to the video could have influenced subjects' preferences. To ensure that the video was not biased towards any particular perspective,[42] the video content underwent extensive scrutiny by expert physicians. Additionally, subjects' comfort level with the video is also reassuring against the possibility of a visceral reaction to the video.

Our findings underscore important similarities between the end-of-life preferences in the setting of dementia among the rural subjects in our current study and the urban subjects in our prior work. In both rural and urban settings we have observed a very high level of preference for comfort care. Furthermore, a brief educational video decision aid was associated with even a higher likelihood of choosing comfort care. This provides evidence that the differences among those who might choose comfort care, limited care, or life-prolonging care in advanced care planning settings may be due to differences in knowledge as opposed to true cultural differences. Thus, patient education and decision support is particularly warranted. These findings should be verified in further trials in a variety of settings and focusing on additional disease models.

Acknowledgments

We thank the patients and families who agreed to be filmed for this study. We also thank Jeffrey Rothschild, Chuck Pozner, and the STRATUS Center for Medical Simulation.

Dr. Volandes had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

Appendix A. Narrative Describing Advanced Dementia

I am going to describe to you an illness called advanced dementia, like advanced Alzheimer's dementia, that you may or may not be familiar with. Advanced dementia is an incurable disease of the brain in which one is not able to communicate with others. People in advanced dementia are not able to move around or walk, get out of bed independently, eat by oneself, or communicate understandably with others. People with advanced dementia often have difficulty chewing or swallowing, and require assistance with feeding oneself. Advanced dementia is an incurable disease and most commonly occurs after many years of Alzheimer's disease or as the result of strokes. People are not able to answer any questions or tell you about themselves.

Narrative Describing the Goals of Care

I am going to ask you a question about your preferences for medical care if you had a disease called advanced dementia. I will ask you what you prefer. You have three choices for medical care if you had this condition. I will first review these three choices with you. The three choices for medical care that I want you to think about for advanced dementia are life-prolonging care, limited care, and comfort care.

Life-Prolonging Care

The goal of this category of care is to prolong life. There are no limits to care. This choice includes everything a modern hospital has to offer to maintain your life. Such procedures include: cardiopulmonary resuscitation or CPR in which a doctor pushes on your chest when the heart stops and will often use electricity to shock the heart; being placed on a breathing machine, also known as life support, in which a tube is placed down your throat into the lungs; and other medical procedures performed in the intensive care unit or ICU. The goal is to prolong life.

Limited Care

The goal of this category is to maintain physical and mental functions. Care will depend on your physical and mental functioning. Such care includes intravenous (IV) therapies like antibiotics and hospitalization. But does not include cardiopulmonary resuscitation/CPR and intensive care unit/ICU care. The goal is to maintain physical and mental functioning.

Comfort Care

The goal of this category is to maximize comfort. Only measures that comfort or relieve pain are performed. The aim is to relieve pain and to be kept as pain-free as possible. Comfort care does not include cardiopulmonary resuscitation/CPR, respirators, intensive care unit/ICU care, and generally would not include IV therapy or hospitalization. The goal is maximizing comfort and relieving pain.

Imagine you have advanced dementia and became very ill and in need of medical treatment. What category of care would you want to have provided: Life-Prolonging Care, Limited Care, or Comfort Care?

Abstract

Human longevity and healthy aging show moderate heritability (20%–50%). We conducted a meta-analysis of genome-wide association studies from 9 studies from the Cohorts for Heart and Aging Research in Genomic Epidemiology Consortium for 2 outcomes: (1) all-cause mortality, and (2) survival free of major disease or death. No single nucleotide polymorphism (SNP) was a genome-wide significant predictor of either outcome ($p < 5 \times 10^{-8}$). We found 14 independent SNPs that predicted risk of death, and 8 SNPs that predicted event-free survival ($p < 10^{-5}$). These SNPs are in or near genes that are highly expressed in the brain (*HECW2*, *HIP1*, *BIN2*, *GRIA1*), genes involved in neural development and function (*KCNQ4*, *LMO4*, *GRIA1*, *NETO1*) and autophagy (*ATG4C*), and genes that are associated with risk of various diseases including cancer and Alzheimer's disease. In addition to considerable overlap between the traits, pathway and network analysis corroborated these findings. These findings indicate that variation in genes involved in neurological processes may be an important factor in regulating aging free of major disease and achieving longevity.

Keywords: Genome-wide association analysis; Mortality; Disease-free survival; Longevity; Aging; Brain aging

1. Introduction

The recent, remarkable extension of life expectancy is largely attributed to the postponement of mortality at old age (Vaupel, 1997, 2010). The years of life gained in the older population residing in developed nations are a success story of public health measures and improved health care. In addition to such external factors, longevity and healthy aging consistently show a modest heritability between 20% and 50% and aging-associated genetic research may provide further insights into the mechanisms of aging (Herskind et al., 1996; McGue et al., 1993; Reed and Dick, 2003). It has been postulated that genes involved in pathways associated with aging identified in animal models, such as insulin-like growth factor (IGF)-insulin signaling, regulation of lipoprotein metabolism, the mTOR pathway, and the oxidative stress response may also influence survival to old or even exceptionally old age in humans (Christensen et al., 2006; Kenyon, 2010; Vellai et al., 2003). However, in humans, common variants within genes involved in these pathways have not been consistently associated with lifespan (Christensen et al., 2006; Kenyon, 2010; Kuningas et al., 2008; Vijg and Suh, 2005).

The lack of success in the identification of genes related to aging in humans may be due to the complexity of the phenotype. One approach to investigate aging and longevity is to compare frequencies of genetic variants between nonagenarians or centenarians and the general population. This approach led to the discovery of an association between *APOE* (Deelen et al., 2011; Ewbank, 2007; Gerdes et al., 2000) and more recently *FOXO3A* (Anselmi et al., 2009; Flachsbart et al., 2009; Li et al., 2009a; Pawlikowska et al., 2009; Willcox et al., 2008) and human aging and longevity. However, a recent genome-wide association study (GWAS) of individuals reaching the age of 90 or older failed to identify genome-wide significant variants (Newman et al., 2010).

Prospective follow-up studies with a continuous outcome such as time to death are more powerful than case-control analyses. A study of time to death simultaneously addresses the effects of genetic variation related to life span, the progression toward death, and disease-specific mortality. This design has been successfully applied in animal models (Finch and Ruvkun, 2001; Kenyon, 2010) and also in human genetics research of blood pressure (Levy et al., 2009; Newton-Cheh et al., 2009; van Rijn et al., 2007), a trait with heritability similar to longevity, where examination of a continuous outcome has been more successful in identifying genetic loci than studies that have solely used hypertension

as a dichotomous trait. Frailty and survival free of disease have been suggested as more promising phenotypes for studies of aging because mortality is a very heterogeneous outcome caused by multiple chronic conditions (Vijg and Suh, 2005).

This study addresses the genetics of aging in a broad, sequential way using data from cohort studies participating in the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium. First, we aimed to identify single nucleotide polymorphism (SNPs) associated with all cause mortality (time to death) in a hypothesis-free GWAS in approximately 25,000 unselected persons of European ancestry. Second, we performed GWAS of time to event, defined by major incident events (myocardial infarction, heart failure, stroke, dementia, hip fracture, or cancer) or death, as an alternative phenotype for healthy aging. Last, we analyzed the SNPs along with their respective most likely associated genes identified in the GWAS meta-analyses to identify pathways and networks associated with aging and longevity.

2. Methods

2.1. Participants

The participants are of recent European ancestry and stem from cohorts of the CHARGE Consortium (Psaty et al., 2009). All cohorts are follow-up studies periodically assessing the health and vital status of their participants. Although some of the cohorts included multiple ethnic groups, only data from self-reported Caucasians were used. In addition, population structure was assessed using principal components in each CHARGE study and outliers were removed. Any remaining within-study structure was adjusted for using appropriate methods (Price et al., 2006). All participants included in this analysis were at least 55 years of age at the time of blood draw for DNA and provided written informed consent. A brief description of each population is given in the Supplementary Information.

2.2. Phenotype

We conducted a survival analysis, adjusted for age at baseline and sex, to model continuous time to death or end of follow-up in 25,007 participants (deceased "cases" = 8444; mean follow-up time = 10.6 [SD 5.4] years) that were older than 55 years at baseline. As research demonstrated that the likelihood of incident disease is genetically determined, we defined a second phenotype: survival free of major disease or mortality (Atzmon et al., 2004; Lunetta et al., 2007; Vijg and Suh, 2005). The outcome was defined as time to the first of the following adjudicated events: myocardial infarction, heart failure, stroke, dementia, hip fracture, cancer, or death. For this analysis, participants at baseline were older than 55 years of age and free of any of the aforementioned conditions. Inclusion in the study required complete follow-up information on mortality and at least 4 out of 6 of the health conditions. Genome-wide information on polymorphisms was available for 16,995 participants free of disease at the beginning of the study. These participants were followed for 8.8 (SD 5.7) years and we registered 7314 major events.

2.3. Genotyping and imputation

As different genotyping platforms were used across studies, we imputed to 2.5 million SNPs using the HapMap 22 CEU (Build 36) genotyped samples as a reference. For details on the study-specific quality control procedures for genotyping and imputation please consult Supplementary Table S1.

2.4. Statistical analysis

We used the semiparametric Cox proportional hazard to model time to event for both phenotypes in each study. Follow-up time since baseline was used as time scale. An additive genetic model was used in this analysis. We subsequently combined the individual study results in a meta-analysis using a fixed effects model that combined the study-specific regression parameters and standard errors using inverse variance weighting. We included SNPs that had a minor allele frequency (MAF) of at least 1% and an imputation quality ratio (de Bakker et al., 2008) (equivalent to the MaCH r^2 statistic; Li et al., 2009b) of at least 0.3. The study-specific inflation factors (λ_{GC}) were computed using the set of chi-square statistics used for the meta-analysis for each study. The inflation factor is computed as the median of all chi-square statistics divided by the expected median of the statistics (approximately 0.456) for a chi-square distribution with 1 degree of freedom. SNP associations at $p < 5 \times 10^{-8}$ were considered to be genome-wide significant. SNPs with $p < 5 \times 10^{-5}$ were considered suggestive associations. The combined meta-analysis hazard ratio (HR) can be interpreted as the increase in the risk of dying or having a major event during follow-up per additional copy of the coded allele. Power analysis revealed 80% statistical power to detect SNPs with a minor allele frequency of 5% and relative risk of 1.10 using a nominal significance level of 0.05 (Supplementary Table S2).

In addition, we incorporated gene annotation information, a technique that has successfully been applied in the field of aging research (de Magalhaes et al., 2009a, 2010). Protein ANalysis THrough Evolutionary Relationships (PANTHER; Mi et al., 2007; Thomas et al., 2003) and Ingenuity Pathway Analysis (IPA) (www.ingenuity.com) were used for identification and classification of networks, pathways, biological processes, and molecular functions of the genes identified in this study. For both phenotypes we generated lists of candidate genes. These genes were the closest reference genes to the SNPs associated with the outcome at $p < 1 \times 10^{-3}$. PANTHER compares these gene lists to the reference list using the binomial test for each molecular function, biological process, or pathway term.

IPA builds networks by searching the Ingenuity Pathways Knowledge Base for interactions between the identified genes and all other gene objects stored in the knowledge base.

3. Results

We conducted a meta-analysis of GWAS on time to death adjusted for baseline age and sex in participants of European origin, 55 years of age or older from 9 longitudinal cohort studies participating in the CHARGE Consortium (Psaty et al., 2009). In total, we observed 8444 deaths (mean age at death: 81.1, SD 8.4) in 25,007 participants (55% female) after an average follow-up of 10.6 (SD 5.4) years. Descriptive characteristics of participants and Manhattan plots showing genome wide *p*-values for association are displayed in the Supplementary data (Supplementary Fig. S1, and Supplementary Tables S3 and S4). The quantile-quantile plot (Q-Q plot) of observed versus expected *p*-values showed only a small deviation from the null hypothesis, indicating no significant population stratification (Fig. 1a, $\lambda_{GC} = 1.066$). Although there were no genome-wide significant findings ($p < 5 \times 10^{-8}$), 14 independent SNPs were associated with time to death at a suggestive threshold of $p < 1 \times 10^{-5}$ (Table 1). Among these SNPs, rs4936894 (chromosome 11, near the von Willebrand factor A domain containing 5A gene [*VWA5A*]) had the strongest association with time to death ($p = 3.4 \times 10^{-7}$). We sought replication for 5 of the 14 top SNPs with the strongest association with time to death in 4 independent samples ($n = 10{,}411$, deaths = 1295) of the same ancestry. None of the SNPs were consistently associated with time to death at a nominally significant level of $p < 0.05$ across all replication samples (Supplementary Tables S5–S8). In the combined meta-analysis of the discovery and replication studies only rs1425609 in the vicinity of otolin-1 (*OTOL1*) showed a stronger association (1.61×10^{-6}).

Likewise, no genome-wide significant findings were identified in the time to event analysis following 16,995 participants free of disease at baseline and registering 7314 events over an average of 8.8 (SD 5.7) years of follow-up (Table 2). Events included incident myocardial infarction, heart failure, stroke, dementia, hip fracture, and cancer or death. The Q-Q plot (Fig. 1a, $\lambda_{GC} = 1.019$) showed no evidence of inflation of type I error. In total, there were 8 independent SNPs associated with event-free survival at $p < 10^{-5}$. The SNP with the strongest association was rs10412199 (chromosome 19, $p = 3.02 \times 10^{-6}$), which is in close proximity to ataxia, cerebellar, Cayman type (*ATCAY*). Additional descriptive information including definitions of each event and association results with $p < 10^{-4}$ are provided in Supplementary Figure S2, and Supplementary Tables S9–S12.

As both phenotypes may provide different but complimentary information about the aging process, we evaluated the overlap between their association results (Table 3). Interpretation of the overlap between the phenotypes requires caution as both phenotypes are correlated, nevertheless it helps to focus on specific loci and put them into the context of aging. From the 14 loci passing the prespecified, suggestive threshold of $p < 1 \times 10^{-5}$ in the time to death analysis, 5 had corresponding SNPs within 500 kilo base pairs distance, in linkage disequilibrium (LD; $r^2 > 0.1$) associated with $p < 1 \times 10^{-4}$ and the same overall direction of the effect in the time to event analysis. These 5 regions were in the vicinity of the following genes: *OTOL1* (3q26.1), bridging integrator 2 (*BIN2*, 12q13), ATG4 autophagy related 4 homolog C (*ATG4C*, 1p31.3), origin recognition complex,

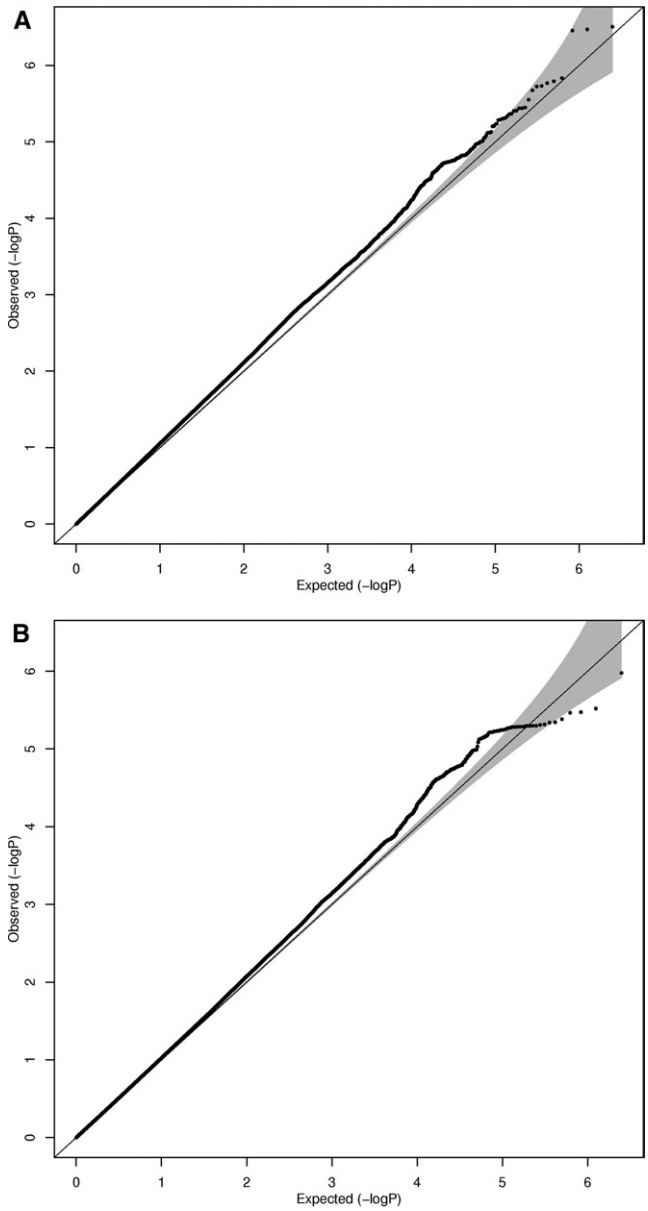

Fig. 1. (a) Quantile-quantile (Q-Q) plot after meta-analysis for time to death. (b) Quantile-quantile (Q-Q) plot after meta-analysis for time to event.

Key: bp, base pair; Chr, chromosome; HR, hazard ratio; LD, linkage disequilibrium; SNP, single nucleotide polymorphism.
[a] Study-specific information is presented in the order: RS, CHS, FHS, ARIC, AGES, HABC, BLSA, InCHIANTI; "+" = coded allele increases risk of event; "-" = coded allele decreases risk of event; "?" = not tested.

subunit 5-like (*ORC5L*, 7q22.1), and potassium voltage-gated channel, KQT-like subfamily, member 4 (*KCNQ4*, 1p34). Similarly, in the time to event analysis 3 of the 8 top SNPs showed considerable overlap and the same direction of effect in the time to death analysis. These SNPs were close to the following genes: MDS1 and EVI1 complex locus (*MECOM*, 3q24-q28), succinate-CoA ligase, ADP-forming, beta subunit (*SUCLA2*, 13q12.2-q13.3), and ST3 beta-galactoside alpha-2,3-sialyltransferase 3 (*ST3GAL3*, 1p34.1).

Finally, we evaluated candidate genes for aging by identification and classification of networks, pathways, biological processes, and molecular functions. The candidate genes were derived from the meta-analyses of GWAS and included the reference genes closest to the SNPs associated with $p < 1 \times 10^{-3}$ (time to death: 862 genes, time to event: 704 genes). We used PANTHER (Mi et al., 2007; Thomas et al., 2003, 2006) and IPA software (www.ingenuity.com) for these analyses. PANTHER compares these gene lists to the reference list using the binomial test for each molecular function, biological process, or pathway term. IPA builds networks by searching the Ingenuity Pathways Knowledge Base for interactions between the identified genes and all other gene objects stored in the knowledge base.

For the analysis of time to death, the relevant biological processes overrepresented in the PANTHER analysis were developmental processes, neuronal activities, signal transduction, neurogenesis, ectoderm development, and cell adhesion. For the analysis of time to incident event, developmental processes and neuronal activities were overrepresented among other biological process (Table 4). The analyses also highlighted the Wnt signaling pathway. The Wnt signaling pathway is ubiquitous and known to be involved in cancer but also plays an important role in the early stages of the development of the central nervous system, in synaptic formation by axon guidance, and in modulating fibrosis during muscle repair scored high in both traits under study (Brack et al., 2007; Inestrosa and Arenas, 2010; Keeble et al., 2006; Ulloa and Martí, 2010). For extended tables see Supplementary Tables S13 and S14. In addition, Ingenuity identified 1 network with $p = 10^{-31}$ containing 26 genes involved in processes related to nervous system development and function for the analysis of time to death (Fig. 2) and 1 network with $p = 10^{-40}$ containing 28 genes involved in cellular function and development for time to event (Supplementary Fig. S3).

IPA analysis highlighted the following genes associated with the time to death trait: *NTRK2* (neurotrophic tyrosine kinase, receptor, type 2)—a member of the neurotrophic tyrosine receptor kinase family. This kinase is a membrane-bound receptor that, upon neurotrophin binding, phosphorylates itself and members of the mitogen-activated protein kinase (MAPK) pathway. Signaling through this kinase leads to cell differentiation. Second in line were *NCAM1* (neural cell adhesion molecule 1)—a cytoskeletal binding

Table 3

Candidate genes (genes observed) were in the neighborhood of single nucleotide polymorphisms (SNPs) associated with p value $< 1 \times 10^{-3}$. For time to death 862 candidate genes were identified; 826 could be matched to the Protein ANalysis THrough Evolutionary Relationships (PANTHER) gene list. For time to event 704 candidate genes were identified; 679 could be matched to the PANTHER gene list. Extended lists of PANTHER pathways, biological processes, and molecular functions are listed in the Supplementary Tables (S13, S14).

[a] Bonferroni correction multiplying the single-test *p*-value by the number of independent tests to obtain an expected error rate.

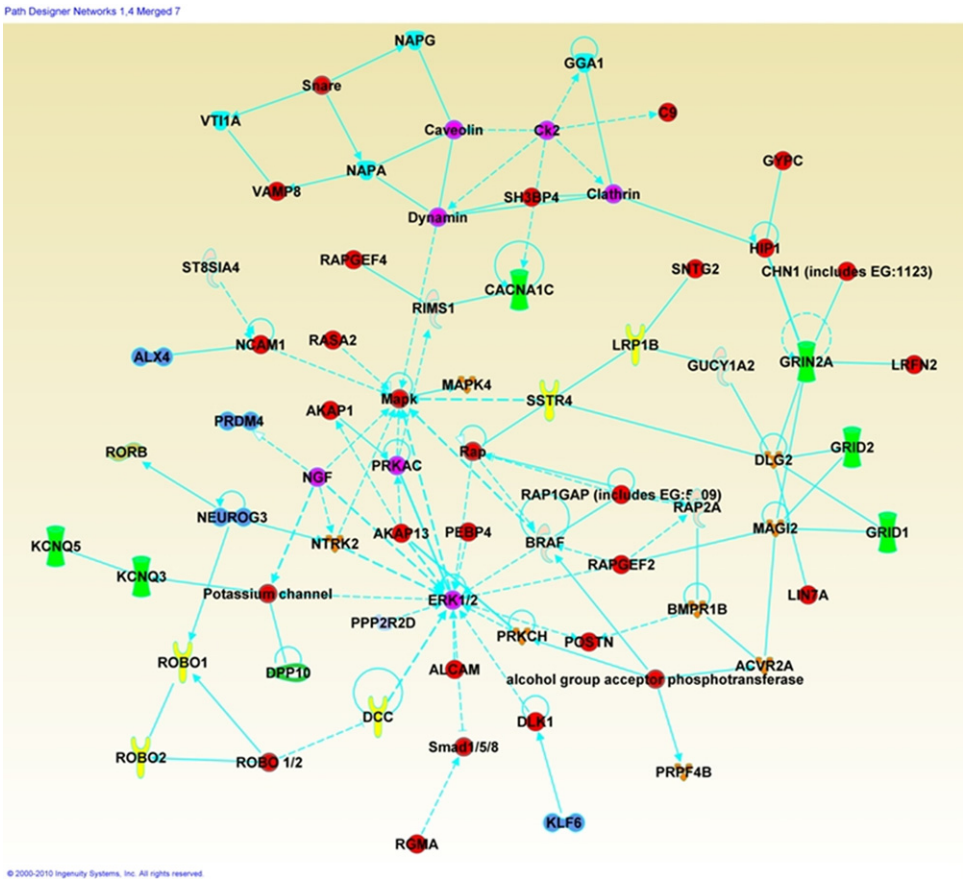

Fig. 2. Network describing neuronal activities related to time to death. Pathway analysis of genes (single nucleotide polymorphisms; SNPs) associated with time to death. Genes are represented as nodes; edges indicate known interactions (solid lines depict direct and hatched lines depict indirect interaction). Human gene functions are color-coded as follows: red = unknown, yellow = transmembrane receptor and G protein coupled receptor, magenta (pink-purple) = group/complex/other, bright green = ion channel, hunter green (dark green) = peptidase, navy blue = transcription regulator, light blue = transporter, beige = enzyme, orange = kinase, light green = cytokine, light purple = phosphate, gray = translation regulator, olive green = ligand-dependent nuclear receptor.

protein, *GRID2* (glutamate receptor, ionotropic, delta 2)—a relatively new member of the family of ionotropic glutamate receptors which are the predominant excitatory neurotransmitter receptors in the mammalian brain, and have a role in neuronal apoptotic death, and *RIMS1* (regulating synaptic membrane exocytosis 1), which regulates synaptic vesicle exocytosis and may be part of the protein scaffold of the cell.

Among the genes that were highlighted through the IPA analysis in the analysis of time to event was *MYC* (v-myc myelocytomatosis viral oncogene homolog)—a multifunctional, nuclear phosphoprotein that plays a role in cell cycle progression, apoptosis, and cellular transformation. *MYC* functions as a transcription factor that regulates transcription of specific target genes. Second in line were *E2F1* (E2F transcription factor 1), *EGFR* (epidermal growth factor receptor), and *CEBPA* (CCAAT/enhancer binding protein [C/EBP], alpha). *EF21*, a transcription factor, plays a crucial role in the control of cell cycle and action of tumor suppressor proteins can mediate both cell proliferation and p53-dependent/independent apoptosis. *EGFR* is a transmembrane glycoprotein that serves as a receptor for members of the epidermal growth factor family and supports cell proliferation. *CEBP*-Alpha, a bZIP transcription factor, can bind as a homodimer to certain promoters and enhancers. *CEBPA* also forms heterodimers with the related proteins CEBP-beta and CEBP-gamma and modulates the expression of leptin, interacts with *CDK2* and *CDK4*, and thereby inhibits these kinases and causes growth arrest in cultured cells.

4. Discussion

In our analyses of over 25,000 individuals of 55 years and older followed for an average of 11 years, we did not identify genome-wide significant associations for all-cause mortality and survival free of major diseases. However, both traits highlighted loci with suggestive significance that were in the neighborhood of genes related to neural regulation. In addition, our pathway and network analyses identified an enrichment of genes associated with cellular and neural development and function, and cell communication that may contribute to variation in human aging. Brain development might be responsible for the creation of redundancy in brain circuitry, which is associated with functional reserve and resiliency. Brain function regulates most of the compensatory strategy supporting maintenance of homeostatic equilibrium. Both of these processes are essential to healthy aging and longevity.

Several explanations are possible for the lack of genome-wide significant findings. First, mortality is arguably 1 of the most complex phenotypes, and several trajectories toward extreme old age have been identified (Evert et al., 2003). Multiple genes could mediate the aging process but would have their effects through numerous different pathophysiological processes and diseases that act as intermediate factors on the pathway to death (de Magalhaes et al., 2010). Therefore, any common variation in genes associated with aging probably has a small effect.

Second, the largely negative findings of this and other studies contrast with the intriguing animal studies of longevity. Very large effects of single genes on lifespan have indeed been observed in laboratory animals, but humans often have several homologues of these genes which might significantly differ in function or compensate for mutated genes through redundant mechanisms (Kuningas et al., 2008). This could explain why our top findings did not include genes in these pathways found in animal models. Animal models also represent genetically homogenous populations and are exposed to controlled environmental influences. The lack of replication of animal model findings in humans suggests that the use of knockout animals may not provide the optimal approach to understanding the variation in survival in humans as interactions with environmental factors may obscure the associations and prevent the identification of loci in humans.

Third, our study is based on common genetic variants and therefore we cannot exclude effects due to low frequency and rare variants ($< 5\%$) or due to the presence of structural variation, such as copy number polymorphisms. Our discovery set may lack the power to identify all the relevant loci, even though we had sufficient power to detect common SNPs (minor allele frequency = 5% or more) with a relative risk of 1.10 (Supplementary Table S2).

Last, we cannot exclude that phenotypic heterogeneity influenced our findings. While all cohorts had prospectively collected information on major health events and diagnoses, heterogeneity in the methods of assessment and classification might have limited the ability to identify true effects.

Complex diseases may result from the effects of a large number of low frequency variants, with substantial allelic heterogeneity at disease-causing loci (Pritchard, 2001; Pritchard and Cox, 2002; Swarbrick and Vaisse, 2003). Theoretical modeling that incorporates mutation, random genetic drift, and purifying selection suggests that many of the variants that affect complex traits may be in the 1%–5% frequency range (Pritchard, 2001). Indeed, sequencing of candidate genes in an attempt to capture such low frequency variants, has led to the identification of rare variants with modest effects on body mass index (Ahituv et al., 2007; Challis et al., 2002; Cone, 2000), triglyceride levels (Romeo et al., 2007), high-density lipoprotein (HDL; Cohen et al., 2004; Romeo et al., 2007) and low-density lipoprotein (LDL) cholesterol levels (Cohen et al., 2005, 2006; Kotowski et al., 2006).

It is impossible to determine the functional variant of a gene by GWAS. Moreover, we cannot conclude from the location of an SNP that this variation is involved in the expression of the closest gene. However, our top results suggested a possible role of genes involved in neurological

processes in human longevity and aging. Ten of the 22 suggestive associations identified in our analyses are in or near genes that are highly expressed in the brain (*HECW2* [Rotin and Kumar, 2009], *HIP1* [Blanpied et al., 2003], *BIN2*, *GRIA1*), were previously related to the regulation of neuronal excitability and plasticity (*KCNQ4* [Van Eyken et al., 2006], *LMO4* [Joshi et al., 2009; Leuba et al., 2004], *GRIA1*), and the maintenance of neural circuitry and synaptic plasticity (*NETO1*), or are associated with neurological diseases such as Alzheimer's disease (*LMO4* [Leuba et al., 2004], *BIN2*, GRIA1, GRIN2B), and amyotrophic lateral sclerosis (*GRIN2B*). In addition, 6 of the 22 SNPs were in close proximity to genes associated with other phenotypes of aging such as autophagy (*ATG4C* [Kenyon, 2010]), cancer (*ATG4C* [Maiuri et al., 2009], *HIP1* [Bradley et al., 2007], *HECW2* [Rotin and Kumar, 2009], *VWA5A* [Zhou et al., 2009], *MECOM*), and mitochondrial depletion syndrome (*SUCLA2*). Notably, *BIN2*, *ATG4C*, *KCNQ4*, *MECOM*, and *SUCLA2* showed associations with both traits in our study.

Using the expression quantitative trait loci (eQTL) browser (eqtl.uchicago.edu/cgi-bin/gbrowse/eqtl/) we detected eQTL associated with *HIP1*, *COL5A1*, *LOC340156*, and *SMARCA2* in time to death only.

Interestingly, SNPs known to be associated with longevity and disease in the neighborhood of APOE (Deelen et al., 2011) or *FOXO3A* (Flachsbart et al., 2009; Willcox et al., 2008) only reached nominal significance (results not shown). These genes were originally identified in studies of centenarians; it is possible that our study of cohorts comprised of individuals from the general populations did not have sufficient statistical power to identify these genes with certainty. (Tan et al., 2008).

While meta-analysis of GWAS has the power to detect small changes of allele frequencies between groups with the analyzed trait, true association signals may not be revealed based on a stringent genome-wide significance threshold. This situation, although limiting false positive findings, performs poorly in identifying false negatives as they may fall below the threshold. Network analyses using a less stringent significance threshold do not amend the overall negative finding of this study. However, it is well-recognized that within the many associations that failed to attain this level of significance lie true positive associations. Network analyses can provide useful information exploring multiple gene effects and their interactions.

In fact the interpretation of most GWAS results is difficult because individual results may involve many seemingly unrelated genes. Because PANTHER and IPA are built on different conceptual approaches, database sources and different pathway classifications, they can be seen as complementary approaches. Our pathway and network analyses highlighted neuronal activities and organism developmental processes as major biological processes involved aging. In addition, it highlighted Wnt signaling and showed that those genes that were involved in most pathways indeed had substantial effects within the analyzed trait. *NTRK2* (Rico et al., 2002), *NCAM1* (Rutishauser et al., 1988), *GRID2* (Hirai et al., 2003), and *RIMS1* (Johnson et al., 2003; Schoch et al., 2002) are associated with neuronal development and disease pathways that were highlighted in the analysis of time to death. *MYC* (Cole, 1986; Goga et al., 2007), *E2F1* (Nevins, 2001), *EGFR* (Wang et al., 2004), and *CEBPA* (Ménard et al., 2002; Wang et al., 2001) are associated with "cancer," "cell function," and "development" pathways.

Few if any of the top hits from the GWAS were involved in common pathways of aging, typically addressed in candidate gene studies. For example, there was no specific evidence for genes involved in IGF-insulin signaling. However, this negative finding cannot be interpreted as evidence against the importance of IGF-insulin signaling, as well as other processes such as inflammation, oxidative stress, cellular damage and repair, growth hormone, and cell proliferation in aging. Moreover, it is possible that polymorphisms in related genes have an effect in the oldest old, who were represented by fewer numbers in our study population such that our study design would be underpowered to detect it. It is also conceivable that the neurological pathways identified by our analysis interact with the known candidate genes involved in aging (Bishop et al., 2010; Finch and Ruvkun, 2001). It is feasible that the traditional aging pathways are hierarchically controlled by neurons and that the brain might be the location coordinating physiological changes (Bishop et al., 2010; Finch and Ruvkun, 2001). Because neurons are particularly susceptible to damage caused by reactive oxygen species, limitations in cellular maintenance and repair might reinforce these pathways and accelerate aging (Finch and Ruvkun, 2001). An increased ability of neuronal cells to prevent or repair oxidative damage might result in beneficial hormonal signaling, otherwise deregulated with age, thus delaying the onset of age-related disease and directly regulating cognitive aging and life span (Bishop et al., 2010; Cutler and Mattson, 2006; de Magalhães and Sandberg, 2005).

In conclusion, our analysis did provide suggestive evidence that aging is under neuronal control. Unfortunately, we have no relevant tissue or expression experiment available to further underscore or validate our findings. Future investigations of changes of gene expression with age at cellular and population levels are warranted.

Disclosure statement

The authors declare that no competing interests exist.

All participants included in this analysis provided written informed consent.

Replication Samples

Whitehall II: Whitehall II has been supported by grants from the Medical Research Council; Economic and Social Research Council; British Heart Foundation; Health and Safety Executive; Department of Health; National Heart Lung and Blood Institute (HL36310), US NIH National Institute on Aging (AG13196), US NIH Agency for Health Care Policy Research (HS06516); and the John D. and Catherine T. MacArthur Foundation Research Networks on Successful Midlife Development and Socio-economic Status and Health.

English Longitudinal Study of Aging: Samples from the English Longitudinal Study of Ageing (ELSA) DNA Repository (EDNAR), received support under a grant (AG1764406S1) awarded by the National Institute on Ageing (NIA). ELSA was developed by a team of researchers based at the National Centre for Social Research, University College London and the Institute of Fiscal Studies. The data were collected by the National Centre for Social Research.

Religious Order Study: Grants P30AG10161, R01AG15819, and R01AG30146 from the National Institute on Aging, and the Translation Genomics Research Institute.

Memory and Aging Project: Grants R01AG17917 and R01AG15819 from the National Instiute on Aging, and the Translation Genomics Research Institute.

The Longevity Consortium, funded by the National Institute of Aging, grant number U19 AG023122, provided administrative resources to CHARGE investigators for this phenotype as well as scientific opportunity funds for de novo genotyping of the 5 selected SNPs in the ELSA and Whitehall II replication studies.

Acknowledgements

Rotterdam Study: The Rotterdam Study is supported by Netherlands Genomics Initiative/Netherlands Consortium for Healthy Aging (050-060-810); Netherlands Organisation for Scientific Research (NWO) (904-61-090, 904-61-193, 480-04-004, 400-05-717, SPI 56-464-1419, 175.010. 2005.011, 911-03-012 and 017.106.370); Netspar—Living longer for a good health; the Erasmus Medical Center, and Erasmus University in Rotterdam; the Netherlands Organization for Health Research and Development, the Netherlands Research Institute for Diseases in the Elderly; the Dutch Ministry of Education, Culture and Science, and the Ministry for Health, Welfare and Sports; the European Commission; and the Municipality of Rotterdam, the Netherlands.

Cardiovascular Health Study: The CHS research reported in this article was supported by contract numbers N01-HC-85079 through N01-HC-85086, N01-HC-35129, N01 HC-15103, N01 HC-55222, N01-HC-75150, N01-HC-45133, grant numbers U01 HL080295 and R01 HL087652 from the National Heart, Lung, and Blood Institute, the National Institute of Aging R01 AG031890 with additional contribution from the National Institute of Neurological Disorders and Stroke. A full list of principal CHS investigators and institutions can be found at www.chs-nhlbi.org/pi.htm. DNA handling and genotyping was supported in part by National Center for Research Resources grant M01-RR00425 to the Cedars-Sinai General Clinical Research Center Genotyping core and National Institute of Diabetes and Digestive and Kidney Diseases grant DK063491 to the Southern California Diabetes Endocrinology Research Center.

Framingham Heart Study: Phenotype-genotype analyses were supported by the National Institute of Aging grant number R01AG029451 (PI: JMM). The Framingham Heart Study of the National Heart Lung and Blood Institute of the National Institutes of Health and Boston University School of Medicine were supported by the National Heart, Lung and Blood Institute's Framingham Heart Study Contract No. N01-HC-25195 and its contract with Affymetrix, Inc., for genotyping services (Contract No. N02-HL-6-4278). Analyses reflect intellectual input and resource development from the Framingham Heart Study investigators participating in the SNP Health Association Resource (SHARe) project. A portion of this research was conducted using the Linux Cluster for Genetic Analysis (LinGA-II) funded by the Robert Dawson Evans Endowment of the Department of Medicine at Boston University School of Medicine and Boston Medical Center. Dr. Kiel's effort as well as all hip fracture data from the Framingham Osteoporosis Study was supported by a grant from the National Institute of Arthritis, Musculoskeletal and Skin Diseases and the National Institute on Aging; R01 AR/AG 41398. This research was additionally supported by the following grants: AG033193, AG081220, NS17950, P30AG013846, 1R01-AG028321.

Atherosclerosis Risk in Communities Study: The Atherosclerosis Risk in Communities Study is carried out as a collaborative study supported by National Heart, Lung, and Blood Institute contracts N01-HC-55015, N01-HC-55016, N01-HC-55018, N01-HC-55019, N01-HC-55020, N01-HC-55021, and N01-HC-55022. The authors thank the staff and participants of the ARIC study for their important contributions.

Age, Gene/Environment Susceptibility -Reykjavik Study: The Age, Gene/Environment Susceptibility-Reykjavik Study is funded by NIH contract N01-AG-12100, the NIA Intramural Research Program, Hjartavernd (the Icelandic Heart Association), and the Althingi (the Icelandic Parliament). Genotyping was conducted at the NIA IRP Laboratory of Neurogenetics.

Invecchiare nel Chianti: The InCHIANTI study baseline (1998–2000) was supported as a "targeted project" (ICS110.1/RF97.71) by the Italian Ministry of Health and in

part by the U.S. National Institute on Aging (Contracts: 263 MD 9164 and 263 MD 821336).

Baltimore Longitudinal Study of Aging: The BLSA was supported in part by the Intramural Research Program of the NIH, National Institute on Aging. A portion of that support was through an R&D contract with MedStar Research Institute.

Health, Aging and Body Composition: This research is supported in part by the Intramural Research Program of the NIH, National Institute on Aging. This research was supported by NIA contracts N01AG62101, N01AG62103, N01AG62106 and NIA grant 1R03AG032498-01. The genome-wide association study was funded by NIA grant 1R01AG032098-01A1 to Wake Forest University Health Sciences and genotyping services were provided by the Center for Inherited Disease Research (CIDR). CIDR is fully funded through a federal contract from the National Institutes of Health to The Johns Hopkins University, contract number HHSN268200782096C.

Study of Health in Pomerania: SHIP is part of the Community Medicine Research net of the University of Greifswald, Germany, which is funded by the Federal Ministry of Education and Research (grants no. 01ZZ9603, 01ZZ0103, and 01ZZ0403), the Ministry of Cultural Affairs as well as the Social Ministry of the Federal State of Mecklenburg-West Pomerania. Genome-wide data have been supported by the Federal Ministry of Education and Research (grant no. 03ZIK012) and a joint grant from Siemens Healthcare, Erlangen, Germany and the Federal State of Mecklenburg, West Pomerania. The University of Greifswald is a member of the "Center of Knowledge Interchange" program of the Siemens AG.

Appendix. Supplementary data

"Pay-for-performance" as a Quality Improvement Tool: Perceptions and Policy Recommendations of Physicians and Program Leaders

J. Frank Wharam, MB, BCh, BAO, MPH; Matthew B. Frank, MDiv; Ann-Marie Rosland, MD, MS; Michael K. Paasche-Orlow, MD, MPH; Neil J. Farber, MD; Christine Sinsky, MD; Lisa Rucker, MD; Kimberly J. Rask, MD, PhD; Michael J. Barry, MD; M. Kathleen Figaro, MD, MS

Background: *Although pay-for-performance (P4P) compensation is widespread, questions have arisen about its efficacy in improving health care quality and consequences for vulnerable patients.* ***Objective:*** *To assess perceptions of general internists and P4P program leaders regarding how to implement fair and effective P4P.* ***Methods:*** *Qualitative investigation using in-depth interviews with P4P program leaders and focus groups with general internists.* ***Results:*** *Internists emphasized a gradual and cautious approach to P4P implementation. They strongly recommended improving P4P measure validity and had detailed suggestions regarding how. Program leaders saw a need to implement perhaps imperfect programs but with continual improvement. Both groups advocated protecting vulnerable populations and made overlapping recommendations: improving measure validity; adjusting for patient characteristics; measuring improvements in quality (vs cutpoints); and providing incentives to physicians of vulnerable populations. Internists tended to favor explicit protections, while program leaders felt that P4P might inherently protect vulnerable patients by improving overall quality.* ***Discussion:*** *Internists favored gradual P4P implementation, while P4P leaders saw an immediate need for implementation with iterative improvement. Both groups recommended specific measures to protect vulnerable populations such as*

improving measure validity, assessing improvements in quality, and providing special incentives to physicians of vulnerable populations.

Key words: *ethics, health policy, pay for performance, quality improvement, vulnerable patients*

Lowering health care costs and improving quality are the top priorities in the United States.[1] To motivate change, payers increasingly seek to pay physicians based on "quality index" measures that account for patient outcomes or evidence-based management.[2-3] This trend is likely to accelerate; the recent national health insurance reform legislation substantially expands Medicare "pay-for-performance" (P4P).[4]

Translating the idea of P4P into an effective[5-8] and ethical[9-10] quality improvement system will prove challenging for various reasons. For example, judging physician "quality" can be difficult in clinical scenarios that have no evidence basis or in those necessitating a balance of physician judgment and patient preferences. P4P might induce physicians to refuse care for patients whom they deem less likely to help them achieve high performance benchmarks.

Previous qualitative studies have largely focused on the current impact of P4P rather than on recommended policy changes and have examined viewpoints of key stakeholders in isolation. This study assesses and compares policy perceptions of administrators and physicians regarding how to improve the fairness and effectiveness of P4P programs. Primary care physicians face the greatest intensity of measurement under P4P[11] and are well positioned to understand how financial incentives interact with complex patient care systems. P4P program leaders have detailed knowledge of P4P designs and intended outcomes.

METHODS

Study data

Between September 2006 and October 2007, we conducted an investigation of policy and ethical issues in P4P compensation by using qualitative techniques. We evaluated 2 key stakeholder groups: leaders of major P4P programs and academic general internists.

We recruited P4P program leaders by using a "snowball" sampling technique,[12] beginning with a knowledgeable index informant and then

iteratively soliciting recommendations for others to interview. P4P program leaders were from the Centers for Medicare and Medicaid Services, Bridges to Excellence, the Agency for Healthcare Research and Quality, the LeapFrog Group, United Healthcare, the Veterans' Administration, the Center for Health Care Strategies, Integrated Healthcare Association, and the Health Information and Management Systems Society. We conducted one-on-one semistructured telephonic interviews with these informants and transcribed interviews by hand.

General internists came from 6 regions of the United States (Midwest, Mid-Atlantic, Southern, New England, Northwest, and California) and, except for the California focus group, all were attendees of regional Society of General Internal Medicine meetings. Members of the Society of General Internal Medicine are mostly practicing general internists who also conduct academic research or teach. We recruited general internists through notifications in a monthly Society of General Internal Medicine e-mail news bulletin and in the program accompanying meetings. We conducted focus groups with these participants, audiorecorded discussions, and transcribed them verbatim.

Participation in both the focus groups and P4P program leader interviews was confidential and voluntary, and we notified all participants before the discussion that aggregated material would be used for research purposes. The institutional review board of Harvard Pilgrim Health Care approved the study.

We constructed open-ended questions to generate discussion of important policy and ethical aspects of P4P on the basis of a pilot discussion with general internists at a national Society of General Internal Medicine meeting. Before focus group sessions, facilitators presented a standardized overview presentation of P4P to orient all attendees to essential P4P components. We then conducted discussions based on a topic guide. We included questions about the theoretical foundation of P4P, its benefits and ethical drawbacks, and recommendations to create fair and effective P4P systems and focused on the impact for vulnerable populations. We assessed similar themes with key informants, again using a topic guide. Focus group facilitators and the one-on-one interviewer (M.K.F.) pursued relevant and important themes based on participants' comments as well as a set of predeveloped subthemes ("probes") that the study team had identified as important during the pilot focus group.

Our primary question to internists about policy recommendations was, "How could P4P be implemented in a way that would improve the care you provide your patients without unintended adverse effects?" Probes specifically asked about recommendations for vulnerable populations, the value of articulating the goals of patients and physicians in P4P systems, and any other ideas that could improve the fairness of P4P to patients, providers, and payers. The questions for P4P program leaders were (1) "How could pay-for-performance be implemented in a way that would improve patient care while minimizing unintended ethical consequences?" (2) "How do you think specific provisions could be made to improve the outcomes of vulnerable patients using pay-for-performance?" and (3) "How do you think pay-for-performance could be made a fairer and more ethical system for all patients/ providers/ payers?" Respondents also made policy recommendations when discussing other topic questions such as when asked about the benefits and drawbacks of P4P.

One-on-one interviews lasted approximately 30 to 45 minutes and focus groups were generally 60 to 90 minutes. Study team members (J.F.W., M.B., N.F., C.S., and M.K.F.) and volunteer Society of General Internal Medicine members facilitated all discussions. The study team conducted a coding validation exercise on an initial transcript. A team of 6 investigators (J.F.W., M.P.-O., A.-M.R., M.B., N.F., and M.K.F.) then applied thematic analysis to code and categorize transcripts by using standard qualitative techniques. We also identified similar and contrasting themes between focus group participants and the one-on-one interviewees. The principal investigator (J.F.W) validated or coded all transcripts. A team of 3 investigators (J.F.W., A.-M.R., and M.B.F.) summarized the coded transcripts and validated these summaries by using MaxQDA software, VERBI GmbH Marburg, Germany. We

employed grounded theory approach to develop a comprehensive interpretation of a data set that included a large frequency of individuals and data points for each group.[13,14]

RESULTS

P4P program informants were high-level leaders of 9 major insurance and coalition P4P programs. At 1 organization, 2 leaders represented the P4P program for our interview. Seven of these leaders were men and 3 were women. Seventy-six individuals participated in 6 focus groups (Table 1). Most focus group members were practicing physicians, and approximately 57% served vulnerable patient populations. Twenty-nine percent had participated in a clinical practice P4P program, and 25% reported nonclinical experience with P4P, for example, contributing to the design of a P4P program at a veteran's administration hospital.

Coding of policy recommendations revealed 5 major themes (Table 2): (1) Research, evaluation, or careful implementation of P4P is needed; (2) Vulnerable populations in P4P systems or their physicians should be protected; (3) Health care systems and infrastructure changes are needed to make P4P fair and an accurate gauge of quality; (4) The validity of P4P quality measures should be improved; and (5) Physician involvement is crucial for optimal P4P development.

Research, evaluation, or careful implementation of P4P is needed

Internist group

All general internist groups emphasized either that research on P4P is urgently needed or that key questions about P4P must be answered before its widespread implementation. In particular, internists cited a need to determine whether P4P is truly efficacious in improving quality and to understand or minimize unintended consequences. Multiple participants stated or implied that P4P should not be widely implemented until proven safe and effective, for example:

> [I]f you're going to implement all these performance systems, I think there should be some type of evaluation on what are they actually measuring, what are some of the impacts. (California focus group participant)

Table 2

COMMON POLICY RECOMMENDATIONS OF INTERNISTS AND P4P PROGRAM LEADERS

	Common or Notable Subthemes	
Common Policy Recommendations	**General Internists**	**P4P Program Leaders**
Research, evaluation, or careful implementation of P4P is needed	How is health care quality defined?	P4P organizations should self-monitor or use published literature to determine the impact of P4P
	What are the causes of poor health care quality?	Ongoing research is needed about effective and ineffective methods of implementing P4P
	Is P4P truly effective in improving quality?	Implement P4P carefully in an evolutionary manner, learning from successes and failures
	What is the impact of patient registries/ dashboards on quality?	
	What is the impact of P4P on vulnerable populations?	
	Implement P4P very carefully or only after proven effective	
Vulnerable populations in P4P systems or their physicians should be protected	Prioritize protecting vulnerable populations and their physicians	Adjust for patient characteristics
	Use valid quality measures	Measure disparities or develop measures relevant to vulnerable populations
	Adjust for patient characteristics	Measure improvements or provide incentives to physicians caring for vulnerable populations
	Provide incentives to physicians caring for vulnerable populations	Minimize the size of bonus payments to physicians
Health care systems and infrastructure changes needed to make P4P fair and an accurate gauge of quality	Improving systems and infrastructure might be adequate for quality improvement	Information technology for monitoring quality, such as electronic medical records, is needed
	P4P should incentivize improved systems and infrastructure	
The validity of quality measures should be improved[a]	Measure at the group/system level rather than the individual level	Expand measurement to cover more realms of care and specialties
	Adjust for different case mix between physicians or groups	Use evidence-based process measures
	Measure improvements in quality rather than absolute achievement	
Physician involvement is crucial for optimal P4P development	General internists or their specialist society should help to health care quality and develop valid quality measures	Physicians or their specialty societies should help to determine appropriate P4P measures

[a]The P4P program leaders also often made recommendations about measures when asked how to protect vulnerable populations under P4P.

> [N]o performance measure should be put in place unless it's been pilot tested, has been evaluated for methodological [rigor]... (Midwest focus group participant)

Physicians expressed a need to know whether the infrastructure to measure quality exists or the minimum set of tools needed to improve quality under P4P systems are in place. Several groups stated or implied that research determining the impact on vulnerable populations was important. Physicians also suggested research on nonfinancial incentives such as patient registries/dashboards (systems that monitor and display patients who fail to reach quality standards). Other suggestions included accurately defining health care quality, determining the causes of poor health care quality, improving the science of quality measurement, using pilot studies of P4P programs before widespread rollout, and conducting longer-term studies, given that a learning curve might exist after P4P implementation.

> [W]e need to start with: do we have the infrastructures to actually measure? Do the doctors who are being measured believe the information? And begin to see how our practice of medicine might change just simply by participating in measurement... (Northwest focus group participant)

> I think we have to look at why is it that the care doesn't seem to be as good as it should be. And if you don't address that problem, giving someone an extra $5,000 or penalizing them $5,000 isn't going to change a thing. (Mid-Atlantic focus group participant)

P4P program leaders

Almost all P4P program leaders mentioned that their organization was evaluating the impact of their P4P program or that they sought out published research for guidance on implementation. They were optimistic that P4P could improve outcomes for patients and that any negative consequence of their implementation could be evaluated and amended going forward. However, suggested evaluations often did not mention ethically relevant outcomes such as expelling vulnerable patients from physician panels. P4P program leaders focused less on potential negative impacts of P4P on quality, emphasizing a potential positive or neutral effect of implementation. Several mentioned a need for ongoing evaluation, continual assessment of P4P effectiveness, or an evolutionary "learning" approach to implementation:

> Being appropriately iterative [is needed]; whatever unintended consequences occur, watching what happens. Consistent iteration can overcome it. (P4P program leader 3)

> [W]e are currently contracting with Mathematica to conduct a study on vulnerable patients in the clinical setting... We can minimize the down side by making the changes evolutionary; implementations piece by piece. (P4P program leader 6)

Vulnerable populations in P4P systems or their physicians should be protected

Internist group

There was strong agreement in all focus groups that vulnerable populations must be specifically protected under P4P. For example, participants mentioned that the creation of valid quality measures adjusted for demographic patient characteristics could help to protect disadvantaged populations from expulsion. Two groups mentioned that physicians could be provided incentives or higher bonuses to care for disadvantaged patients. Others felt that being rewarded for improved quality could help to protect vulnerable populations:

> So both measuring overall performance and measuring change over time, improvement over time, I feel like balances that a little bit so that... providers who care for traditionally disadvantaged populations are not going to be at a disadvantage with these performance measures. (California focus group participant)

> I think there's a potential, and I've kind of seen it happen, for people to discharge patients from their practice who are

> noncompliant or who are known for really not meeting goals, like the uninsured, or they have certain mental health issues—with people saying, "You know, I don't think you're a right fit for me. Maybe you should find another provider." And so I worry about those patients. I think what was commented before is to have more money flowing into those patients [which] would be an incentive for people to take [care] of them. (Northwest focus group participant)

P4P program leaders

When asked specifically about vulnerable populations, several P4P program leaders endorsed perceptions of "vulnerable patients" that were unformed before the interviews. Most had to operationalize what a "vulnerable patient" might be, and their perceptions of members of that group varied. All P4P program leaders endorsed the need to protect these patients and their physicians from undue bias. However, they did not perceive the need to focus on vulnerable patients, largely believing that a well-constructed quality evaluation would benefit all patients. They most frequently recommended risk adjustment to improve fairness:

> One solution is risk-adjustment; it's a way to combat racial disparities. By looking at case mixes you can adjust for higher proportion of minorities, etc. (P4P program leader 1)

> P4P is being very careful of measuring severity; case-mix adjusting of programs. Generally, initiators are not trying to create an incentive for cherry picking. (P4P program leader 3)

Five leaders implied that simply measuring disparities was the essential starting point to reducing them:

> [Y]ou will measure all patients. If there are disparities you will see it. We realize there are communities where the improvement is going to take special effort. (P4P program leader 4)

> By vulnerable patients I presume you mean the chronically mentally ill, those at the ends of life or early life, people who are not competent for whatever reasons. The main question is: are measures of interest to them being included in P4P. (P4P program leader 8)

A related idea voiced by several leaders was to either measure improvement or create financial or other incentives to improve the care of vulnerable populations.

> The dilemmas include payments and bonuses and balancing them. Seventy-five percent of docs are already doing well. If we don't reward performance and improvement, we may exacerbate the disparities you are seeing in patients in poorer neighborhoods that are without infrastructure. (P4P program leader 9)

In contrast, 1 leader did not believe that disparities existed in the population that his or her organization served or that it was the responsibility per se of payers to protect vulnerable patients.

> Well, I don't think these differences exist anyway so we are not measuring for them. Overall, I would say don't reward on subtypes of patients but on total population. If compliance rate is 10% and if the balance of patients is all Medicaid, it is up to the physician to bring up this issue to the payer. (P4P program leader 2)

Program leaders also suggested that lower bonus amounts (eg, less than 10% of total pay) might reduce the likelihood that physicians would expel vulnerable patients from their patient panels. They also perceived that process rather than outcomes measures could improve fairness and that continuing evaluation or an iterative process could help to develop methods for improving outcomes of vulnerable patients under P4P.

Health care systems and infrastructure changes needed to make P4P fair and an accurate gauge of quality

Internist group

All focus groups emphasized the importance of health systems, care teams, or infrastructure in

improving health care quality. Physicians either mentioned that P4P should encourage improved systems or that systems, rather than individual physicians, should be measured and rewarded. Some felt that infrastructure improvement was adequate to improve quality in the absence of financial incentives. Several groups mentioned specific infrastructure that could improve quality with or without P4P, such as electronic medical records, patient dashboards/registries, or added ancillary staff.

> [I]f you can have this greater alignment of the incentives and the structure that would facilitate those, that would kill all birds with one stone... And kind of going back to the system structural level actually might be the most effective way of improving care, at the same time minimizing all potential downsides. (California focus group member)

> And the analogy is that if you have 10 doctors in a group and you get $50,000 extra, well then maybe you can hire computer consultant to finally come and get the electronic record. Or you can hire a part-time person who is going to get on the phone and say "Hi, Mrs. Jones, you haven't had a Pap smear in 2 years, why don't we schedule that for you?" Using the money to do what it is intended to do. (Mid-Atlantic focus group member)

P4P program leaders

The P4P program leaders presumed a more robust health care infrastructure and system compared with internists. Leaders mostly focused on the need for improved information technology such as electronic medical records for tracking quality information, aggregating it, and then making necessary iterative changes to the P4P program.

> Health care is information; the better data goes towards better management... The lack of information sharing among different providers is likely killing patients. This is a terrible tragedy, the lack of IT. Information is not good if it can't come with you. (P4P program leader 5)

> We are moving towards outcome-based payments. We aren't there yet; we need accurate data and universal electronic medical records. (P4P program leader 7)

The validity of P4P quality measures should be improved

Internist group

General internists focused heavily on how measurement could be made more valid, and 3 common themes emerged. Almost all groups mentioned the tension between individual physician and practice-level compensation and the potential effect on quality measurements. Participants expressed concerns about individual incentives and penalties when performance is measured too narrowly or superficially; they perceived that assessment at a systems level could improve the validity of quality measures:

> [There are] a lot of deficits which could potentially be helped by having performance measures based on system-level characteristics and care processes. (California focus group participant)

> And that is where I think this whole systems thing comes into play; where, whether they give me money or not, I cannot make any changes. I just can't. I am working within this ridiculous system and it is not until they give the system an incentive that anything is going to actually change. (Mid-Atlantic focus group participant)

Typically, at least 1 participant in each focus group expressed the opinion that group level measurement was inferior because it was less effective in motivating individual physician change.

> [S]ometimes [physicians] can use the system problems as a cop out and not take personal responsibility for what we can do to change the system or for advocating for changing the system. So maybe there is something to being punished because your system is bad, because it means everybody sinks or swims together. (California focus group participant)

A second recommendation to improve measurement validity was the use of risk adjustment to

account for different case mix between physicians or groups.

> That between issues of sample size and issues of case-mix adjustment, these are things that can make the complete difference between having meaningful numbers and meaningless numbers. And if you incentivize meaningless results, then you are going to create more chaos in the system. (Mid-Atlantic focus group participant)

> I take care of an under-served population and it is a huge problem. We haven't gone to pay-for-performance—obvious issues of adverse selection. We need to adjust for case mix index in order for pay-for-performance to really work in these populations... If we don't adjust for these populations, we are going to be blocking people out of practices if this becomes a huge incentive in the wrong way. (Mid-Atlantic focus group participant)

Physicians were generally concerned that rewarding only certain high achievement levels would divert funds to groups already performing at high levels, give little incentive for improvement to groups already performing at high or low levels, and put physicians caring for vulnerable populations at a disadvantage.

> And really the perfect system is to say you've got a population of patients and you can't do exceptions and your job is to improve the status of that population rather than necessarily fitting a specific point. (New England focus group participant)

> And it seems like something that the VA is already doing, is something that I'd push strongly for—something that only can work is you have robust data systems—is to track improvements over time along with one-time measures because there you have two types of measures that have different biases. (California focus group participant)

P4P program leaders

Almost all P4P program leaders stated that quality incentives should be objective, measurable, and amenable to tracking; they believed that these same incentives would equally protect vulnerable populations. Given their belief in the validity of P4P goals, 4 P4P program leaders recommended expanding incentives to cover more aspects of care and specialties:

> Expanded measures are needed; more objective measures of a lot more things; I know physicians like yourself don't agree, but a lot more things happen than are being measured; and the more measurement, the more things that are not even being measured improve. (P4P program leader 4)

> So the question is equity. A lot of the population that need these services don't have quality measures. The quality of the performance measures is not great and not equitable across segments of the populations that we serve. (P4P program leader 8)

Four leaders perceived that either evidence-based measures or process measures led to better patient outcomes; they understood the possible ethical tension between patients' preferences that could impact outcomes and physician behavior, which drives process measures to a greater extent:

> Outcomes-based performance is a huge ethical dilemma; for instance, number-one fertility clinics don't take hard-to-treat patients since they don't want to worsen their statistics... You could not ignore process measures; they could be weighted. (P4P program leader 5)

> I think we need to focus on process that is evidence-based. Process needs to be very specific; the P4P must be structured from the provider's point of view. The measurements should be specific to, for example, cardiac surgeons, psychiatrists, internists. (P4P program leader 8)

One notable recommendation was that providers take the initiative to prove to payers that they already provide high-quality care, as the respondent had seen in 1 instance:

> There is a new trend, of providers trumping payers, trying to improve outcomes themselves. For instance, there is a small heart practice where the payer sent them claims info [asking them to change their practice]. They had clinical data, proving that it would be wrong for them to change; the payer learned from their superior clinical data and it improved its P4P program. (P4P program leader 5)

Physician involvement is crucial for optimal P4P development

Internist group

Focus group participants perceived that general internists' involvement was necessary in the development of P4P, especially in defining health care quality, physician excellence, and valid measures. Participants often lamented that P4P was a reality that must be accepted, though it was far from ideal:

> [W]e also have an ethical obligation to try to make constructive policy suggestions that will make an inevitable program better and more responsive to the needs of generalists rather than just pointing out the downside. (Mid-Atlantic focus group participant)

> So I think this is an opportunity to actually help define what quality is and... of determining a methodology. And actually taking a stand on what it is that we feel we should be evaluated on, not [leaving P4P development up to] some outside organization, private, for-profit company. (California focus group participant)

Other participants endorsed a greater need for patient involvement either in the development of incentives or in the measurement of physician quality. These same participants suggested that that corporate influence should be minimized in the development of P4P measures.

P4P program leaders

When asked about what physicians could do to help to improve P4P, almost all program leaders endorsed the involvement of physicians or their specialty societies in improving P4P. The most common theme was the perception of greater validity for quality measures that had physician input. Two leaders perceived a great need for physician involvement in P4P research and implementation and offered a warning about physician unwillingness to become active.

> Since P4P is inevitable, we appreciate physicians' concerns, but it's already here. So [you] can help do it or it will be done to you. (P4P program leader 5)

DISCUSSION

We assessed the policy recommendations of primary care physicians and P4P program leaders regarding performance incentives. Compared with P4P program leaders, general internists perceived a greater need to employ a highly cautious approach to implementation. Internists also focused more on improving the validity of P4P measures and had more detailed suggestions regarding how this could be accomplished. Both internists and P4P program leaders understood the importance of protecting vulnerable patients, although they had divergent suggestions on how to implement such safeguards. Their suggestions included improving the validity of measures, adjusting for patient characteristics, measuring improvements in quality, and providing "improvement" incentives to physicians caring for vulnerable populations. While physicians expressed a concern for fairness in implementation, program leaders might have perceived that all patients, including vulnerable populations, would benefit from P4P. Finally, both groups endorsed an urgent need for the direct involvement of physicians in creating or improving P4P systems.

Several previous studies have analyzed the attitudes of key stakeholders regarding P4P, though none have compared policy recommendations of physicians and P4P program leaders. Weinick and colleagues[15] interviewed hospital executives about

the use of P4P to reduce racial/ethnic disparities in care. Similar to our findings, stakeholders recommended using financial incentives to reward safety net hospitals for reducing disparities. Another study found that P4P program leaders recommended that performance improvement as well as absolute achievement should be rewarded and that measures of disparities should be developed.[16] Physicians in the United Kingdom raised concerns regarding the validity of performance targets for chronic kidney disease.[17] Neuman and colleagues[18] found that surgeons were skeptical about the use of quality measures at the individual level, and most felt they should not be used in P4P programs. A survey demonstrated that nonprimary care physicians support grants to improve infrastructure, such as electronic medical records.[19]

Our study has several limitations. Our findings might not be representative of primary care physicians or P4P program leaders. However, internists came from all areas of the country and had a range of demographic and patient panel characteristics. We included leaders of some of the most prominent US P4P programs whose views are important in shaping the direction of performance incentive programs. In addition, our aim was not to determine representative views but to gather recommendations that might have a beneficial impact on physician compensation policy. Our results might be biased by selection effects; for example, more ardent opponents of P4P might have attended focus groups or more highly committed P4P program leaders might have agreed to interviews. Nevertheless, our technique of interviewing informants from opposite ends of the opinion spectrum provides a counterbalance. We found that the major policy recommendations of the 2 stakeholder groups contained substantive overlap, so that more extensive sampling might not be highly revealing. Because we assessed a topic controversial to physicians and focused on vulnerable populations, social desirability bias could have influenced our findings. Physicians and P4P program leaders might have felt that it was more acceptable in the interview environment to advocate for vulnerable populations. Physicians might have been more likely to criticize P4P when surrounded by other physicians, given that studies have found that many physicians have negative attitudes about payers. The P4P program leaders could have altered their views to be less enthusiastic about P4P because they were being interviewed by a primary care physician.

Our research has important policy implications. Despite physicians' substantial reservations about P4P, we found overlap with program leaders regarding recommendations to improve health care quality or at least minimize unintended consequences of P4P. Both groups supported cautious P4P implementation, although physicians recommended a much more methodical and meticulous approach than has been realized to date. Steps recommended by general internists include ensuring appropriate infrastructure for quality improvement, defining quality in a manner acceptable to physicians, carefully developing measures that assess genuine quality, and then testing for efficacy before widespread use. Both stakeholder groups acknowledged the need for a strong emphasis on creating measures and incentives that protect vulnerable populations. Physicians and P4P program leaders also acknowledged that direct physician involvement in designing compensation systems is important, and performance incentives seem unlikely to succeed without physician acceptance. Nevertheless, physician focus groups generally had a visceral "us against them" tone, and the involvement of a minority of physicians in high-level design decisions might be unlikely to change this negative dynamic. Thus, although such high-level physician involvement is fully necessary, it is unlikely to be sufficient. Allowing physicians to choose individualized improvement options such as reporting rather than incentives or tailoring measurement to their specific panels might be much more beneficial in reducing the sense of powerlessness that physicians sometimes experience under P4P. For their part, P4P program leaders had a tone of frustration with the pace of research and physicians whom they viewed as resistant to change or only interested in protecting reimbursement. They also recognized the limitation of "top-down" tools in improving quality. Physicians and their societies should therefore

demonstrate commitment to quality improvement—not simply fair reimbursement—through their advocacy efforts.

Policy makers should strongly consider the perceptions of the stakeholder groups that we interviewed, with particular attention to harmonizing the attitudes of physicians and P4P program leaders. Further study should bring physicians and P4P program leaders together to establish detailed plans for performance incentives that will optimally improve health care quality.

ORIGINAL RESEARCH

Determinants of Mammography in Women With Intellectual Disabilities

Joanne E. Wilkinson, MD, MSc, Emily Lauer, MPH, Karen M. Freund, MD, MPH, and Amy K. Rosen, PhD

Background: **Women with intellectual disabilities have the same rate of breast cancer as other women but are less likely to undergo screening mammography. Characteristics associated with mammography for women with intellectual disabilities in the United States are unknown.**

Methods: **This study was based on a secondary data analysis of the Massachusetts Department of Developmental Services database, comparing women who had a mammogram within 2 years with women who had not on variables related to the ecological model. Bivariate analyses, logistic regression, and assessment of interactions were performed.**

Results: **The study sample's (n = 2907) mean age was 54.7 years; 58% lived in 24-hour residential settings, 52% received nursing health coordination, and more than 25% had clinical examination needs (eg, sedation). Residential setting, health coordination, and recent influenza vaccination were all associated with mammography. Having a guardian, higher level of activities of daily living needs, and examination needs (requiring sedation or limited wait time for examinations) were associated with lower rates. Interactions between health coordination and examination needs confirmed the potential of the nurse to ameliorate barriers to mammography.**

Conclusion: **Several system-level variables were significantly associated with mammography and, in some cases, seemed to ameliorate intrapersonal/behavioral barriers to mammography. Community agencies caring for intellectually disabled women have potential to impact mammography rates by using health coordination. (J Am Board Fam Med 2011;24:693–703.)**

Keywords: **Cancer Screening, Learning Disabilities**

Adults with intellectual disabilities are increasingly likely to live in the community and be cared for by community primary care practices.[1] Intellectually disabled adults are known to have health disparities,[2] especially regarding preventive care and health screening.[3,4] National efforts are underway[5,6] to identify the sources of these disparities and to improve screening/preventive services for adults with intellectual disabilities. One important disparity for women with intellectual disabilities is in breast cancer screening.[7] Although the rate of breast cancer among women with intellectual disabilities[8,9] mirrors that of the general population, they seem to have higher mortality rates from

breast cancer (30.9 per 100,000 women with intellectual disabilities vs 24.2 per 100,000 women in the general population of women in Massachusetts since 2002).[10,11] Though these estimates are based on small sample sizes, it is a provocative preliminary finding given that intellectually disabled women are also thought to have lower screening rates compared with the general population. The Center for Disease Control and Prevention's Behavioral Risk factor Surveillance System data report 75% of US women older than 40 having a mammogram, and in Massachusetts that number is 85%.[12] Rates of mammography among women with intellectual disabilities are significantly lower internationally[13,14] (12% to 30%) and are unknown in the US. Researchers are investigating individual-, caregiver-, and system-level issues linked to this disparity.[15] Because most people with intellectual disabilities live in the community and are patients of neighborhood primary care practices, it is important to consider their unique vulnerabilities and barriers to screening when striving to deliver care in the patient-centered medical home.

An intellectual disability is defined as an intelligence quotient at least 2 standard deviations below the mean accompanied by significant difficulties in at least one area of adaptive functioning: conceptual (language); social (understanding of and ability to follow rules, gullibility, interpersonal relationships); and practical (activities of daily living, taking medications, handling money).[16] These difficulties must exist before age 18. Because the diagnosis of intellectual disabilities encompasses multiple areas of function, the ecological model[17] is most appropriate when considering theories of health behavior applicable to breast cancer screening (Table 1), particularly the intra- and interpersonal and "institutional" (referred to herein as "system-level") domains. This model is particularly well-suited to women with intellectual disabilities because they may make health care decisions with some amount of support—from family, staff, or a guardian/agency charged with their care. Therefore, the multiple environmental domains of this model provide a broader perspective for intellectually disabled women. Interactions between domains also may be relevant for understanding associations with screening mammography. The aim of this study was to determine characteristics associated with mammography, both variables and interactions between variables, related to domains of the ecological model. A secondary aim was to make preliminary recommendations based on these findings for interventions to improve screening and prevention of breast cancer in women with intellectual disabilities in the setting of the patient-centered medical home.

Methods

Database

The Massachusetts Department of Developmental Services (DDS) began collecting and tracking health information on clients with intellectual dis-

Table 1. Proposed Domains of the Ecologic Model Affecting Breast Cancer Screening for Women with Intellectual Disabilities

Concept	Concept Description	Example of Effect on Breast Cancer Screening	Related Variables of Interest
Intrapersonal	Individual factors or ideas influencing behavior	Extremely anxious about mammogram so does not have one	Psychiatric diagnoses Requires sedation or other accommodations for clinical visits Down syndrome Functional status
Interpersonal	Social supports, family, peer groups influencing behavior	Supportive guardian encourages patient to go and accompanies her	Communication status Whether guardian is assigned Whether subject is receiving other screening/preventive services
Institutional	Rules and policies that may promote or prevent behavior	Residential program provides care coordination by a nurse and encourages cancer screenings	Residential setting Day/work program Care coordination by registered nurse
Community	Social groups/organizations in the community that can be formal or informal	Advocacy organizations for adults with disabilities publishes information encouraging mammography	None in this database
Public policy	Local policies and laws to support healthy behaviors	Publications raise awareness of physicians about preventive services for adults with disabilities	None in this database

abilities within the last 10 years. We obtained data for this study from these administrative "health record" entries of this electronic client management database, which was tailored for the needs of adults with intellectual disabilities and included information about functional status and special needs related to medical care. It is important to note that these records are not the same as electronic medical records used by health care providers. The database is used to track health outcomes for clients of DDS, not to provide medical care. It was determined through prior analyses[18] that the database does not have uniform representation of all clients. The database is most generalizable to women with intellectual disabilities living in residential settings with 24-hour support (>90% of clients in this group were represented in the database). The mammography data in the DDS database were validated using matched records from a large electronic medical record database in Boston,[18] and a high correlation in data element reliability was found between the databases.

The state requires annual updates of this record by the service provider and recommends updating whenever the individual's information changes significantly. Information about each subject's service enrollment, such as state-funded residential programs, was taken directly from enrollment tables, which are updated frequently, when enrollment determines payment to the service provider.

Subjects were included in the analyses if they were women 42 to 74 years old on January 1, 2007 (to ensure that all were eligible for mammography for the entire time period), eligible for state services for at least 1 month between October 2007 and April 2009, and had complete records. To eliminate exposure time bias, subjects were included only if they had documentation for the entire time period. Reporting bias was minimized by collecting data on mammograms completed between January 1, 2007, and December 31, 2008, but entered into the database between December 31, 2008, and April 30, 2009. Women with a history of breast cancer were excluded. Also excluded were approximately 200 women who were 75 years of age or older because data currently reflect no mortality benefit from screening women in this age group.[19]

Variables

Dependent

Appropriate breast cancer screening was defined as having received a mammogram between January 1, 2007, and December 31, 2008 (yes or no). During this time period, most guidelines recommended mammography every 1 to 2 years starting at age 40.[19] (We did perform a sensitivity analysis looking only at subjects aged 50 years and older because of the revised recommendations in 2009). "Unknown" mammograms were classified as not completed because the scheduling/logistic issues involved (transporting the person to a separate test) make it likely that either the subject or her caregiver would remember the mammogram if it had occurred.

Independent

Information about independent variables was captured for each subject at baseline to 6 months before the period in which mammography screening was examined. Several variables were examined related to the intrapersonal domain of the ecological model. Age was analyzed categorically (40–49 years, 50–59 years, 60–69 years, and ≥70 years). A summary score of 0 to 4 was created for functional status based on assistance needs with four activities of daily living (ADLs): toileting, eating, personal hygiene, and ambulation. A separate variable was included for psychiatric diagnoses (one or more vs none, two or more vs none, three or more vs none; sensitivity analyses compared this classification with a classification by type of psychiatric diagnosis) and another for Down syndrome (because of possible lower rates of breast cancer).[20,21] Variables related to clinical visits were examined: need for special positioning, sedation, or limited waiting times or a tendency to be "uncooperative" during medical visits. Variables from the interpersonal domain included communication (able vs unable using any modality) and the assignment of a guardian.

Variables were examined related to the receipt of other preventive services (Papanicolaou smear, influenza vaccination after 2007, and colonoscopy/sigmoidoscopy and bone densitometry for women older than 50 years) as belonging to the "institutional," or system-level, domain. Receipt of the influenza vaccine was selected as a recent care marker in multivariate analyses because it is an easily administered annual preventive measure generally recommended for this population,[22] and its receipt likely signifies that the support staff and agencies involved with the client are pursuing preventive services for them.

Other variables related to the system-level domain were also examined, including several catego-

ries of residential setting: state-funded 24-hour support (usually provided in group home settings) and less than 24-hour support, which is a combination of shared living, subjects living independently or with family, or subjects receiving limited support at home. Health coordination by a registered nurse (RN) was also examined because many subjects receive health coordination by nurses familiar with the health needs of this population. Nurses review clients' records and make recommendations regarding medications, side effects, chronic conditions, and testing/evaluation. The RN is involved in planning for physical examinations and/or accompanies the patient to the visit, so they may influence the receipt of preventive services. Health insurance was not examined; more than 95% of the participants had Medicaid benefits.

Statistical Analyses

Bivariate analyses identified variables associated with mammography. To assess for multicollinearity, a Pearson correlation matrix was constructed between all variables considered for inclusion in multivariate regression, and tolerance/variance inflation factors were reviewed. A multivariate logistic regression model was built through stepwise reduction; the dependent variable was "recent mammography." The multivariate model was first built with univariate-level variables, using a significance criterion of 0.05 for the Wald χ^2 as the elimination threshold. This step was repeated using Akaike Information Criterion statistics[23] and yielded similar results. Interactions were tested across domains of the ecological model based on consultation of the literature and health care experts in intellectual disabilities. Two-way interactions (age as a categorical variable, care coordination by a nurse, and 24-hour supported residential setting) were tested for all variables. Finally, a three-way interaction between guardian status, nursing coordination, and being "uncooperative" or requiring limited waiting times during examinations was tested to examine how the presence of a guardian affects the interaction between these two predictors. SAS software (version 9.2, SAS Inc, Cary, NC) was used for all analyses. Several sensitivity analyses were also performed (see Table 2). For example, we examined the subset of women who did not receive the influenza vaccine; within this subset, we compared those who did and did not receive breast cancer screening.

Multivariate Model's Predictive Ability

To assess the model's sensitivity and specificity, the estimated model was applied to the dataset, and the

Table 2. Methods and Results of Sensitivity Analyses Performed

Variable of Interest	Methods Used to Perform Sensitivity Analyses	Results
ADLs	Each individual ADL score was compared to the summary score. Two different grouped levels of summary score were tested.	No significant improve in the model
Psychiatric diagnosis	Types of psychiatric diagnoses (eg, anxiety, psychosis) were compared to the number of diagnoses recorded (one, two, three or more vs none).	No significant improve in the model
Age	Categorical groupings in Table 1 were compared with continuous variable versus categorical groupings with the last category of ≥60 years.	No significant improve in the model
24-Hour residential setting	Entire analysis was re-run using only clients from 24-hour residential settings because their representation in the database was relatively complete.	All variables remained in the model except guardian and summary ADL score. Effect sizes were similar but slightly higher for all remaining variables in the model. C statistic = 0.723
Recent influenza vaccination	Characteristics of influenza vaccine were negative; women who did not receive a mammogram were analyzed and compared with women who did receive a mammogram and had influenza.	Less able to communicate (64% vs 79%) More likely to have a guardian (58% vs 46%) Less likely to have one or psychiatric diagnosis (54% vs 62%) More likely to have high ADL need (31% vs 19%) More likely to require sedation (22% vs 15%)

ADL, activity of daily living.

model's predicted mammography outcome for each subject was compared with their observed outcome.

Results

There were 2907 subjects included in the analysis. One hundred ninety-five records (6%) were excluded because of missing values. The average age of the cohort was 54.7 years (median, 53.6 years; SD, 8.2 years; range, 42.0–74.9 years).

The overall mammography rate was 53%. Table 3 shows the bivariate analyses of mammography receipt. All the variables except age show statistically significant ($P < .05$) associations with mammography. In the intrapersonal domain, all the categories reflecting higher need for support (needing special positioning, uncooperative during examinations, higher ADL need) were associated with lower odds of mammography (odds ratios [ORs] ranging from 0.69 to 0.84) except psychiatric diagnoses: subjects with a higher number of diagnoses had higher odds of receiving a mammogram. Among system-level variables, residential setting (unadjusted OR, 1.32; 95% CI, 1.14–1.53) and health coordination by an RN (OR, 1.40; 95% CI, 1.21–1.63) are most strongly associated with mammography. All the preventive care variables were strongly associated with mammography, with recent influenza vaccination being the strongest (OR, 4.38, 95% CI 3.74 to 5.12).

Table 4 shows results from the multivariate regression model. After adjusting for other variables in the model, the system-level factor most positively associated with mammography was receipt of influenza vaccination in the same time period (adjusted OR, 4.67; 95% CI, 3.84–5.66). Intrapersonal factors such as high ADL need (adjusted OR, 0.68; 95% CI, 0.55–0.84); requiring special positioning for examination (adjusted OR, 0.65; 95% CI, 0.44–0.95); and having Down Syndrome (adjusted OR, 0.63; 95% CI, 0.48–0.82) were associated with *lack* of mammography. Family history of breast cancer was positively associated with mammography (adjusted OR, 1.91; 95% CI, 1.35–2.70). Finally, two interpersonal variables showed significant associations: ability to communicate (adjusted OR, 1.44; 95% CI, 1.14–1.81) was positively associated with mammography, and assignment of a guardian (adjusted OR, 0.77; 95% CI, 0.61–0.95) was negatively associated with mammography. The C statistic for the final model was 0.728.

Two interactions illustrate the mitigating effect of system-level factors on barriers to mammography presented by intrapersonal factors. A significant interaction was noted between the subjects labeled "uncooperative" or limited waiting period and having health coordination by RN. Subjects who were labeled "uncooperative" or required a limited wait time for examinations were less likely to obtain mammography (adjusted OR, 0.79; 95% CI, 0.71–0.89) than those who were cooperative and did not require a limited wait. However, when "uncooperative" subjects also had health coordination, they did not exhibit significantly different odds of mammography (adjusted OR, 0.92; 95% CI, 0.81–1.05) compared with subjects who were considered cooperative. In addition, a significant interaction was noted between a subject's ADL score and the presence of 24-hour residential supports. Subjects with high daily assistance needs (support needs in three or more domains across four total) were less likely to receive mammograms if they received less than 24-hour residential supports (adjusted OR, 0.77; 95% CI, 0.68–0.87). In comparison, subjects with similar support needs who received 24-hour residential supports had odds of receiving a mammogram (adjusted OR, 0.88; 95% CI, 0.78–1.01) statistically similar to subjects in this setting with lower support needs. Results of the sensitivity analyses are summarized in Table 2.

We also looked at the effect of removing subjects in the 40- to 50-year-old age range from the analyses because the US Preventive Services Task Force guidelines were reissued during the course of this research project and emphasized routine screening mammography in women 50 and older. We found that when the analyses were repeated with subjects only 50 years of age and older, the overall findings were quite similar (eg, the effects of residential setting, health coordination by RN, requiring sedation for visits, ADL status) but that a few variables were not included in the final model: communication status, having a guardian, and needing special positioning for examinations (the last variable did not reach statistical significance because of the smaller sample size when women 40 to 50 years old were excluded).

Predictive Ability

The model demonstrated a sensitivity of 75.3% and a specificity of 59.3%. The positive predictive value

was 70.2% and the negative predictive value was 65.4%.

Discussion

There are few data about screening mammography in the United States among women with intellectual disabilities. These data indicate an overall rate of screening within the past 2 years of 53%. This is higher than other non-US populations of women with intellectual disabilities but much lower than the rate of 84.9% found in the general population in Massachusetts.[12] These data show several individual and system-level variables positively associated with mammography in intellectually disabled women: living in 24-hour supported residential settings, having health coordination by a nurse, having a family history of breast cancer, receiving the influenza vaccine (a likely marker for preventive care), and communication ability. Though not all these variables are modifiable, several have been associated with preventive care in other studies. Some variables were negatively associated with mammography: having a guardian, Down syndrome, or higher levels of ADL needs. In the sensitivity analysis examining only subjects living in 24-hour residential settings, ADL needs and having a guardian disappeared from the final model.

The association of health coordination by a nurse with mammography (and particularly the interaction between health coordination and special needs relative to the examination) underscores the potential of an RN already involved with the subject to positively advocate for them to receive preventive services. Though few rigorous studies have analyzed the impact of health coordination on health care for people with intellectual disabilities,[24] the relationship has been noted indirectly. For example, researchers note that nurses play an important role in facilitating access to breast cancer screening for women with intellectual disabilities[25–27] in terms of both helping their clients overcome barriers to screening and the effect of their own knowledge about screening on their clients' screening patterns. During health coordination activities, it is likely that the RN prompts the health care provider to consider a mammogram and then problem-solves the logistic aspects of getting the test for the client (ie, calling the mammography center to reserve extra time or ensuring that women who require sedation are adequately medicated and the staff are prepared for the experience). For older women in the general population, researchers have noted that practice-level factors[28] and relationship-centered aspects of the medical home[29] affect preventive screening, again pointing to the potential for a health care professional to advocate for preventive services.

Though the population of women living outside settings with 24-hour support was not as well represented in this study, the above findings likely have significance for this group as well. We suspect that women with intellectual disabilities who live more independently in the community or with family are less able to consistently access preventive care. They may also receive advice and assistance from family members who are not as well-informed about prevention as the RN providing health care coordination would be. For example, having a guardian was associated with a lower likelihood of

mammography, except in the population of women living in settings with 24-hour support.

For women living outside these residential settings, the issue of how to approximate health care coordination and improve access is not easily resolved. One potential solution would be to shift that responsibility to the health care provider, requesting that all primary care practices review the prevention and screening practices for vulnerable patients (potentially extending beyond women with intellectual disabilities), facilitating their involvement in screening and prevention. The patient-centered medical home movement may be an excellent initiative to develop practice-based procedures and/or pilot interventions around this issue. However, these potential solutions do not address the issue of women with intellectual disabilities in the community who do not receive consistent primary care.

An interesting and somewhat counterintuitive finding was the association of higher numbers of psychiatric diagnoses with mammography. Although this finding is preliminary (based on secondary data analyses), one potential explanation is that women with psychiatric diagnoses in their record probably receive care and medication for these

diagnoses, potentially affecting their ability to tolerate the anxiety of mammography.

In addition, subjects with high ADL support needs (requiring assistance in at least three domains out of four) who did not receive 24-hour residential supports were less likely to receive mammography. It is unknown whether this is reflective of a more medically complex, fragile group who may not represent good candidates for screening and preventive care versus a group overwhelmed by the logistic difficulties of getting some of these patients to the examination. However, because this barrier seems to be ameliorated by the involvement of 24-hour residential supports, it is likely at least some of these subjects represent people who are good candidates for screening but experience logistic challenges. Researchers have noted health disparities among people with disabilities who have relatively more functional impairments[30] and an increased likelihood of preventive care for people with intellectual disabilities who live in 24-hour residential settings.[31] Future research should determine whether the high ADL support needs generally represent a person who may not be considered eligible for screening versus someone who is eligible but is not receiving mammograms.

It was also intriguing to note low rates of mammography among women with Down syndrome. There are scant US data on this topic, but European researchers have suggested that the breast cancer risk is so low for women with Down syndrome that they are actually at higher risk of radiation injury from mammography[20] and should be counseled not to have routine mammography. It is unclear whether the low rates among women with Down syndrome in our population reflect application of this recommendation by US physicians. It has not been shown, however, that there is a significant risk of radiation injury from mammography for women without Down syndrome.[32]

This study had several limitations. Because mammography is not a rare event, the ORs presented here are higher than a comparable rate ratio would be; ORs were used to be consistent with other, similar studies. The database, though highly representative of women with intellectual disabilities who live in supported settings, has lower representation of women who live with families or in the community without state supports. Therefore, generalizing to the entire population of intellectually disabled women is not possible. Second, this database was designed for other purposes and lacked certain variables that are usually considered, ie, race, ethnicity, and level of education. Third, some records may have underreporting of certain disabilities or medical conditions. However, these misclassifications are not suspected to be biased with regard to mammography screening. Fourth, the database lacked information about obesity, which is known to be common in people with intellectual disabilities[33–35] and to be associated with lower rates of screening for some cancers.[36] Fifth, because the study was conducted in Massachusetts, a state that has universal health insurance, we were unable to assess the impact of lack of insurance coverage on the likelihood of mammography. Despite these limitations, this database is large, only includes intellectually disabled women, and yielded results that confirmed the model's validity.

Several Federal initiatives[5,6] have encouraged providers and health systems to improve primary and preventive care for adults with intellectual disabilities. These data indicate potential areas for intervention; at the system level, health coordination could be broadened or made available to more clients, and guardians could be targeted for more education about screening and health recommendations for people with intellectual disabilities. At the provider level, women with intellectual disabilities who do not live in supported settings could be particularly vulnerable and should be educated and supported in pursuing breast cancer screening.[37] Primary care physicians also should be aware of the extent to which residential setting can determine prevention and screening opportunities for people with intellectual disabilities. These findings should be helpful in increasing awareness of characteristics associated with lower rates of screening and prevention for members of a vulnerable, underserved population present in many community primary care practices.

Osteoporosis
Bone mineral density

ABSTRACT

Background: The presence of a vertebral fracture identifies a patient who has clinical osteoporosis. However, approximately 2/3 to 3/4 of VFs are asymptomatic. Vertebral Fracture Assessment is a method derived from dual-energy X-ray absorptiometry (DXA) to assess vertebral fractures. The objectives of this study were 1) to determine the association between the degree of height loss in older men and women and the risk of a vertebral fracture, and 2) to determine if the knowledge of vertebral fractures will alter the classification of osteoporosis based on bone mineral density alone.
Methods: 231 men and women over the age of 65 underwent DXA scan of their spine and hip (including bone mineral density and Vertebral Fracture Assessment), measurement of their height, and a questionnaire.
Results: We found that height loss was significantly associated with a vertebral fracture ($p = 0.0160$). The magnitude of the association translates to a 19% increase in odds for 1/2 in. and 177% for 3 in. Although 45% had osteoporosis by either bone mineral density or fracture criteria, 30% would have been misclassified if bone mineral density criteria were used alone.
Conclusions: Height loss is an indicator for the presence of vertebral fractures. Bone mineral density criteria alone may misclassify older patients who have osteoporosis.

Introduction

In addition to low bone mass, a previous fracture significantly increases the risk of developing a future fracture. A vertebral fracture increases the risk of a new fracture up to 4-fold [1–4]. In addition to needing therapy, patients with vertebral fractures may suffer from increased back pain, increased days of bed rest, decreased time at work, depression, and a higher rate of hospitalization and mortality [5,6]. Thus, the presence of a vertebral fracture has a significant clinical impact.

Approximately two-thirds to three-quarters of vertebral fractures are asymptomatic [7]. Diagnosis of an asymptomatic vertebral fracture is not common in clinical practice, because it requires a lateral X-ray, often performed at a different facility (hospital or radiology unit) and increases the patient's expense and radiation exposure. By contrast, Vertebral Fracture Assessment (VFA) is a dual-energy X-ray absorptiometry (DXA)-based technology that can be performed at the same point of service during bone density assessment and uses a much lower radiation dose than a standard lateral X-ray. Greenspan et al. has previously found that vertebral fractures assessed by VFA were present in 18.3% of asymptomatic, postmenopausal women who were screened for osteoporosis by DXA [8]. When using BMD to classify osteoporosis using the World Health Organization classification, sensitivity ranged from 40 to 74%. When VFA was included to classify patients with osteoporosis, as much as 60% of osteoporotic individuals would have been missed by BMD alone. Therefore, VFA may be a useful adjunct in the clinical identification of osteoporosis and may prevent mismanagement of osteoporotic patients.

The International Society of Clinical Densitometry has suggested indications for VFA including women who have had a height loss from the peak height of ≥ 1.6 in., men who have had a height loss of ≥ 2.4 in., or patients with a prospective height loss of >0.8 in. in women or >1.2 in. in men [9]. However additional data are needed to support these recommendations. The objective of this study was to determine the association between the degree of height loss in both older men and women and the risk of a vertebral fracture, and to determine if VFA will increase the prevalence of osteoporosis diagnosis in men and women who are being screened for osteoporosis by BMD alone.

Material and methods

Study subjects

Two hundred and thirty-one men and women over the age of 65 were recruited from the Claude D. Pepper Registry, Benedum Geriatric Clinic at the University of Pittsburgh Medical Center, Braddock

Hospital, and through advertising. The Claude D. Pepper Registry is a database of more than 2000 Pittsburgh participants over the age of 60 who are willing to participate in research. Reasons for exclusion were morphological abnormalities, metabolic bone disease other than osteoporosis, and consumption of medication that affect bone mineral metabolism positively or negatively other than calcium and vitamin D. The study was approved by the institutional review board at the University of Pittsburgh Medical Center, PA, and all participants signed written informed consent.

Outcome variables

Bone mineral densitometry of the PA spine and hip were assessed by dual-energy X-ray absorptiometry (DXA) using a Hologic Discovery A bone densitometer located in the Benedum Geriatric Clinic and the Clinical Translational Research Center at the University of Pittsburgh Medical Center. Measurements were obtained and analyzed using standard manufacturer protocols. World Health Organization (WHO) criteria were used to classify bone health and osteoporosis [10]. A T-score of −1.0 SD and above is considered normal, a T-score between −1.0 SD and −2.5 SD is considered low bone mass (osteopenia), and a T-score of −2.5 SD and below is considered osteoporotic [11]. Bone mineral density measurements were taken for the spine, total hip, and the femoral neck as suggested by recommendations of the International Society for Clinical Densitometry [12]. The site with the lowest T-score was included in the classification of osteoporosis.

VFA was performed through lateral spine imaging of T4–L4 on Hologic Discovery A using manufacturer standard protocols. The vertebral bodies from the scan were visually inspected by a technician and fractures were classified using the method of Genent (semiquantitative visual assessment) with the assessment of computer-calculated reduction in vertebral height [13]. Two technicians trained in VFA examined VFA results independently and were blinded to the BMD results. If differences were noted, the VFA was reanalyzed by both technicians together.

Clinical characteristics

A questionnaire was administered that contained medical, surgical, gynecological, fracture, and family history in addition to medications, alcohol, tobacco, and exercise. Participants were also asked to report their tallest height ever from memory. Nontraumatic fragility fractures were defined as fractures that occurred from a fall from standing height or lower. Known traumatic nonvertebral fractures were excluded.

Current height was measured 3 times with a Harpenden stadiometer and an average was calculated. Participants' height loss was calculated as tallest height ever minus current height.

Statistical analysis

The presence of vertebral fractures was operationally defined as a dichotomous variable indicating one or more and three or more fractures. We compared characteristics of subjects with and without VF using independent samples *t*- and chi-square tests, as appropriate, for continuous and categorical measures. We used logistic regression models with the presence of vertebral fractures as the dependent variable, height loss as the primary predictor variable of interest, and exercise, smoking, and calcium/vitamin D intakes covariates. The logistic regression coefficient for height loss was scaled appropriately and then exponentiated to obtain odds ratios for magnitudes of risk increases corresponding to a height loss between 1/2 in. and 3 in. We used a two-way contingency table cross tabulation of subjects meeting criteria of osteoporosis using BMD alone by VF alone. All analyses were performed both with and without stratification by gender. We used SAS® version 9.2 (SAS Institute, Inc., Cary, North Carolina) for all statistical analyses.

Table 1
Clinical characteristics.

	Total	Men	Women
# Participants (%)	231	124 (54%)	107 (46%)
Age (years)	75 ± 6	75 ± 6	75 ± 7
Average height loss (inches)	1.86 ± 1.22	1.93 ± 1.26	1.77 ± 1.17
Average % height loss	2.75% ± 1.79%	2.75% ± 1.79%	2.75% ± 1.80%
Average BMI (kg/m^2)	29 ± 5	28 ± 5	29 ± 6
# with 1+ vertebral fracture (%)	91 (39%)	45 (36%)	46 (43%)
# with 3+ vertebral fracture (%)	20 (9%)	9 (7%)	11 (10%)
History of fragility fractures	49 (21%)	15 (12%)	34 (32%)

Results: mean ± SD or N (%)			

Results

We recruited 231 participants, including 124 men and 107 women. The average age was 75 ± 6 years and their average height loss from peak was 1.86 ± 1.22 in. (mean ± SD). Ninety-one participants had one or more vertebral fractures and 20 had three or more vertebral fractures. Twenty-one percent had a previous history of an adult fragility fracture (including 3 with a hip fracture), 77% participated in exercise, and 58% took calcium and vitamin D supplements. There were no significant differences between men and women in terms of their vertebral fracture rate (Table 1). However, those who exercised were less likely to have one or more vertebral fractures than those who did not (35% with exercise vs 54% with no exercise, $p = 0.014$). Furthermore, those with 3 or more vertebral fractures were less likely to take calcium and vitamin D (5%) than those who did not (13%, $p = 0.029$) (Table 2).

Participants with one or more vertebral fractures had greater height loss (mean 2.18 ± 1.30 in.) than subjects without vertebral fractures (1.64 ± 1.11 in.). Forty-three percent of women had one or more VF and 36% of men had one or more vertebral fractures. In women, those with no VF had an average height loss of 1.54 in., whereas those with one or more vertebral fractures had lost an average of 2.07 in. ($p = 0.0184$). In men, those with no vertebral fracture had an average height loss of 1.72 in., whereas those with one or more vertebral fractures had lost an average of 2.30 in.

Table 2
Rates of having VFs based on exercise, smoking, and calcium/vitamin D intake.

		Rate of having 1 or more VFs	P value	Rate of having 3 or more VFs	P value
All	Exercise	35%	0.014	7%	>0.05
	No exercise	54%		13%	
	Smoking	38%	>0.05	7%	>0.05
	No smoking	41%		10%	
	Ca/VitD	34%	>0.05	5%	0.029
	No Ca/VitD	46%		13%	
Women	Exercise	30%	0.0008	6%	>0.05
	No exercise	63%		17%	
	Smoking	38%	>0.05	6%	>0.05
	No smoking	45%		12%	
	Ca/VitD	40%	>0.05	9%	>0.05
	No Ca/VitD	49%		14%	
Men	Exercise	38%	>0.05	8%	>0.05
	No exercise	23%		0%	
	smoking	38%	>0.05	7%	>0.05
	No smoking	33%		7%	
	Ca/VitD	28%	0.0508	2%	0.0116
	No Ca/VitD	45%		13%	

Table 3
Height loss and odds of having a vertebral fracture.*

Unit of height loss (inches)	Odds ratio	95% confidence limits
0.5	1.19	1.06–1.34
1	1.40	1.12–1.79
1.5	1.66	0.71–2.15
2	1.97	0.64–2.77
2.5	2.34	0.57–3.58
3.0	2.77	0.51–4.61

P<0.05.
* Adjusted for smoking, exercise, and vitamin D intake.

(p = 0.0146). For each additional 0.5 in. of height loss, the odds ratios for having one or more vertebral fractures increased significantly when adjusted for smoking, exercise, calcium, and vitamin D intake (OR = 1.19, 1.40, 1.66, 1.97, 2.34, 2.77, p<0.05) (Table 3).

According to WHO classification, 60 out of 107 women (56%) from our study had low bone mass and 23 out of 107 (22%) had osteoporosis, compared to 64 out of 124 (52%) and 10 out of 124 (8%) for men, respectively (Table 4). The prevalence of osteoporosis varied when defined by BMD site only vs. BMD site and vertebral fractures combined. For example, 29 out of 231 participants (12.6%) were categorized as osteoporotic when using femoral neck BMD as the sole criteria, but 101 out of 231 participants (43.7%) were categorized as osteoporotic when using femoral neck BMD and vertebral fracture as criteria (Table 4).

In all our participants, 91 out of 231 (39%) had one or more vertebral fractures, and 20 out of 231 (9%) had three or more vertebral fractures (Table 1). Twenty-eight out of 74 subjects (38%) who were categorized as normal by BMD and 42 out of 124 subjects (34%) who were categorized as having low bone mass had one or more vertebral fractures (Fig. 1). In patients with one or more vertebral fractures, the distribution of a normal or low bone mass classification was similar in men and women. One hundred and three out of 231 patients (45%) had osteoporosis by BMD classification or the presence of a vertebral fracture (Table 5). If BMD classification was used alone, 70 out of 231 total participants (30%) would have been misclassified (Table 5). If we exclude 3 patients who had a hip fracture and who should have been classified with clinical osteoporosis by NOF guidelines, in the remaining 228 participants, 69/228 or 30% would have been misclassified.

Table 4
Prevalence of osteoporosis by WHO BMD classification.

		Spine only	Total hip only	Femoral neck only	Any site
All	BMD with vertebral fracture (true classification)				
	Osteoporosis	42.4%	41.1%	43.7%	45.0%
	Low bone mass	16.5%	17.7%	33.8%	35.1%
	Normal	41.1%	41.1%	22.5%	19.9%
	BMD alone				
	Osteoporosis	6.5%	3.5%	12.6%	14.7%
	Low bone mass	26.4%	34.2%	52.4%	53.2%
	Normal	67.1%	62.3%	35.1%	32.0%
Men	BMD with vertebral fracture (true classification)				
	Osteoporosis	38.7%	36.3%	37.1%	38.7%
	Low bone mass	12.9%	13.7%	35.5%	35.5%
	Normal	48.4%	50.0%	27.4%	25.8%
	BMD alone				
	Osteoporosis	4.0%	1.6%	5.6%	8.1%
	Low bone mass	20.2%	25.8%	52.4%	51.6%
	Normal	75.8%	72.6%	41.9%	40.3%

Discussion

We found that height loss was significantly associated with a vertebral fracture. The magnitude of the association translates to a 19% increase in odds of having a vertebral fracture for 0.5 in. of height loss and 177% for 3 in. Those with a vertebral fracture, on average, had a 0.54 in. greater height loss than those without a vertebral fracture. Although 45% had osteoporosis by either BMD or fracture criteria, 30% would have been misclassified if BMD criteria was used alone.

Similar to studies by Siminoski et al., our study showed that the relationship between height loss and prevalent vertebral fractures was significant [14]. Our study also agreed with the cross-sectional studies by Tobias et al., and Gunnes et al. which determined that prevalent vertebral fracture rates increased with greater height loss [15,16]. In the study by Tobias et al. where they included 509 women, the difference in height loss between the two groups was 0.31 in. Our participants with one or more vertebral fractures lost an average height of 0.54 in. more than our participants with no vertebral fractures.

Prospective studies have also demonstrated a correlation between height loss and incident fractures. Moayyeri et al. [17] recruited 25,623 men and women 40–79 years old, measured their height and followed their fracture status over several years. The study showed that height loss is an independent risk factor for osteoporotic fractures. Kaptoge et al. [18] showed that the risk of incident vertebral fracture significantly increased with increased height loss. Some studies have suggested a height loss cutoff to indicate increased risk of vertebral fractures. Due to the small number of participants, we were unable to find a statistically significant threshold value. However, our data did suggest a sharp increase in the number of vertebral fractures once participants have lost more than 3 in. This finding is similar to that of Vallarta-Ast et al. [19] who found an increase in fracture prevalence in men when the historical height loss is >2.5 in. and also to that of Siminoski, who suggested the cutoff to be 6 cm (2.4 in.).

Table 5
Misclassification of osteoporosis.

	No VF	Yes VF	Total
BMD: normal or low bone mass	128	70	198
BMD: osteoporosis	12	21	33
Total	140	91	231

Siminoski conceded that height loss was not a good screening test for vertebral fracture because it had low sensitivity values and high specificity. Combined with other risk factors, such as age and previous history of fractures, the sensitivity of predicting vertebral fractures may be higher [15,20].

Our study differed from others that looked at vertebral fractures and height loss. Unlike the study by Siminoski et al., our study excluded participants with metabolic bone diseases and those taking bone-altering medications. Unlike the study by Tobias et al. and Gunnes et al., our study included both men and women over the age of 65 with no upper age limit. Compared to previous studies, the prevalent vertebral fracture rate in our study was higher: 36% of men and 43% of women had one or more vertebral fractures. When using BMD WHO classification and the presence of vertebral fractures as criteria for diagnosing osteoporosis, as many as 51% of women and 39% of men had osteoporosis. In Tibias et al., UK women 65–76 years old were recruited; 7.3% of the 509 subjects had one or more vertebral fractures. They identified vertebral fractures with standard X-ray, while we used VFA. However, previous studies have documented that vertebral fractures are often missed on X-rays [21]. Our VFA criteria used a quantitative assessment and identified a vertebral fracture with a loss of height of 20% or more. This quantitative assessment differs from the qualitative technique used by many radiologists. The prevalence of osteoporosis in our population was also higher than those reported by Cheng et al. who reviewed Medicare claims data of 911,327 beneficiaries over the age of 65. Cheng's paper estimated 41.8% of Caucasian females between 75–79 years have osteoporosis, and 8.4% Caucasian males between 75–79 years have osteoporosis. In addition to the quantitative technique, our higher rates of osteoporosis may be explained by the fact that many of our patients were recruited from Benedum Geriatric Clinic. Patients who visit the clinic tend to be more frail, more likely to have fractures, and be osteoporotic. Furthermore, we obtained VFA to assess for vertebral fractures while Medicare claim data could miss asymptomatic fractures. Our high male osteoporotic rate may also be due to the fact that only a minority of vertebral fractures in men comes to clinical attention, contributing to lower rates seen through insurance claims.

Our study demonstrated that men and women with vertebral fractures were often misclassified as having normal or low bone mass by BMD alone. In a study by Freitas et al., 5995 men were recruited and out of those with incident vertebral fractures, 41% had normal BMDs and 46% were categorized as having low bone mass [22]. Similarly, the Rotterdam study by Schuit et al. showed that many women and men with nonvertebral fractures were categorized as normal or having low bone mass by BMD alone [23]. They concluded that BMD needs to be used with other predictors of fractures — such as height loss — to increase its sensitivity. We suggest that in addition to clinical risk factors such as height loss, the VFA is a useful adjunct to BMD and may prevent misdiagnosis of osteoporosis in men and women.

Because this is a cross-sectional study, we cannot determine cause and effect. Although we observed that those who exercised were less likely to have vertebral fractures than those who did not exercise, patients with fractures may be less likely or able to exercise after they fracture. We observed that patients with 3 or more fractures were less likely to take calcium and vitamin D. However due to other comorbid conditions in these patients, they may be less likely to comply with calcium and vitamin D. Furthermore we could not determine if these vertebral fractures were caused by a previous high trauma accident. We did however query participants for known traumatic fractures and only included nontraumatic fragility fractures by their history. A prospective study is needed to corroborate these cross-sectional findings.

This study has many strengths. It is one of the few studies that compare BMD, height loss, and vertebral fractures in both men and women from the same population. Our population included men and women in many stages of health. We recruited healthy, active volunteers as well as frail visitors to the Benedum Geriatric Clinic. Our study also has several limitations. The sample size is small. There may also be selection bias because many of our patients came from Benedum Geriatric Clinic and may be more frail than the general population. Our results may not be applicable to people <65 years old and not applicable to minorities since most of our participants were Caucasian. Moreover our study may be subject to recall bias regarding a patient's previous height. Finally, we did not verify vertebral fractures with a standard X-ray. However, the VFA technique has been validated in the past for moderate and severe vertebral fractures [24,25].

In summary, height loss is an indicator for the presence of vertebral fractures; and the Vertebral Fracture Assessment increases the prevalence of osteoporosis diagnosis in men and women who are being screened for osteoporosis by bone mineral density alone. Those misclassified by BMD alone — 30% of all participants — were correctly classified after having a VFA performed. Further studies are needed to assess longitudinal height loss and incident vertebral fractures assessed by VFA in other clinically relevant cohorts.

ABSTRACT

Background The Food and Drug Administration issues black-box warnings (BBWs) regarding medications with serious risks, yet physician adherence to the warnings is low.

Methods We evaluated the impact of delivering BBW-based alerts about drug–drug, drug–disease, and drug–laboratory interactions for prescription medications in outpatients in an electronic health record with clinical decision support. We compared the frequency of non-adherence to all BBWs about drug–drug, drug–disease, and drug–laboratory interactions for 30 drugs/drug classes, and by individual drugs/drug groups with BBWs between the pre- and post-intervention periods. We used multivariate analysis to identify independent risk factors for non-adherence to BBWs.

Results There was a slightly higher frequency of non-adherence to BBWs after the intervention (4.8% vs. 5.1%, $p = 0.045$). In multivariate analyses, after adjustment for patient and provider characteristics and site of care, medications prescribed during the pre-intervention period were less likely to violate BBWs compared to those prescribed during the post-intervention period (OR 0.67, 95% CI, 0.47–0.96). However, black-box warning violations did decrease after the intervention for BBWs about drug–drug interactions (6.1% vs. 1.8%, $p < 0.0001$) and drug–pregnancy interactions (5.1% vs. 3.6%, $p = 0.01$).

Conclusions Ambulatory care computerized order entry with prescribing alerts about BBWs did not improve clinicians' overall adherence to BBWs, though it did improve adherence for specific clinically important subcategories. Copyright © 2010 John Wiley & Sons, Ltd.

INTRODUCTION

Each year, more than 770 000 people are injured or die in hospitals from adverse drug events (ADEs).[1] Reports of in-hospital ADE rates range from 2.4 to 15.0 per 100 admissions[1–5] while in outpatients, the rate of ADEs has been reported to be as high as 27% in a study using direct patient contact to detect ADEs.[6] A 2006 report from the Institute of Medicine on medication errors estimated that at least 1.5 million preventable ADEs occur annually in the United States, with most occurring in the outpatient setting.[7] The high ADE rate found in adult primary care settings is likely due to the high frequency and long duration of exposure to medications in the outpatient population.[6]

Many medication-related injuries are potentially preventable,[2] especially by changing medication-ordering systems.[8] Growing evidence shows that implementing these applications results in benefit; a meta-analysis by Shamliyan *et al.*[9] showed a 66% reduction of prescribing errors on average, and another meta-analysis

by Wolinsky *et al.*[10] evaluated 10 studies, and found that in 5 ADE rates fell, in 4 there were non-significant trends toward benefit, and in one there was no effect. Most studies evaluating ADE prevention have been conducted in hospital settings; relatively little is known about ADE prevention in the ambulatory setting.[11,12] Through the introduction of advanced computerized prescribing, the medication error rate was reduced by 81% in an adult inpatient population in one study[13] and by 40% in a pediatric inpatient population in another.[14] However, in the outpatient setting, one basic computerized prescribing system did not significantly decrease the frequency of prescribing errors.[15] However, more advanced systems with better decision support should be beneficial in outpatients.[16]

Black-box warnings (BBWs), which are reported among other places in the Physicians' Desk Reference (PDR) are developed by the US Food and Drug Administration (FDA) and are intended to help prescribers avoid the most serious ADEs.[17] Prior studies, including our own,[18] have shown that adherence by prescribers to such warnings is low among ambulatory patients.[19] As a prelude to the present study, we analyzed data on patients from 51 ambulatory practices using one electronic health record (EHR) who received a prescription for a medication in 2002. Of these patients, 10.4% were prescribed a drug with BBWs about drug–drug interactions, drug–disease interactions, drug–lab interactions, or drug–pregnancy interactions, and of patients who were prescribed a BBW drug, 7% received a prescription in violation of a BBW.

In order to improve medication safety and make black-box warnings accessible to clinicians, we added BBW-based drug–drug, drug–disease, drug–lab, and drug–pregnancy alerts to our electronic record. The objective of this study was to evaluate prescribing in violation of BBW before and after delivering BBW-based medication safety alerts to clinicians using ambulatory electronic medical records.

METHODS

Study site

We conducted the intervention at 51 outpatient practices in the greater Boston area that use a common EHR. These included 40 hospital-based clinics, 4 community health centers, and 7 community-based practices. Both primary care and specialty practices were included—many of the hospital based clinics are specialty practices. Most of these practices include non-physician prescribers, the vast majority of prescriptions are written by physicians. We collected information in EHR, known as the longitudinal medical record (LMR) including patient demographics, lists of medical problems and prescription drugs (with start and stop dates), and results of laboratory tests. Partners HealthCare System Institutional Review Board approved this study.

Patient population

We included all patients aged 18 years or older who received at least one prescription medication with a BBW from 1 January to 31 December in 2002 and in 2005. We focused our analysis on patients who received a prescription for a drug that contains a BBW pertaining to drug–drug interactions, drug–laboratory interactions, drug–disease interactions, and/or drug–pregnancy interactions. In the present study, we used the same list of drugs with BBWs as in our previous study.[18] The full list of drugs is available in an online Appendix.

Data collection

For all patients, we collected data on age, gender, race, insurance status, language, medical problems on the problem list (with a date entered on or before 31 December 2005), all medication prescriptions (with start date and/or stop date on or before 31 December 2005), laboratory test results (with report date between 1 January 2001 and 31 December 2002, and between 1 January 2004 and 31 December 2005), type of prescriber (primary care physician, nurse practitioner, physician assistant, specialist physician, and others) and site of care (private offices, hospital-based clinics, or community health centers). Staff at ambulatory practice sites routinely record patient race (white, black, and Asian) and ethnicity (Hispanic); we analyzed these variables to determine if they were associated with prescribing patterns. We defined 'insurance of poverty' as Medicaid or Free Care. We also collected data about alerts and reminders in the LMR at the time of the study. Finally, we reviewed information about BBWs and monitoring recommendations, and any changes in such information between 2002 and 2005, to enable updating of the intervention, but no changes were found.

Interventions

During the intervention, a physician and pharmacist expert panel created a knowledge base. The decision support knowledge database only included alerts

DOI: 10.1002/pds

judged clinically relevant to the ambulatory care setting. We added alerts based on all BBWs regarding drug–pregnancy interactions along with most drug–drug interactions, most drug–lab monitoring, and some drug–disease interactions. We placed each alert into one of four clinical severity tiers.[20,21] Level 1 alerts indicate a fatal or life-threatening interaction. Level 2 alerts indicate an undesirable interaction with the potential for serious injury. Level 3 and level 4 alerts indicate the possibility of an undesirable interaction in which a drug should only be used with caution or may require increased monitoring. All alerts judged sufficiently important were implemented in the LMR.

Prescribing alerts

The LMR generated alerts using information from each patient's active medication list, problem list, and laboratory results, and applied logic rules to identify potential contraindications. The alerts appeared as an on-screen warning that identifies the alerted drug and the issues (examples indicated in Figures 1–3). A single medication could generate multiple alerts displayed on a single screen, each requiring a separate clinician action. These alerts appeared to clinicians as soon as they entered a new medication. Clinicians were interrupted with pop-up boxes displaying the alerts for level 1 and level 2 alerts only, and these required an action to acknowledge the alert (Figures 1 and 2). Level 3 alerts were non-interruptive and no action was required (Figure 3). Other warnings besides the BBW were also displayed. There was no specific notation when a BBW alert was displayed as compared to one of these other non-BBW-based warnings. All alerts were presented in hierarchical order based on their alert level with level 1 being the most severe where the user has to take action and cannot continue with the order followed by level 2 alerts where the user may override the alert but must give a reason followed by level 3 and level 4 alerts where monitoring or follow-up is recommended but is only presented as informational.

Follow-up for lab monitoring alerts

Follow-up lab alerts (Level 4) were non-interruptive and presented in the LMR as reminders. If a patient had been on a medication for more than 12 months and had not had the appropriate labs checked during the 12-month time period, the user was presented with a reminder to check labs. For example, a provider could receive the following alert: 'Pt on Metformin >365 consecutive days. Checking Creatinine (serum) is recommended.'

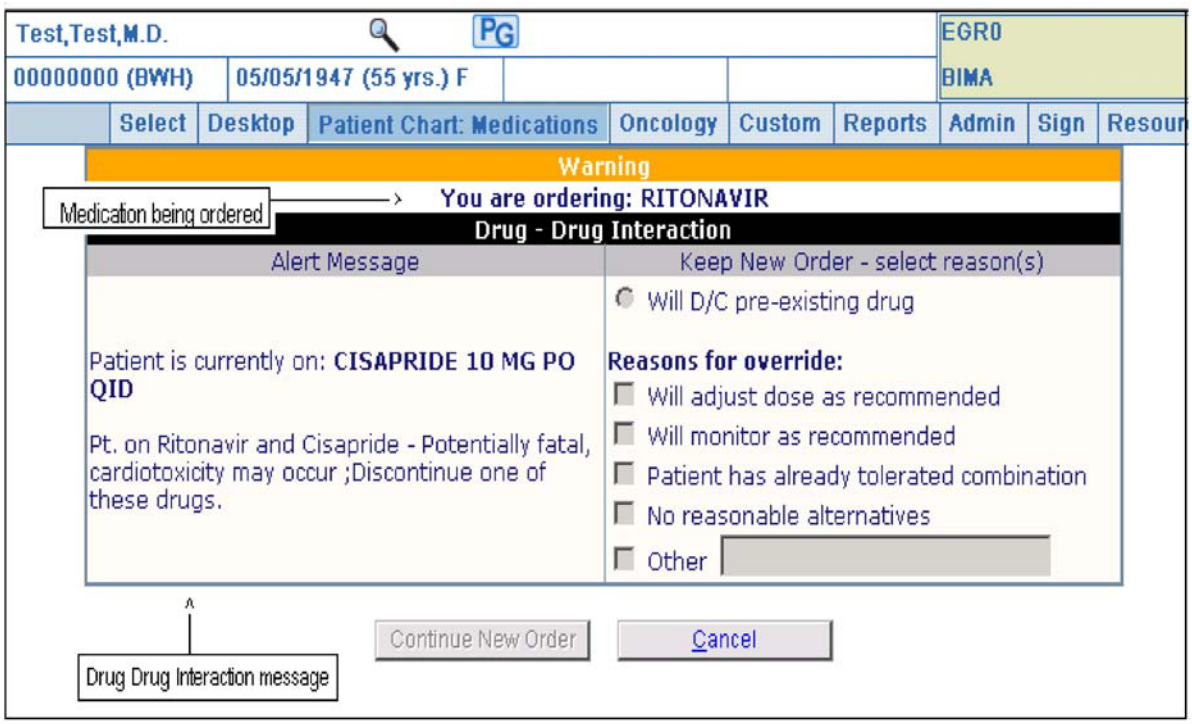

Figure 1. Level 2 alert for drug–drug interaction, the clinician may choose either to keep both orders or stop one of them

DOI: 10.1002/pds

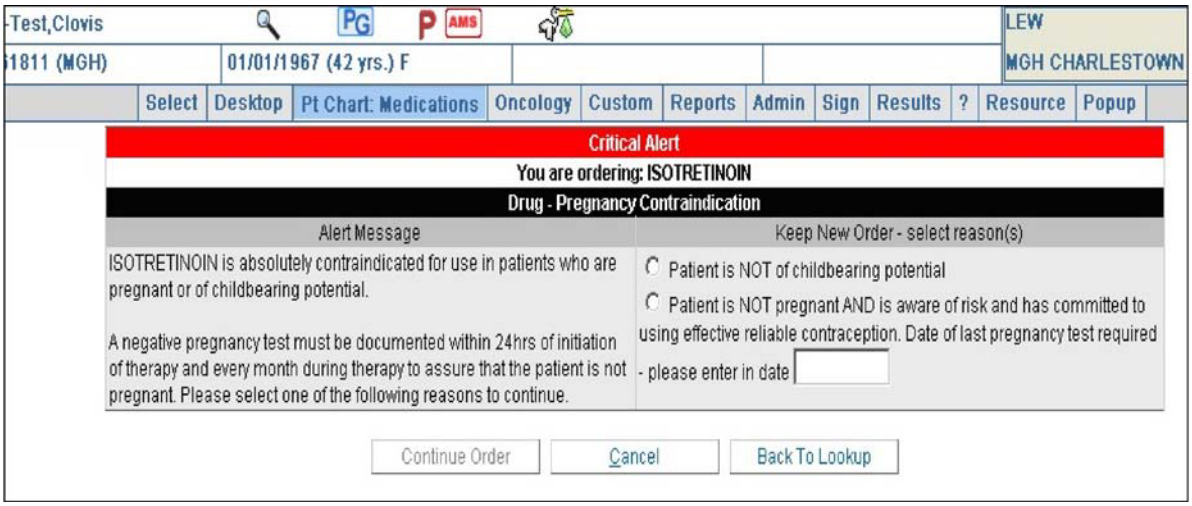

Figure 2. Level 1 alert for drug–pregnancy contraindication, requiring order to be stopped if patient has a positive pregnancy test within the past 9 months or is of childbearing potential

Outcome measures

The primary outcomes were the frequency of non-adherence to BBWs in total; by individual categories of drug–drug, drug–disease, drug–laboratory, and drug–pregnancy warnings; and by each individual drug with a BBW. Secondary outcomes were correlates of non-adherence to BBWs. To measure non-adherence to BBWs, we used the same definitions as those used in our previous study.[18] For example, for a patient starting a drug for which baseline hepatic or renal function was required, we scored the prescribing as adherent if tests for hepatic or renal dysfunction occurred within 3 months before the start of the drug. Similarly, if baseline pregnancy testing was indicated, then clinicians were deemed adherent if a pregnancy test

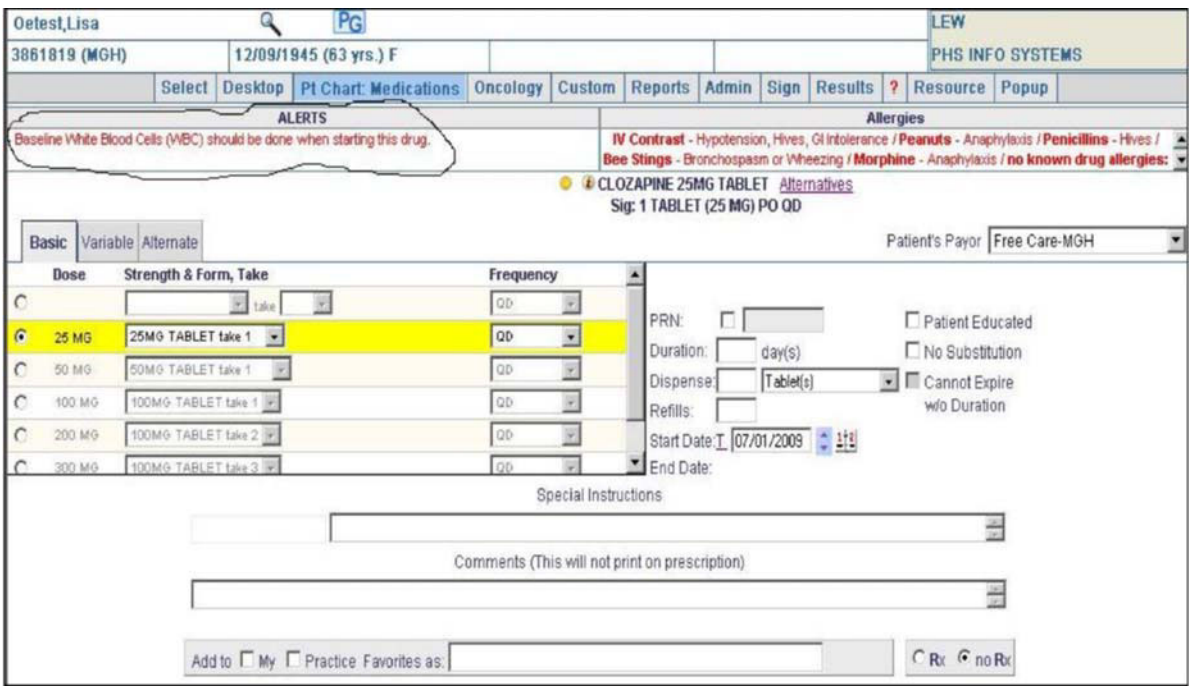

Figure 3. Level 3 alert for drug–laboratory interaction, clinician is reminded that baseline white blood cells (WBC) count should be obtained when starting the drug

DOI: 10.1002/pds

occurred within 1 month before starting the drug. For all other required baseline laboratory tests, we considered the prescribing to be adherent if the tests were performed within 12 months prior to starting the drug. We considered non-adherence to BBWs for drug–drug interactions or drug–disease interactions to be present if either a drug with BBW or the interacting drug was prescribed while the other was administered on the same day, or a medication with a BBW was prescribed to a patient with a disease contraindicating the drug. However, we scored prescribing as adherent if a prescriber entered a discontinuation date for the drug within 3 months of the appearance of a contraindicated drug, disease, or laboratory value. The term 'non-adherence' used throughout the paper has the same meaning as the term 'violation.' Any reason for overriding by a prescriber as the response to an alert was considered to be a violation of a BBW.

Analyses

We conducted before–after comparisons between the pre- (2002) and post-intervention (2005) periods among all medication prescriptions with a BBW and with an alert implemented in the LMR during the intervention period. The unit of analysis was the individual medication prescription. Among 69 individual drugs or drug classes with BBWs, we excluded beta-blocker medications from the analysis because we were unable to perform manual chart reviews that would have been required to fully assess the relevance of BBWs. Further, no alert was implemented for this class of drug during the intervention. Five other drugs were also excluded from the analysis as they were not used in the study clinics during the post-intervention period. Among the remaining 63 individual drugs or drug classes with BBWs, we analyzed the 30 more frequently prescribed medications that had BBW-related alerts implemented in the LMR during the intervention period. We calculated the proportion of medication prescription orders in which patients received a contraindicated drug, had a contraindicated disease, or did not receive adequate laboratory monitoring. We performed these calculations in both the pre- and post-intervention patient populations. We evaluated differences between the pre- and post-intervention periods using the chi-square test or Fisher exact test for discrete variables and the Student's *t*-test for continuous variables. We performed multiple logistic regression analyses of the outcome (violation of a BBW) applying the exchangeable covariance structure of generalized estimating equation (GEE) approach to adjust for within-patient correlations.[22] We examined potential risk factors as the independent variable, including the intervention (pre- vs. post-), and characteristics of the patients and providers. We included all variables with *p*-values less than 0.05 in the bivariate analyses in the baseline multivariable model. We examined interaction terms between covariates in the baseline model and retained them using a threshold *p*-value less than 0.05. We used backwards selection to drop insignificant effects one at a time. The baseline model included the following variables: intervention; patient age, sex, race, and language; provider type, site of care; number of medical problems, and medications. The model also included the following interaction terms: combinations of any two characteristic variables for patients at the beginning of the pre- and post-intervention period, combinations of any two characteristic variables for patients and providers when drugs with BBWs were prescribed, and combinations of intervention and every characteristic variable of patients and providers. Examples of interaction terms include: age group - × gender, provider type × number of medical problems on problem list, intervention × race, and intervention × site of clinic.

All variables in the final model were statistically significant ($p < 0.05$ with the score statistic in the Type 3 GEE analysis). We computed adjusted odds ratios (ORs) and 95% confidence intervals (CIs) based on the multiple logistic regression parameter estimates as measures of effect size. We performed all analyses using SAS System for Windows, version 8.2 (SAS Institute, Cary, NC).

RESULTS

During the pre-intervention period, 1014 providers prescribed 31 118 medication orders with BBWs to 24 477 patients. During the post-intervention period, 2270 providers prescribed 63 010 medication orders with BBWs to 45 744 patients.

The proportion of physicians who were primary care physicians was lower in the post-intervention period (48% vs. 36%, $p < 0.0001$), with more specialists (28% vs. 44%, $p < 0.0001$) post-intervention, because specialists were adopting the EHR during the study and our network focused on getting primary care providers on-line first. Among all 2661 providers, 623 (23%) functioned as providers in both periods. On average, each provider placed 31 medication orders with BBWs in the pre-intervention period and 28 medication orders with BBWs in the post-intervention period. Those 30 drugs/drug classes with BBW-related alerts implemented in the LMR

DOI: 10.1002/pds

accounted for 28 359 (91%) and 56 869 (90%) of all medication orders with BBWs in the pre- and post-intervention period, respectively.

Characteristics of the study patients and providers

A summary and comparison of patient demographic characteristics at the beginning of the pre- and post-intervention periods are shown in Table 1. Patients in the post-intervention period were more likely to be younger, male, white and without insurance of poverty relative to patients in the pre-intervention period. During the post-intervention period, specialists prescribed more orders with BBWs, while primary care physicians prescribed fewer orders with BBWs (Table 2). Providers in hospital-based clinics prescribed more orders with BBWs in the post-intervention period, while providers in other settings prescribed fewer. More medications with BBWs were prescribed to patients with fewer (<4) medical problems on the problem list and with more (>3) medications on their active medication list.

BBW, black-box warning.
*Medicaid or free care.

Non-adherence to BBWs in the pre- and post-intervention periods

Among all medication orders with alerts implemented during the intervention period (Table 3), there were slightly more violations of the BBW after the intervention (4.8% vs. 5.1%, $p = 0.045$). The frequency of orders with violations of BBWs was not significantly different between the pre- and post-intervention periods for drug–disease and drug–laboratory interactions. In contrast, there was a decrease in the frequency of BBW violations in the post-intervention period among orders with drug–drug and drug–pregnancy interactions (drug–drug interaction, 6.1% vs. 1.8%, $p < 0.0001$; drug–pregnancy interaction, 5.1% vs. 3.6%, $p = 0.01$).

The frequency of violation of BBWs for individual medications with alerts in the LMR is shown in Table 4. During the post-intervention period, a significant

All, No. (%)	1357/28 359 (4.8)	2902/56 869 (5.1)	0.045

BBW, black-box warning.

decrease in the frequency of violation of the BBWs was found for clozapine, ticlopidine, ketorolac, metformin, isotretinoin, and ketoconazole while an increase was found for drugs including amiodarone, carbamazepine, and thioridazine. After excluding the level 3 and level 4 alerts, the violation rate decreased in the post-intervention period (0.46% vs. 0.32%, $p = 0.01$).

Multivariate correlates of BBW violation

In multivariate analyses, the final models included the following variables: intervention; patient age, sex, race, and language; provider type and site of care; and number of medical problems and medications (Table 5). Patients who were 75 years and older, had 0–3 medical problems, were not on any medication and who were seen by a primary care provider or a specialist at the hospital-based clinics were significantly more likely to receive a drug in violation of a BBW than were other patients (all $p \leq 0.03$). Patients in the pre-intervention period were less likely to be prescribed a drug in violation of a BBW when compared to those after the intervention period (OR 0.67, 95% CI, 0.47–0.96).

DISCUSSION

About 1 in 20 medication prescriptions written during the post-intervention period for drugs that had a black-box warning were in violation of a BBW. The implementation of BBW-related alerts as advanced decision support for electronic prescribing in the LMR had no impact on improvement of the overall BBW adherence rate, although we did observe modest improvement for specific subcategories which may be of particular clinical importance.

Computerized order entry (CPOE) systems with advanced decision support through alerts and reminders at the time of prescribing have been shown to be effective for reducing medication errors for inpatients, with a relative risk reduction for medication errors of 20–99%.[13,23–31] In comparison, relatively few studies have evaluated the effects of computerized decision support on medication errors in the outpatient setting. In one recent study to evaluate the effect of CPOE with decision support for selected medications prescribed in primary care clinics, Feldstein *et al.* [32] found that medication interaction alerts reduced warfarin-interacting medication prescription rates by 14.9% after the alert was implemented. The list of drugs with BBWs in our study did not include warfarin because the FDA did not begin warfarin-based BBWs until after our post-intervention period.[33] However, general alerts for warfarin–drug interactions and warfarin–pregnancy interactions were implemented in the LMR during the intervention period.

Why was there no improvement in adherence to BBWs in this study? It is possible that physicians may generally consider the warnings unimportant, since violations of BBWs were not found to result in increased levels of detectable harm in this patient population, though low levels of harm could have been missed.[18] Thus, alerting the physicians to the presence of a particular warning may make little difference to their adherence rates. We have previously found that high-level alerts—which in our system are level 1 and level 2 alerts—result in a high proportion of cancellations.[20] However, level 3 and level 4 alerts (indicating a lower level of potential harm) were common among the BBW medications and these appear to have little effect on behavior. We previously found that non-interruptive medication laboratory monitoring alerts did not improve receipt of recommended laboratory test monitoring in ambulatory care.[34] Regarding including all BBW alerts in CPOE, we would on the basis of these data recommend that other hospitals not include them, except for the clinically important subcategories which represent a small proportion of all BBWs.

In this study, we identified independent risk factors for prescribing in violation of BBWs. These included older patient age, and being seen by a primary care provider or a specialist at the hospital-based clinics. Patients not on any medication and having no or fewer

Table 4. Frequencies of individual drug prescription orders non-adherent to the BBW

Drug name	Warning or monitoring recommendation*	Level of Alert related to BBW	Pre-intervention	Post-intervention	*p*-Value
Amiloride	Monitor serum potassium levels [every 6 months]	Level 4 (reminder 12 months) and level 3 (baseline 12 months)	32/197 (16.2)	65/284 (22.9)	0.074
Amiodarone	Monitor liver enzymes on high dose [every 6 months]	Level 4 (reminder 12 months) and level 3 (baseline 6 months)	16/263 (6.1)	120/745 (16.1)	<0.0001
ACE Inhibitors and Angiotensin II Antagonists	Unsafe in pregnancy	Level 2 alert if patient is pregnant	0/1424 (0)	0/3019 (0)	N/A
Bumetanide	Monitor electrolytes, creatinine, and BUN [every 6 months]	Level 3 baseline serum potassium only (12 months)	9/55 (16.4)	15/123 (12.2)	0.452
Carbamazepine	Monitor CBC-platelets at baseline and during therapy [once per year]	Level 3 baseline platelets only (6 months)	134/566 (23.7)	303/1031 (29.4)	0.014
Cisapride	Drug interactions with agents causing QT prolongation	DDI (levels 1–3)	0/6 (0)	0/5 (0)	N/A
Clozapine	(1) Do not initiate if WBC < 3500	Level 3 baseline WBC only (14 days)	0	0	
	(2) Do not initiate if history of myeloproliferative disease		0	0	
	(3) Weekly WBC for first 6 months of continuous treatment; if WBC ≥ 3000 may reduce to every other week; post-treatment WBC each week for 4 weeks		45/51 (88.2)	97/145 (66.9)	0.003
	Non-adherence to any of above		45/51 (88.2)	97/145 (66.9)	0.003
Cyclosporine	(1) Monitor renal function during therapy [every 3 months]	Level 3 (baseline 6 months) and level 4 (reminder 12 moths) for serum creatinine	36/136 (26.5)	81/394 (20.6)	0.15
	(2) If administered with methotrexate monitor CBC and LFTs monthly		1/136 (0.7)	4/394 (1.0)	1.00
	Non-adherence to any of above		36/136 (26.5)	83/394 (21.1)	0.193
Danazol	Negative pregnancy test prior to therapy	Level 2 alert if patient is pregnant and level 3 if patient is not pregnant but of child bearing potential	4/4 (100.0)	3/3 (100.0)	N/A
Ergotamine or dihydroergotamine	Concurrent use of CYP 3A4 inhibitors is contraindicated	DDI (levels 1–3)	7/56 (12.5)	10/37 (27.0)	0.076
Ganciclovir	Monitor CBC-platelets [every 2 weeks]	Level 3 (baseline 14 days) and level 4 (reminder 12 months) WBC only	38/61 (62.3)	100/207 (48.3)	0.055
Isoniazid	Not for use in patient with "active liver disease." [transaminases > 5 times upper limit of normal]	Level 3 (baseline 6 months) ALT only	0/629 (0)	0/996 (0)	N/A
Isotretinoin	Negative urine or serum pregnancy test (2 samples)	Category XX level 1 alert if patient is pregnant	15/24 (62.5)	40/147 (27.2)	0.0006
Itraconazole	(1) May not be administered to patients with onychomycosis and CHF	DDI (level 2 and level 3)			
	(2) Drug interactions with: cisapride, pimozide, quinidine, dofetilide				
	Non-adherence to any of above		0/91 (0)	0/112 (0)	N/A
Ketoconazole	(1) Monitor LFTs and bilirubin at baseline and then frequent intervals [3 weeks after baseline]	DDI (levels 1–3)	92/112 (82.1)	223/317 (70.4)	0.015
	(2) Drug interaction with cisapride, astemizole, terfenadine		0/112 (0)	0/317 (0)	N/A
	Non-adherence to any of above		92/112 (82.1)	223/317 (70.4)	0.015
Ketorolac	(1) Concurrent use with NSAIDs contraindicated	DDI (level 2) and level 2 critical serum creatinine	13/56 (23.2)	0/141 (0)	<0.0001
	(2) Contraindicated in patients with advanced renal impairment [creatinine ≥ 3]		0/56 (0)	1/141 (0.7)	1.00
	(3) Contraindicated in patients with peptic ulcers, GI bleeding and/or perforation (active or history)		1/56 (1.8)	2/141 (1.4)	1.00
	Non-adherence to any of above		14/56 (25.0)	3/141 (2.1)	<0.0001
Leflunomide	Exclude pregnancy prior to initiation of therapy	Category XX level 1 alert if pt is pregnant	53/54 (98.2)	65/67 (97.0)	1.00

DOI: 10.1002/pds

Metformin	(1) Avoid in patients with hepatic disease [transaminases > 3 times upper limit of normal]		14/4219 (0.3)	60/8810 (0.7)	0.01
	(2) Avoid in patients with renal dysfunction [Cr > 1.4 in women or > 1.5 in men]	Creatinine alert levels 2–4 (all 12 months) or CrCl 15 and 50 (Creatinine clearance alert)	61/4219 (1.5)	127/8810 (1.4)	0.98
	(3) Patients ≥ age 80 need creatinine clearance measured		123/4219 (2.9)	129/8810 (1.5)	<0.0001
	(4) Avoid in patients with CHF requiring pharmacologic treatment		25/4219 (0.6)	33/8810 (0.4)	0.08
	Non-adherence to any of above		216/4219 (5.1)	344/8810 (3.9)	0.001
Misoprostol	Women who take drug for NSAID ulcer reduction should have negative HCG	Category XX level 1 alert if pt is pregnant	0/5 (0)	0/22 (0)	N/A
Nefazodone	Contraindicated in patients with 'active liver disease' [AST or ALT ≥ 3 times upper limit of normal], Withdraw therapy if AST or ALT ≥ 3 times upper limit of normal	ALT level 2 (12 months) and 3 (6 months)	0/283 (0)	0/140 (0)	N/A
Nevirapine	Patients should be closely monitored at baseline and for first 12 weeks for signs of liver reactions [monitor LFTs every 4 months]	ALT level 3 (baseline 12 months) only	21/78 (26.9)	9/63 (14.3)	0.068
Procainamide	CBC-diff-platelets weekly during first 3 months and periodically thereafter [once per year]	HCT and platelet level 3 (baseline 6 months) and level 4 (reminder 12 months)	0/5 (0)	0/5 (0)	N/A
Ribavirin/Interferon	Contraindicated in pregnancy	Category X level 2 alert if patient is pregnant	0/0 (0)	0/0 (0)	N/A
Ritonavir	Drug interactions with some non-sedating antihistamines, sedative hypnotics, antiarrhythmics, and ergot alkaloids	DDI (levels 1–3)	0/44 (0)	0/278 (0)	N/A
Thalidomide	Contraindicated in pregnancy, negative HCG 24 hours prior to therapy initiation, weekly during first month, monthly thereafter	Category XX level 1 alert if patient is pregnant	6/6 (100)	12/21 (57.1)	0.07
Thioridazine	(1) Contraindicated with P450 2D6 inhibitors and agents that prolong QT	DDI (level 2 and level 3)	3/14 (21.4)	7/34 (20.6)	0.3
	(2) Contraindicated in patients with history of cardiac arrhythmia or congenital long QT syndrome		0/14 (0)	1/34 (2.9)	1.00
	(3) Monitor serum potassium [once per year]		7/14 (50.0)	33/34 (97.1)	0.0003
	(4) Baseline and periodic EKG [once per year]		10/14 (71.4)	29/34 (85.3)	0.42
	Non-adherence to any of above		11/14 (78.6)	34/34 (100)	0.02
Ticlopidine	CBC-diff, platelets, and smear at baseline and every 2 weeks during first 3 months. If patient stops therapy in first 3 months continue monitoring for 2 more weeks.	HGB and neutrophils level 3 (baseline 12 months)	12/12 (100)	11/18 (61.1)	0.024
Tretinoin	Negative serum or urine pregnancy test within 1 week prior to therapy	Category D level 2 alert if pt is pregnant	0/0 (0)	0/18 (0)	N/A
Triamterene	Monitor serum potassium [every 6 months]	Serum potassium levels 2–4 (12 months)	389/1785 (21.8)	902/4195 (21.5)	0.8
Valproate	Baseline LFTs and frequent monitoring [once per year]	ALT level 3 (baseline 12 months)	207/701 (29.5)	463/1746 (26.5)	0.12

ACE, angiotensin-converting enzyme; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BBW, black-box warning; BUN, blood urea nitrogen; CBC, complete blood cell; CHF, congestive heart failure; Cr, creatinine; CrCl, creatinine clearance; DDI, drug drug interaction; EKG, electrocardiography; GI, gastrointestinal; HGB, hemoglobin; HCG, human chorionic gonadotropin; LFT, liver function test; NSAID, non-steroidal anti-inflammatory drug; N/A, non-applicable; WBC, white blood cell.

*In cases where the black box warning was unclear, an operational definition appears in brackets, as determined by discussions with specialists.

BBW, black-box warning; OR, odds ratio; CI, 95% confidence interval; MD, medical doctor; NP, nurse practitioner; PA, physician assistant.

*Final model including 10 single terms and 12 interaction terms: age group × (gender, race, language), race × insurance, provider type × (site of clinic, number of medications), number of medications × (site of clinic, number of problems), intervention × (race, language, site of clinic, number of medication); All variables with $p < 0.05$ in final model.

†Defined as the number of medical problems on the problem list when the drug with BBWs was prescribed.

‡Defined as the number of medications taken by the patient when or before the drug with BBWs was prescribed.

medical problems were also at higher risk of overrides. Other studies have found little clustering.[35]

This study has a number of implications for the FDA warning process. Adapting this set of warnings for clinical decision support made it clear that the BBWs would be more useful and easier to implement in computerized systems generally if the need for implementation in clinical decision support was explicitly considered at the time of development. In addition, many of the warnings appear to be of marginal value given the frequency with which they are overridden. One function of the Sentinel Network which has been sponsored by the FDA might be to evaluate how specific warnings are regarded by prescribers, whether or not they are overridden, and if they are overridden, what is the absolute risk of associated harm. Some warnings could be rescinded if it appears the risk is low.

Our study has a number of limitations. We did not assess the frequency of harm associated with alert overrides in the current study. In addition, the study was done as a before–after trial, because it was judged that it would have been unethical to withhold black-box warnings, so that we did not have a contemporaneous control group. Having a contemporaneous control group would have been a stronger design. For medications requiring laboratory testing at baseline and/or during therapy, we determined the adherence/violation status based on the reports of laboratory results and medication start and stop dates. We may have overestimated the frequency of prescribing violation as laboratory monitoring tests could be done outside the study clinics. In addition, providers could tell patients to hold a medication in response to a specific circumstance without discontinuing the drug from the patient's medication list. Finally, this study was conducted in urban medical practices affiliated with academic teaching centers so that the results may not be generalizable to other settings.

We evaluated the effectiveness of implementing black-box related alerts in an EHR in the outpatient setting. Our results suggest that current EHR alerts did not improve overall adherence to the BBWs for drug–drug, drug–laboratory, drug–disease, and drug–pregnancy interactions, although we observed improvement in sub-group comparisons for drug–drug and drug–pregnancy interactions, and for some individual drugs. Further evaluation is needed regarding the absolute risk associated with specific BBWs.

KEY POINTS

- Implementation of alerts about black-box warnings through electronic prescribing in outpatients had no impact on improvement of the overall black-box warnings adherence rate.
- However, alerts did improve adherence for a few specific clinically important subcategories.

Abstract

Dehydroepiandrosterone sulphate (DHEAS) is the most abundant circulating steroid secreted by adrenal glands—yet its function is unknown. Its serum concentration declines significantly with increasing age, which has led to speculation that a relative DHEAS deficiency may contribute to the development of common age-related diseases or diminished longevity. We conducted a meta-analysis of genome-wide association data with 14,846 individuals and identified eight independent common SNPs associated with serum DHEAS concentrations. Genes at or near the identified loci include *ZKSCAN5* (rs11761528; $p = 3.15 \times 10^{-36}$), *SULT2A1* (rs2637125; $p = 2.61 \times 10^{-19}$), *ARPC1A* (rs740160; $p = 1.56 \times 10^{-16}$), *TRIM4* (rs17277546; $p = 4.50 \times 10^{-11}$), *BMF* (rs7181230; $p = 5.44 \times 10^{-11}$), *HHEX* (rs2497306; $p = 4.64 \times 10^{-9}$), *BCL2L11* (rs6738028; $p = 1.72 \times 10^{-8}$), and *CYP2C9* (rs2185570; $p = 2.29 \times 10^{-8}$). These genes are associated with type 2 diabetes, lymphoma, actin filament assembly, drug and xenobiotic metabolism, and zinc finger proteins. Several SNPs were associated with changes in gene expression levels, and the related genes are connected to biological pathways linking DHEAS with ageing. This study provides much needed insight into the function of DHEAS.

Author Summary

Dehydroepiandrosterone sulphate (DHEAS), mainly secreted by the adrenal gland, is the most abundant circulating steroid in humans. It shows a significant physiological decline after the age of 25 and diminishes about 95% by the age of 85 years, which has led to speculation that a relative DHEAS deficiency may contribute to the development of common age-related diseases or diminished longevity. Twin- and family-based studies have shown that there is a substantial genetic effect with heritability estimate of 60%, but no specific genes regulating serum DHEAS concentration have been identified to date. Here we take advantage of recent technical and methodological advances to examine the effects of common genetic variants on serum DHEAS concentrations. By examining 14,846 Caucasian individuals, we show that eight common genetic variants are associated with serum DHEAS concentrations. Genes at or near these genetic variants include *BCL2L11*, *ARPC1A*, *ZKSCAN5*, *TRIM4*, *HHEX*, *CYP2C9*, *BMF*, and *SULT2A1*. These genes have various associations with steroid hormone metabolism—co-morbidities of ageing including type 2 diabetes, lymphoma, actin filament assembly, drug and xenobiotic metabolism, and zinc finger proteins—suggesting a wider functional role for DHEAS than previously thought.

Introduction

Dehydroepiandrosterone sulphate (DHEAS), mainly secreted by the adrenal gland, is the most abundant circulating steroid in humans. It acts as an inactive precursor which is converted initially into DHEA and thereafter into active androgens and estrogens in peripheral target tissues [1]. In humans the serum concentration of circulating DHEAS is 100- to 500-fold or 1000 to 10,000 higher than that of testosterone and estradiol respectively. Unlike DHEA, which is swiftly cleared from the circulation and shows diurnal variation, serum DHEAS concentrations are stable and facilitate accurate measurement and diagnosis of pathology [2].

DHEAS is distinct from the other major adrenal steroids (cortisol and aldosterone) in showing a significant physiological decline after the age of 25 and diminishes about 95% by the age of 85 years [3]. This age-related decline has led to speculation that a relative DHEAS deficiency may contribute to the development of common age-related diseases or diminished longevity [4,5]. Low DHEAS concentrations are possibly associated with increased insulin resistance [6,7] and hypertension [8], but not with incident metabolic syndrome [9]. It is strongly associated with osteoporosis in women [10,11] but not in men [12]. Concurrent change in DHEAS tracks with declines in gait speed, modified mini-mental state examination score (3MSE), and digit symbol substitution test (DSST) in very old women but not in men [13]. Low circulating DHEAS is also strongly associated with cardiovascular disease and mortality in men [14–18] but not in women [19]. A recent 15-year follow-up study showed that DHEAS was negatively related to all-cause, all cancers, and other medical mortality, whereas high DHEAS concentrations were protective [20]. This has led to its widespread and uncontrolled use as a controversial anti-ageing and sexual performance supplement in the USA and other western countries without any clear data about efficacy, potential risks or benefits [21].

Despite these observations, the physiological function of DHEAS and its importance in maintaining health are poorly understood. Although previous twin [22,23] and family-based studies [24,25] have shown that there is a substantial genetic effect with a heritability estimate of 60% [22], no specific genes regulating serum DHEAS concentration in healthy individuals have been identified to date. Therefore, the current study meta-analyzed the results of genome-wide association studies (GWAS) performed in a total of 14,846 individuals from seven cohorts to identify common genetic variants associated with serum DHEAS concentrations. The findings not only advance understanding of how serum DHEAS concentration is regulated by genes but also provide clues as to its mechanism of action as well as Mendelian randomisation principles [26].

Results

We carried out a meta-analysis of 8,565 women and 6,281 men of European origin from collaborating studies: TwinsUK (n = 4,906), Framingham Heart Study (FHS) (n = 3,183), SHIP (n = 1,832), Rotterdam Study (RS1) (n = 1,597), InCHIANTI (n = 1,182), Health ABC (n = 1,222), and GOOD (n = 924). Serum samples were collected either after overnight fasting or non-fasting in each cohort and DHEAS was measured by either immunoassay or liquid chromatography tandem mass spectrometry (LC-MS/MS) methods (Table 1). Mean age differed across the cohorts from 19 to 74 years in men and 50 to 74 years in women and corresponding mean DHEAS concentrations varied from 1.20 to 7.05 μmol/L (Table 1).

Each cohort performed GWA tests for log transformed DHEAS on ~2.5 million imputed single nucleotide polymorphisms (SNPs) in men and women separately with adjustment for age, and additionally for age and sex for those cohorts who had data in both men and women. Then Z-scores from each cohort were pooled for the meta-analysis at each SNP.

In all our individual GWAS, λ_{GC}, which is defined as the median χ^2 (1 degree of freedom) association statistic across SNPs divided by its theoretical median under the null distribution [27], ranged from 0.984 to 1.023, indicating that there was no population stratification or it was very minor. Further, we corrected for population stratification by applying the genomic control method [27]; the λ_{GC} in the meta-analysis is 1.017. In addition, the effect direction was consistent across all the cohorts and there is no between-study heterogeneity as indicated by I^2 ranging between 0 and 0.12 (Table 2).

We found 44 SNPs were associated with serum DHEAS concentrations in men at conventional genome-wide significance ($p<5\times10^{-8}$), which are all located on chromosome 7q22.1 (Figure 1B; Table S1). All these SNPs except for three were significant in women (Figure 1A; Table S1). In addition, 19 SNPs located on chromosome 19q13.3 were found in women to be associated with serum DHEAS concentrations with $p<5\times10^{-8}$. In the sex-combined meta-analysis, the significance became stronger for all these SNPs (Figure 1C; Table S1). Further, we found 8 SNPs located on chromosome 10q23.33 which represents two regions more than 2 MB apart, 12 SNPs on chromosome 15q15.1, and in addition, 4 SNPs on chromosome 19q13.3 were associated with serum DHEAS concentrations with $p<5\times10^{-8}$. Together we found a total of 87 SNPs associated with serum DHEAS concentrations with $p<5\times10^{-8}$, representing five chromosomal regions of less than 1 Mb each (Table S1).

The most significantly associated SNPs in each of these five regions are presented in Table 2. The minor allele of rs11761528 ($p=3.15\times10^{-36}$) on chromosome 7q22.1, rs2637125 ($p=2.61\times10^{-19}$) on chromosome 19q13.3, and rs2497306 ($p=4.6\times10^{-9}$) and rs2185570 ($p=2.29\times10^{-8}$) on chromosome 10q22.33 (more than 2 Mb apart), were negatively associated with

DHEAS concentrations. In comparison, the minor allele of rs7181230 ($p = 5.44\times10^{-11}$) on chromosome 15q15.1 was positively associated with serum DHEAS concentrations. Based on the HapMap3 release2 CEU data, the significant 87 SNPs from within the five regions have low pair-wise r^2, indicating potentially multiple independent signals. To verify this, we performed a conditional meta-analysis with adjustment for the five most significant SNPs plus age and sex in each cohort.

After this adjustment, all other SNPs on chromosome 10, 15, and 19 became non-significant (Figure 1D). However, on chromosome 7, we found two independent signals; one defined by rs11761528 and a second located 370 kb upstream in the 3′ UTR of the *TRIM4* and *CYP3A43* genes (rs17277546, $p = 4.50\times10^{-11}$). Furthermore, we identified two additional significant loci associated with DHEAS, one on chromosome 2q13 (rs6738028, $p = 1.72\times10^{-8}$), and another on chromosome 7 within the *ARPC1A* gene (rs740160 located 161 kb downstream of rs11761528, $p = 1.56\times10^{-16}$) (Table 2; Figure 1D). In total, we found eight independent SNPs associated with serum DHEAS concentrations at conventional genome-wide significant level ($p<5\times10^{-8}$) (Table 2). The effect was consistently in the same direction across all cohorts (Table 2). No heterogeneity among cohorts was observed (Table 2). These SNPs together explained ~4% of the total and ~7% of genetic variance of serum DHEAS concentrations (based on TwinsUK data). To further look at whether the magnitude of these genetic association varies with age,

we carried out an interaction analysis between age and each of these 8 SNPs on serum DHEAS concentrations by including an interaction term of age×SNP in the linear regression model in each cohort and then meta-analyzed the results. We found that there was no significant interaction between age and each of these SNPs (all p values≥0.05).

The genes at, or near the identified SNPs, include *BCL2L11* on chromosome 2, *ZKSCAN5*, *ARPC1A*, *TRIM4* and *CYP3A43* on chromosome 7, *HHEX* and *CYP2C9* on chromosome 10, *BMF* on chromosome 15, and *SULT2A1* on chromosome 19 (Figure 2). To explore the potentially functional impacts and likely genetic mechanisms, we used two resources: Genome-wide expression data from the Multiple Tissue Human Expression Resource (MuTHER) [28] (http://www.muther.ac.uk/) based on ~777 unselected UK twins sampled for skin, adipose tissue, and lymphoblastoid cell lines (LCLs) (more details in Text S1); and published gene expression data in human liver [29]. We found that 3 DHEAS-associated SNPs were clearly associated with the related

gene expression levels in at least one tissue after accounting for multiple testing (Table 3). These specific transcript associations provide further evidence for the likely functional gene at each locus.

Further, we carried out gene ontology and pathway analyses using a gene set enrichment analysis (GSEA) approach in MAGENTA [30] which consists of four main steps: First, DNA variants, e.g. SNP, are mapped onto genes. Second, each gene is assigned a gene association score that is a function of its regional SNP association p-values. Third, confounding effects on gene association scores are identified and corrected for, without requiring genotype data. Fourth, a GSEA-like statistical test is applied to predefined biologically relevant gene sets to determine whether any of the gene sets are enriched for highly ranked gene association scores compared to randomly sampled gene sets of identical size from the genome. More details of these four steps are described in the method section. In this analysis, we identified three pathways which passed our significance threshold (false discovery rate (FDR)$<$0.05); xenobiotic metabolism with FDR = 0.001 (pathway database: KEGG and Ingenuity), retinoid X receptor (RXR) function with FDR = 0.003 (pathway database: Ingenuity), and linoleic acid metabolism with FDR = 0.02 (pathway database: KEGG) (Figure S1). The top significant genes with $p<5.0\times10^{-8}$ include *CYP3A4*, *CYP3A43*, *CYP3A5*, and *CYP3A7* on chromosome 7, and *CYP2C8* and *CYP2C9* on chromosome 10 for all three pathways, and *SULT2A1* for RXR pathway. The best index SNPs are rs17277546 for *CYP3A4* and *CYP3A43*, rs4646450 for *CYP3A5* and *CYP3A7*, rs2185570 for *CYP2C9*, rs11572169 for *CYP2C8*, and rs2637125 for *SULT2A1*. The full list of the genes in each of the three pathways and the best index SNPs for each gene are listed in Table S2. Three SNPs – rs17277546, rs2185570, and rs2637125 are the DHEAS-associated SNPs found in our meta-analysis. Both rs4646450 and rs11572169 were associated with DHEAS with p values of 8.8×10^{-17} and 4.8×10^{-8}, respectively, but become non-significant in the conditional meta-analysis because rs4646450 is in linkage disequilibrium (LD, $r^2 = 0.429$) with rs11761528 which is the most significant DHEAS-associated SNP while rs11572169 is in high LD ($r^2 = 0.778$) with rs2185570. Intriguingly, two pathways - xenobiotic metabolism and linoleic acid metabolism, have been linked to ageing in model organisms [31–36].

Discussion

This is the first meta-analysis of GWA studies on serum DHEAS in 14,846 Caucasian subjects. We found 8 common SNPs that implicate nearby genes that are independently associated with serum DHEAS concentrations and provide clues to its role in ageing.

Among the genes identified, *SULT2A1*, a specialized sulphotransferase which converts DHEA to DHEAS in the adrenal cortex, is an obvious candidate gene [3]. *SULT2A1* has a broad substrate specificity, which includes conversion of pregnenolone, 17α-hydroxypregnenolone, and DHEA to their respective sulphated products [37]. Once sulphated by *SULT2A1*, pregnenolone and 17α-hydroxypregnenolone are no longer available as substrates for *HSD3B2*. Therefore, *SULT2A1* sulphation of pregnenolone and 17α-hydroxypregnenolone removes these substrates from the mineralocorticoid and glucocorticoid biosynthetic pathways. This suggests that high levels of *SULT2A1* would ensure the formation of DHEAS [3].

Variation in *SULT2A1* expression has previously been associated with variation of DHEAS concentration [38]. The *SULT2A1* gene is predominantly expressed in the adrenal cortex and to a lesser extent in the liver. We found that rs2547231 ($p = 1.76\times10^{-17}$), located 12 kb downstream of *SULT2A1*, was strongly associated with expression levels of *SULT2A1* in human liver tissues. Although this SNP is not the most strongly associated with serum DHEAS, it is itself in strong LD with the most significant SNP rs2637125 ($r^2 = 0.658$). However, we did not find a significant association with *SULT2A1* expression levels in LCL, skin, and adipose tissues, suggesting a tissue specific effect. The *SULT2B1b* is also reported to play a role in sulphation of DHEA, but in comparison, the strongest signal from that genomic region was rs10417472 with a p = 0.06. In contrast, enzymatic removal of the sulphate group from DHEAS to form DHEA is performed by steroid sulphatase gene (*STS*), but that gene is on the X chromosome and so was not assessed in this meta-analysis.

CYP2C9 is an important cytochrome P450 enzyme, accounts for approximately 17–20% of the total P450 content in human liver, and catalyzes many reactions involved in drug metabolism as well as synthesis of cholesterol, steroids and other lipids [39]. We found that rs2185570 located in the *CYP2C9* gene region is associated

Table 3. Association between DHEAS-associated SNPs and related gene expression levels in different human tissues.

doi:10.1371/journal.pgen.1002025.t003

with serum DHEAS concentrations. This SNP is in strong LD with rs4086116 and rs4917639 ($r^2 = 0.67$ for both) which were found to be associated with acenocoumarol [40] and warfarin maintenance dosage [41] respectively in recent GWAS.

Two other cytochrome P450 enzymes – *CYP11A1* and *CYP17A1*, are two important enzymes which are required in the synthesis of DHEAS in the adrenal gland [3], however, the strongest signals in the genomic region were rs2930306 with p = 0.29 for *CYP11A1* and rs4919686 with p = 0.04 for *CYP17A1*.

The decline in serum DHEAS concentrations with increasing age has been proposed as a putative biomarker of ageing [21]. We found that two putative ageing genes – *BCL2L11* and *BMF* [42] are associated with serum DHEAS concentrations. Both of them encode proteins which belong to the *BCL2* family and act as anti- or pro-apoptotic regulators that are involved in a wide variety of cellular activities. *BCL2L11* has been implicated in chronic lymphocytic leukaemia (rs17483466, $P = 2.36 \times 10^{-10}$) [43] and follicular lymphoma (rs3789068, P for trend = 0.0004) [44]. The DHEAS-associated SNP rs6738028 is not however one of the same SNPs associated with lymphocytic leukaemia and follicular lymphoma nor is it in LD with them. Nevertheless, rs6738028 is strongly associated with *BCL2L11* gene expression levels in both LCL and adipose tissues, suggesting its putative regulatory role. There is relatively little data on the human *BMF* gene or the protein product, but $Bmf^{-/-}$ mice show altered immune and hematopoietic phenotypes as well as defects in uterovaginal development. However, we were not able to detect any association between rs7181230 and the expression levels of *BMF* in the tissues we studied.

HHEX encodes a member of the homeobox family of transcription factors, many of which are involved in developmental processes. This gene has been found to be associated with type 2 diabetes by several recent GWAS [45–51]. The risk alleles of the diabetes-associated SNPs rs1111875 and rs5015480 are associated with low serum DHEAS concentrations although the p values (p = 0.0009 for both SNPs) didn't reach to the GWAS significance level. This is consistent with the observation in which the low serum DHEAS concentrations were associated with insulin resistance [6,7]. The identified DHEAS-associated SNP rs2497306 is in moderate LD with rs1111875 and rs5015480 ($r^2 = 0.38$). And the major allele of rs2497306 is associated with increasing serum DHEAS concentrations. The reason for the observed association is unknown. Studies showed that insulin infusion increases the metabolic clearance of DHEA and DHEAS [52,53], resulting in decreased DHEA and DHEAS concentrations, and DHEA administration significantly enhances insulin sensitivity attenuating the age-related decline in glucose tolerance [54], partly explaining why the diabetes-associated gene is also associated with DHEAS. Interestingly, *HHEX* null mice show cardiovascular, endocrine, liver, muscle, nervous system, and metabolic phenotypes, suggesting extensive multisystem roles for the protein product of this gene. The findings could help dissect causal pathways for the observed associations between DHEAS, insulin resistance, age-related decline in glucose tolerance [54], and other age related phenotypes [55].

Three identified DHEAS-associated SNPs on chromosome 7 (Figure S2), which were independent, and 161 kb downstream (rs740160) and 370 kb upstream (rs17277546) apart from rs11761528 which is located in the middle of the region, are located in four genes - *ZKSCAN5*, *ARPC1A*, *and TRIM4/CYP3A43*. *ZKSCAN5* encodes a zinc finger protein of the Kruppel family and is expressed ubiquitously in adult and fetal tissues with the strongest expression in testis [56]. rs11761528 is located in the intron of the *ZKSCAN5* gene. It is the strongest signal we found and explains 1% of the total variance of serum DHEAS concentration alone. *ARPC1A* encodes one of seven subunits of the human Arp2/3 protein complex which has been implicated in actin polymerization and filament assembly in cells [57]. *TRIM4* encodes a member of the tripartite motif (TRIM) family whereas *CYP3A43* is another cytochrome P450 enzyme. The potential mechanisms for the association are unknown, but we found that rs17277546 is strongly associated with expression levels of *TRIM4* not *CYP3A43*, suggesting *TRIM4* is the possible candidate for DHEAS. However, rs17277546 is the best index SNP for both *CYP3A43* and *CYP3A4* genes in the pathway analysis, indicating a fine mapping in this region is needed to reveal the potential mechanism for the association. Further, the region harbours many other genes including *CYP3A7* which has been reported to increase the clearance of DHEA and DHEAS [58] and a common haplotype polymorphism in the gene has been associated with DHEAS [59,60]. However, none of the DHEAS-associated SNPs are associated with its expression levels in the tissues we studied, and the best index SNP rs4646450 for *CYP3A7* found in our pathway analysis is in LD with rs11761528 and become non-significant in the conditional analysis.

In the pathway analysis, two DHEAS-associated SNPs (rs2185570 and rs17277546) were contained in all three pathways we found and one SNP (rs2637125) was contained in the RXR function pathway. Intriguingly, components of the xenobiotic metabolism pathway have been linked to ageing in model organisms, for example, age-associated changes in expression of genes involved in xenobiotic metabolism have been identified in rats [31,32], up-regulation of xenobiotic detoxification genes has been observed in long-lived mutant mice [33], and adrenal xenobiotic-metabolizing activities increase with ageing in guinea pigs [34]. Furthermore, linoleic acid metabolism has also been linked to changes with ageing in rat cardiac muscle [35] and in human skin fibroblasts [36]. Taken together, these findings suggest that molecular pathways involved in ageing and longevity may also underlie DHEAS regulation, suggesting shared genetic components in both processes and corroborating a role for DHEAS as a marker of biological ageing.

In summary, this first GWAS identified eight independent SNPs associated with serum DHEAS concentrations. The related genes have various associations with steroid hormone metabolism, comorbidities of ageing including type 2 diabetes, lymphoma, actin filament assembly, drug and xenobiotic metabolism, and zinc fingers - suggesting a wider functional role for DHEAS than previously thought.

Methods

Study population

Seven study samples contributed to this meta-analysis of GWA studies on serum DHEAS concentrations, comprising a total of 14,846 men and women of Caucasian origin. The consortium was made up of populations from TwinsUK (n = 4,906), Framingham Heart Study (FHS) (n = 3,183), SHIP (n = 1,832), Rotterdam Study (RS1) (n = 1,597), InCHIANTI (n = 1,182), Health ABC (n = 1,222), and GOOD (n = 924). Full details can be found in Text S1.

DHEAS methods

Blood samples were collected from each of the study participants either after overnight fasting or non-fasting and the serum levels of DHEAS were measured by either immunoassay or liquid chromatography tandem mass spectrometry (LC-MS/MS) methods (Text S1). Because the distribution of the serum DHEAS

levels was skewed, we log transformed the concentrations and the transformed data used in the subsequent analysis.

Genotyping and imputation

Seven study populations were genotyped using a variety of genotyping platforms including Illumina (HumanHap 317k, 550k, 610k, 1M-Duo BeadChip) and Affymetrix (array 500K, 6.0). Each cohort followed a strict quality control on the genotyping data. More details on the quality control and filtering criteria can be found in Text S1. In order to increase genomic coverage and allow the evaluation of the same SNPs across as many study populations as possible, each study imputed genotype data based on the HapMap CEU Build 36. Algorithms were used to infer unobserved genotypes in a probabilistic manner in either MACH (http://www.sph.umich.edu/csg/abecasis/MACH), or IMPUTE [61]. We exclude non-genotyped SNPs with an imputation quality score <0.2 and SNPs with allele frequency <0.01 from meta-analysis.

Statistical method

Each study performed genome-wide association testing for serum concentrations of DHEAS across approximately 2.5 million SNPs under an additive genetic model separately in men and women (Text S1). The analyses were adjusted for age. In addition, the association testing was performed in the combined men and women data with adjustment for age and sex. Studies used PLINK, GenABEL, SNPTEST, QUICKTEST, or MERLIN for the association testing. The summary results from each cohort were meta-analyzed by Z-score pooling method implemented in Metal (http://www.sph.umich.edu/csg/abecasis/metal/). We chose this method to minimize the impact of the different assays used for serum DHEAS measurements. Specifically, for each study, we converted the two-sided P value after adjustment for population stratification by the genomic control method to a Z statistic that was signed to reflect the direction of the association given the reference allele. Each Z score was then weighted; the squared weights were chosen to sum to 1, and each sample-specific weight was proportional to the square root of the effective number of individuals in the sample. We summed the weighted Z statistics across studies and converted the summary Z score to a two-sided P value. We also used I^2 index to assess between-study heterogeneity and the inverse variance weighted method to estimate the effect size. Genome-wide significance was defined as $p<5\times10^{-8}$. The association between the DHEAS-associated SNPs and the related gene expression levels in MuTHER data were examined by mixed linear regression modelling which takes both family structure and batch effects into account. The significance was defined as $p<0.006$ after accounting for multiple testing (Bonferroni method, correcting 9 independent tests).

Pathway analysis. Meta-Analysis Gene-set Enrichment of variaNT Associations (MAGENTA) was used to explore pathway-based associations in the full GWAS dataset. MAGENTA implements a gene set enrichment analysis (GSEA) based approach, the methodology of which is described in Segrè et al [30]. Briefly, each gene in the genome is mapped to a single index SNP with the lowest P-value within a 110 kb upstream, 40 kb downstream window. This P-value, representing a gene score, is then corrected for confounding factors such as gene size, SNP density and LD-related properties in a regression model. Genes within the HLA-region were excluded from analysis due to difficulties in accounting for gene density and LD patterns. Each mapped gene in the genome is then ranked by its adjusted gene score. At a given significance threshold (95th and 75th percentiles of all gene scores), the observed number of gene scores in a given pathway, with a ranked score above the specified threshold percentile, is calculated. This observed statistic is then compared to 1,000,000 randomly permuted pathways of identical size. This generates an empirical GSEA P-value for each pathway. Significance was determined when an individual pathway reached a false discovery rate (FDR)<0.05 in either analysis. In total, 2529 pathways from Gene Ontology, PANTHER, KEGG and Ingenuity were tested for enrichment of multiple modest associations with serum DHEAS levels.

Ethics statement

All studies were approved by local ethics committees and all participants provided written informed consent as stated in Text S1.

Acknowledgments

TwinsUK: The study was funded by the Wellcome Trust, Arthritis Research Campaign, European Community's Seventh Framework Programme (FP7/2007-2013)/grant agreement HEALTH-F2-2008-201865-GEFOS and Seventh Framework Programme grant 200800 Treat OA/(FP7/2007-2013), ENGAGE project grant agreement HEALTH-F4-2007-201413, and the FP-5 GenomEUtwin Project (QLG2-CT-2002-01254). The study also receives support from the UK Department of Health via the National Institute for Health Research (NIHR) comprehensive Biomedical Research Centre award to Guy's & St Thomas' NHS Foundation Trust in partnership with King's College London. TDS is an NIHR senior investigator. The project also received support from a Biotechnology and Biological Sciences Research Council project grant (G20234). The authors acknowledge the funding and support of the National Eye Institute (NEI) via an NIH/Center for Inherited Disease Research (CIDR) genotyping project. We thank the staff from the Genotyping Facilities at the Wellcome Trust Sanger Institute for sample preparation, quality control, and genotyping; Le Centre National de Génotypage, France, for genotyping; Duke University, NC, USA, for genotyping; and the Finnish Institute of Molecular Medicine, Finnish Genome Center, University of Helsinki. Genotyping was also done by CIDR as part of an NEI/NIH project grant.

SHIP: Computing resources have been made available by the Leibniz Supercomputing Centre of the Bavarian Academy of Sciences and Humanities (HLRB project h1231). SHIP is part of the Community Medicine Research net of the University of Greifswald, Germany, which is funded by the Federal Ministry of Education and Research (grants no. 01ZZ9603, 01ZZ0103, and 01ZZ0403), the Ministry of Cultural

Affairs as well as the Social Ministry of the Federal State of Mecklenburg - West Pomerania. Genome- wide data have been supported by the Federal Ministry of Education and Research (grant no. 03ZIK012) and a joint grant from Siemens Healthcare, Erlangen, Germany and the Federal State of Mecklenburg West Pomerania. This work is also part of the research project Greifswald Approach to Individualized Medicine (GANI_MED). The GANI_MED consortium is funded by the Federal Ministry of Education and Research and the Ministry of Cultural Affairs of the Federal State of Mecklenburg – West Pomerania (03IS2061A). The University of Greifswald is a member of the 'Center of Knowledge Interchange' program of the Siemens AG. The DHEAS reagents used were sponsored by Siemens Healthcare Diagnostics, Eschborn, formerly DPC Biermann GmbH, Bad Nauheim, Germany. Novo Nordisc provided partial grant support for the determination of serum samples and data analysis.

Health ABC: This study was supported by National Institute on Aging contracts N01-AG-6-2101, N01-AG-6-2103, and N01-AG-6-2106. The genome-wide association study was funded by NIA grant 1R01AG032098-01A1 to Wake Forest University Health Sciences and genotyping services were provided by the Center for Inherited Disease Research (CIDR). CIDR is fully funded through a federal contract from the National Institutes of Health to The Johns Hopkins University, contract number HHSN268200782096C." This research was supported (in part) by the Intramural Research Program of the NIH, National Institute on Aging.

RS1: The generation and management of GWAS genotype data for the Rotterdam Study is supported by the Netherlands Organisation of Scientific Research NWO Investments (nr. 175.010.2005.011, 911-03-012). This study is funded by the Research Institute for Diseases in the Elderly (014-93-015; RIDE2), the Netherlands Genomics Initiative (NGI) - Netherlands Consortium of Healthy Aging (NCHA) project nr. 050-060-810, and funding from the European Commision (HEALTH-F2-2008-201865, GEFOS; HEALTH-F2-2008-35627, TREAT-OA). The Rotterdam Study is funded by Erasmus Medical Center and Erasmus University, Rotterdam, Netherlands Organization for the Health Research and Development (ZonMw), the Research Institute for Diseases in the Elderly (RIDE), the Ministry of Education, Culture and Science, the Ministry for Health, Welfare and Sports, the European Commission (DG XII), and the Municipality of Rotterdam. We thank Pascal Arp, Mila Jhamai, Dr Michael Moorhouse, Marijn Verkerk, and Sander Bervoets for their help in creating the GWAS database. The authors are grateful to the study participants, the staff from the Rotterdam Study and the participating general practioners and pharmacists. We would like to thank Dr. Tobias A. Knoch, Karol Estrada, Luc V. de Zeeuw, Anis Abuseiris, and Rob de Graaf as well as their institutions the Erasmus Computing Grid, Rotterdam, The Netherlands, and especially the national German MediGRID and Services@MediGRID part of the German D-Grid, both funded by the German Bundesministerium fuer Forschung und Technology under grants #01 AK 803 A-H and # 01 IG 07015 G for access to their grid resources.

FHS: DHEAS-genotype genome-wide association analyses were supported by the National Institute of Aging (Genetics of Reproductive Life Period and Health Outcomes, R21AG032598; JMM, KL, DPK, WVZ). "The Framingham Heart Study of the National Heart Lung and Blood Institute of the National Institutes of Health and Boston University School of Medicine was supported by the National Heart, Lung and Blood Institute's Framingham Heart Study Contract No. N01-HC-25195 and its contract with Affymetrix, Inc for genotyping services (Contract No. N02-HL-6-4278). Analyses reflect intellectual input and resource development from the Framingham Heart Study investigators participating in the SNP Health Association Resource (SHARe) project. A portion of this research was conducted using the Linux Cluster for Genetic Analysis (LinGA-II) funded by the Robert Dawson Evans Endowment of the Department of Medicine at Boston University School of Medicine and Boston Medical Center." DPK received support from NIH (Grant R01 AR/AG 41398).

GOOD: Financial support was received from the Swedish Research Council (K2010-54X-09894-19-3, 2006-3832), the Swedish Foundation for Strategic Research, the ALF/LUA research grant in Gothenburg, the Lundberg Foundation, the Torsten and Ragnar Söderberg's Foundation, Petrus and Augusta Hedlunds Foundation, the Västra Götaland Foundation, the Göteborg Medical Society, the Novo Nordisk foundation and the European Commission grant HEALTH-F2-2008-201865-GEFOS. We would like to thank Dr. Tobias A. Knoch, Luc V. de Zeeuw, Anis Abuseiris, and Rob de Graaf as well as their institutions the Erasmus Computing Grid, Rotterdam, The Netherlands, and especially the national German MediGRID and Services@MediGRID part of the German D-Grid, both funded by the German Bundesministerium fuer Forschung und Technology under grants #01 AK 803 A-H and # 01 IG 07015 G for access to their grid resources. We would also like to thank Karol Estrada, Department of Internal Medicine, Erasmus MC, Rotterdam, The Netherlands for advice regarding the grid resources.

InCHIANTI: The InCHIANTI study baseline (1998–2000) was supported as a "targeted project" (ICS110.1/RF97.71) by the Italian Ministry of Health and in part by the U.S. National Institute on Aging (Contracts: 263 MD 9164 and 263 MD 821336); the InCHIANTI Follow-up 1 (2001–2003) was funded by the U.S. National Institute on Aging (Contracts: N.1-AG-1-1 and N.1-AG-1-2111); the InCHIANTI Follow-ups 2 and 3 studies (2004–2010) were financed by the U.S. National Institute on Aging (Contract: N01-AG-5-0002); supported in part by the Intramural research program of the National Institute on Aging, National Institutes of Health, Baltimore, Maryland. JRBP is funded by a Sir Henry Wellcome Postdoctoral Fellowship (092447/Z/10/Z).

Author Contributions

Study design: TD Spector, G Zhai, M Mangino, A Hofman, AG Uitterlinden, AD Coviello, C Ohlsson, A Teumer, L Ferrucci, M Maggio, TM Frayling, H Wallaschofski, JM Murabito, A Koster, TB Harris, DP Kiel. Sample collection and preparation: TD Spector, D Glass, A Hofman, FH de Jong, C Ohlsson, M Lorentzon, A Eriksson, L Vandenput, HK Kroemer, H Völzke, H Wallaschofski, S Bhasin, L Ferrucci, M Marcello, F Rivadeneira. Statistical analyses: G Zhai, M Mangino, N Soranzo, KS Small, ÅK Hedman, E Grundberg, A Nica, L Stolk, L Vandenput, J Eriksson, A Teumer, F Ernst, JRB Perry, KL Lunetta, WV Zhuang, Y Liu, F Rivadeneira. Manuscript writing: G Zhai, TD Spector, M Mangino, L Stolk, F de Jong, AD Coviello, C Ohlsson, JM Murabito, A Koster, JRB Perry. Review and revision of the manuscript: G Zhai, M Mangino, TD Spector, N Soranzo, JT Bell, KS Small, A Hofman, E Grundberg, A Nica, SG Wilson, L Stolk, A Teumer, H Koster, H Völzke, F Ernst, R Haring, HK Kroemer, H Wallaschofski, FH de Jong, AD Coviello, C Ohlsson, L Vandenput, M Lorentzon, J Eriksson, A Eriksson, JRB Perry, D Melzer, TM Frayling, M Maggio, L Ferrucci, A Murray, JM Murabito, ÅK Hedman, RS Vasan, DP Kiel, A Koster, TB Harris, Y Liu, BWJH Pennix, I Miljkovic, KL Lunetta, L Xi. Intellectual input: SG Wilson, JT Bell, C Ohlsson, R Haring, A Teumer, JRB Perry, TM Frayling, A Murray, H Wallaschofski.
