Relation of Socioeconomic Position With Ankle–Brachial Index

Golareh Agha, MSc[a,*], Joanne M. Murabito, MD[b,c], John W. Lynch, PhD[d,e], Michal Abrahamowicz, PhD[f], Sam B. Harper, PhD[f], and Eric B. Loucks, PhD[a]

Potential upstream determinants of coronary heart disease (CHD) include life-course socioeconomic position (e.g., childhood socioeconomic circumstances, own education and occupation); however, several plausible biological mechanisms by which socioeconomic position (SEP) may influence CHD are poorly understood. Several CHD risk factors appear to be more strongly associated with SEP in women than in men; little is known as to whether any CHD risk factors may be more strongly associated with SEP in men. Objectives were to evaluate whether cumulative life-course SEP is associated with a measurement of subclinical atherosclerosis, the ankle–brachial index (ABI), in men and women. This study was a prospective analysis of 1,454 participants from the Framingham Heart Study Offspring Cohort (mean age 57 years, 53.8% women). Cumulative SEP was calculated by summing tertile scores for father's education, own education, and own occupation. ABI was dichotomized as low (≤1.1) and normal (>1.1 to 1.4). After adjustment for age and CHD risk factors cumulative life-course SEP was associated with low ABI in men (odds ratio [OR] 2.04, 95% confidence interval [CI] 1.22 to 3.42, for low vs high cumulative SEP score) but not in women (OR 0.86, 95% CI 0.56 to 1.33). Associations with low ABI in men were substantially driven by their own education (OR 4.13, 95% CI 1.86 to 9.16, for lower vs higher than high school education). In conclusion, cumulative life-course SEP was associated with low ABI in men but not in women. **(Am J Cardiol 2011;108:1651–1657)**

Very little is known about whether life-course socioeconomic position (SEP) is associated with the ankle–brachial index (ABI), a subclinical measurement of atherosclerosis. ABI is the ratio of systolic blood pressure in the ankle to systolic blood pressure in the arm. It is well recognized that ABI is a measurement of generalized atherosclerosis and that an ABI <0.9 indicates peripheral arterial disease. In the Atherosclerosis Risk In Communities (ARIC)[1] study and in a systematic review including longitudinal studies from the United States and Europe,[2] low ABI was associated with increased incidence of total mortality, cardiovascular mortality, myocardial infarction, and stroke. The increased relative risks were shown to be independent of baseline cardiovascular disease and risk factors, suggesting that the ABI might have an independent role in predicting cardiovascular events. Consequently, the primary objective of this study was to investigate whether cumulative life-course SEP is associated with ABI in the Framingham Offspring Study cohort independent of classic coronary heart disease (CHD) risk factors.

Methods

The Framingham Heart Study is a community-based observational cohort study initiated in 1948 to investigate risk factors for CHD. The present investigation was based on participants in the Framingham Offspring Study, which began in 1971 with recruitment of 5,124 United States men and women who were offspring (or spouses of offspring) of the original cohort of the Framingham Heart Study. The design and selection criteria of the Framingham Offspring Study have been described elsewhere.[3] Participants were examined every 4 to 8 years, undergoing medical history, physical examination, anthropometry, and laboratory assessment of CHD risk factors at each examination, as previously described.[3] Framingham Study participants signed informed consent and the Framingham Study is reviewed annually by the Boston University Medical Center institutional review board.

Childhood SEP was measured by father's educational attainment in primary analyses and father's occupation in secondary analyses. Father's education and occupation were obtained directly from the participants' fathers who were enrolled in the Framingham Heart Study original cohort from 1948 through 1950 (mean age 44 years, range 28 to 62). Father's education was categorized as 3 levels: lower than high school, completed high school, and higher than high school. Father's occupation was categorized as 3 lev-

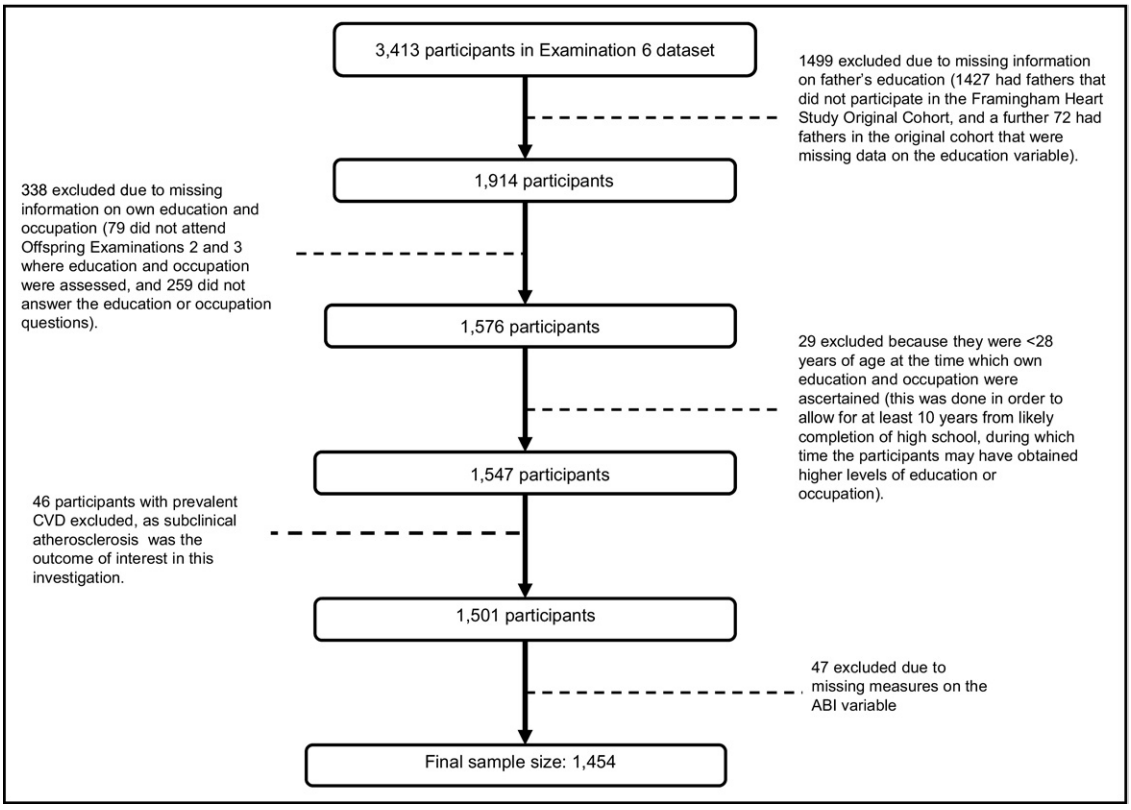

Figure 1. Exclusion criteria and final sample size for the present investigation from the Framingham Heart Offspring Study cohort in the United States (1971 to 1998). CVD = cardiovascular disease.

els: laborer, clerical/sales, and professional/executive/supervisory/technical. Young adulthood SEP was measured by own educational attainment, obtained directly from the Framingham Offspring Study participants at examinations 2 (1979 to 1982) and 3 (1984 to 1987). Education was categorized as 3 levels: ≤12, 13 to 16, and ≥17 years of education. Active professional-life SEP was measured as own occupation, ascertained at examination 2 (1979 to 1982), and categorized as 3 levels: laborer, homemaker/clerical/sales, and professional/executive/supervisory/technical. Analyses testing the accumulation-of-risk framework used a cumulative SEP score that was created by summing values for SEP at 3 successive life-course periods: childhood SEP (measured as father's education: lower than high school = 0, high school = 1, higher than high school = 2), young adulthood SEP (measured as own education: ≤12 years = 0, 13 to 16 years = 1, ≥17 years = 2), and active professional-life SEP (measured as own occupation: laborer = 0, clerical/sales/homemaker = 1, executive/professional/supervisory/technical = 2). Cumulative SEP score was categorized as low (score of 0 or 1), medium (score of 1 or 2), and high (score of 4 to 6) for analyses. Higher cutpoints were used for educational categories of offspring compared to fathers to account for secular trends of increased normative levels of education across generations.

Measurements of ABI were obtained at offspring examination 6 (1995 to 1998). Ankle–brachial systolic blood pressure measurements were performed by trained technicians according to standardized protocols.[4] Systolic blood pressure was measured using an 8-MHz Doppler pen probe and an ultrasonic Doppler flow detector (Parks Medical Electronics, Inc., Aloha, Oregon) 2 times for each limb (right arm, left arm, right ankle, left ankle). ABI was then calculated for each leg as the ratio of average systolic blood pressure in the ankle divided by average systolic blood pressure in the arm with the higher blood pressure. The lower of the ABI values calculated for the left and right ankles was used for analyses. If ABI was missing for 1 ankle, data from the nonmissing ankle were used (n = 8 for the present investigation).

Emerging evidence has demonstrated increased risk for coronary and carotid atherosclerosis, coronary events, and cardiovascular disease mortality with ABI values up to 1.1.[5–7] Consequently the ABI Collaboration defined normal ABI as >1.1 to 1.4.[5] Therefore, ABI was dichotomized as low (ABI ≤1.1) versus normal (ABI >1.1 to 1.4) for the present investigation. However, additional analyses were carried out for women using a lower cutpoint of 1.0 to define low ABI. This was done in light of recent evidence suggesting that normal ABI values may be intrinsically lower in healthy women than in men.[8] Participants with ABI values >1.4 were excluded because an ABI >1.4 has been demonstrated to confer increased risk for cardiovascular and total mortality, possibly because of poor arterial compressibility resulting from stiffness and calcification.[5] Because of a very small number of subjects (n = 41) with an ABI value ≤0.9 (i.e., definite peripheral arterial disease), there was inadequate statistical power to carry out analyses with ABI dichotomized as ≤0.9 versus >0.9 to 1.4.

Table 1
Age-adjusted characteristics according to cumulative life course socioeconomic position, Framingham Heart Study Offspring cohort, United States (1971 to 1998)

	Cumulative SEP Score		
	0 or 1	2 or 3	4–6
Men	192 (28.6%)	189 (28.1%)	291 (43.3%)
Age (years)*	58.9 (57.63–60.2)	56.3 (55.1–57.6)	55.6 (54.7–56.5)
Mean ankle–brachial index	1.15 (1.14–1.16)	1.15 (1.14–1.17)	1.17 (1.16–1.19)
Body mass index (kg/m^2)	29.0 (28.3–29.6)	29.0 (28.3–29.6)	28.2 (27.7–28.8)
Systolic blood pressure (mm Hg)	128.1 (125.9–130.3)	129.6 (127.4–131.7)	128.5 (126.8–130.3)
High-density lipoprotein cholesterol (mg/dl)	42.9 (41.1–44.8)	43.1 (41.3–44.9)	45.3 (43.8–46.8)
Total/high-density lipoprotein cholesterol ratio	5.1 (4.8–5.4)	5.4 (5.1–5.8)	4.7 (4.4–5.0)

* Calculated using bivariate analysis.

All covariates were measured at offspring examination 6 (1995 to 1998). Smoking status (current, former, or never) was determined by self-report. Systolic blood pressure was calculated as the average of the clinic physician's 2 measurements of systolic blood pressure while a subject was seated. Body mass index was calculated as weight in kilograms divided by the square of height in meters. High-density lipoprotein (HDL) and total cholesterol concentrations were measured by automated enzymatic techniques.[9] Participants were considered to have diabetes if they reported receiving treatment with insulin or a hypoglycemic agent or if they had fasting plasma glucose levels ≥126 mg/dl (7.0 mmol/L). Participants who were missing information on treatment status or fasting glucose were classified as having diabetes if they had a nonfasting glucose concentration ≥200 mg/dl (11.1 mmol/L), or a nonfasting glucose concentration from 126 to 200 mg/dl plus a history of diabetes, or if nonfasting glucose concentration was 126 to 200 mg/dl with a diabetes diagnosis at a subsequent Framingham examination. Use of antihypertensive and cholesterol-lowering medication was self-reported. Depressive symptomatology was measured using the Center for Epidemiologic Studies Depression scale (range 0 to 51).

There were 3,413 participants in the dataset who completed offspring examination 6, on which the present investigation was based. After implementation of exclusion criteria (details shown in Figure 1), the final sample was 1,454 (782 women and 672 men). Cardiovascular disease events (as part of exclusion criteria) were identified in participants since the onset of the Framingham Offspring Study (1971 to 1975) and included recognized myocardial infarction, coronary insufficiency, cerebrovascular events (including cerebral atherothrombotic infarction, cerebral embolism, intracerebral hemorrhage, subarachnoid hemorrhage, and other cerebrovascular accident), and congestive heart failure. Those excluded (n = 1,913) were more likely to be older (mean age 60.0 vs 57.2 years, respectively, $p < 0.0001$), to be taking antihypertensive medication (31.6% vs 23.5%, $p < 0.0001$) and cholesterol-lowering medication (15.2% vs 10.0%, $p < 0.0001$), and to be diabetic (11.3% vs 8.4%, $p = 0.006$). Included and excluded participants did not differ significantly for other variables including gender, body mass index, HDL/total cholesterol ratio, depression score, and current smoking.

Age-adjusted means and proportions were calculated for baseline covariates and compared across cumulative SEP categories. Multivariable logistic regression analyses evaluated associations between cumulative SEP (categorized as low [score of 0 or 1], medium [score of 1 or 2], and high [score of 4 to 6] as described earlier) and ABI (≤1.1 vs >1.1 to 1.4 for primary analyses, ≤1.0 vs >1.0 to 1.4 for secondary analyses in women). All analyses were adjusted for age. Subsequent models were also adjusted for the CHD risk factors smoking, body mass index, systolic blood pressure, total/HDL cholesterol ratio, antihypertensive medication, cholesterol-lowering medication, depressive symptomatology, and diabetes. Further analyses of individual SEP measurements (father's education, own education, own oc-

cupation) in relation to ABI were performed to evaluate whether SEP at any of these life-course periods particularly contributed to associations of cumulative SEP with ABI. These latter analyses were adjusted for age with subsequent adjustment for other individual SEP measurements and final adjustment for the CHD risk factors described earlier. All analyses performed were gender-specific because there was evidence of effect modification by gender ($p = 0.01$ for interaction between cumulative SEP score and gender). Generalized estimating equations were used to account for clustering of outcomes by family. Pearson correlation coefficients and variance inflation factors were used to evaluate colinearity, and no evidence of colinearity was found. The 3 primary SEP variables (father's education, own education, and own occupation) were not correlated highly enough to be of concern when simultaneously including all 3 in a single multivariable model (pairwise correlation coefficients ranged from 0.25 to 0.51). Power analyses were performed using PS Power and Sample Size Calculation 3.0.2 (Dupont and Plummer, Vanderbilt University, Nashville, Tennessee) according to methods for cohort studies with dichotomous outcomes.[10,11]

Results

Participants in the study sample had a mean age of 57 years (range 38 to 80) and 53.8% were women. Mean ABIs ± SDs were 1.16 ± 0.10 in men and 1.09 ± 0.10 in women ($p < 0.0001$). Prevalences of low ABI defined as ≤1.1 were 21% in men and 49% in women; low ABI defined as ≤1.0 demonstrated prevalences of 4.8% in men and 16% in women. In age-adjusted analyses in men lower cumulative SEP was associated with older age, lower ABI, higher body mass index, lower HDL cholesterol, higher total/HDL cholesterol ratio, higher prevalence of current smoking, and higher depression score. In women lower cumulative SEP was associated with older age, higher body mass index,

* Adjusted for age.

† Adjusted for age and other socioeconomic position measurements (i.e., socioeconomic position other than the exposure of interest; e.g., analyses on father's education are adjusted for own education and own occupation).

‡ Adjusted for age, other socioeconomic position measurements, smoking, body mass index, systolic blood pressure, total/high-density lipoprotein cholesterol ratio, antihypertensive medication, cholesterol-lowering medication, depressive symptomatology, and diabetes.

lower HDL cholesterol, higher total/HDL cholesterol ratio, higher prevalence of diabetes and current smoking, and higher depression score (Table 1). In addition, R^2 from univariate linear regression analyses showed that cumulative SEP explained 1.4% of the variance in ABI in men and 0.7% of the variance in women. Examples of the contribution of other specific CHD risk factors to the variance (R^2) in ABI were smoking (5.5% in men, 3.0% in women), hypertension medication (2.9% in men, 1.8% in women), systolic blood pressure (1.5% in men, 4.1% in women), and diabetes (1.3% in men, 0.1% in women).

Age-adjusted logistic regression analyses showed that lower cumulative SEP across the life course was associated with greater prevalence of low ABI in men (odds ratio [OR] 2.00, 95% confidence interval [CI] 1.28 to 3.14, for low vs high cumulative SEP score) and not in women (OR 0.94, 95% CI 0.63 to 1.38; Table 2). Further adjustment for CHD risk factors did not attenuate the association in men (OR 2.04, 95% CI 1.22 to 3.42). In analyses of individual SEP measurements own education was associated with low ABI in men with associations remaining after adjustment for age, other SEP measurements, and CHD risk factors (OR 4.13, 95% CI 1.86 to 9.16, for ≤12 years of education vs ≥17 years; Table 3). Own occupation was also associated with low ABI in men in age-adjusted analyses. Further adjustment for other SEP measurements and CHD risk factors attenuated the association for the laborer category (OR 1.22, 95% CI 0.70 to 2.11) but not for the homemaker/clerical/sales category (OR 1.92, 95% CI 1.01 to 3.62). No significant associations were observed between father's education and ABI in men (Table 3). In women no association was observed between own education and ABI (OR 1.23, 95% CI 0.76 to 2.00) or between own occupation and ABI (OR 1.36, 95% CI 0.76 to 2.41; Table 4). However, father's education in the lower-than-high-school category was weakly associated with a lower prevalence of low ABI after adjustment for other SEP measurements and CHD risk factors (Table 4). Additional analyses with low ABI alternatively defined as ≤1.0 in women revealed somewhat higher effect sizes; however, associations were still not statistically significant (supplementary Tables 1 and 2, available online). Patterns of association for cumulative SEP when using father's occupation as the measurement of childhood SEP were similar to results obtained when father's education was used (supplementary Table 3, available online). In addition, associations between father's occupation and ABI were not significant in men or women (data not shown), similar to analyses using father's education.

Discussion

Life-course cumulative SEP was inversely associated with low ABI, an indicator of subclinical atherosclerosis, in men and not in women. The effect in men appeared to be largely due to early adulthood SEP measured as participants' education compared to childhood SEP or active professional-life SEP. Adjustment for CHD risk factors did not attenuate the association in men, suggesting these may not be explanatory mechanisms. Few studies have investigated associations of cumulative SEP in relation to ABI. Carson et al[12] reported inverse associations between cumulative SEP and peripheral arterial disease (ABI <0.9) in middle-aged white men (n = 4,284) and women (n = 5,170) of the ARIC. Similar to our findings, they found that SEP in the young adulthood period was associated more strongly with peripheral arterial disease than in the childhood or older adulthood periods. Furthermore, associations of SEP with peripheral arterial disease were found in men and women, whereas our study did not find associations in women.

In previous publications evaluating relations between adulthood SEP only (rather than cumulative SEP) and ABI, studies in developed countries have shown generally similar findings to our study. Fowkes et al[13] demonstrated in a cross-sectional survey of participants 55 to 74 years old in the Edinburgh Artery Study that mean ABI decreased consistently with decreasing educational level in men and not in

women. Rooks et al[14] found inverse associations between various measurements of adulthood SEP (education, income, home ownership, and financial assets) and ABI in an elderly population of black and white men and women (n = 3,075). However, after adjustment for race, age, household family size, marital status, and study site, associations between education and low ABI persisted in men but not in women. Another study of 1,025 subjects in the Chianti area of Italy reported significantly lower age-adjusted mean ABIs in men but not in women with low education versus high education.[15]

Because there were large SEP gradients in some of the strongest risk factors for peripheral arterial disease (smoking and diabetes), lack of associations in women was somewhat surprising although consistent with other studies focused on associations of adulthood SEP with ABI.[13–15] One potential explanation is that the use of inappropriate cutpoints for defining low ABI in women may have contributed to null findings. There is evidence that ABI values are intrinsically lower in women compared to men[8] even after adjustment for height (which is suggested to contribute to the lower ABI observed in women).[13] McDermott et al[6] found evidence of excess coronary and carotid atherosclerosis with an ABI value up to 1.1 in men but only with an ABI value up to 1.0 in women. In our analyses, using lower ABI cutpoints ($\leq$1.0 instead of $\leq$1.1) to define low ABI somewhat increased effect sizes for associations between SEP and ABI in women; however, these effects were small and not statistically significant.

In our investigation measurements of childhood SEP (father's education and father's occupation) were not associated with low ABI with the exception of a slight positive association between father's education and low ABI in women. To the best of our knowledge the association between childhood SEP and subclinical atherosclerosis measured as ABI has rarely been examined. However, inverse associations between childhood SEP and clinically manifest CHD are more established and consistently observed.[16,17] In the present investigation those who were excluded from analyses because of cardiovascular disease were more likely to have lower childhood SEP and low ABI (data not shown) compared to those included. This may have led to an underestimation of an association between childhood SEP and low ABI in the study sample.

There is evidence suggesting that the effect of SEP on subclinical and clinically manifest CHD is partly mediated through CHD risk factors.[18–21] In this investigation adjustment for CHD risk factors did not attenuate the associations observed, similar to results from several previous studies reporting on associations between SEP and subclinical atherosclerosis.[22–25] Carson et al[12] reported that none of the risk factors tested in their study was a strong or moderate mediator of the association between SEP and peripheral arterial disease (ABI $<$0.9). However, it is important to note that methodologic biases may arise because of statistical adjustment for potential mediators and confounders.[26] Other potential risk factors not accounted for in this study may also play a role in the association between SEP and atherosclerosis development such as novel CHD risk markers,[27] psychosocial stressors,[28] and genetic susceptibility.[29]

A strength of this investigation was that measurements of childhood SEP were assessed directly from the participants' parents. Thus this measurement was less likely to be subject to measurement error compared to studies that obtained measurements of childhood SEP retrospectively through personal recall by participants.[16] Furthermore, rigorous quality assurance and quality control methods were used in this study to ensure high-quality measurements of outcomes and covariates.

Several limitations of this study should be noted. Subjects in this study population were predominantly of European descent (representing the demographics of the city of Framingham, Massachusetts at study onset); thus results from this study are not necessarily generalizable to other races and ethnicities. Furthermore, primary analyses on life-course SEP included only 3 measurements: father's education, own education, and own occupation. Additional measurements (such as SEP during in utero period) or more comprehensive measurements (such as multiple measurements of occupation throughout the life course) of life-course SEP would provide richer data on the potential contributions of life-course SEP to low ABI.

HEALTH CARE REFORM

Collaborative Care of Opioid-Addicted Patients in Primary Care Using Buprenorphine

Five-Year Experience

Daniel P. Alford, MD, MPH; Colleen T. LaBelle, RN; Natalie Kretsch, BA; Alexis Bergeron, MPH, LCSW; Michael Winter, MPH; Michael Botticelli, MEd; Jeffrey H. Samet, MD, MA, MPH

Background: Opioid addiction is a chronic disease treatable in primary care settings with buprenorphine hydrochloride, but this treatment remains underused. We describe a collaborative care model for managing opioid addiction with buprenorphine hydrochloride–naloxone hydrochloride dihydrate sublingual tablets.

Methods: Ours is a cohort study of patients treated for opioid addiction using collaborative care between nurse care managers and generalist physicians in an urban academic primary care practice during a 5-year period. We examine patient characteristics, 12-month treatment success (ie, retention or taper after 6 months), and predictors of successful outcomes.

Results: From September 1, 2003, through September 30, 2008, 408 patients with opioid addiction were treated with buprenorphine. Twenty-six patients were excluded from analysis because they left treatment owing to preexisting legal or medical conditions or a need to transfer to another buprenorphine program. At 1 year, 196 of 382 patients (51.3%) underwent successful treatment. Of patients remaining in treatment at 12 months, 154 of 169 (91.1%) were no longer using illicit opioids or cocaine based on urine drug test results. On admission, patients who were older, were employed, and used illicit buprenorphine had significantly higher odds of treatment success; those of African American or Hispanic/Latino race had significantly lower odds of treatment success. These outcomes were achieved with a model that facilitated physician involvement.

Conclusion: Collaborative care with nurse care managers in an urban primary care practice is an alternative and successful treatment method for most patients with opioid addiction that makes effective use of time for physicians who prescribe buprenorphine.

OPIOID ADDICTION IS A chronic, relapsing brain disease that affects millions of Americans and produces tremendous burden on the health care system.[1,2] Recent epidemiologic studies[3] have revealed alarming increases in opioid addiction and overdoses, particularly with regard to prescription opioids. Less than 25% of individuals addicted to opioids receive addiction treatment.[3] For more than 45 years, research has confirmed that opioid agonist therapy (ie, methadone hydrochloride) is a highly effective treatment for opioid addiction provided outside primary care.[4-6] In 2002, US physicians gained the opportunity to treat opioid-addicted patients with buprenorphine hydrochloride in primary care settings, commonly referred to as office-based opioid treatment (OBOT).[7] This treatment has been shown to be effective in primary care settings[8-15]; however, it remains underused in traditional care models.[16] One consistently cited barrier preventing OBOT expansion is lack of adequate clinical support given the additional needs for patient monitoring.[16-18] Although collaborative care improves management of other chronic diseases (eg, hypertension[19] and diabetes mellitus[20]), experience with this model for the treatment of opioid addiction in primary care has not been described.[21]

On September 1, 2003, an OBOT program using a collaborative care model was started at Boston Medical Center, an urban academic medical setting. This model accommodated the large public demand for OBOT and faculty physicians with part-time clinical practices. We describe Boston Medical Center's OBOT program and report on patient and program outcomes.

METHODS

PROGRAM DESCRIPTION

Collaborative Model of Care

The collaborative care OBOT program included a full-time nurse program director, nurse care managers (NCMs), a program coordinator, and generalist physicians with part-time clinical practices. The nurse program director (0.40 full-time equivalent) supervised the NCMs and program coordinator and integrated care with OBOT physicians. The program coordinator (1 full-time equivalent), a former medical assistant, was trained to collect standardized intake information regarding individuals requesting OBOT. The NCMs, registered nurses who completed a 1-day buprenorphine training program, performed patient care roles, followed treatment protocols, and maintained a standard of clinical practice that satisfied federal regulations for buprenorphine treatment. Their clinical responsibilities included assessing for the appropriateness for OBOT, educating patients, obtaining informed consent, developing treatment plans, overseeing medication management, referring to other addiction treatment, monitoring for treatment adherence, and communicating with prescribing physicians, addiction counselors, and pharmacists. Collaboration with pharmacists reduced the OBOT physician burden by allowing buprenorphine prescriptions with multiple refills while allowing for cancellation of the refills if the patient showed nonadherence. The OBOT program currently includes NCMs (2.2 full-time equivalents) for 22 clinical half-day sessions per week. The OBOT physicians, all generalists with part-time clinical practices, reviewed and supplemented the NCM assessments (including laboratory results), performed physical examinations, prescribed buprenorphine, and followed up patients at least every 6 months or more frequently if needed. The OBOT program includes 9 generalist physicians, all waivered to prescribe buprenorphine by completing the required 8 hours of buprenorphine training; 3 of them (including D.P.A. and J.H.S.) are certified by the American Board of Addiction Medicine. The physicians had an average of 3 primary care half-day sessions each week, ranging from 1 to 6.

The treatment model included 3 stages: (1) NCM and physician assessment (appropriateness for OBOT and intake evaluations), (2) NCM-supervised induction and stabilization (buprenorphine dose adjustments during days 1-7), and (3) maintenance (buprenorphine treatment with monitoring for illicit drug use and weekly counseling) or discharge (voluntary or involuntary).

Assessment

The program coordinator conducted a scripted screening, by telephone or in person, documenting substance use, addiction treatment history, medical and psychiatric history, medications, addiction treatment goals, and availability of social support. The nurse program director reviewed the screen and triaged the patient to NCM and physician intake appointments or to other treatment options. Patients were triaged to other treatment options (eg, detoxification program) if they had active co-occurring substance use disorders. The NCM intake included documentation of opioid dependence diagnosis based on a checklist of the *Diagnostic and Statistical Manual of Mental Disorders* (Fourth Edition, Text Revision)[22] criteria, assessing ability to adhere to treatment plan, mental health stability, polysubstance use, absence of painful conditions requiring long-term opioid analgesic therapy, and absence of medical contraindications (eg, pregnancy). All patients transferring from methadone maintenance were required to taper their methadone dose to 30 mg/d.[23] Individuals were excluded if they were unwilling to stop all illicit drug use or were not interested in buprenorphine maintenance lasting at least 6 months. Patients were educated regarding the scientific basis of buprenorphine maintenance. All patients signed an informed consent and treatment agreement, which included a weekly counseling requirement with a release for communication. Initial laboratory tests included viral hepatitis and syphilis serologic tests, liver function tests, pregnancy tests, and a urine drug test for opiates, cocaine, benzodiazepines, barbiturates, and amphetamines. Because many of these patients were new to primary health care, laboratory tests for a broader primary care evaluation were also ordered, including a complete blood cell count and electrolyte levels. Starting June 1, 2006, all patients were also tested for oxycodone, methadone, and buprenorphine. Patients were required to test negative for all nonprescribed substances other than opioids before starting buprenorphine treatment.

The OBOT physician intake included reviewing and supplementing the NCM assessment and treatment plan, performing a physical examination, and evaluating any medical issues (eg, need for hepatitis vaccinations). Patients with active psychiatric diagnoses were comanaged with a psychiatrist, with releases to facilitate communication.

Induction and Stabilization

The physician prescribed buprenorphine based on federal guidelines.[23] Induction and stabilization occurred during the first 7 days. Induction occurred on site (ie, in the office) with direct observation by the NCM for signs of opioid withdrawal before the first dose of buprenorphine and signs of precipitated withdrawal after the first dose. Physicians were not present during buprenorphine induction but were available by pager for consultation. Dose adjustments were made based on OBOT program protocols. The combination tablet buprenorphine hydrochloride–naloxone hydrochloride dihydrate was used for all inductions. During dose stabilization (days 2-7), dosing occurred off site (ie, at home), with patients having at least daily telephone contact with the NCM to assess for withdrawal and adverse effects. Telephone support continued until a stable maintenance dose was achieved, usually 8 to 16 mg. All patients were reassessed in person by the NCM on day 8 or sooner if needed.

Maintenance

Ongoing monitoring occurred at follow-up appointments at least weekly for the first 4 to 6 weeks followed by visits every 2 to 4 weeks if adherent (ie, 4 consecutive urine drug tests with negative results for illicit drugs and positive results for buprenorphine and attending at least 3 of 4 counseling sessions per month). Patients who maintained sobriety and treatment adherence for 3 months had their NCM visit frequency decreased to a monthly basis, then once every 3 months. Patients seen on a less than monthly basis had up to 6 random callbacks per year for unscheduled urine drug testing and pill counts. Patients were always subject to requests to return to the clinic within 72 hours for urine drug tests, observed dosing, pill counts, or treatment plan revisions. Urine drug tests occurred at every NCM visit and OBOT physician visit at least every 6 months. All patients with abnormal urine drug test results were called in the following week to meet with the NCM. If a patient continued to use illicit drugs (eg, opiates, cocaine, and benzodiazepines) or showed nonadherence with scheduled appointments or monitoring requests (ie, urine drug tests or pill counts), the NCM intensified treatment, including increased visits to 2 or more times per week for pill

counts, observed urine drug tests and adjusted buprenorphine dose, reengaged social supports, and intensified counseling.

The NCMs and physicians encouraged patients to attend self-help groups and mandatory weekly addiction counseling. Most addiction counseling (individual and group) was offered by outside addiction services with confidentiality releases. For an 18-month period, a few patients were seen by an in-house counselor. The NCM reminded patients of upcoming appointments with addiction counselors and OBOT physicians.

Discharge

Patients were referred to methadone maintenance treatment if they continued to use illicit opiates as determined by 3 consecutive urine drug test results positive for opiates despite increased buprenorphine dose or if they needed more structured care (eg, daily observed dosing due to concerns regarding medication misuse) than could be offered in an office-based practice. Patients were involuntarily discharged if they declined transfer to methadone maintenance after continued illicit opiate use or showed repeated nonadherence with more than 3 OBOT appointments or monitoring requests (ie, supplying urine sample for drug testing or bringing in remaining pills for pill counts). Patients were also discharged if they engaged in disruptive behavior. Patients could request a buprenorphine taper at any time but were encouraged to wait until they had achieved at least 6 months of abstinence and treatment adherence.

PATIENT CHARACTERISTICS AND DATA COLLECTION PROCEDURE

Patient characteristics documented included age; sex; race; employment; history of psychiatric illness; human immunodeficiency virus and hepatitis status; opioid of choice; years of opioid use; history of overdose; other substance use (tobacco, alcohol, cocaine, or benzodiazepines); previous addiction treatment, including history of opioid agonist therapy (ie, methadone or buprenorphine); and current use of illicit buprenorphine. A retrospective clinical medical record review was conducted for all patients admitted to the Boston Medical Center OBOT program from September 1, 2003, through September 30, 2008, with 12-month outcome data continued through September 30, 2009. All data were originally collected by OBOT clinical staff for the purposes of clinical care.

OUTCOME ASSESSMENTS

Treatment Outcomes at 12 Months

Treatment status (ie, successful, unsuccessful, or methadone maintenance transfer) was determined for all patients at 12 months or at program departure, whichever came first. Successful treatment was defined as treatment retention or buprenorphine taper after treatment adherence and absence of illicit drug use for at least 6 months. Treatment retention required patients to demonstrate a consistent pattern of adherence, including physician, nursing, and counseling appointments; monitoring requests (ie, urine drug tests or pill counts); no buprenorphine diversion (ie, accurate pill counts or positive buprenorphine drug test results); and willingness to engage in intensified treatment (eg, increased frequency of NCM visits) when illicit drug use occurred. Unsuccessful treatment included loss to follow-up, involuntary discharge due to continued illicit drug use, treatment nonadherence or disruptive behavior, or voluntary discharge due to adverse effects of buprenorphine. Treatment was considered neither successful nor unsuccessful if patients voluntarily transferred to methadone maintenance treatment for more structured care (eg, observed daily dosing) or for full opioid agonist therapy due to opioid craving while taking maximum doses of buprenorphine. Records were reviewed for the specific date of and reason for discharge from the program. Patients who left the program because of preexisting legal or medical conditions or transferred to another OBOT program because of relocation or consolidation of their care (eg, the same psychiatrist to treat mental illness and opioid addiction) were not included in analyses because treatment discharge was not related to the buprenorphine treatment program.

Illicit Drug Use

Both scheduled and random callback urine drug tests were conducted at least once every 3 months. In each study assessment window (ie, 3, 6, 9, and 12 months), the result of the test performed the closest, yet prior, to the time point was examined. For those patients who missed appointments within the 3-month interval, no urine sample was obtained; consequently, the number of urine samples available at each testing interval was less than the number of patients enrolled in that interval. Patients who were unable to be contacted were still considered enrolled in the program until their 30-day prescriptions ran out. Urine drug tests were mostly unsupervised, but measures were taken to try to minimize falsified tests (eg, testing urine temperature). Urine collections were supervised for patients with a recent abnormal urine test result, including a cold or diluted specimen, and for patients with aberrant behaviors (eg, missed appointments).

Program Activity

The average workload for the program coordinator was determined by tracking inquiries for OBOT treatment. Caseload for NCMs and OBOT physicians was determined by their schedules.

STATISTICAL ANALYSIS

Descriptive statistics (eg, means and proportions) were used to characterize the sample. Exploratory, hypothesis-generating tests were then performed to compare characteristics between patients with successful and unsuccessful treatments at 12 months. The χ^2 or Fisher exact tests (for dichotomous variables) and t tests or Wilcoxon rank sum tests (for continuous variables) were used to assess factors associated with treatment success at 12 months. Characteristics that were significantly associated in bivariate analyses, along with other characteristics deemed clinically important, were entered into a multivariable logistic regression model, with treatment success as the dependent variable. Reported P values are 2-tailed, and $P < .05$ was considered statistically significant. All analyses were run using SAS/STAT software, version 9.1 (SAS Institute Inc, Chicago, Illinois). This research was approved by the institutional review board at Boston University Medical Center.

RESULTS

PATIENT CHARACTERISTICS

In 5 years, 408 patients with opioid dependence were admitted to the OBOT program. Twenty-six patients were excluded from exploratory analysis because they left treatment owing to preexisting legal issues leading to incarceration (n=13) and medical conditions unrelated to their buprenorphine treatment (chronic pain [n=3] and

Table 2. Treatment Outcomes at 12 Months of 382 Opioid-Dependent Patients Entering Office-Based Opioid Treatment in Primary Care

Outcome	Patients, No. (%)
Successful treatment	196 (51.3)
Treatment retention	187 (49.0)
Successful taper after 6 months of adherence[a]	9 (2.4)
Unsuccessful treatment	162 (42.4)
Lost to follow-up	113 (29.6)
Nonadherence despite enhanced treatment[a]	46 (12.0)
Administrative discharge due to disruptive behavior	2 (0.5)
Adverse effects of buprenorphine hydrochloride	1 (0.3)
Transfer to methadone hydrochloride treatment program	24 (6.3)

[a] Adherence was defined as attending scheduled office-based opioid treatment program appointments, complying with required monitoring (ie, urine drug tests or pill counts), absence of evidence of buprenorphine diversion, and lack of sustained illicit opiate use.

advanced-stage AIDS [n=1]) or transferred to another OBOT program because of relocation or consolidation of their care (n=9), leaving 382 patients. This group, described in **Table 1**, was predominantly male (252 [66.0%]) and white (254 [66.5%]). The mean age was 39 years; 132 (34.6%) were employed at admission. Comorbidities were common; 252 (66.0%) reported psychiatric illness and 192 (50.3%) tested positive for hepatitis C antibody. On admission, patients were using the following: heroin (with or without prescription opioids), 231 (60.5%); prescription opioids exclusively, 64 (16.8%); methadone from a maintenance program, 51 (13.4%); and buprenorphine from another OBOT program, 36 (9.4%). Past-year use of tobacco (304 [79.6%]) and cocaine (165 [43.2%]) was common. A total of 323 (84.6%) reported a history of inpatient detoxification; 221 (57.9%), past opioid agonist maintenance treatment; 40 (10.5%), current use of illicit buprenorphine; and 176 (46.1%), history of opioid overdose.

PATIENT OUTCOMES

Patient outcomes are described in **Table 2**. At 12 months, 196 of the 382 patients (51.3%) showed a successful outcome (187 [49.0%] remained in treatment and 9 [2.4%] were tapered after 6 months of adherence and the absence of illicit drug use), and 162 patients (42.4%) showed an unsuccessful outcome (113 [29.6%] lost to follow-up and 49 [12.8%] discharged). A few patients (24 [6.3%]) had courses of treatment that were considered neither successful nor unsuccessful because those patients voluntarily transferred to methadone maintenance treatment for more structured care or for full opioid agonist therapy.

Patients who achieved successful outcomes were compared with those who had unsuccessful outcomes to determine factors associated with treatment success. In bivariate analyses, treatment success at 12 months was significantly associated with the following characteristics on admission: female sex, white race, being employed, self-maintaining with illicit buprenorphine, prescription opioid abuse or methadone maintenance, and no self-report of past-year cocaine use.

Abbreviations: CI, confidence interval; OR, odds ratio.
[a] Twenty-four patients transferred to methadone maintenance were excluded from this analysis, and data were missing for an additional 2 patients.
[b] $P<.05$.
[c] $P<.01$.

These characteristics, along with factors considered to be clinically important to successful treatment (ie, age, past methadone maintenance treatment, self-reported psychiatric illness, and history of opioid overdose), were entered into a multivariable logistic regression model (**Table 3**). The patients who were transferred to methadone maintenance treatment were excluded from the analysis of treatment success because they could arguably be perceived as having successful or unsuccessful courses of treatment; 358 patients remained. On admission, patients who were older, employed, and self-maintained with illicit buprenorphine had significantly higher odds of treatment success, whereas those of African American or Hispanic/Latino race had significantly lower odds of treatment success. Of patients remaining

Table 4. Urine Drug Tests During 12 Months[a] for Opioid-Dependent Patients Retained in Office-Based Opioid Treatment in Primary Care

[b] Oxycodone testing started on June 1, 2006.

in treatment at 12 months, 154 of 169 (91.1%) were no longer using illicit opioids or cocaine based on the results of urine drug testing (**Table 4**).

PROGRAM ACTIVITY

On average, the program coordinator received 20 calls per week requesting OBOT. An NCM saw 75 patients per week, and each OBOT physician prescribed to an average of 35 patients (range, 13-68) per month.

COMMENT

This large observational study of OBOT with buprenorphine in an academic medicine practice serves as a treatment model for facilitating access and improving outcomes in patients with opioid addiction. Collaborative care with NCMs resulted in feasible initiation and maintenance of buprenorphine for most patients (51.3%) admitted, which is comparable to previous studies in primary care settings involving smaller numbers of patients with 6- to 12-month follow-up.[9-15]

The collaborative care model ensured program compliance with federal laws[24] (eg, limits to the number of patients treated per OBOT physician) while maintaining access to a large number of patients. OBOT is ideal for collaborative care because much of the clinical work (eg, assessment, medication management, and monitoring) is based on established protocols.[23] Having relevant clinical data (eg, nursing assessments, documentation of treatment adherence, and urine drug test results) before physician visits allowed efficient use of physician time to focus on patient management (eg, dose adjustments and continued maintenance vs taper). In this particular setting, collaborative care allowed academic generalist physicians with research, administrative, and part-time clinical responsibilities to treat a large number of patients, many of whom had complex psychosocial needs. As described, the NCM was central to day-to-day clinical care with daily open access to address the myriad needs (eg, housing, employment, and health insurance) of this complicated population. This model satisfied a key principle of coordinated care by "assuring accessibility, continuity and high quality care that includes effective communication with, education of, and outreach to patients."[25(p404)]

Other important factors may have affected the outcomes of this intervention. Open communication between the NCM and addiction counselors improved patients' ability to comply with this essential element of good addiction care. Access to methadone maintenance allowed the program to safely transfer patients who required a more structured treatment modality.

We identified several preadmission factors associated with treatment success, some of which were consistent with the finding of previous studies and some that were not. Similar to previous reports, patients who were older[12] and employed[11,15] had more successful outcomes. The finding that self-maintaining with illicit buprenorphine on admission predicted success has not been previously published. These patients reported self-treating their opioid addiction with illicit buprenorphine rather than trying to get high. This suggests that these patients were highly motivated to obtain a dependable and health insurance–covered source of buprenorphine and to avoid relying on the illicit market. This finding is similar to that of other studies[26,27] that found that patients who self-treated with illicit methadone were more likely to have positive treatment outcomes. We did not find that cocaine use and psychiatric illness were associated with worse outcomes. This suggests that patients with these co-occurring issues should not be excluded from consideration for office-based treatment. We found that African American or Hispanic/Latino race lowered the odds of treatment success in our program. This finding requires confirmation and further study to better understand the ways that race and clinic structure may affect success in OBOT.

Several limitations of this study should be considered. Although data were collected prospectively using a medical record designed for OBOT patients, the study was retrospective, examining patients from a clinical program. In addition, follow-up information was not available after patient departure from the program. However, of patients who left the program earlier than 12 months, the reasons for leaving (ie, successful or unsuccessful treatment or methadone maintenance treatment transfer) were known. Urine drug test protocols also changed over time: testing for semisynthetic and synthetic opioids was not standardized un-

til June 1, 2006, so early urine results may underestimate prescription opioid abuse. However, once prescription opioid testing began, the rates of positive urine test results for illicit opioids did not change. This study did not have a control group, but this was acceptable because its purpose was not to retest the efficacy of buprenorphine treatment but to evaluate the feasibility of delivering this known effective treatment using a collaborative care model. Lastly, an experienced, skilled NCM played an essential role in caring for patients, and the ability to generalize such a model may depend on skills of such key individuals. However, the issue simply speaks to the need for the training of a nursing workforce with skills in caring for patients with addictions. In an effort to increase nursing involvement in buprenorphine treatment, a federally supported "Guide for Nurses" has recently been developed.[28]

In conclusion, OBOT can be offered effectively in a primary care practice using a collaborative care model. In this model, heavily reliant on NCMs, patient-level outcomes were comparable to those derived from other physician-centered approaches. This study of collaborative care adds to the growing body of evidence that office-based treatment of opioid addiction is feasible in primary care settings.

Original Article

Assessing the Impact of Patient Navigation

Prevention and Early Detection Metrics*

Tracy A. Battaglia, MD, MPH[1]; Linda Burhansstipanov, MSPH, DrPH[2]; Samantha S. Murrell, MPH[1]; Andrea J. Dwyer, BS[3]; and Sarah E. Caron, MPH[1]; on behalf of The Prevention and Early Detection Workgroup from the National Patient Navigation Leadership Summit

BACKGROUND. The lack of comparable metrics to evaluate prevention and early detection patient navigation programs impeded the ability to identify best practices. **METHODS.** The Prevention and Early Detection Workgroup of the Patient Navigation Leadership Summit was charged with making recommendations for common clinical metrics specific to the prevention and early detection phase of the cancer care continuum. The workgroup began with a review of existing literature to characterize variability in published navigation metrics; then developed a list of priority recommendations that would be applicable to the range of navigation settings (clinical, academic, or community-based). **RESULTS.** Recommendations for researchers and program evaluators included the following: 1) Clearly document key program characteristics; 2) Use a set of core data elements to form the basis of your reported metrics; and 3) Prioritize data collection using methods with the least amount of bias. **CONCLUSIONS.** If navigation programs explicitly state the context of their evaluation and choose from among the common set of data elements, meaningful comparisons among existing programs should be feasible. ***Cancer*** **2011;117(15 suppl):3553–64.** © *2011 American Cancer Society.*

INTRODUCTION

Cancer control begins with primary and secondary prevention efforts which aim to reduce cancer incidence and advanced disease, respectively. The evidence is clear that certain cancers—those caused by tobacco use, viruses, or sun exposure, for example—can be prevented completely. Regular use of proven screening modalities, such as Pap tests for cervical cancer and colonoscopy for colorectal cancer, also result in prevention through the removal of precancerous lesions. Other screening tests can detect cancers of the breast, colon, rectum, cervix, prostate, oral cavity, and skin at early stages and translate into a direct mortality benefit when abnormal screening is followed by prompt diagnosis and treatment. Mounting evidence suggests that the delivery of prevention and early detection (PED) services are responsible for a substantial portion of the documented reduction in both cancer incidence[1] and mortality[1,2] in the United States.

It is also well documented that not all populations benefit equally from these prevention efforts, in part because our current healthcare delivery system does not provide consistent, high-quality care to all.[3] Whether defined by age, gender, race, insurance status, geographic location, or comorbid medical condition, certain populations face significant barriers to accessing timely and quality cancer PED services consistently, if at all.[4-6] Patient Navigation, which targets barriers faced by

vulnerable populations in accessing timely, quality cancer care,[7] was designed to address the critical disconnect between the discovery and delivery of life-saving cancer care services. In fact, the first patient navigation program was started in Harlem, New York, to increase the delivery of mammography screening to Black women who were too often presenting with advanced cancer as a result of a lack of screening.[8] This groundbreaking work used lay navigators from the local community to help at-risk women overcome barriers to accessing screening and diagnostic services and resulted in profound improvements in breast cancer care.[8] Since then, a growing number of studies documenting the promise of navigation have resulted in its widespread adoption as a means to deliver PED services.[9-15]

As navigation becomes integrated into standard cancer care services across the country,[16] the lack of comparable metrics to evaluate these programs in different settings with diverse target populations impedes our ability to identify best practices and realize the full potential of this promising intervention. Thus, we aim here to provide recommendations for researchers and program evaluators to consider adopting when measuring the impact of their PED navigation programs. The intent is to facilitate consistent use of priority metrics, including process and intermediate outcome measures, that document the type and quality of work performed by prevention and early detection Patient Navigators (PN) working in diverse settings (clinical, academic, community-based organizations). Through the use of such measures, public health and health reform policies may be generated to provide reimbursement for services that ensure the delivery of timely, quality cancer prevention.

METHODS

In March 2010, the American Cancer Society hosted the first National Patient Navigation Leadership Summit, where it convened cancer clinicians, researchers, and practicing public health experts to develop a national evaluation agenda for patient navigation. The Prevention and Early Detection (PED) Workgroup was charged with making recommendations for common clinical metrics specific to the prevention and early detection phase of the cancer care continuum. The workgroup comprised 10 individuals, representing community-based organizations, clinical programs and academia with decades of experience implementing and evaluating patient navigation programs across diverse populations. The workgroup began with a review of existing literature to characterize variability in published metrics, then through discussion and consensus developed a list of priority recommendations.

In early 2010, the Summit Planning Committee conducted a comprehensive review of the navigation literature to guide discussion at the March meeting. The PED work group updated the literature review in October of 2010. We searched the Pubmed database to identify original articles published any year, in English, using the key terms "patient navigation," "patient navigator," "navigation," "navigator," or "case management." We also searched the references of each publication for additional relevant literature. In keeping with the scope of navigation as outlined by Dr. Freeman at the Summit, we included only intervention studies where navigators actively link patients to clinical services. Educational or outreach navigation for the delivery of prevention education in community settings were excluded. Likewise, studies that used labels for functional navigators, such as community outreach worker, community health advisor/aide, promotores, or lay health advisor/educator, may have been excluded. We present here findings from the synthesis of 32 published articles we believed exemplified the breadth of published metrics. Although not meant to be an exhaustive review of the extensive literature, the studies included are representative of the variability in existing metrics.

FINDINGS FROM LITERATURE REVIEW

Most studies target breast and colorectal cancer, with fewer targeting cervical, lung and/or prostate cancer. Reported clinical outcome metrics fall into 2 discrete points along the continuum of cancer care: 1) screening and 2) diagnosis, while the remaining metrics focus on the processes specific to the navigation program. To date, no patient navigation intervention study has reported final endpoints such as survival or mortality. Rather, the current literature focuses mainly on intermediate clinical outcomes in the form of the delivery of recommended cancer prevention services. Only 2 studies[17,18] document a potential mortality benefit in the form of a stage shift at the time of diagnosis. As discussed below and summarized in Tables 1 and 2, there exists wide variation in both the reporting of nonmodifiable program characteristics as well as how study outcome metrics are defined and reported.

Screening

We reviewed 20 navigation studies that targeted cancer screening as an outcome (Table 1). We include studies

Table 1. Variability in Published Patient Navigation Studies: Screening Metrics

Study	Setting		Disease	Eligibility Criteria	Navigation Mode	Outcome Metric	Follow-Up Period	Data Collection
Weber, 1997	Urban	Clinical	Breast	Age 52 - 77 Last mammo > 24 mo	Telephone	Receipt of mammo	10 mo	Medical record review
Burhansstipanov L, 2000	Urban	Community	Breast	Age ≥39 Last mammo > 18 mo	Face-to-face Telephone	Receipt of screening test	NR	Self-report
Dignan, 2005	Urban	Community	Breast	Age 40+ Last mammo > 18 mo	Face-to-face Telephone	Receipt of mammo	12 mo	Self-report
Jandorf, 2005	Urban	Clinical	Colorectal	Age 50+ FOBT > 1 yr FS or BE >5 yr Colonoscopy >10 yr	Telephone	Receipt of CRC screening	6 mo	Medical record review
Dietrich, 2006	Urban	Clinical	Breast Cervical Colorectal	Age 50 - 69 Overdue screening	Telephone	Adherence to recommended screening	18 mo	Medical record review
Ford, 2006	Urban	Clinical	Prostate Lung Colorectal	Age ≥55	Telephone	Receipt of next scheduled screening test	Time to next trial screening	Medical record review
Nash, 2006	Urban	Clinical	Colorectal	All colonoscopies	NR	Receipt of colonoscopy	11 mo	Medical record review
Paskett, 2006	Rural	Community	Breast	Age ≥ 41 Last mammo > 12 mo	Face-to-face Telephone	Receipt of mammo Barriers to mammo	12 mo	Medical record review
Myers, 2008	NR	Clinical	Colorectal	Age 50 - 79 Last visit < 24 mo	Telephone	Receipt of CRC screening	6 mo	Self-report Medical record review
Percac-Lima, 2008	Urban	Clinical	Colorectal	Age 52 - 79 FOBT > 1 yr FS or BE >5 yr Colonoscopy >10 yr	Telephone	Receipt of CRC screening Barriers to CRC screening	9 mo	Medical record review
Clark, 2009	Urban	Clinical	Breast	Age 18 - 75	Telephone	Receipt of mammo Maintenance screening behavior Timely adherence to diagnostic resolution	3 yr	Medical record review
Fernandez, 2009	Rural	Community	Breast Cervical	Age ≥50 Farm worker status	Face-to-face	Receipt of mammo, pap test	6 mo	Self-report Medical record review for validity
Han, 2009	NR	Community	Breast	Age 40+ Last mammo > 24 mo	Face-to-face Telephone	Receipt of mammo	6 mo	Self-report
Lasser, 2009	Urban	Clinical	Colorectal	Age 52 - 80 No CRC screening	Telephone	Receipt of CRC screening # patients contacted # hours spent navigating	6 mo	Medical record review
Ma, 2009	NR	Community	Colorectal	Age 50+ ACS guidelines for CRC screening	Face-to-face	Receipt of CRC screening Barriers to CRC screening	12 mo	Self-report verified with physician's office
Burhansstipanov L, 2010	Urban	Community	Breast	Age ≥ 39 Last mammo > 18 mo	Face-to-face Telephone	Receipt of screening mammo	NR	Self-report
Phillips, 2010	Urban	Clinical	Breast	Age 51 - 70 Last mammo > 18 mo	Telephone	Adherence to recommended screening	24 mo	Medical record review
Wang, 2010	Urban	Community	Cervical	Age 18+ Last pap > 12 mo	Face-to-face	Receipt of pap test	12 mo	Self-report

with community- and clinically based navigators in urban[19-25] and rural settings.[14,26] The studies targeted diverse populations, including American Indians,[14,15,19,26] Korean-Americans,[27] Chinese women,[28] Latinas,[14,29] Blacks,[14,26,30,31] non-English speaking,[32] poor Whites,[14] low-income.[32-34] Few programs were comprehensive targeting multiple cancer sites,[29,30,33] while most target only 1 disease-specific screening.[14,15,19-28,31,32,34-36] Even among studies targeting the same disease, eligibility criteria for inclusion in programs vary, including the age of participants and the time since their last screening. For example, 1 mammography screening navigation study included women 52 to 77 years who had not had a mammogram in the previous 2 years,[21] while another included women over 40 years whose last mammogram was 12 or more months prior.[26]

Most studies document receipt of a screening test as the goal of navigation and report the outcome simply as a screening rate, defined as the proportion of eligible subjects who complete a recommended test, such as a mammogram, Pap test, or colonoscopy, during the intervention period. The range of the intervention period across studies was wide, such that the time subjects were followed to assess the outcome varied from 6 months[21,24,32-34] to 3 years.[30] The most common follow-up period was 6 months.[22,23,27,29,36] Two studies document adherence to recommended screening[20,33] as the goal of navigation and report the outcome as an adherence rate, defined as the proportion of eligible subjects who are up-to-date with a screening test as recommended by an existing guideline or standard. These 2 breast navigation studies differed in how they defined "adherent"; 1 used United States Preventive Task Force (USPTF) guidelines,[33] another Healthcare Effectiveness Data and Information Set (HEDIS) criteria.[20] Only 1 study reports maintenance screening behavior,[31] which was defined as the percentage of annual mammograms that were actually obtained during the study period. Data collection methods were either self-reported behaviors[13-15,19,27-29,35] or objective evidence from medical record review.[20-24,26,31-33,36]

Diagnosis

Of the 13 studies included targeting the diagnostic phase of the cancer care continuum, 12 targeted breast cancer diagnosis[8-10,12,13,17,18,31,37-40] while only 1 targeted cervical cancer.[11] As shown in Table 2, we include studies with a range of program settings that target diverse populations with variable eligibility criteria. Similar to screening navigation studies, the range of the intervention period across studies was wide, and the time subjects were followed to assess the outcome varied. Studies report 4 clinical metrics at the point of diagnostic evaluation: 1) receipt of diagnostic resolution,[8-11,38,40] 2) time to diagnostic resolution,[8,37-39] 3) timely adherence to diagnostic resolution,[9-13,31,37,38] and less commonly 4) stage at diagnosis.[17,18]

Five studies report receipt of diagnostic resolution[8-11,38,40] as the goal of navigation. These studies present this outcome simply as a resolution rate, defined as the proportion of eligible subjects who complete diagnostic testing during the intervention period. The majority of studies reviewed report timeliness of diagnostic care as the goal of patient navigation. These studies report timely in 2 distinct ways: either 1) the time to diagnostic resolution[8,37-39] as a continuous outcome, or 2) the rate of timely adherence to diagnostic resolution as a dichotomous outcome.[9-13,31,37,38]

The most striking finding in reviewing these metrics is the lack of a consistent definition for what constitutes "diagnostic resolution" or the "timely" diagnostic interval. Most studies use the date the abnormal screening test was performed as the index event or start date.[9,10,31,37,38] However, there is widespread variability in the data point indicating diagnosis, diagnostic resolution or adherence to recommended follow-up, ranging from the date of arrival to first diagnostic clinical visit[12] to the actual date a tissue sample was obtained.[8] When tissue diagnosis is not recommended, studies vary in reporting how a "diagnostic resolution" is determined. For example, 1 study reports the endpoint as "until negative mammogram, benign biopsy, 6 month follow-up test, or start of cancer treatment",[10] while other studies only include benign or malignant tissue as a diagnosis.[39] There is similar variability in how investigators define "timely" ranging from 60 to 180 days.[9,13]

The Patient Navigation Research Program, a collaborative multisite research program designed to evaluate the efficacy of navigation after abnormal cancer screening, developed a set of "common" data points using the National Comprehensive Cancer Network (NCCN) guidelines as the major focus of clinical outcomes.[41] While the results of this program are not yet published, the PNRP is the largest study to date on PED navigation. In their program, diagnostic resolution is defined as completion of the diagnostic test that results in a diagnosis or clinical evaluation that determines that no further evaluation is indicated. For example, a colonoscopy with biopsy confirming a malignant polyp or a colonoscopy in which no malignant lesion is identified would both serve as a diagnostic resolution.

The 2 studies reporting breast cancer stage at diagnosis as the outcome similarly reported population level data to assess the impact of a navigation program targeting individuals.[17,18] These studies suggest a positive impact of patient navigation; however, due to the methods used, a causative association cannot be determined.

Process Metrics

In addition to intermediate clinical outcomes, 6 studies included here report metrics that evaluate whether the intervention was implemented as intended. Five studies report navigator-documented barriers to care.[9,10,25,31,35] One study by Lasser et al documents the median number of contacts per patient and mean hours of telephone outreach per patient.[23] A descriptive study by Lin et al documented the types of barriers to care and time spent by the navigator.[42] The PNRP is collecting the following process metrics in their multi-site program: barriers to care identified by navigator, actions taken by the navigator, and details of navigation encounters such as type of encounter and time spent.[41] Only 1 of these studies[33] have examined the association between these process measures and their outcomes, which represents an area in critical need for further study.

Recommendations for PED Metrics

In keeping with the goal of having a common set of priority metrics for navigation programs to measure impact on individuals and populations, it would be ideal to have consistent study characteristics, including eligibility criteria, follow-up time intervals and outcome metrics. Obviously, this is not possible for several reasons. First, there are certain program characteristics that are inherently nonmodifiable such as program setting and the populations they serve. In addition, the specific needs of populations appropriately dictate the intended outcomes of navigation, the ideal mode of navigator contact or specific navigator activities. Finally, there is wide variability in the amount and type of resources available for evaluation efforts. Community programs wishing to conduct an evaluation of their program may well have fewer resources than a federally funded research project such as the PNRP. Regardless, the existing literature illuminates the need for consistency in reporting both modifiable and nonmodifiable program characteristics. Stating these clearly will facilitate meaningful program comparisons even in the absence of common outcome metrics.

Table 3. Reportable Program Characteristics for Prevention and Early Detection Navigation Programs

Construct	Common Metric
Setting	Urban v. Rural v. Suburban
	Clinical v. community
Eligibility criteria of patients	Age
	Race
	Primary language spoken
	Time since last screening
Mode of navigation	In person v. telephone
	# encounters per patient
	Time spent per patient
	# patients navigated
Follow-up interval	# months or years

Therefore, our first recommendation is to clearly document the following minimal set of program characteristics (Table 3):

1. *Program setting*. At a minimum knowledge of geographic settings such as urban, rural, suburban is an important distinction. More importantly, the system setting is essential to know when considering replicating a program. Beyond describing whether a program is community versus clinically-based, some detail on the specific area within a clinical setting (e.g. primary care versus radiology), or community setting (e.g. church versus YWCA) is important.
2. *Eligibility criteria of navigated subjects*. These programmatic elements are necessary to order to interpret the outcomes and their potential impact for other populations. Most important are age, race/ethnicity, primary spoken language and time since last screening.
3. *Mode of navigation*. The primary mode of delivering the navigation program is a minimal program element essential to comparing study findings. Specifically, did the navigator interact with their target community in person (in a community setting, in a clinical setting) or on the telephone? How many encounters did the navigator have over the course of the intervention? In addition, the amount of time spent per patient and overall navigator case load is important to document (with how many patients per week does the navigator interact, how many navigators worked with the same patient to access follow-up diagnostic services).
4. *Time interval of the follow-up period at which outcomes are assessed*. This detail is critical to

Table 4. Recommended Common Data Elements for Screening Metrics

Construct	Common Data Elements	Common Outcome Metrics
Receipt of screening test	A. Date enrolled into navigation B. Date referred for screening C. Date test scheduled (#1, #2, #3, etc) D. Date test completed E. Date test results are read/reported F. Date patient informed of test result	Completion of screening test *(Yes/No)* Timely completion of screening *(Yes/No)* • Must define "timely" Time to complete screening *(# days A - D)*
Adherence to single recommended screening interval	A. Name of professional guidelines that defines recommended screening (ie, USPSTF, NCCN) B. Date current test completed C. Date most recent screening test completed	Adherent to single recommended screening *(Yes/No)*
Adherence to longitudinal recommended screening = maintenance	A. Name of professional guidelines that defines recommended screening maintenance (ie, USPSTF, NCCN) B. Date current screening test completed C. Date most recent screening test completed D. Date past screening tests completed	Adherent to longitudinal screening *(Yes/No)* • Must define "longitudinal screening"

interpreting the meaning of a defined outcome. For example, it would important to know that 2 programs reporting a similar clinical outcome (ie, 90% of program participants completed their mammogram) each measured their outcome at different time intervals (ie, 1 year vs 6 months).

Many of the observed differences in published PED outcomes are not in the data elements collected, rather in either the nomenclature used to describe them or the analyses used to report them. Thus, defining a common set of *data elements*, rather than firm outcome metrics is a much more realistic approach and comprises our second set of recommendations. Prioritizing the collection of these data elements will allow for the variability inherent in navigation programs that target different communities and systems of care while also allowing for meaningful comparisons. From these data elements, common metrics to represent prevention and early detection constructs can be created (see Tables 4, 5, and 6).

Table 4 displays recommendations for common data elements that may be used to create a set of intermediate outcome metrics that fit within the constructs of screening. The first construct is *receipt of the screening test*. Documenting the core data elements to measure this construct allows for the reporting of dichotomous outcomes metrics like "completion of screening test (yes/no)" or "timely completion of screening test (yes/no)" as well as the continuous outcome of "time to complete screening". Either of these metrics may be reported using any or all of the common data elements outlined in Table 4. This measure is limited when comparing programs with different eligibility criteria and follow-up time periods. Thus, a more comparable construct to consider is *adherence to recommended screening*, which requires of course that a screening guideline (such as the USPSTF) be stated explicitly. This common metric allows for programs to compare their adherence rates across different populations. Because the full benefit of screening on survival is dependent on the longitudinal use of "routine" screening tests, or maintenance of screening over time, there should be an emphasis toward documenting screening maintenance behavior.

Table 5 displays recommendations for common data elements that may be used to create a set of intermediate outcome metrics that fit within the constructs of diagnostic outcomes. Common metrics for reporting the construct of *diagnostic resolution* must begin with a clear definition of which core data elements constitute diagnosis and/or resolution of the screening abnormality. Once this is clear, reporting of the dichotomous outcome metrics may include "completion of diagnostic resolution (yes/no)," "timely completion of diagnostic resolution (yes/no)" and the continuous outcome of "time to complete diagnostic resolution." These metrics may be reported using any or all of the common data elements outlined in Table 5. Resources and program intent will create variability in which data elements programs are interested in and capable of collecting. The priority should be to have an explicit and consistent definition of diagnostic *resolution* and to collect the date corresponding with that definition, as recommended by the PNRP.[41] When the diagnostic resolution is a diagnosis of cancer,

Table 5. Recommended Common Data Elements for Diagnostic Metrics

Construct	Common Data Elements	Common Outcome Metrics
Receipt of diagnosis or resolution of screening abnormality	A. Date index screening test performed B. Date patient informed of test result C. Date enrolled into navigation clinical evaluation D. Date of first scheduled diagnostic test/clinic visit • Date of second scheduled, third scheduled, etc E. Date of completion of first diagnostic test/clinic visit F. Date of completion of final diagnostic test/clinic visit G. Result of final test performed (cancer Yes/No) H. Date diagnostic test read/reported I. Date patient informed of test results	Completion of diagnostic resolution *(Yes/No)* • Must define "diagnosis" • Must define "resolution" Time to completion of diagnostic resolution[42] *(# days A - F)* Timely completion of diagnostic resolution *(Yes/No)* • Must define "timely"
Adherence to recommended diagnostic testing	A. Name of professional organization/guidelines B. Type of test resulting in diagnostic resolution	Adherent to recommended diagnostic testing *(Yes/No)* Completion of appropriate test *(Yes/No)* • Must define appropriate test (eg, percutaneous biopsy v. open biopsy)
Stage at diagnosis	A. TNM Classification of Malignant Tumors cancer staging criteria[56]	Stage 0-4

Table 6. Recommended Common Data Elements for Process Metrics

Construct	Common Data Elements	Common Outcome Metrics
Phase of cancer care targeted by navigation program	Outreach / Screening or Diagnostic clinical visit / Follow-up	Phase of cancer care
Adherence to scheduled clinical visit	A. Date of appointment B. Type of appointment C. Status of appointment • Arrive • No show • Cancel • Reschedule	Adherent to appointment *(Yes/No)*
Caseload	A. # of patients navigated per navigator B. Time spent per patient (minutes, hours) C. # days in navigation	Navigator Caseload *(# patients / time period)*
Communication	A. Encounter type: in person, phone, letter B. Interpreter used *(Yes/No)* C. Date of first encounter D. Date of last encounter	Mode of communication
Barriers	A. See PNRP Methods paper[41]	# of barriers / per patient Type of barriers
Actions	A. See PNRP Methods paper[41]	# of actions / per barrier or per patient Type of actions

metrics such as stage at diagnosis are also important to record. Another recommended construct that is often omitted from program evaluation is *adherence to recommended testing*, as determined by documentation of the type of diagnostic test performed in approaching diagnostic resolution. This common metric, *completion of appropriate test*, is another measure of quality to ensure populations have access to appropriate diagnostic testing.

Our third set of recommendations call for a minimal set of process data elements (Table 6). Process measures are intended to measure whether navigation was delivered as planned or designed. Without these details, replication of programs with successful outcomes is not possible.

Figure 1. Native American Cancer Research Corporation tool for documenting common process data elements: Navigator Actions.

Knowledge of the specific components of a navigation program is necessary to apply lessons learned from 1 program to the next. The PED Working Group identified 3 distinct phases of PED where processes of navigation may differ: 1) outreach/promotion (helping community understand the need and availability of cancer screening); 2) support during clinical appointments and tests; and 3) tracking and follow-up after appointments/tests completed.

At a minimum, programs should document which phase(s) of PED their navigators address, as this captures broadly the types of activities involved in the navigation program.

In addition, we strongly recommend that programs document clinical appointment data to report health services process measures related to adherence to scheduled clinical visits. Also of importance to program function and impact is the number of patients navigated (over some specified time period: daily, weekly, or monthly) and the time spent with individual patients. From this information measures of caseload may be created. Mode of communication and whether an interpreter was used in an encounter is another important process measure. Documenting the date of last navigator encounter ensures a way to attribute the screening outcome to navigation. For example, we would not want to attribute a screening outcome to navigation if there has been no contact with a navigator in the prior 12 months.

Considering that addressing barriers to care are at the very center of the conceptual model of navigation, it is essential to measure these barriers along with navigator activities, or actions, taken to address them. Creating an optimal set of patient-level barriers to care is challenging given the specific needs of diverse populations, as barriers in 1 community may be vastly different from barriers in another. Freund et al describe recommendations for barriers used by the PNRP[41] and provide a framework for documenting navigation activities that would facilitate meaningful comparisons. The Native American Cancer Research Corporation (NACR) provides another example of documenting barriers and actions routinely used in their program (Fig. 1).[15] Finally, documenting healthcare usage along the screening process is an alternative way of capturing benefits of navigation, such as reduction in rates of missed appointments.

Our fourth and final set of recommendations is related to data collection efforts. Data elements may be collected using patient self-report, navigator logs, clinical

data sources, and/or objective observation. At a minimum, programs should document their data source, given the limitations/strengths of these various sources. In a research context, it would be inappropriate to have navigators administer outcome assessments for their own patients as it would introduce potential bias. Whereas it would be acceptable to have navigators document process measures, programs should avoid using navigators to document clinical outcomes without extensive quality assurance in place.

PN daily logs are an obvious source for process measures. Electronic programs can be used for those PN who have access to computers and/or the Internet. Tremendous effort should be made to ensure the layout consists of closed question format or checkboxes that address most prevalent responses with an "other" category that allows for text input. These lists or checkboxes should include space to document the amount of time the PN spent doing each task, or better yet checkboxes with time intervals.

Patient self-reported screening behaviors are often inaccurate[43] and how the questions are asked may influence the responses. However, if patient self report is used, phrasing of questions should be drawn from standardized, validated instruments such as the National Health Interview Survey (NHIS), the Behavioral Risk Factor Surveillance System (BRFSS), or the National Medical Care Expenditure Survey (NMEPS). Likewise, there are differences in the types of responses when such instruments are administered face-to-face, over the phone, completed by the patient, use of CADI (Computer Aided Design Instrument) systems and/or through the Internet.[44]

While objective observation methods of patients and navigators have been developed,[45] most programs will not have the resources to use them. With federal mandates requiring transition to electronic medical records, there is tremendous opportunity to use objective clinical data sources to measure these outcomes and should be the standard for navigation programs to aspire. For example, electronic medical records may be queried for the presence of screening reports or as a means to complete certain data points, while electronic registration systems may be queried to report adherence outcomes for scheduled appointments.

DISCUSSION

Patient navigation programs that target the prevention and early detection spectrum of care share similar goals, yet vary widely in how they document their success. Differences in program structure, population needs, outcomes of interest, and reported evaluation metrics make cross-study comparisons impossible. However, a review of the literature suggests that a common set of evaluation metrics relevant to multiple stakeholders can be developed. Based on a synthesis of existing navigation literature and expert consensus, we present here a set of 4 recommendations related to measuring and reporting PED navigation program success so that dissemination of the evidence may be used to delineate best practices in the design of care processes across diverse settings.

Our recommendations call for a core set of quality indicators that measure the intent of navigation—to bridge the critical disconnect between the discovery and delivery of life saving cancer care services. Knowledge of basic program characteristics is the starting point to contextualize comparisons between programs. While clinical outcome measures of quality (eg, stage of diagnosis or mortality) are generally more difficult or not feasible to measure, we provide a framework of common data elements that may be used to report a common set of intermediate clinical metrics. Equally important, we provide recommendations for collecting and reporting process measures (activities performed while receiving care) which are the most frequently used quality indicators,[47,48] because they are sensitive, unambiguous, and easily measured.[49-51] Our review of the literature highlights the lack of evidence linking these processes to clinical outcomes, making these data elements of high priority for future study as process measures should be associated to outcome measures for effective quality assessment.[52,53]

A limitation of this study was focusing the literature review to PubMed, certainly the most commonly used database. However, some navigation projects and studies using labels for staff who function as navigators linking individuals from community to the health system, such as community outreach worker, community health advisor/aide, promotores, or lay health advisor/educator, may have been excluded. Likewise, several of the latter articles are accessible through publication databases that focus on education, social work, and psychology that may or may not also be within PubMed. As a result, this article is less inclusive of community-based and academic-based navigation programs and emphasizes the clinical settings. Regardless, most of the recommended measures presented here are relevant to navigators working in these other settings as well.

Priorities should focus on defining the needs and demographics of the target population, which in turn

should drive the expected outcomes of the intervention. As long as programs explicitly state the context of their evaluation and choose from among the core set of data elements, meaningful comparisons among existing programs should be feasible. While methods for collecting these metrics will depend upon resources and existing infrastructure, programs should aspire for rigor with objective sources when possible. When objective electronic data are not available, sites need creativity to determine the best way to retrieve the information, either from manual chart abstraction or navigator documentation. These recommendations are a first step toward adopting a minimal dataset for PED navigation programs, as has been done by other population based approaches to improving quality care.[54]

Navigation is emerging as an expected "standard" for cancer programs,[54] yet the literature has yet to provide consistent insight into activities or processes of navigation that are linked to favorable outcomes. We demonstrate here the growing body of knowledge regarding the impact of prevention and early detection navigation on cancer care would benefit from some thoughtful standardization. In keeping with recommendations from the 2001 IOM report to deliver patient-centered care that is timely, efficient and equitable[3] it is imperative that we evaluate the ability of PED patient navigation programs to realize that potential. Only then can we "apply evidence to health care delivery" as recommended. The responsibility for the analysis and synthesis of this medical evidence falls on all of us involved in the delivery of these services.

Improving Disposition Outcomes for Patients in a Geriatric Skilled Nursing Facility

Randi E. Berkowitz, MD,† Richard N. Jones, ScD,*† Ron Rieder,* Margaret Bryan,* Robert Schreiber, MD,*† Sharon Verney, RN/NP,* and Michael K. Paasche-Orlow, MD, MA, MPH‡*

OBJECTIVES: To evaluate an intervention to improve discharge disposition from a skilled nursing unit (SNU).

DESIGN: Historical control comparison of discharge disposition before and after implementation.

SETTING: Fifty-bed SNU.

PARTICIPANTS: All patients admitted from acute care hospitals to a SNU between June 2008 and May 2010.

INTERVENTION: Physician admission procedures were standardized using a template, patients with three or more hospital admissions over the prior 6 months received palliative care consultations, and multidisciplinary root-cause analysis conferences for patients transferred back to the hospital acutely were conducted bimonthly to identify problems and improve processes of care.

MEASUREMENTS: Patients' discharge disposition (i.e., acute care, long-term care, home, or death) before and after implementation were compared.

RESULTS: Discharge dispositions were determined for all 1,725 patients admitted during the study; 862 patients before (June–May 2008) and 863 during (June 2009–May 2010) the intervention. Discharge dispositions were significantly differently distributed across the two periods ($P = .03$). Readmission to acute care declined (from 16.5% to 13.3%, a nearly 20% decline). Multivariable logistic regression, controlling for age, sex, and case-mix index and adjusting for clustering due to repeated admissions of individual patients, suggests that, during the intervention period, patients were more likely than during the baseline period to die on the unit in accordance with their wishes than to be transferred out to the hospital (odds ratio = 2.45, 95% confidence interval = 1.09–5.5).

CONCLUSION: Interventions such as the ones implemented can lead to fewer hospital transfers for SNUs. **J Am Geriatr Soc 59:1130–1136, 2011.**

Key words: rehospitalization; skilled nursing unit; palliative care; multidisciplinary team

One in five Medicare beneficiaries was rehospitalized within 30 days of hospital discharge in 2004, at an estimated cost of $17.4 billion.[1] Hospitalized patients admitted to a skilled nursing facility (SNF) have a high rate of early unplanned rehospitalization.[2] In 2006, the national rate for patients discharged to a SNF who were rehospitalized directly from the SNF or within 2 days of discharge from the SNF was 23.5%. Two reasons to believe that a fair amount of these events are likely to be avoidable are the high prevalence of preventable diagnoses and significant geographic variation.[3] For example, whereas patients in Utah discharged to SNF had a rehospitalization rate of 15.1%, patients in Louisiana had a rate of 28.2%.[2]

Hospitals are currently required to report readmission rates, but few SNFs use repeat hospitalizations as a measure of quality of care. Because SNFs typically serve patients who are admitted to and discharged from multiple hospitals—and SNF administrators may not have access to these data—SNF administrators cannot generally determine the rate of readmission for their patients once they have been discharged to the community. SNFs do have access to Minimum Data Set (MDS) data to follow the number of patients they are sending out acutely to the hospital, but this is currently not a required quality indicator.

Many factors contribute to rehospitalization risk. Risk factors include prior recent hospitalization, specific diagnoses (e.g., congestive heart failure), and indices such as carbon dioxide levels for patients with chronic obstructive pulmonary disease, renal function, and other clinical parameters.[4–8] Clinical instability, lack of medication reconciliation, depression, and multiple other factors also

0002-8614/11/$15.00

contribute to rehospitalization risk.[9–17] Geriatric assessment, nurse practitioner involvement, and type of facility have been found to be associated with a lower rate of readmissions from SNFs.[18–21]

This project was a prospective quasi-experimental trial to change discharge dispositions for patients on a skilled nursing unit (recuperative services unit, RSU). The intervention included three elements: Physician admission procedures were standardized with a template, which included care guidelines for common geriatric syndromes, a template for medicine reconciliation, a standardized goals of care discussion, and a question of how many times the patient had been hospitalized over the past 6 months; patients with more than three hospital admissions over the prior 6 months received automatic palliative care consultation; and multidisciplinary conferences were conducted every 2 weeks examining the care of patients acutely transferred to the hospital to identify problems and improve processes of care. The distribution of discharge dispositions before the intervention and after initiation of the intervention were compared to evaluate the efficacy of the program.

METHODS

The Hebrew SeniorLife (HSL) institutional review board approved the project, and an advisory committee composed of nurses, secretarial staff, aides, therapists, nurse practitioners, doctors, administrators from HSL and an acute care hospital, and a daughter of a patient who had experienced repeat hospitalizations was convened and met before implementation of the intervention and biannually to guide the project. The main outcome of interest was the distribution of discharge dispositions, including readmission, transfer to long-term care facility, discharge to home, and death. Readmission includes people transferred directly from the RSU to an acute care hospital or psychiatric unit, transferred to an acute care hospital or psychiatric unit at the time of a physician office visit during the time they are an RSU patient, and transferred to acute care or psychiatric unit from a dialysis unit during the time they are an RSU patient. The HSL medical care review committee reviewed all deaths and acute care transfers at HSL to ascertain potential errors and avoidable causes and to determine whether deaths were expected.

The baseline distribution of discharge dispositions, before initiation of the intervention, included data from all patients admitted to the RSU from June 2008 to May 2009. The intervention began in June 2009, and data for the first 12 months of the intervention were used for the current analyses. Specifically, the intervention period included final disposition data from all patients admitted to the RSU from June 2009 to May 2010. Administrative data were used to determine the discharge disposition for each person. In addition, initial information was collected from the MDS assessment, including age, sex, race, ethnicity, functional level (activity of daily living long-form scale), cognitive performance level (Cognitive Performance Scale), pain index, depression rating scale, and case-mix index (CMI). All patients were on Medicare Part A or managed care. The RSU is part of HSL, a nonprofit institution with a closed medical staff, and is located in a facility that also includes a 400-bed long-term care hospital. Doctors and nurse practitioners are on site until 6 p.m. Monday to Friday and for rounds on weekends and holidays, and physicians are on-call by telephone at other times.

In 2008, a standardized template was developed with input from all members of the HSL Department of Medicine and important nursing, administrative, and social service leaders. The American Medical Directors admission history and physical template was used, and care guidelines for common geriatric syndromes, medicine reconciliation, goals of care, and a question of how many times the patient had been hospitalized over the past 6 months were included (Appendix 1). The advance directives section included a discussion about whether the patient or healthcare proxy would want subsequent hospitalizations if the patient's condition deteriorated while on the SNF. To determine fidelity to this aspect of the intervention protocol, a random sample of 40 patients' charts was surveyed to determine whether the admitting attending used the template.

If a patient had had three or more hospitalizations (including the hospitalization immediately preceding the current SNF admission) in the past 6 months, a palliative care consultation was obtained with patient consent to identify realistic goals of care and address barriers to discharge home. The palliative care team was composed of a physician board certified in palliative care, a geriatric nurse, a geriatric social worker, and a chaplain. All members of the team were also encouraged to ask for a palliative care consultation if they believed there was discordance between the team, the family, and the patient's expectations for progress. The objective of the palliative care consultation was to determine whether rehospitalization was consistent with the patient's goals of care or if worsening symptoms would best be managed in the SNF, long-term care, or at home.

Team Improvement for the Patient and Safety (TIPS) conferences were held twice a month for 30 minutes, starting in June 2009, to examine the root causes of rehospitalization events. Nurses, nursing aides, physicians, therapists, social workers, and a nursing home administrator attended sessions. Meeting times were varied to ensure that night and evening staff were included, and aides were compensated for attending TIPS conferences after their shifts had ended.

At TIPS conferences, selected cases of rehospitalization that were deemed to have been potentially avoidable were reviewed to identify ways in which the team could have operated more effectively. Before the TIPS conference, physicians called the readmitting hospital and spoke with the hospital care team to gain insights into problems that might have been missed on the SNF. According to the specific causes identified, additional information would be sought, and additional staff or outside experts were invited to participate in the TIPS session. During the course of the year, representatives from security, maintenance, home care agencies, inpatient and outpatient pharmacies, information technology, psychiatry, recreation therapy, dietary, admissions, covering physicians, palliative care, respiratory therapy, families, and laboratory staff were included in the TIPS conference. Attendance was measured. An email list of all direct care staff was created, and a "lessons learned" email was shared after each meeting.

Components of the intervention are summarized in Table 1.

Table 1. Interventions

Physician history and physical template with goals-of-care discussion including code status, number recent admissions in past 6 months, and whether repeat hospitalization is consistent with patient's wishes
Palliative care consult with patient consent if more than three hospitalizations over past 6 months
Physician call to hospital on unplanned discharges to determine whether diagnosis missed in skilled nursing facility
Multidisciplinary conferences every 2 weeks to review cases of unplanned discharges to identify and fix system failures

Statistical Methods

The distribution of demographic and clinical characteristics of patients and the pattern of discharges were compared between the two study periods, and the hypothesis that the two samples represented random samples from the same population was tested using simple bivariate tests (analysis of variance, chi-square) (Table 2).[22–25] Because some patients were represented multiple times in the data, with repeat RSU admissions, and straddled study periods, typical linear regression model assumptions of independence of observations are not consistent with these data. This was addressed, and the differences in the distribution of discharges across the two study periods were formally tested using multinomial logistic regression modeling with robust standard errors controlling for clustering on individual residents. For both study periods, 6% of patients were missing covariate data, because they did not have an MDS assessment before discharge. Missing data were handled with multiple imputation methods, using the discharge outcome as the predictor in the multiple imputation models. Regression models used standard methods for pooling results over multiple estimations.[26] Parameter estimates were obtained using Stata software (version 10.1, Stata Corp., College Station, TX).

SD = standard deviation; χ^2 cont = contribution to overall chi-square for the row-wise comparison.

RESULTS

Eight hundred sixty-two people were admitted to the RSU in the 12 months before the intervention, and 863 were admitted during the 12 months of the intervention. Patient age, sex, race, functional status, cognitive level at baseline, case-mix adjustment, and length of stay did not differ significantly between the control and intervention years (Table 2). In 2007, the latest year available, the CMI for the unit was 1.21, whereas the national average for hospital based facilities was 0.94 ± 0.19.

In each year, 52 patients had incomplete MDS assessment (were discharged or died before MDS assessment). Seventy-nine percent of the patients had one admission to the RSU during the 2-year interval, 16% had two, and 5% had three or more (maximum of 6). Physicians used the standardized admission assessment template in 35 of 40 (87.5%) audited charts. All patients had physician orders documenting code status. There were 55 palliative care consultations in the control year and 116 in the intervention year.

During the course of the intervention period, 22 TIPS conferences were held; of staff on duty at the time of the conference, there was an average attendance rate at TIPS conferences of 81%.

Discharge dispositions differed significantly between years ($P = .03$), with the rate of rehospitalization declining from 16.5% to 13.3%, a drop of 19.4% (Table 3). Discharges to home increased from 68.6% to 73.0%, deaths on the RSU increased from 1.2% to 2.2%, and discharges to long-term care fell from 13.8% to 11.5%. The medical care review committee judged all deaths to be expected and consistent with patient wishes.

Multivariable logistic regression, controlling for age, sex, case-mix index, and repeated admissions of individual patients, indicated that patients were more likely to die on the unit than be transferred out to the hospital during the intervention than during the baseline period (odds ratio = 2.45, 95% confidence interval = 1.09–5.5).

DISCUSSION

After implementing the three-pronged intervention, there was a change in discharge disposition from the SNF, with a decline in discharges to acute and long-term care and increases in discharges to home and palliative care deaths on the unit. Two components of the intervention—standardized admission assessments and multidisciplinary conferences discussing root-cause analysis for patients acutely transferred back to the hospital—were conducted with existing staff. Many SNFs could embed similar programs within their current care processes. Instituting this program may require additional resources such as time to institute the admission template, palliative care services, and staff time for TIPS conferences. Teams from hospice organizations that are already embedded in many long-term care facilities could aid organizations without a palliative care service.

The authors feel that the change in discharge disposition observed between the two periods reflects a true improvement in patient outcomes, although some caution is required when interpreting these results. Specifically, a lower acute transfer rate probably reflects better processes of care in the SNF, but there is no criterion standard to evaluate physician judgments regarding the appropriateness to transfer or not transfer patients to the hospital. In addition, all deaths on the unit were concordant with patient wishes, another important indicator that the observations reflect an improvement in patient care.

This model can be disseminated. Organizations considering projects to improve care transitions can compare their population with the current study population using a resource developed by the Shaping Long Term Care in America Project on their Web site http://www.ltcfocus.org.[27]

Table 3. Discharge Status: Multivariable Multinomial Logistic Regression Modeling

	Odds Ratio			
Outcome	**Community**	**Hospitalization**	**Facility**	**Died**
Adjusted for clustering on individual only				
Died	1.78	2.35*	2.28*	—
Facility	0.78	1.03	—	0.44*
Hospitalization	0.76	—	0.97	0.43*
Community	—	1.32	1.28	0.56
Adjusted for clustering on individual and covariates				
Died	1.91	2.45*	2.42*	—
Facility	0.79	1.01	—	0.41*
Hospitalization	0.78	—	0.99	0.41*
Community	—	1.28	1.27	0.52
Test time effect = 0 (χ^2 (degrees of freedom))				8.76 (3)*
F-test $P > \chi^2$				0.033

* $P < .05$, test that individual level regression parameter is significantly different from the null. Covariates include age, sex, functional level (activity of daily living long-form scale), cognitive performance level (Cognitive Performance Scale), and case-mix index. *Note on interpreting parameter estimates*: 1.91 is the increase in the odds of dying versus being discharged to the community, comparing persons visiting the recuperative services unit in the intervention period versus the baseline period holding other variables in the model constant. Significance tests in all models are estimated using robust standard errors adjusting for clustering on individual.

Because the population in the current study was in the top 10% of acuity based on national CMI data, other SNFs with lower acuity may expect different results.

This study has several limitations that should be discussed. First, it was not possible to separate the effect of the three components of the intervention, partly because of limited details collected regarding the effect of each component of the intervention and the nature of the study design. For example, it is unknown whether the template improved the rate of guideline-concordant care for geriatric syndromes. Issues of transitions of care are multifactorial and need systematic response from the beginning to the end of the care process. The intervention was designed to promote the importance of patient's goals of care and to help staff see transitions of care as an important part of their work product. Attitudes of culture change are currently being studied, and the Agency for Healthcare Research and Quality Long-Term Care Patient Survey is being used to quantify these changes.[28] Further studies would be needed to delineate the relative contribution of each aspect of the intervention.

The second limitation to address is generalizability to other SNFs. Further studies, for example, would be needed to see how to adapt the intervention for facilities without an onsite medical staff. In addition, the baseline hospital readmission rate of 16.5% on the RSU is already particularly low. The average 30-day readmission rates for people who have been in a SNF in Massachusetts is approximately 22% for patients going from home to hospital to SNF and 28% for SNF patients who are hospitalized and discharged to a SNF.[2] It is likely that the low transfer rates at the RSU may reflect the ability of onsite medical staff to assess acute medical conditions quickly. Similar projects might have an even larger effect in facilities with higher baseline rates of acute transfers.

A third limitation of this study is that it was not a randomized trial. As an intervention that aimed to influence the interaction between staff and patients and to improve organizational attention to care transitions, randomization could not be done at the patient level because of the likelihood of contamination. Cluster randomization according to site of care was outside the scope of the current project but would be feasible with adequate funding. Despite the limitations of the quasi-experimental design, the fact that the case-mix index and other patient characteristics were unchanged from the baseline period to the intervention period are reasons to feel confident that the observed improvement in discharge dispositions reflects a true intervention effect.

A fourth limitation of this study is that data for what happens to people after they are transferred from the RSU were not available. Although complete data on discharge disposition were available, data on subsequent care transitions were not. People who are discharged to their homes may then be admitted to various hospitals or facilities, and there is no easy way to track these events. An important development would be for states to facilitate data collection and analysis of readmission rates to enable facilities to monitor the effectiveness of their discharge planning. Until facilities have access to such data, SNFs should be required to report risk-adjusted acute transfer rates.

A final limitation is that the fidelity of the intervention was not fully monitored. Of the 863 patient admissions that occurred in the intervention period, 40 were monitored, and evidence of adherence to the intervention was found in 87.5%. It is unclear how much additional benefit a higher rate of adoption of the intervention activities might have yielded.

The three components of the intervention—the standardized admissions template, palliative care consultations, and the TIPS conference—represent different types of activities that were designed to improve transitions of care. Order sets have been shown to promote quality of care in various settings but have not been evaluated in SNFs.[29–31] The template includes triggers to aid goals-of-care discussions and evaluation of the rehospitalization rate to trigger consultation by the palliative care team. The purpose of discussing goals of care and of having the palliative care team involved is to ensure that the care delivered is consistent with patients' wishes. Rehabilitation staff are frequently focused on restoring a patient's function and are not necessarily equipped to help families and patients recognize when there may be a permanent decline in function. The palliative care team not only educated families and patients, but also coached nursing and therapy staff for symptom management. Although these activities involved important members of the care team, the TIPS conference series was designed to include a broad representation of staff, allowing for ongoing organizational emphasis on the importance of transitions of care in a manner that highlighted opportunities for improvement.

During the intervention period, sick patients were kept on the unit if they did not wish to be rehospitalized. This potentially increased the cost of providing care. Because SNFs are not reimbursed for the extra care such patients require, it is easy to see why patients are routinely sent back to acute care settings simply for lack of staffing at the SNF. Financial incentives should promote avoidance of unneeded rehospitalizations. It is hoped that the bundled payment scheme of the Accountable Care Act will provide physicians and hospitals with adequate incentives to coordinate care for patients at SNFs.

ACKNOWLEDGMENTS

We thank Julie Harris, Ann Masterson, Scott Ariel, the palliative care team, Jonathan Regosin, Fran Hinckley, Susan McCurley, Terry O'Malley, Eli Shea, Lou Woolf, Len Fishman, Richard Della Penna, Kyle Allen, and Patricia Leddy for their advice and encouragement. The Shaping Long-Term Care in American Project provided data for national CMI. We also thank every aide, nurse, therapist, provider, and social worker who attended to the needs of our patients at HSL.

Conflict of Interest: None of the authors report any personal, potential, or financial conflicts of interest.

This project was funded by the Practice Change Fellowship, Denver, Colorado and Hebrew SeniorLife.

Author Contributions: Randi Berkowitz: primary investigator and designer of project and TIPS conferences and preparation of manuscript. Richard N. Jones: statistician and preparation of manuscript. Ron Reider: information technology consultant. Margaret Bryan: database manager.

Robert Schreiber: helped with formulating project and with TIPS conferences. Sharon Verney: case reviews and TIPS conferences. Michael K Paasche-Orlow: analysis and interpretation of data and preparation of manuscript.

Sponsor's Role: The Practice Change Fellowship supported 20% of Dr. Berkowitz's salary to complete a performance improvement project and had no role in the data or the manuscript preparation. The fellowship also supported leadership training and mentoring.

HSL donated 20% of Dr. Berkowitz's salary with in-kind support to lead and plan TIPS conferences and data management in addition to supporting the salary of the palliative care team members.

Use of a DASH Food Group Score to Predict Excess Weight Gain in Adolescent Girls in the National Growth and Health Study

Jonathan P. B. Berz, MD, MSc; Martha R. Singer, MPH; Xinxin Guo, MPH; Stephen R. Daniels, MD, PhD; Lynn L. Moore, DSc

Objective: To study the effects of selected dietary patterns, particularly a DASH (Dietary Approach to Stop Hypertension) eating pattern, on body mass index (BMI) throughout adolescence.

Design: Prospective National Growth and Health Study.

Setting: Washington, DC; Cincinnati, Ohio; and Berkeley, California.

Participants: A total of 2327 girls with 10 annual visits starting at age 9 years.

Main Exposures: Individual DASH-related food groups and a modified DASH adherence score.

Main Outcome Measure: The BMI value from measured yearly height and weight over 10 years.

Results: Longitudinal mixed modeling methods were used to assess the effects of individual DASH food groups and a DASH adherence score on BMI during 10 years of follow-up, adjusting for race, height, socioeconomic status, television viewing and video game playing hours, physical activity level, and total energy intake. Girls in the highest vs lowest quintile of the DASH score had an adjusted mean BMI of 24.4 vs 26.3 (calculated as weight in kilograms divided by height in meters squared) ($P<.05$). The strongest individual food group predictors of BMI were total fruit (mean BMI, 26.0 vs 23.6 for <1 vs ≥ 2 servings per day; $P<.001$) and low-fat dairy (mean BMI, 25.7 vs 23.2 for <1 vs ≥ 2 servings per day; $P<.001$). Whole grain consumption was more weakly but beneficially associated with BMI.

Conclusions: Adolescent girls whose diet more closely resembled the DASH eating pattern had smaller gains in BMI over 10 years. Such an eating pattern may help prevent excess weight gain during adolescence.

OBESITY IS A MAJOR PUBLIC health problem, with 17% of American children overweight and 67% of adults either overweight or obese.[1-3] Excess weight during childhood leads to numerous health problems and is even associated with premature death as an adult.[4,5] Few studies have examined the relation of food-based dietary patterns with weight gain, especially in children.

The examination of food-based dietary patterns acknowledges the synergistic effects on health that food nutrients may have when eaten together.[6] One example is the DASH (Dietary Approach to Stop Hypertension) diet pattern. It emphasizes increased intakes of low-fat dairy products; fish, chicken, and lean meats (to decrease saturated fat and increase calcium levels); and nuts, fruits, whole grains, vegetables, and legumes (to increase potassium, magnesium, and dietary fiber levels).[7] The DASH eating pattern was originally studied in clinical trials of adults as a treatment for hypertension[8]; these clinical trials assessed the effects of increased fruit and vegetable intake, with or without increasing the intake of low-fat dairy products. In these studies,[9-11] the combined diet (rich in fruit, vegetables, and low-fat dairy products) led to the greatest reductions in blood pressure. The DASH pattern has also been studied in relation to the metabolic syndrome and selected cardiovascular end points.[8-14] Little has been done, however, to examine the effects of a DASH eating pattern on measures of excess weight, frequently a precursor of the aforementioned conditions. In addition, the DASH eating pattern has

See also pages 567 and 580

been infrequently studied in children, and the American Academy of Pediatrics states that there is no reason to suggest that using DASH would not be safe as long as pro-

tein and calories are consumed in quantities adequate to support child and adolescent growth and development needs.[15] In this study, we examined the effects of adherence to a DASH-style eating plan and its components on the change in body mass index (BMI) in a racially diverse sample of adolescent girls.

METHODS

STUDY POPULATION

The National Growth and Health Study was initiated by the National Heart, Lung, and Blood Institute to investigate racial differences in dietary, physical activity, family, and psychosocial factors associated with the development of obesity in black and white girls. The National Growth and Health Study enrolled 2379 girls aged 9 and 10 years in 3 cities (Washington, DC; Berkeley, California; and Cincinnati, Ohio) in 1987-1988 and observed them for 9 years. Data were collected in a longitudinal manner on 10 occasions via follow-up at annual examinations. Height and weight were measured by trained study staff using standardized assessment protocols at each examination. Additional details of the methods used for ascertaining data are described elsewhere.[16] Almost 90% of the girls originally enrolled were observed through study year 10. This study was approved by the Boston University institutional review board.

MAIN OUTCOME VARIABLE

The main outcome of interest was BMI (calculated as weight in kilograms divided by height in meters squared) at each age from 9 to 19 years.

DIETARY EXPOSURE VARIABLES

Dietary data were collected using 3-day diet records; the collection included 2 weekdays and 1 weekend day during each of 8 examination years. Participants were trained by a study nutritionist to record detailed dietary information using standard household measuring instruments for the estimation of portion sizes. Standardized debriefing was performed, and diet records that were considered unreliable by the research dietitian were excluded.

Dietary data were entered into the Nutrition Data System of the University of Minnesota, Minneapolis, to estimate the intake of total calories, macronutrients, and micronutrients.[17] The Nutrition Data System also outputs food codes for each food and each ingredient from composite foods (eg, from lasagna, macaroni and cheese, and even condiments). The Nutrition Data System food code data were combined with the US Department of Agriculture's survey food code database, the Food and Nutrient Database for Dietary Studies, version 2.0.[18] By matching these food codes, the child's average daily intake was derived in each of the 5 major food groups and in all the subgroups as defined by *Nutrition and Your Health: Dietary Guidelines for Americans* by the US Department of Agriculture.[19] Thus, we derived total servings for each group and subgroup. For example, fruit servings included fruit from all sources, such as whole fruit, fruit-based desserts, 100% fruit juice, and that portion of fruit drinks derived from fruit juice.

DASH FOOD GROUP SCORE

We created a modified DASH food group score based on a previous publication by Levitan et al.[20] This original score was designed to reflect adherence to a DASH eating pattern as described in the 2005 *Dietary Guidelines for Americans*.[21] Levitan et al[20] compared DASH scores for this scale with those of another DASH score by Fung et al[13] and found them to be moderately well correlated (r=0.61). Because the *Dietary Guidelines for Americans* differs across levels of energy intake, we used energy-specific standards for intake in each food group. The score contained 10 food groups or subgroups, 3 of which were excluded from the modified score: added sugars, discretionary fats and oils, and alcohol. Added sugars were excluded because the high intake of sugar in this population led to almost all the participants having a score of zero for this component. Discretionary fats and oils contributed nothing to the prediction of BMI in this analysis, and the alcohol component was excluded because of the ages of the girls. Therefore, we focused on the 7 DASH-related food groups in these analyses: fruits, vegetables, low-fat dairy products, total and whole grains, lean meats, and nuts, seeds, and legumes.

Low-fat dairy products were defined as those containing 2% fat or less. Lean meat was defined as fish, eggs, beef, and poultry that was 85% lean or greater. To obtain more stable estimates of intake, we included only girls with 2 or more sets of 3-day diet records collected between ages 9 and 17 years (2330 of the original 2379 participants). One girl with an average intake of less than 1000 kcal/d and 1 with an average of more than 3500 kcal/d at ages 9 to 17 years were excluded from the study, as well as 1 girl with absent physical activity data, leaving a final sample of 2327 girls with available data who were included in these analyses.

We followed the scoring protocol of Levitan et al.[20] Each food group was assigned a score ranging from 0 to 1. For total grains, meats, low-fat dairy products, and nuts, seeds, and legumes, participants with intake meeting the guidelines were assigned 1 point. Those with intake above the recommended levels were assigned partial points as follows: 1 minus the percentage of intake over the guideline. For intake below the guideline level, partial points were assigned by dividing the actual intake by the recommended intake. For fruits, vegetables, and whole grains where optimal intake was deemed to be at or greater than recommended, a full point was assigned to those who consumed the recommended level of intake or higher. Partial points were given only for those who had less than the recommended intake. Because DASH recommends that most grains be whole, we used 50% of the total grain recommended as the goal for whole grain intake in accord with American Heart Association guidelines.[15] The total DASH score was, thus, a sum of the scores for each individual food group.

POTENTIAL CONFOUNDING VARIABLES

Potential confounding factors that were evaluated for inclusion in these analyses included race, height at each age, socioeconomic status (SES), physical activity level, television viewing and video game playing (hours per day), total energy intake, and other dietary factors.[22] The SES was classified as low, moderate, or high by combining information about parental income and education. Low-SES families were those with incomes of less than $10 000 per year or parental education level of less than high school; high-SES families included those with incomes of at least $40 000 per year and at least a high school education. All the other participants were classified as moderate SES. Physical activity was measured at each visit using a validated questionnaire that asked the participants to report the frequency and duration per week (during the school year and summer) of participation in a variety of structured physical activities in the past year.[23] These data were combined with published information on metabolic equivalent levels to obtain a final score estimating daily energy expenditure.[24-26]

Table 1. Characteristics of the Study Population by Quintile of DASH Adherence Score[a]

Characteristic	Quintile 1 (n=465)	2 (n=465)	3 (n=466)	4 (n=466)	5 (n=465)
DASH adherence score, range[b]	1.3-2.6	2.6-2.9	2.9-3.3	3.3-3.6	3.6-5.2

White (n = 1139)	14.8	15.3	19.2	20.6	30.0
Black (n = 1189)	24.9	24.5	20.8	19.4	10.4
SES, row %					
Low (n = 548)	26.9	27.2	21.0	16.3	8.6
Middle (n = 996)	21.4	20.1	22.3	19.4	16.9
High (n = 784)	13.4	14.8	16.5	23.5	31.9

Abbreviations: DASH, Dietary Approach to Stop Hypertension; SES, socioeconomic status.
[a] $P < .001$ for all.
[b] The maximum possible DASH score was 7.
[c] Dietary intakes are averages across approximately 20 days of diet records.

STATISTICAL ANALYSIS

Confounders were evaluated using a forward selection method. Factors determined to be confounders and those that were independent predictors of the outcome were retained in the final models (ie, race, height, SES, physical activity level, television viewing and video game playing, and total energy).

Categories of average intake in each of the DASH food groups were determined by balancing information about the distributions of the intake population (which affects study power) with the recommended intake levels. For example, DASH recommended intake level of fruits is 4 to 5 servings per day, but the category cutoff values used in the analysis were less than 1, 1 to less than 2, and 2 or more servings per day because few participants actually consumed 4 to 5 servings. Additional analyses were conducted to evaluate the sensitivity of the results to subtle changes in category definitions.

To determine the association between level of DASH food group intake and BMI over time, we used longitudinal data analysis methods, accounting for correlated observations from the repeated-measures data. In separate models, each categorical food group variable was entered as the main exposure variable, with age as an interaction factor, while controlling for fixed and changing potential confounders as previously described. This allowed us to estimate the adjusted mean BMI at each age in each category of intake for each food group. Analyses were conducted using an unstructured covariance matrix in Proc Mixed with the repeated option in SAS (SAS Institute Inc, Cary, North Carolina).[22] The same longitudinal mixed modeling methods were used to estimate the adjusted mean BMI at each age according to quintile of DASH score.

In each model, the interaction of age and food group was examined first. When a significant interaction was found, further testing was performed to evaluate differences between the slopes, intercepts, and BMIs at the end of follow-up. When there was no significant age–food group interaction ($P > .05$), the statistical significance of the fixed effects for the main dietary exposure variable was examined (using type III sums of squares). Approximate linearity of the relationship between age and BMI was assumed. All analyses were performed using a commercially available statistical software program (SAS, version 9.1).

RESULTS

STUDY CHARACTERISTICS

Dietary and population characteristics by quintile of DASH score are presented in **Table 1**. The overall mean DASH adherence score was 3.1, with a median of 3.1 (range, 1.3-5.2). Food group means in each quintile show that higher DASH scores were associated with higher intake in most food groups. Higher DASH scores were also associated with higher total energy intake. Black participants and those with lower SES were more likely to be in a lower quintile of DASH scores. In addition, there was higher mean physical activity and lower mean television viewing and video game playing hours in the highest quintile of the DASH score.

The distribution of actual intakes for each food component of the DASH score is given in **Table 2**, along with the recommended DASH intakes. Even study participants in the 95th percentile of intake had relatively low intake of fruits, vegetables, whole grains, and low-fat dairy products compared with the DASH recommendations. The average intake of added sugars was approximately 10 times higher than recommended. Discretionary fat intake was also relatively high, although no direct equivalent DASH recommendation applies.

Table 2. Actual and Recommended Intakes of DASH Food Groups[a]

Food Group	Servings per Day, Percentile[b]			DASH Recommendations, Servings per Day
	5th	50th	95th	
Discretionary fat	7.5	11.7	17.7	NA
Grains	4.0	6.2	8.9	6
Added sugar	3.7	7.2	12.0	0.7
Vegetables	1.0	2.0	3.6	3-4
Lean meat	0.5	1.6	3.6	1-2
Fruits	0.3	1.1	2.9	4
Whole grains	0.1	0.5	1.2	3
Nuts/seeds/legumes	0	0.2	0.7	0.5

Abbreviations: DASH, Dietary Approach to Stop Hypertension; NA, no DASH recommendation applies.
[a] Based on intake of 1600 kcal/d.
[b] Serving sizes for each food group: lean meat, 3 oz; low-fat dairy, 1 cup milk or yogurt or 1.5 oz cheese; nuts/seeds/legumes, ⅓ cup nuts, 2 tbsp seeds, and ½ cup cooked dry beans; (whole) grains, 1 slice of bread, 1 oz dry cereal, and ½ cup cooked rice, pasta, or cereal; vegetables, 1 cup raw/leafy, ½ cup cooked, and 6 oz vegetable juice; fruits, 6 oz fruit juice, 1 medium piece, ¼ cup dried, and ½ cup fresh, frozen, or canned; added sugar, 1 tbsp; and discretionary fat, 5 g/1 tsp.

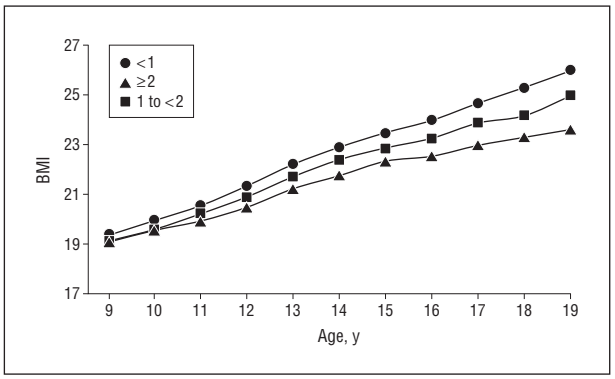

Figure 1. Body mass index (BMI) (calculated as weight in kilograms divided by height in meters squared) over 10 years associated with fruit consumption (mean servings per day). Adjusted for race, height, socioeconomic status, physical activity level, television viewing and video game playing hours per day, added sugar, total dairy, vegetables, total grains, nuts/seeds/legumes, processed and nonprocessed meat, and total energy intake. Slopes: $P<.001$ for differences between each line. Difference in BMI at end of follow-up: less than 1 vs 1 to less than 2 servings, less than 1 vs 2 to less than 8 servings, and 1 to less than 2 vs 2 to less than 8 servings, $P<.001$ for all.

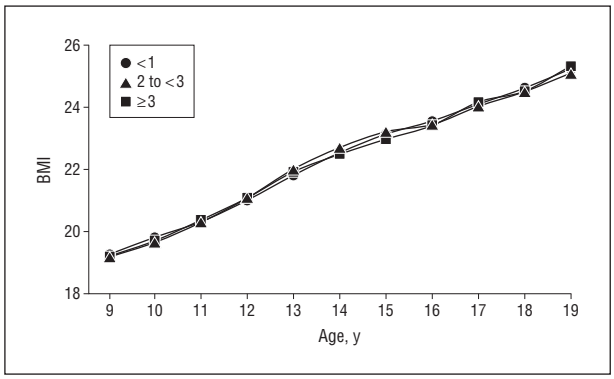

Figure 2. Body mass index (BMI) (calculated as weight in kilograms divided by height in meters squared) over 10 years associated with vegetable consumption (mean servings per day). Adjusted for race, height, socioeconomic status, physical activity level, television viewing and video game playing hours per day, added sugar, total dairy, fruit, total grains, nuts/seeds/legumes, processed and nonprocessed meat, and total energy intake. For the overall difference between age and total grain interaction, $P=.16$. For the overall difference between intake categories, $P>.99$. The BMI at the end of follow-up did not statistically differ significantly among the 3 consumption groups.

INTAKE OF INDIVIDUAL FOOD GROUPS VS BMI

Figures 1, **2**, **3**, and **4** show the adjusted mean BMI at each age associated with average intake in 4 DASH food groups: fruits, vegetables, whole grains, and low-fat dairy products. Participants who consumed 2 or more servings of fruit per day had the smallest gain in BMI over time ($P<.001$) and the lowest BMI at the end of follow-up (23.6, 25.0, and 26.0 for low, moderate, and higher intakes of fruit, respectively) (Figure 1 and **Table 3**). No differences were noted in BMI according to intake of vegetables (Figure 2 and Table 3). Highest (vs lowest) whole grain intake conferred lower BMI increases over time ($P=.01$) and a lower BMI at the end of follow-up (Figure 3 and Table 3). Higher intake of low-fat dairy products led to lower BMI gains over time (Figure 4 and Table 3). In data not shown, we compared models including and excluding total energy and total and saturated fat as a percentage of energy intake. No substantive differences in the BMI trajectory were observed.

DASH FOOD GROUP SCORE AS A PREDICTOR OF BMI

Figure 5 shows adjusted mean BMIs at each age associated with quintiles of the DASH score, averaged over ages 9 to 17 years. Girls in the highest quintile had the smallest gains in BMI over time and the lowest BMIs at the end of follow-up (Table 3). In addition, at age 19 years, those in the lowest quintile of the DASH score (compared with those in the highest quintile) had a mean BMI that was greater than the threshold for overweight as defined by the 85th percentile for age.[27]

COMMENT

In this longitudinal cohort of adolescent girls, we found that higher adherence to a DASH-style diet resulted in a consistently lower BMI between the ages of 9 and 19 years. These findings were stable over a 10-year follow-up and

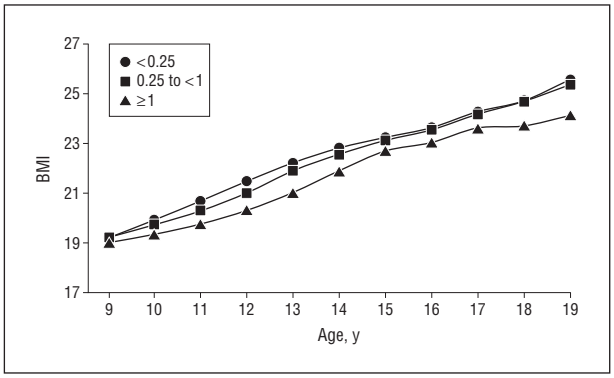

Figure 3. Body mass index (BMI) (calculated as weight in kilograms divided by height in meters squared) over 10 years associated with whole grain intake (mean servings per day). Adjusted for race, height, socioeconomic status, physical activity level, television viewing and video game playing hours per day, added sugar, total dairy, fruit, vegetables, nuts/seeds/legumes, processed and nonprocessed meat, and total energy intake. Slopes: less than 0.25 vs 0.25 to less than 1 serving, $P=.62$; less than 0.25 vs 1 to less than 7 servings, $P=.05$; and 0.25 to less than 1 vs 1 to less than 7 servings, $P=.01$. The BMI at the end of follow-up: less than 0.25 vs 0.25 to less than 1 serving, $P=.51$; and less than 0.25 vs 1 to less than 7 servings, $P=.002$.

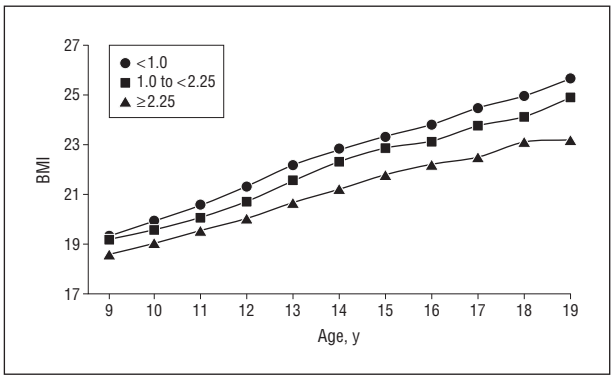

Figure 4. Body mass index (BMI) (calculated as weight in kilograms divided by height in meters squared) over 10 years associated with low-fat dairy products intake (mean servings per day). Adjusted for race, height, socioeconomic status, physical activity level, television viewing and video game playing hours per day, added sugar, fruit, vegetables, total grains, nuts/seeds/legumes, processed and nonprocessed meat, and total energy intake. Slopes: less than 1 vs 1 to less than 2.25 servings, $P=.001$; less than 1 vs 2.25 to less than 5 servings, $P<.001$; and 1 to less than 2.25 vs 2.25 to less than 5 servings, $P=.02$. The BMI at the end of follow-up: less than 1 vs 1 to less than 2.25 servings, $P=.007$; and less than 1 vs 2.25 to less than 5 servings, $P<.001$.

after controlling for nondietary factors associated with eating patterns and excess weight gain.

Few studies have examined dietary patterns in children or used longitudinal data to examine their effects on weight gain. A cross-sectional study[28] of Korean preschool children found that a diet pattern that shares components of the DASH eating pattern was not associated with measured weight status. One longitudinal study[29] of women showed that a pattern of intake lower in fruit, vegetables, and low-fat foods was associated with a greater chance of becoming overweight, and another study[30] showed that a diet consisting of many components present in the DASH pattern resulted in smaller gains in BMI over time.

The present findings for the DASH score were mirrored by the effects of some of the individual food group components. In particular, higher consumption of fruits, whole grains, and low-fat dairy products led to less weight

Table 3. BMI at Baseline and End of Follow-up for 4 DASH Food Groups and DASH Adherence Score[a]

Food Group and Intake, Mean Servings per Day	Participants, No.	BMI, Mean (SD)	
		Baseline	End of Follow-up
Fruits			
<1	1060	19.4 (0.16)	26.0 (0.19)
1 to <2	882	19.1 (0.16)	25.0 (0.21)
≥2	385	19.1 (0.22)	23.6 (0.32)

Quintile 3	466	19.3 (0.20)	25.2 (0.28)
Quintile 4	466	19.0 (0.20)	25.3 (0.29)
Quintile 5	465	19.1 (0.20)	24.4 (0.30)

Abbreviations: BMI, body mass index (calculated as weight in kilograms divided by height in meters squared); DASH, Dietary Approach to Stop Hypertension.

[a]The mixed models did not drop the girls below 1000 kcal/d (1 girl) and above 3500 kcal/d (1 girl). Dropping them and rerunning the program gives results that only differ at the second decimal place, so the data do not need to be changed. However, data are from 2327 instead of 2328 girls because one girl is missing activity at all ages.

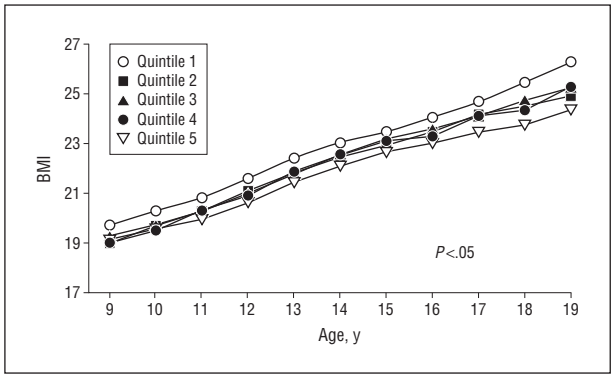

Figure 5. Body mass index (BMI) (calculated as weight in kilograms divided by height in meters squared) over 10 years associated with DASH (Dietary Approach to Stop Hypertension) adherence score (quintile). Adjusted for race, height, socioeconomic status, physical activity level, television viewing and video game playing hours per day, and total energy intake. Slopes: quintiles 1 to 4 vs quintile 5, $P<.05$. The BMI at the end of follow-up: quintiles 1, 3, and 4 vs quintile 5, $P<.05$.

gain. The observed fruit intake in this study was well below the DASH recommendation of 4 servings per day; on average, at 9 to 17 years of age, only 15% of girls reached this goal. In addition, higher vegetable consumption was not associated with decreased weight gain over time. It is possible that relatively low intakes of vegetables and the narrow range of types of vegetables con-

sumed (ie, a predominance of starchy vegetables) may explain the absence of a protective effect. Indeed, in a subanalysis, a higher intake of nonstarchy vegetables was associated with a lower BMI at the end of follow-up (data not shown).

The diet records used in the present study may provide more precise ascertainment of total fruit intake in children than do Frequency Food Questionnaire methods because we extracted fruit servings from composite dishes, as previously described. Thus, the present study is likely to have less nondifferential misclassification of diet exposures and a greater ability to detect meaningful associations between diet and BMI.

Higher low-fat dairy product consumption resulted in smaller increases in BMI during adolescence. Data on dairy consumption and excess weight change during adolescence show mixed results in the larger literature. Two small studies[31,32] found no effect of dairy intake on weight gain, and another study[33] showed an adverse effect of higher dairy consumption on weight gain, even for low-fat milk, although the effect seemed to be mediated by excess energy intake. In contrast, 2 other studies,[34,35] one using diet records and another using the Frequency Food Questionnaire, found that higher dairy intake protected young adults from excess weight gain.

The present study may be the largest long-term study using diet records that has shown a protective effect of dairy intake on weight gain. Dairy may act to decrease weight gain through a variety of possible mechanisms, including an association with a healthier diet in general; its protein content has been shown to increase satiety.[36]

Higher intakes of whole grains were associated with decreased BMI gains during study follow-up. Although there are few studies on grain intake and weight in children, the present finding is in line with other studies[37-40] showing grain to be protective. Although the level of whole grain intake across this study population was low and well below the target threshold of 50% of total grains, it was nonetheless protective. Whole grain intake may result in less weight gain via its higher fiber content and, thus, higher satiety or as a marker for a healthier lifestyle, something we may not have been able to completely capture in the multivariate models.

The study strengths include use of a large socioeconomically and geographically diverse sample that incorporates more than 50% black girls, a population particularly beset by the obesity epidemic. An additional strength is the availability of detailed dietary information that allows us to examine the change in BMI in relation to food group exposure, a method that has seen little study in the adolescent literature so far. Finally, the use of repeated measures collected in a longitudinal manner over 9 years of study increased power substantially and likely decreased random variation in exposure and covariate data.

A limitation of this study is the low level of intake in certain food groups that may have restricted our ability to detect true beneficial effects of these food groups. In addition, there are food groups that other studies have found to be important predictors of obesity, such as sugar-sweetened beverages that are not a part of the DASH eating pattern and unavailable in this analysis, that may be important predictors of excess weight gain.[41,42] Finally, it is possible that there is biased reporting for some dietary factors, especially in obese individuals, that could affect the results of these analyses. However, the longitudinal nature of the study and the multiple measures of dietary intake beginning in preadolescence suggest that this explanation for these findings is unlikely. In conclusion, greater consistency with the DASH eating plan resulted in lower excess weight gains in girls from early adolescence to young adulthood.

Linear mixed models (LMMs) are frequently used to analyze longitudinal data. Although these models can be used to evaluate mediation, they do not directly model causal pathways. Structural equation models (SEMs) are an alternative technique that allows explicit modeling of mediation. The goal of this paper is to evaluate the performance of LMMs relative to SEMs in the analysis of mediated longitudinal data with time-dependent predictors and mediators. We simulated mediated longitudinal data from an SEM and specified delayed effects of the predictor. A variety of model specifications were assessed, and the LMMs and SEMs were evaluated with respect to bias, coverage probability, power, and Type I error. Models evaluated in the simulation were also applied to data from an observational cohort of HIV-infected individuals. We found that when carefully constructed, the LMM adequately models mediated exposure effects that change over time in the presence of mediation, even when the data arise from an SEM.

1. Introduction

In clinical research, both outcomes and predictors are frequently collected repeatedly over time and complex mediated relationships may be present among the variables of interest. For example, in a study of the relationship between alcohol use and HIV disease progression, heavy alcohol consumption may affect antiretroviral therapy (ART) adherence which, in turn, affects CD4 cell count. However, alcohol consumption itself may also directly affect CD4 count. If the goal is to evaluate the total effect of the main independent variable (e.g., alcohol consumption) on the outcome (CD4 count), a single linear mixed effects model (LMM) [1] could be fit to the data. LMMs account for correlation among repeated observations within an individual and are frequently used to analyze longitudinal data. To disentangle the direct versus indirect effects of alcohol use on HIV disease progression, however, a series of LMMs could be fit according to the steps described by Baron and Kenny [2] and demonstrated by Krull and MacKinnon [3] in the mixed model setting. In contrast, if these data were analyzed with a structural equation model (SEM) [4], variables in the causal pathway could be modeled directly by incorporating adherence into the SEM as a mediating variable between heavy alcohol consumption and HIV disease progression. Given the objective is to evaluate the total effect of the main independent variable, it is unclear whether there are benefits to modeling the mediated relationship in terms of bias, coverage, and power for the primary study aim.

Tradeoffs between the use of SEMs and LMMs have been previously evaluated in general settings, and the equivalence of LMMs and SEMs in some settings without mediation has been well documented in the SEM literature [5–12]. The potential advantages of using SEMs over LMMs to analyze longitudinal or hierarchical data include the capacity to explicitly model complex relationships such as mediation [4, 5, 7, 13–16], the flexibility in modeling covariance structures [7, 15], the availability of fit indices [8, 9], and the capability to account for measurement error [5, 9, 10, 15]. One disadvantage is the potential complexity of the SEM model and, therefore, the possibility of model misspecification. In addition, from a practical perspective, the SEM may be less convenient to implement given the need for specialized software. Nonetheless, its flexibility and capacity to directly

model variables in the causal pathway make it an appealing modeling technique for mediated longitudinal data.

In the absence of mediation, the type of SEM evaluated in this paper is often referred to as a latent growth curve model [13, 17–20]. Incorporating mediation into a latent growth curve framework has been demonstrated using either a time-invariant mediating factor that influences the latent intercept and slope factors of an outcome trajectory [14] or a time-varying mediator that assumes a parallel growth process in which both the mediator and outcome follow growth trajectories [21, 22]. For both of these approaches, mediation occurs at the random effect level (individual), rather than the observation level and, therefore, cannot vary over time. Modeling mediation that occurs at multiple levels in longitudinal data has been described using separate linear mixed effects models [3, 23, 24]. These multilevel models allow for mediation at the individual as well as observation level, but indirect and total effects are estimated from separate regressions. In the multi-level context, methods for assessing mediation at the observation level have been described with the added complexity that all mediated effects are random [25, 26]. Finally, longitudinal mediation has been described outside of the latent growth curve framework using autoregressive structural equation models [24, 27]. These models assume change over time, where the correlation between observations is not due to underlying random effects (latent intercept and latent slope), but rather results from direct association between an outcome and its value at a previous time point. Autoregressive models are, therefore, not a direct extension of LMMs but represent an alternative approach to model mediated longitudinal data. In this paper, we examine an SEM in which mediation is present at each time point and can, therefore, vary at the observation level. We do not assume that the mediator follows a parallel growth process and assume fixed, not random, effects of the mediator on the outcome. The mediated effects are estimated simultaneously rather than through separate multi-level models.

The performance of LMMs relative to SEMs in a longitudinal data setting with a predictor and mediator both measured only at baseline with longitudinal outcomes has previously been studied [28]. The LMM was accurate and efficient in a variety of settings in estimating the total effect of the main independent variable. The main advantage of the SEM was found to be the ability to simultaneously model the direct and indirect effects of the main independent variable. The objective of this study is to extend this previous work to the setting where the predictor and mediator are both time dependent with fixed effects that change across time.

2. Methods

In the current study, we evaluate the performance of the LMM relative to the SEM in the analysis of mediated longitudinal data with a time-varying predictor and mediator. As an example, we consider a prospective cohort study assessing the effect of heavy alcohol consumption on HIV disease progression [29]. The continuous outcome, CD4 cell count, is denoted by Y_j. The main independent variable, heavy alcohol consumption, is a time-varying binary variable denoted by z_j; ART adherence, the mediating variable, is a time-varying variable denoted by M_j; and baseline age, a continuous covariate, is denoted by w. ART adherence is a mediator if the primary independent variable, heavy alcohol use, affects CD4 count indirectly through ART adherence. In addition to indirect effects, heavy alcohol use may also have a direct effect on CD4 cell count that is not mediated by ART adherence or other variables. We focus on a setting where the primary aim is to determine the total effect (direct and indirect effect) of heavy alcohol use on CD4 cell count while appropriately accounting for the mediating effect of ART adherence. We arbitrarily assume there are six time points at which the outcome, predictor, and mediator are measured. Time is represented by t_j ($j = 1, 2, \ldots, 6$), and times are assumed equally spaced. In this setting, an LMM could be used to evaluate the total effect of alcohol consumption on CD4 cell count while accounting for correlation due to multiple assessments from the same individual and confounding effects of covariates. Using a LMM would not, however, allow for directly modeling mediation among the variables. SEMs are an alternative approach with the advantage of simultaneous modeling of direct and indirect effects of alcohol consumption on CD4 cell count. The objective of this paper is to evaluate whether the LMM performs adequately relative to the SEM when the goal is to determine the total effect of alcohol consumption, rather than to evaluate whether a variable (e.g., adherence) is a mediator. A series of simulation studies is carried out to evaluate the performance of several LMMs and SEMs under different conditions. We also describe the application of the various models to data from a prospective cohort study evaluating the impact of alcohol use on HIV disease progression.

2.1. General SEM Incorporating Mediation. There are two components to an SEM, the measurement model and the structural model [4]. The measurement model relates unobserved latent variables and covariates to outcomes and exposure indicators. In the measurement model, outcomes are observed variables, while predictors may be observed or latent variables. This model attempts to capture measurement error in observed variables. In the SEM, the repeated observations of CD4 count are the outcomes in the measurement model. The predictors in this model include underlying individual intercept and slope variables as well as time-varying primary independent variable (heavy alcohol use) and the time-varying mediator (ART adherence).

The second component to an SEM, the structural model, models latent variables as a function of observed variables and other latent variables. This model attempts to capture individual variation in the latent variables. In our model, the underlying individual intercept and slope variables are treated as latent variables and modeled as the outcomes of the structural model. In the case of the SEM incorporating time-varying mediators, the repeated mediators (ART adherence), while not latent variables, are also outcomes predicted with

some error by the time-varying primary independent variable (alcohol use) so they are incorporated in the structural model.

The general SEM incorporating mediation is described in the following equations. The subject index has been dropped in the equations below for simplicity:

$$Y_j = U_1 + t_j U_2 + \lambda_j M_j + \kappa_j z_j + \epsilon_j, \quad (1)$$

$$U_1 = \alpha_1 + \gamma_2 w + \zeta_1, \quad (2)$$

$$U_2 = \alpha_2 + \zeta_2. \quad (3)$$

for $j =$ 1 to 6,

$$M_j = \alpha_3 + \gamma_{1j}\, z_j + \zeta_{2+j}, \quad (4)$$

where $\text{var}(\epsilon) = \sigma^2 I$ and $\text{cov}(\zeta_1, \zeta_2) = \Psi$ and $\text{cov}(\zeta_3 : \zeta_8) = \Phi$.

The parameters and latent variables in the above equations are interpreted as follows.

(i) U_1 is the random intercept of the repeated outcomes.

(ii) U_2 is the random slope of the repeated outcomes.

(iii) λ_j represents the effect of the mediator on the outcome at time j.

(iv) γ_{1j} represents the effect of the main independent variables on the mediator at time j.

(v) κ_j represents the direct effect of the main independent variable on the outcome at time j.

(vi) The product $\lambda_j \times \gamma_{1j}$ represents the indirect effect of the main independent variable on the outcome at time j.

(vii) γ_2 represents the constant effect of the continuous covariate on the repeated outcomes.

The SEM mediation model is represented in Figure 1. In the following diagram we have used the conventions for SEM path diagrams including rectangles representing observed variables, ovals representing latent variables, triangles representing intercept terms, and arrows representing regression relationships between variables.

2.2. SEM Used for Data Generation. The simulated mediated data for this study are generated from an SEM, because our goal is to evaluate the performance of the LMM in a setting where the SEM is assumed to be optimal. We considered a setting where the effects of alcohol, the main independent variable, changed across time. Specifically, we assumed a constant short-term effect of alcohol on CD4 count for the first three time points and a constant long-term effect of alcohol across the last three time points. We refer to this as a "delayed effect" of the main independent variable. To model this delayed effect, we allowed κ_j in (1) to vary. Specifically, we set the first three κ's to be equal ($\kappa^* = \kappa_1 = \kappa_2 = \kappa_3$) and the last three κ's to be equal ($\kappa' = \kappa_4 = \kappa_5 = \kappa_6$), where $\kappa' > \kappa^*$. Short and long-term effects were similarly defined for λ_j and γ_{1j}. Under these assumptions, it can be shown that the predictive formula for a given outcome at time t_j, for $j = 1, 2, 3$ is

$$Y_j = (\alpha_1 + \lambda^* \alpha_3) + \gamma_2 w + \alpha_2 t_j + (\lambda^* \gamma_1^* + \kappa^*) z_j + \left(\zeta_1 + \lambda^* \zeta_{2+j}\right) + \zeta_2 t_j + \epsilon_j, \quad (5)$$

and for $j = 4, 5, 6$ is

$$Y_j = (\alpha_1 + \lambda' \alpha_3) + \gamma_2 w + \alpha_2 t_j + (\lambda' \gamma_1' + \kappa') z_j + \left(\zeta_1 + \lambda' \zeta_{2+j}\right) + \zeta_2 t_j + \epsilon_j. \quad (6)$$

The model assumes a linear effect of time on the outcome.

2.2.1. Simulation Procedures. For the initial set of simulations, we varied the distribution of the total effect of the predictor on the outcome. We evaluated three situations: (i) the total effect was equally distributed between the direct and indirect effect, (ii) the total effect was primarily direct (i.e., the direct effect was larger than the indirect effect through the mediator), and (iii) the total effect was primarily indirect (i.e., the indirect effect through the mediator was larger than the direct effect of the predictor on the outcome).

These simulations considered a setting where the true total effect of the primary independent variable was small (0.05) for the first three time points and small to moderate for the second three time points (0.25), as defined by Cohen [30]. These effect sizes were selected as they are considered feasible and realistic for a wide range of clinical settings. Effect size was defined as the true value of the regression parameter divided by the true standard deviation of the residual error term (ϵ_{ij}). We fixed the true standard deviation of all residual error terms in the simulated data to one, so the effect size is equal to the true value of the regression coefficient. We used a sample size of 350 as this sample size yielded adequate power for the second three time points with the effect size we assumed.

In addition to the initial set of simulations, we also performed simulations evaluating sample sizes ranging from 100–500 and alternative effect sizes, for example, small negative effect sizes as observed in the example data set described in Section 4, a moderate effect size (0.50) as defined by Cohen [30], and a null effect size to evaluate the Type I error properties of the models.

Model performance with respect to the effect of the primary independent variable on the outcome was evaluated separately for each time-point.

We generated data using the SEM described above with repeated measures of a continuous outcome, a random intercept and slope and a time-varying main independent predictor and mediating variable. The outcome, main independent variable, and mediator were each assessed at 6 time points. The following steps were taken to generate the mediated longitudinal data.

(1) Two multivariate normal random variates were generated, one corresponding to the residual variance of the latent intercept and one to be the residual variance of the latent slope.

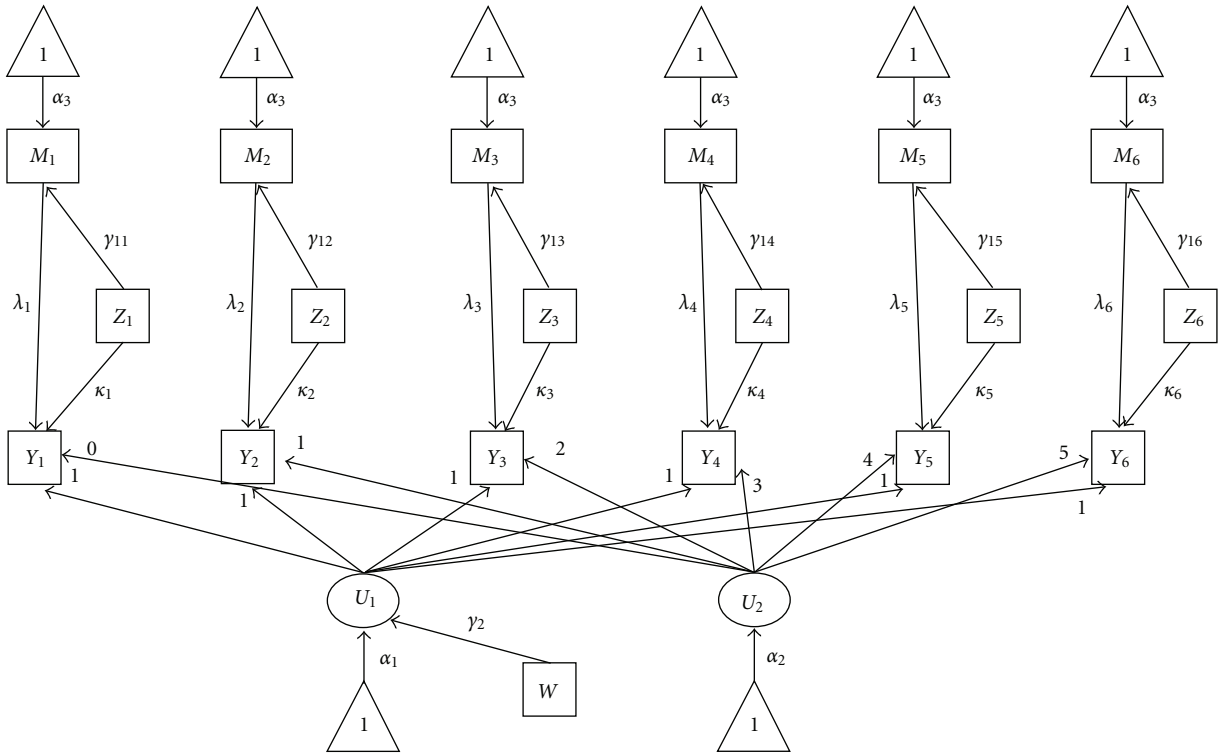

Figure 1: Path diagram of unrestricted structural equation model.

(2) Six multivariate normal random variates were generated corresponding to the residual variance of the mediator variables.

(3) Based on equations (2) and (3), the value of the latent intercept and latent slope were computed.

(4) Based on equation (4), the values of the mediator variables were determined.

(5) Six independent standard normal random variates were generated corresponding to the residual error of the six Y_j's.

(6) Based on equation (1), the value of the Y_j's were generated.

(7) Steps (1) through (6) were repeated 1000 times to create 1000 datasets for each simulation.

The models fit to the simulated data were evaluated by assessing: (i) Bias: estimated as the difference between the true parameter value and the mean observed parameter value divided by the true parameter value. (ii) Coverage probability: estimated as the percentage of the 1000 95% confidence intervals that contained the true parameter value. (iii) Power: estimated as the percentage of the 1000 datasets in which a hypothesis test of the parameter of interest was statistically significant and (iv) Type I error: for settings assuming null effects (for both direct and indirect effects), Type I error was estimated as the percentage of the 1000 datasets in which a hypothesis test of the parameter of interest was statistically significant.

2.3. SEMs and LMMs Fit to the Simulated Data. After the simulated data were generated as described above, the data were fit with three SEMs and five LMMs representing a range of possible models that could be fit to mediated longitudinal data.

2.3.1. Constant Effect SEM. The first SEM we evaluated represents one of the simplest and most common models that can be fit. This model assumes that the direct effect of alcohol on CD4 count is constant (i.e., $\kappa = \kappa_1 = \cdots = \kappa_6$), the effect of alcohol on ART adherence is constant (i.e., $\gamma_{11} = \gamma_{12} = \cdots = \gamma_{16}$), and the effect of ART adherence on CD4 count is constant (i.e., $\lambda_1 = \lambda_2 = \cdots = \lambda_6$). The total effect of the repeated primary independent variable on the repeated outcome is therefore represented by $\kappa + \lambda\gamma_1$. We refer to this model as the constant effect SEM (CESEM).

2.3.2. Delayed Effect SEM. The second SEM fit to the simulated data is the model that was used to simulate the data and defined in Section 2.2; that is, it assumes an early versus late effect. In this model, a short-term total effect of alcohol on CD4 count ($\kappa^* + \lambda^*\gamma_1^*$) is assumed for the first three time points, and a long-term effect of alcohol on CD4 count is assumed for the second three time points ($\kappa' + \lambda'\gamma_1'$).

2.3.3. Unrestricted SEM. The last SEM evaluated is the unrestricted model defined in (1)–(4) and represented in Figure 1. The unrestricted SEM is a model that could be used

to evaluate the nature of a mediated longitudinal relationship between alcohol and HIV disease progression without assuming how the effects may change across time.

2.3.4. Constant Effect Linear Mixed Model. The first mixed model fit to the simulated data assumes the effect of the repeated primary independent variable to remains constant over time. The formula for this constant effect mixed model is

$$Y_j = \beta_0 + \beta_1 w + \beta_2 t_j + \beta_3 z_j + b_1 + b_2 t_j + \epsilon_j, \quad (7)$$

where $\text{var}(\epsilon) = \sigma^2 I$ and $\text{cov}(\mathbf{b}) = \Psi$.

In this model, the interpretation of the parameters is as follows.

(i) β_0 is the intercept of the repeated outcomes.

(ii) β_1 is the effect of the continuous covariate, w, on the repeated outcomes.

(iii) β_2 is the effect of time, t_j, on the repeated outcome.

(iv) β_3 is the effect of the repeated primary independent variable, z_j, on the repeated outcomes.

(v) b_1 is the random intercept of the repeated outcomes.

(vi) b_2 is the random slope of the repeated outcomes.

We note that the mediating variable has been excluded from this model, since the goal is to evaluate the total effect of the main independent variable. If a known mediator is included in a model, then the parameter estimate associated with the primary predictor estimates the direct, rather than the total effect, of that predictor on the outcome [28]. Under the constant effect LMM defined in (7), the total effect of alcohol on CD4 count at any time-point is represented by β_3.

2.3.5. Full Delayed Effect Mixed Model. To capture potential short-term and long-term effects, we allowed the effect of alcohol at the first three time points to differ from that at the last three time points. To accomplish this, an indicator variable representing observations from the last three time points was entered into the model (i.e., indicator variable $I(j > 3) = 1$ at time points 4, 5 and 6 and $I(j > 3) = 0$ otherwise) and the following model was fit:

$$\begin{aligned} Y_j = {} & \beta_0 + \beta_1 w + \beta_2 t_j + \beta_3 I(j > 3) \\ & + \beta_4 z_j + \beta_5 I(j > 3) z_j + b_1 + b_2 t_j + \epsilon_j. \end{aligned} \quad (8)$$

Therefore, the regression model for $j = 1, 2, 3$ would be

$$Y_j = \beta_0 + \beta_1 w + \beta_2 t_j + \beta_4 z_j + b_1 + b_2 t_j + \epsilon_j, \quad (9)$$

and for $j = 4, 5, 6$, it would be

$$Y_j = (\beta_0 + \beta_3) + \beta_1 w + \beta_2 t_j + (\beta_4 + \beta_5) z_j + b_1 + b_2 t_j + \epsilon_j \quad (10)$$

In this model, the total effect of the repeated primary independent variable is represented by β_4 for the first three time points and $\beta_4 + \beta_5$ for the second three time points. In addition, the intercept of the repeated outcomes is given by β_0 for the first three time-periods and by $\beta_0 + \beta_3$ for the second three time-periods. Thus, this model allows for (a) estimating a potentially delayed effect of alcohol (z_j) and (b) accounting for a period effect, by allowing different intercept values for the early and late time periods. The period effect may be induced by the mediator's changing direct effect (in the SEM from which the data are generated, the mediator effect is $\lambda^* \alpha_3$ from (5) for the first three time points and $\lambda' \alpha_3$ from (6) for the last three time points).

2.3.6. Naive Delayed Effect Mixed Model. As described above, the simulated data are generated from an SEM where the effect of the mediator changes over time. In practice, such time dependent effects can be modeled directly as part of the mediation process using SEMs. In contrast, in LMM models, this difference in mean outcome value for early versus late effects can be captured by a time-varying intercept. However, the need for a time-varying intercept term is not immediately clear when fitting a mixed model in this setting, and thus, a model without time-varying intercepts may be more commonly fit. We refer to such a model as the naive delayed effect model

$$\begin{aligned} Y_j = {} & \beta_0 + \beta_1 w + \beta_2 t_j + \beta_3 z_j \\ & + I(j > 3) \beta_4 z_j + b_1 + b_2 t_j + \epsilon_j. \end{aligned} \quad (11)$$

This model is similar to the full delayed model but assumes the intercept of the repeated outcomes, β_0, is the same for all six time periods. In this naive model, the total effect of alcohol on HIV disease progression is given by β_3 for the first three time points and by $\beta_3 + \beta_4$ for the second three time points.

2.3.7. Time Interaction Linear Mixed Model. In mixed models, an interaction between time and the main independent variable is commonly included to assess whether the effect of the independent variable changes linearly across time

$$Y_j = \beta_0 + \beta_1 w + \beta_2 t_j + \beta_3 z_j + \beta_4 t_j z_j + b_1 + b_2 t_j + \epsilon_j. \quad (12)$$

In this model, the total effect of alcohol (z_j) is modeled as a linear function of time, t_j, and is represented by $\beta_3 + \beta_4 t_j$.

2.3.8. Unrestricted Mixed Model. The last mixed model we evaluated allowed the effect of alcohol on CD4 count to vary at each time-point, without assuming linearity. The equation for this unrestricted LMM is

$$\begin{aligned} Y_j = {} & \beta_0 + \beta_w w + \beta_{t_j} I\left(t_j\right) + \beta_z z_j + \beta_{z,t_j} I\left(t_j\right) z_j \\ & + b_1 + b_2 t_j + \epsilon_{ij} \end{aligned} \quad (13)$$

where $I(t_j)$ is an indicator of time point and is defined as $I(t_j) = 1$ if $t_j = j$ and $I(t_j) = 0$ otherwise. In this model, the effect of z_j is a function of time and is represented by $\beta_z + \beta_{z,t_j} I(t_j)$. This is the least restrictive model and is sometimes called a profile analysis [31].

2.4. Model Comparisons. To evaluate the performance of the LMM relative to the SEM, we made the following five comparisons.

(1) Constant effect SEM (CESEM) versus constant effect mixed model (CEMM).

(2) Delayed effect SEM (DESEM) versus full delayed effect mixed model (FDEMM).

(3) Unrestricted SEM (USEM) versus unrestricted mixed model (UMM).

(4) Delayed effect SEM (DESEM) versus naive delayed effect mixed model (NDEMM).

(5) Unrestricted SEM (USEM) versus time interaction mixed model (TIMM).

We simulated data under the SEM defined in Section 2.2. The SEMs were fit as a reference standard to compare with the LMM results, since the objective was to evaluate the performance of the LMM in a setting where the SEM is assumed to be optimal. For comparisons (1), (2), and (3), the main difference between the models is that the SEM explicitly models the mediation, while the LMM does not. All other aspects of the model are the same. Comparison 4 is of interest, because with time-varying mediated data, the naive delayed effect model is commonly fit within the mixed model framework. However, as described earlier, this model does not fully capture the time-varying mediation process, and thus, it is useful to evaluate its performance against the SEM. Comparison (5) is evaluated since a time interaction mixed model is also a common approach in the mixed model framework when a time-varying relationship is suspected. However, it relies on the assumption that the effect of alcohol is a linear function of time. It is, therefore, of interest to compare this model to the unrestricted SEM, which does not assume linearity.

3. Results of Simulation Study

3.1. Constant Effect SEM versus Constant Effect Mixed Model. In a setting where the true effect size changed over time, the estimated power to detect the true effect of the primary independent variables on the outcome from a model assuming a constant effect was generally inadequate with a sample size of 350 ($\leq$66% for both the SEM and LMM in all cases) (Table 1). When effects were distributed equally between direct and indirect effects, estimated power was similar for the two models although slightly higher for the SEM (65% versus 62%). The bias estimates for both the CESEM and CEMM were quite large (180% and 171%, resp., for t_1–t_3 and -44% and -45%, resp., for t_4–t_6), overestimating smaller short-term effects and underestimating larger long-term effects as would be expected. The coverage probability was also quite low although for both models, it was higher for the early time points compared to the later three time points. Similar results were observed when effects were primarily direct and also when they were primarily indirect. We note that we deliberately created a small effect at the first three time points to simulate a delayed effect of treatment on outcome and, therefore, did not expect to have adequate power to detect effects at the first three time points with the sample size evaluated. Similar patterns were observed with different sample sizes and effect sizes. Power was markedly lower for sample sizes less than 350 and for the reduced effect sizes.

3.2. Delayed Effect SEM versus Full Delayed Effect Mixed Model. The DESEM and FDEMM had similar power to detect long-term total effects independent of whether effects were equally distributed, primarily direct, and primarily indirect (Table 2). With a sample size of 350 and an effect size of 0.25, the estimated power for the last three time points for the DESEM was slightly higher (83%–85%) than for the FDEMM (82%–84%). The bias for both models was low (-0.1%-1.7% and -0.3%-1.4%, resp.) and the coverage probability was high (95% and 94% for the DESEM and FDEMM, resp.). Similar patterns were observed for other sample sizes with the same effect size. For smaller sample sizes (100 and 200), the power dropped to unacceptable levels (32%–63%).

Again, since the magnitude of the effect at the first three time points is small, we did not expect to have adequate power to detect such an effect in either modeling framework with a sample size of 350. In both models, the power to detect the total effect for the first three time periods was substantially lower than that for the last three (10%–13% in the first three time points versus 82%–85% for the second three time points for both models), where the effects were of a larger magnitude. With a sample size of 400, the power remained low to detect a small effect (-0.11, the observed effect size from the real data example standardized by the residual standard deviation) for both models (30% for DESEM and FDEMM). At all sample and effect sizes, results did not differ substantially between modeling frameworks.

3.3. Unrestricted SEM versus Unrestricted Mixed Model. With a sample size of 350, the performance of the USEM and UMM were very similar, regardless of whether effects were equally distributed, primarily direct, or primarily indirect (Table 3). As seen in previous models, the power to detect the effect at the first three time points was low (6%–9%) for both models. For the last three time points, the power to detect the effects was also low for both models (36%–58% for the USEM and 36%–55% for the UMM). The bias, however, was also quite low for both models (-0.08% to 2.9% for the USEM and -2.6% to 2.6% for the UMM). The coverage probability for both models was good (93%–96% for the USEM and UMM) across the different effect distributions. In these models, no specific relationship with time is assumed in the LMM or the SEM, so both models freely estimate the effect of the time-varying main independent variable on time. The cost of this, however, is that several more parameters must be estimated, and therefore, the power to detect effects is reduced. Similar patterns were observed for other sample sizes and effect sizes.

3.4. Delayed Effect SEM versus Naive Delayed Effect Mixed Model. With the sample size of 350, when the distribution of the effect was equally distributed, the power to detect the

Table 1: Performance of SEM and linear mixed model assuming total effect of main independent variable is constant when true underlying effects are small for early time points and small to moderate for late time points.

Based on 1000 simulated datasets.

total effect for last three time points was very good for the DESEM (83%), the bias was low (−0.1%), and the coverage probability was high (95%) (Table 2). In contrast, for the NDEMM, there was substantial bias (109%) in estimating the total effect for the last three time points. This naive model clearly does not correctly estimate the effect of the primary independent variable on the outcome. Similar trends were observed in the comparison of the two models regardless of how the total effect was distributed, the sample size, or the effect size.

3.5. Unrestricted SEM versus Time-Interaction Mixed Model. Regardless of the distribution of effects, sample size, or effect size, the TIMM and USEM had low power to detect the effect of the repeated primary independent variable on the repeated outcome for the first three time points (Table 3), as expected. With a sample size of 350, power ranged 7%–9% for the USEM and 5%–56% for the TIMM. For the last three time points at this sample size, the USEM had lower bias but also lower power compared to the TIMM. For the TIMM, incorrectly forcing a linear trend resulted in a larger degree of bias. While the TIMM had a large degree of bias at all time points, it has higher power than the USEM at most time points. This increased power relative to the USEM is likely due, at least in part, to fewer parameters being estimated. The higher power and bias of the TIMM relative to the USEM was also observed for other sample sizes and effect sizes (Table 3).

3.6. Type I Error Rates. Table 4 shows the estimated Type I error rates for a range of sample sizes. The nominal Type I error rate was 0.05. The Type I error was remarkably similar between analogous SEM and LMM models. Across all models, the observed Type I error rates ranged from 0.030 (CESEM, sample size of 350) to 0.072 (UMM, sample size of 100).

4. Real-Data Example: Alcohol and HIV Disease Progression

To demonstrate the application of the various LMMs and SEMs evaluated in the simulation study, we analyzed data from a prospective cohort study evaluating the effect of alcohol use on HIV disease progression. Samet et al. have previously reported the analyses from this longitudinal cohort study [29]. The original analyses combined data from two cohorts (the HIV-ALC and HIV-LIVE cohorts). To illustrate the models evaluated in this paper, we have used data from the HIV-LIVE study and fit the various LMMs and SEMs of interest. For clarity of presentation, we limited the analyses to observations where subjects reported any ART use during followup ($n = 319$) and included only the following key variables: heavy alcohol consumption (yes versus no), the main independent variable, ART adherence (percentage of pills taken in the last three days), the mediator;

age, a potential confounder, and CD4 cell count, the primary outcome. Each variable was assessed every six months for up to four years.

The total effect of alcohol consumption on CD4 count was not statistically significant in any of the SEMs or LMMs fit to the data. Estimated total effects are detailed in Table 5. Both constant effect models showed a small negative effect (−3.7 in the CESEM and −3.0 in the CEMM). The delayed effect SEM and LMM showed similar negative effects in the last four time points although the magnitude of effect in the DESEM was slightly larger (−10.3) than that for the DEMM (−4.1). The magnitude of effect at the first three time points was quite small in both delayed effect models but differed in sign in the DESEM (0.41) and DEMM (−2.3) although neither value was significantly different from zero. The unrestricted models generally showed similar results with effects ranging from −41.8 to 5.7 in the USEM and ranging from −15.8 to 9.5 in the UMM. The direction of the estimated alcohol effects were consistent between models with the exception of the third time-point which had a small estimated negative effect in the USEM (−1.4) and a small estimated positive effect in the UMM (6.9); however, neither effect was statistically significant. The magnitude of the effects were similar between the TIMM and USEM. Since a linear effect of time is assumed in the TIMM, however, all effects after time-point 2 are negative, whereas in the USEM, the direction of effects changes between negative and positive.

5. Discussion

Mixed models are a useful technique to analyze longitudinal data, with time-dependent variables. They can be applied to mediated longitudinal data, and a series of models can be fit to disentangle direct versus indirect effects of an exposure. However, it is unknown whether they perform well relative to SEMs, a method used for mediational analysis. In this paper, we evaluated the performance of the linear mixed model relative to the SEM in the setting of a time-dependent predictor and mediator, where the effects of both change over time.

The main simulation study assumed that the primary independent predictor had a delayed effect on the outcome (i.e., a small effect at the first three time points and a moderate effect at the last three time points). A range of SEMs (constant effect SEM, delayed effect SEM, and unrestricted SEM) and LMMs (constant effect mixed model, naive delayed effect mixed model, full delayed effect mixed model, time-interaction mixed model, and unrestricted mixed model) were fit to the simulated data.

Three comparisons were made between "analogous" models in that the main difference between models was that the SEM explicitly models the mediation, while in the mixed model, the mediator is removed from the model. The analogous models were constant effect SEM versus constant effect mixed model delayed effect SEM versus full delayed effect mixed model, and unrestricted SEM versus unrestricted mixed model. For each of the three comparisons,

Table 3: Performance of unrestricted structural equation model (USEM) and unrestricted and time interaction linear mixed models (UMM and TIMM, resp.) when true underlying effects are small for early time points and small to moderate for late time points.

the SEM and LMM yielded similar results. The power, bias, and coverage probability were all similar when the SEM and LMM were compared. The results from the analysis of data from a prospective cohort study evaluating the impact of alcohol use on HIV disease progression further illustrated the similarity of results from analogous SEMs and LMMs.

We also considered two comparisons of nonanalogous models. The first comparison was between the delayed effect SEM and the naive delayed effect mixed model. In the SEM framework, mediation can be directly modeled at each time-point, and therefore, the mediated delayed effect of the time-varying predictor is easily incorporated. In the mixed model framework, however, mediation is not directly modeled. Instead, mediators are removed from the model if the goal is to obtain the total effect of the time-varying predictor on the outcome [28]. Therefore, in the mixed model framework, it may not be clear whether a time-varying intercept term is necessary in the model to properly account for the mediated relationship between the predictor and outcome. Our simulations show that the naive delayed mixed model produced extremely biased estimates of both short- and long-term exposure effects, and coverage probabilities were poor. Therefore, although the naive delayed effect mixed model represents a model that may be a natural choice in the mixed model framework, it may not produce valid estimates. To obtain accurate estimates with the mixed model, fitting the full delayed effect model (with time-specific intercept terms) was required. However, as noted earlier, this model may be nonintuitive. This is a distinct disadvantage of the mixed model framework since the model that may be the most natural to fit may result in inaccurate estimates, whereas a natural choice for the SEM is the full delayed effect model, a model which performed relatively well. The second set of nonanalogous models compared the unrestricted SEM

and the time-interaction mixed model. These two models reflect a potential difference in the way that time is handled in the two frameworks. In longitudinal data analysis, SEMs incorporate the value of time as a fixed regression coefficient in the measurement model. Treatment of time is usually limited to a linear main effect of time. If some unspecified nonlinear relationship over time between the predictor and outcome is suspected, the most natural way to evaluate this is to leave the relationship between the time-varying predictor and outcome unrestricted and obtain separate estimates at each time-point as is done in the unrestricted SEM. In mixed models, however, interactions between time and other predictors (time invariant or time varying) are frequently incorporated. In our simulation study, the time interaction mixed model had substantially larger bias compared to the unrestricted SEM. Power was generally higher for the mixed model, possibly due in part to the fewer number of parameters being estimated. The difference between the time-interaction mixed model and the unrestricted SEM was also observed in the real-data example.

In the setting of mediated longitudinal data where exposure effects change over time, the mixed model performed well relative to analogous SEMs. The delayed effect SEM and full delayed effect mixed model had the best performance in terms of bias, coverage probability, and power in modeling the time-specific relationships between variables. It should be noted that in the setting of mediated time-specific effects, the delayed effect SEM, a natural choice for a model within the SEM framework, yielded substantially better results than the naive delayed mixed model, a natural model to choose within the LMM framework. Two other common models that may be fit, the unrestricted SEM and mixed model, both performed well in terms of bias and coverage probability, however, both had lower power due to the relatively large number of parameters being estimated for the given sample size. We note that the results observed in this study may not be generalizable to other settings, for example, scenarios with more complex pathways and relationships between variables could affect the performance of the LMM.

Linear mixed models can perform well relative to SEMs in the analysis of mediated longitudinal data with a time-dependent predictor and mediator. However, care must be taken to identify an appropriate model that adequately accounts for mediator effects, for example, by including time-varying intercepts and excluding variables in the causal pathway. In the specific setting of delayed effect of the time-varying predictor, common models fit within the mixed model framework may not perform adequately in this mediated longitudinal data setting. However, an appropriately specified mixed model can have good performance relative to the SEM in evaluating the overall effects of a time-varying predictor.

Acknowledgments

The authors wish to thank Howard Cabral and Timothy Heeren for thoughtful discussions of the problem, and the anonymous journal reviewer for constructive and helpful comments. We also thank Jeffrey H. Samet, PI of the HIV-LIVE Study (NIAAA: R01-AA13216), for use of the data.

ORIGINAL PAPER

Clinical Issues in Caring for Former Chattel Slaves

Rebecca D. Blumhofer · Neha Shah · Michael A. Grodin · Sondra S. Crosby

Published online: 17 December 2008

Abstract Over the centuries, slavery has become embedded into the social fabric of Mauritania with generations of abid and bizan (Mauritanian slaves and slave masters, respectively) born and raised knowing nothing but the institution of chattel slavery. Abid fleeing their station in Mauritania come to the USA with unique psychological needs that will affect all of their interactions with the medical community. This paper aims to assist health professionals and others concerned with the welfare of former chattel slaves in competently serving this vulnerable population. Discussion includes an overview of Mauritanian chattel slavery, deduced sequelae of chattel slavery, preliminary recommendations for mental health and medical treatment protocols, and suggestions for future research. A confidential Institutional Review Board (IRB)-approved case report will be used to illustrate these objectives.

Introduction

The Office of the UN High Commissioner for Human Rights asserts that the term "slavery" includes a variety of practices that violate human rights [1]. Some form of slavery is practiced on nearly every continent, involving approximately 27 million enslaved persons [2]. Table 1 describes different kinds of slavery found worldwide. In chattel slavery, slaves are born into a lifetime of bondage [3].

Mauritania is one of the few places on earth where chattel slavery is still practiced. Over the centuries, slavery has become embedded into the social fabric of Mauritania with generations of *abid* and *bizan* (Mauritanian slaves and slave masters, respectively) born and raised knowing nothing but the institution of chattel slavery [4]. An August 2007 Boston Globe article alerted its readers to the persistence of chattel slavery in Mauritania when reporting on the recent passing of a law promising jail time and fines for slaveholders, as well as reparations for those who have been enslaved. "The new law also makes any 'cultural or artistic work defending slavery' punishable by two years in prison, and makes it an offense for governmental authorities not to pursue slaveholders" [5]. Clinicians at the Boston Center for Refugee Health and Human Rights have been aware of Mauritanian chattel slavery because patients who bear the mental and physical scars of Mauritanian chattel slavery seek care and advocacy at the Center, including documentation of their experiences for asylum hearings. These patients have motivated the authors to begin the dialogue on how to sensitively meet the psychological and physical needs of female survivors of chattel slavery. Because Mauritanian chattel slavery is well

Table 1 Forms of slavery occurring worldwide [3, 8]

Forced and bonded labor. According to the International Labor Organization, an estimated 246 million children are engaged in exploitative child labor, with almost three quarters of them working in hazardous environments, such as mines or factories, or with dangerous substances like chemicals and agricultural pesticides. There are several types of forced labor slavery including: chattel, debt and forced labor. Countries involved in this activity include but are not limited to: South Asia, Central American and the United States.
Human trafficking. The use of children as a commodity for labor or sex is a lucrative international trade. An estimated 1.2 million children worldwide are trafficked each year, and some are arrested and detained as illegal aliens. Girls as young as 13, mainly from Asia and Eastern Europe, are trafficked as "mail-order brides". Up to 10,000 women and girls from poor neighboring countries have been lured into commercial sex establishments. Like other forms of criminal activity, trafficking is an underground activity and difficult to address.
Sexual exploitation. About 1 million children, mostly girls but also a significant number of boys, are exploited every year in the multi-billion-dollar sex industry. Such commercial abuse of children is fuelled by local demand, with sexual tourism only a small part of the problem. Since sexual activity is usually regarded as a private matter, Governments and communities alike are often reticent to intervene in cases of sexual exploitation. Countries involved in this activity include but are not limited to: South Asia and the United States.
Child soldiers. At any given time, over 300,000 child soldiers, as young as 8, are exploited in armed conflicts in more than 30 countries around the world. It is estimated that more than 2 million children have died over the last decade as a direct result of armed conflict, and at least 6 million have been seriously injured or permanently disabled. In addition, between 8,000 and 10,000 children are being killed or maimed by landmines each year.

documented, this paper will explore the experience of women enslaved in Mauritania. This overview of chattel slavery in Mauritania, complemented by a confidential IRB-approved case report, is meant to inform the care of survivors of Mauritanian chattel slavery and potentially any patient with a similar history of human rights violations.

Case Report: History

> Ms. B is a 25-year-old female from Mauritania with no prior medical care. She was referred to the Center for Refugee Health and Human Rights at the Boston Medical Center by her attorney for medical and psychological evaluation in preparation for her asylum application. Ms. B was born into slavery, as were previous generations of her family. She was not allowed to own any possessions and worked 7 days a week without any compensation. She was not allowed any form of education. During her enslavement, Ms. B experienced several forms of torture including serving as her master's concubine before entering puberty, being buried to her neck in the ground, and enduring beatings and deliberate burnings as punishment for transgressions. Consistent with her cultural tradition, Ms. B underwent female genital mutilation at a young age. She escaped from Mauritania by stowing away on a ship and sought asylum in the USA.

Chattel Slavery in Mauritania

Mauritania's 1961 Constitution and this nation's affirmation of numerous human rights documents[1] collectively condemn the practice of slavery. Nevertheless, ethnic, religious, social, and gender discrimination have fostered the persistence and discouraged the practical abolition of economic and physical slavery in Mauritania [6, 7]. Economic slavery can be thought of as bondage maintained by slaves' inability to be financially self-sufficient, while physical slavery can be understood as bondage perpetuated by physical forces that prohibit freedom of movement and association [7]. Economic and physical slavery themselves breed psychological slavery. The High Commissioner concurs, suggesting, "even when abolished, slavery leaves traces. It can persist as a state of mind—among its victims and their descendants and among the inheritors of those who practiced it—long after it has formally disappeared" [1]. A continued mental state of slavery in Mauritania has justified the maintenance of barriers preventing slaves from receiving education, training in marketable skills, and the ability to learn about and advocate for their political rights. The normalcy of slavery has also been upheld by propaganda asserting that serving masters is a religious duty of slaves that if shirked, results in eternal damnation. Moreover, many Mauritanian slaves are psychologically secure in their slavery [8], given that freedom in Mauritania may lead to poverty, job discrimination, and relegation to prostitution. Escaping slavery may also result in torture if caught, alienation in a society organized by extended

[1] Mauritania ratified the League of Nation's *Slavery Convention of 1926*, the *Supplementary Convention on the Abolition of Slavery, the Slave Trade, and Institutions and Practices Similar to Slavery* in 1986, the International Labor Organization's *Forced Labor Convention* in 1961, and the ILO's *Abolition of Forced Labor* in 1997. Being a member of the United Nations, Mauritania at least nominally proclaims and promises to promote the human rights principles embedded in the 1948 *Universal Declaration of Human Rights*. Furthermore, Mauritania acceded the *Convention on the Elimination of All Forms of Discrimination Against Women* in 2001, and both the *International Covenant on Civil and Political Rights* and the *International Covenant on Economic, Social, and Cultural Rights* in 2005.

families and ruled by the *bizan* caste, and damnation [6, 8]. Only approximately 100 *abid* escape from bondage in Mauritania per year [9].

Although female *abid* are in no way a homogeneous population, nearly all female *abid* share an ambivalent position in Mauritanian society [10]. Female *abid* are preferred over their male counterparts because of their greater versatility in the division of labor [4]. Though female *abid* can make intimate alliances with both free men and women in *bizan* society, they are continually rejected and deprived of their human rights. Historically, the primary role of female *abid* has been that of a domestic worker or tent slave woman. Domestic labor persists, yet to what extent is not clearly understood. While Ruf reports that it is mainly an outdated phenomenon in Mauritania [10], a former Mauritanian slave-owner recently affirmed the contrary [11].

Tent slave women are meant to unburden the women of the house of all inconsequential tasks [10]. The two most dishonorable chores that any woman in *bizan* society can do is pounding millet and fetching water, both of which are only done by female *abid* or machines. True to their ambivalent status in *bizan* society, tent slave women also have the privilege of entering their masters' homes—normally off-limits for slaves—by serving as their masters' concubines or their mistresses' wet nurses. Both forms of alliance allow female *abid* to achieve social ascension and individual respect. Marriage with a *bizan* man provides a concubine with manumission (though she is never accepted by the world of *bizan* women) and their children share their father's status. Engaging in the institution of milk kinship enables slave women to experience a sense of belonging, enjoy social motherhood, and obtain "the right to locate themselves within the core locality of femininity," i.e. the master's tent [10].

As economics and technology change Mauritanian society, slave practices have not ended. *Bizan* women simply adapt these practices in order to maintain their superiority over *abid*. Since the severe drought of 1969, the destruction of Mauritania's economy has left many *bizan* impoverished. Poverty has prevented many free women from living up to the society's conceptions of ideal femininity: obesity and inactivity. If free women must be active in the home, they can redraw cultural boundaries in order to sustain the differences between *abid* and *bizan* by having slave women perform the most dishonorable jobs in the home. Free women can also deprive female *abid* of respect by disregarding the traditional practice of a strict gender division of labor and thus having slave women engage in men's work outside the camp: herding and cultivation. While pastoral work is no longer common because of sedentarization and the loss of animal capital, women have nearly supplanted men in the fields because of male migration to the cities. When slave women engage in cultivation, they are denied their femininity. "The locus of this battle is both the nature and the location of work" [10].

Psychological Sequelae of Mauritanian Chattel Slavery

> Ms. B's review of symptoms included pelvic pain, headaches, body pain, nightmares, sleep disturbance, flashbacks, and exaggerated startle response. She also suffered from hypervigilance, particularly that "the Master" would find her and return her to his plantation where she would be punished for running away. Ms. B reported witnessing public beatings on her owner's plantation in which recaptured slaves were killed.

The emotional dimensions of slavery have received little historical attention [12]. Only one social scientist, Orlando Patterson, has attempted to investigate and publish his findings on the psychology of Mauritanian slavery. Patterson defines a slave as a "socially dead person," alienated from all 'rights' or claims of birth, and not belonging in his/her own right to any legitimate social order [4]. Furthermore, female *abid* have no independent social existence, as evidenced in their characteristic inability to speak in their own words or consider themselves apart from their masters [10]. Their social identity is bound to their roles within their masters' families which, paradoxically, is the place where they are dehumanized, de-socialized, and de-gendered [10]. Thus, in the midst of serving their masters and mistresses, female *abid* face a terrible and confusing mixture of affection and inclusion, as well as deprivation, rejection, and exclusion.

Made to think that they are helpless children, female *abid* tend to believe that they require their masters to exist. Moreover, prevented from interacting with or marrying people of their own choosing while enslaved, female *abid* learn to depend on their masters' family for affection. This emotional attachment persists even after slaves escape. Also, told to believe that they were placed on earth to serve their masters, female *abid* look to their masters for salvation. Thus, some slaves who have escaped have willingly returned to their masters in order to again receive their master's provision and protection in Mauritania's hostile and discriminatory society [13]. *Bizan*, on the other hand, cannot function without their slaves and would never consider voluntarily freeing them; such an action would be a great dishonor [11]. As a result, a tremendous co-dependency exists between slave women and their masters. Bales describes this co-dependency as an "insidious mutual dependence that is remarkably difficult for slaveholder as well as slave to break out of" [14].

A great measure of personal resiliency is required to continually face the assertion of otherness when living in close proximity to mistresses and engaging in de-socialized and de-gendered slave labor. Not surprisingly, the highest aim of slave women is to become what they are not: they desire to adopt the key characteristics of a noblewoman, including inactivity, obesity, and the practice of a few, most often collectively performed tasks requiring only minimal physical input [10]. Social and behavioral scientists have shown that people having relatively less political power, cultural assets, social assets, honorific status, and human resources than others around them suffer from more physical and mental health problems than people residing in more equitable environments where such gaps in control and resources do not exist [15]. Slave women, therefore, are prone to developing a sense of otherness and shame from always seeing, yet never enjoying, the benefits of being a feminine noblewoman.

Female *abid* are also prone to unique perceptions of powerlessness because their social identity is determined by their current husband. If a slave woman is forced to divorce and marry another freeborn man, she must leave her children and friends from the previous marriage behind. Frequent rapes [16] and forced prioritization of masters' children over slaves' children enhance chattel slaves' feelings of powerlessness and shame [3]. Female *abid*'s role as sexual pleasure objects and their precarious connection with blood and self-selected community ties underscore how *bizan* society views these females as socially dead. Indeed, they are considered ultimate human tools—imprintable and versatile non-persons [4].

Not surprisingly, female *abid* are likely to suffer from a slave mentality. If, when, and to what extent this slave mentality develops, will impact slave women's mental health, their resulting psychological needs, and the timing of their healing process. The longer a female *abid* internalizes her slave identity, the more extended and intensive her treatment will likely be. The slave mentality is marked by three main characteristics: disconnection, disempowerment, and self-blaming. An overwhelming sense of otherness, namelessness, and invisibility can lead to disconnection from others. Endless personal violation and violence intended to maintain a reduced sense of physical and mental integrity are likely to promote feelings of powerlessness. The experience of chronic dishonor, as well as an inability to be like mistresses, care for children, and change their situations, can lead to the projection of shame and outward demonstrations of self-hatred.

Depending on the severity of a slave woman's "servile personality" [4], she may experience corresponding levels of mental exhaustion and depressed ego function [17, 18] that overshadow her will to defend her own interests within bondage, and if freed, to live her freedom [11]. Also depending upon the presence and/or nature of her slave mentality, she may lack interest in becoming aware of her social and religious deprivations and may not feel responsible for her own fate [10]. Therefore, individuals may struggle with the internalized messages of slavery for years after formal manumission or escape. Working through these messages may be even more difficult when it takes place outside of a former slave woman's country, culture, and community, since her relocation-related feelings of alienation and non-efficacy may impede her healing process. Survivors' ability and/or desire to recognize and accept their personhood and desert of human rights may be the final arbiter in determining whether they will win their psychological struggle to become like the *bizan*, the free people. Health professionals when given the opportunity, can assist female survivors of Mauritanian chattel slavery in finding strength within the human spirit to reclaim their social identity, femininity, and personhood—perhaps for the first time.

The situation presented by patients with a history of chattel slavery, though terrible, is not hopeless. Indeed, the institution of slavery is "oppressively weighted against the slave" [4], yet many women, while still in slavery, constantly struggle with the "weapons of the mind and soul" to "minimize the burden of (their) exploitation and enhance the regularity and predictability of (their) existence" [4]. Thus, female *abid* must not be dismissed as "passive victims of their brutal masters" [10] or "powerless, isolated, and degraded" persons lacking spirit, self-interest, and will [4].

Survivors of Mauritanian Chattel Slavery in USA

Roughly 3,000–4,000 Mauritanian refugees and asylees reside in the USA [9]. In 2006, 88 Mauritanian refugees arrived in the USA; 218 Mauritanians gained asylum defensively and 12 were granted asylum affirmatively [19]. Unfortunately, there is no reliable data on the number of Mauritanian survivors of chattel slavery in the USA. Female survivors of Mauritanian chattel slavery who arrive in the USA are likely to have characteristics that distinguish them from the female *abid* discussed earlier that may affect their health care needs. First, they are more likely to have suffered physical violence from their masters [8]. Second, they may have a stronger sense of identity and a greater awareness of or longing for freedom. Third, they may have had an opportunity to learn about their political and civil rights in Mauritania or develop critical thinking skills from their masters' children who themselves questioned slavery and thus secretly educated their and/or their parents' slaves. Lastly, they are likely to have exceptional inner strength, evidenced by their ability to leave at least

part of their families behind, escape from their masters, and journey to the USA.

These differences should help survivors of Mauritanian chattel slavery progress along their healing journey. Though the occurrence of physical violence is tragic, it may help patients recognize that their former *bizan* are not perfect and superior beneficent providers, saviors, or gods, and rather are fallible human beings. Histories of physical violence may also ignite in survivors an intrinsic need to defend themselves. This desire to protect self can be harnessed in the recovery process. The self-awareness and development of ego functions made possible by the other three distinctions between *abid* in Mauritania and survivors of Mauritanian chattel slavery in the USA should all aid in the humanizing, connecting, and empowering goals of mental health and medical treatment.

Proposed Framework for Mental Health and Medical Treatment

No formal research has been published on caring for female survivors of chattel slavery. Nevertheless, western psychology and psychiatry offer three helpful concepts that may facilitate health professionals in serving this and similar patient populations. The first concept is complex posttraumatic stress disorder (PTSD) (Table 2), characterized by systematic and pathological changes in a person's affect regulation, consciousness, self-perception, identity, perception of her perpetrator, relations to others, and systems of meaning [17]. Herman describes complex PTSD resulting from chronic trauma as "classic post-traumatic syndrome" coupled with "profound alterations in (patients') relations with God, with other people, and with themselves" [18]. Complex PTSD involves the fusing of "protracted depression" and "chronic hyperarousal and intrusive symptoms" to create "the 'survivor triad' of insomnia, nightmares, and psychosomatic complaints" [18]—all of which have been reported by survivors of slavery [3]. Complex PTSD further entails the merging of depressive symptoms with chronic trauma's sequelae to form destructive couplets more pathological than the sum of their parts: dissociation with concentration difficulties, apathy and helplessness with paralysis of initiative, isolation with disruption in attachment, depressive guilt with debased self-image, and hopelessness with loss of faith [18]. Patients with complex PTSD also project their intense anger with their perpetrators onto themselves. There are no data specifically on the prevalence of complex PTSD in a population of former slaves, however in an urban population of adult refugees, 9% have experienced PTSD symptoms [20].

Table 2 Complex PTSD symptoms [3, 4, 7, 8, 17, 18]

Alterations in emotional regulation
Including: persistent sadness, suicidal thoughts, explosive anger, anger projected towards self
Alterations in consciousness
Including: chronic hyperarousal, forgetting and/or reliving traumatic events, dissociation, concentration difficulties, insomnia, nightmares, psychosomatic complaints
Alterations in self-perception and identity
Including: apathy, helplessness, shame, guilt, stigma, reduced self-efficacy, sense of being completely different than other human beings
Alterations in the perception of the perpetrator
Including: attributing total power to the perpetrator, preoccupation over the relationship with the perpetrator, preoccupation with revenge
Alterations in relations with others
Including: isolation, distrust, repeated search for rescuer or new master
Alterations in one's system of meanings
Including: loss of sustaining faith, sense of hopelessness and despair

Psychology's second applicable tool is that of mental defeat, which results from multiple, severe, prolonged, and inescapable aversive non-physical attacks done in the context of totalitarian control. Mental defeat can be understood as a perceived loss of autonomy, choice, and free will, as well as the belief that one's identity cannot be maintained [17]. Not all who experience loss of autonomy develop mental defeat, suggesting that mental defeat is an intermediary step between loss of autonomy and mental death. Furthermore, mental defeat may be predictive of PTSD incidence and severity [17].

The third concept is that of mental death, which is a form of complex PTSD that arises from threats to psychological, rather than physical, integrity [17]. Mental death is characterized by a loss of identity possessed before experiencing interpersonal trauma within the context of totalitarian control. It is associated with guilt and shame; distrust and alienation from others; feelings of ineffectiveness, inability to actively cope, loss of self-efficacy, and loss of autonomy; loss of core beliefs and values; and a sense of being permanently damaged.

While the concepts of complex PTSD, mental defeat, and mental death all have similarities with the concept of "slave mentality," they may not be fully adequate in instructing health professionals on how to best care for survivors of slavery. Used in understanding sequelae of organized political torture, complex PTSD, mental defeat, and mental death all assume a pre-trauma identity, as well as alterations or losses to that identity. Women who have been enslaved since birth, however, may have never had such an identity or conceived of a world that does not include their trauma. The

absence of pre-trauma histories, as well as the presence of complex, chronic trauma histories may make conducting psychological assessments and creating treatment plans more difficult. Chronic trauma and its presence during numerous stages of a person's life make reconstruction of trauma history very complicated [18]. Furthermore, disorganized and fragmented memories—characteristic of chronic trauma—are difficult to process [17]. The confusing nature of relationships in chattel slavery and the long-term nature of the trauma endured by survivors of chattel slavery will likely slow their progress. Conversely, survivors of chattel slavery cannot rely on pre-trauma life experiences to guide their current and future behaviors [17].

Mental Health Treatment

Since "real liberation takes place in the mind" [14], survivors of chattel slavery coming to the USA may benefit from mental health care. At best, former slaves who are not ready to hear about or embrace freedom simply laugh at the concept [11]. At worst, they attempt suicide when slavery—the major psychological building block of their lives—is challenged [14]. Therefore, it is important that health professionals recognize the former slave status via an appropriate patient history and then only treat those who desire recovery and freedom. Herman supports this assertion, while Gray et al. [13, 18] suggest that in situations of limited resources, treatment should be further narrowed to those patients who are most at risk for persistent distress.

Although there are no data on effective treatment methods specifically for former chattel slaves, treatment can be initially modeled after protocols for survivors of other forms of trauma. Treatment should be culturally sensitive [21], early, active, empowering, supportive, multidisciplinary, and structured [22]. Moreover, no treatment regimen has been developed specifically for complex PTSD, though it is known that exposure therapy is not helpful [17]. In general, therapists should address survivors' disempowerment, disconnection, co-dependency, self-blaming, and PTSD symptoms. Offering moral solidarity, rather than clinical neutrality, will be especially necessary in caring for survivors of chattel slavery as they learn to embrace and explore their freedom for the first time [18]. Medications have been helpful as adjunct therapy for treating complex PTSD symptoms and major depressive disorder.

Survivors of chattel slavery will likely require a combination of cognitive, interpersonal, and social strategies over the course of a long period of time [18]. Benchmarks for the effectiveness of treatment focused on empowerment should include indications of identity formation, self-efficacy, self-worth, the ability to go to school or work, the aptitude to care for oneself and one's family, the capability to act on dreams and aspirations, and the capacity to formulate and express one's own sense of spirituality. Recovery surrounding relational issues is marked by the lessening of fear, shame, guilt, self-hatred, anxiety, and sense of contamination; the experience of respect and honor; the ability to foster, develop, and maintain safe and meaningful alliances and relationships [23]; and the capacity to enjoy healthy forms of intimacy. Other benchmarks for healing include the absence of or ability to control PTSD symptoms, the formation of a coherent narrative of trauma linked with emotions, and the construction of a coherent system of meaning and belief that encompasses the trauma story [18, 21].

A sense of temporal and eternal safety should be established early in treatment. Temporal safety enables survivors of chattel slavery to feel less vulnerable, to gain a sense of predictability, and to develop self-efficacy and trust. Learning how to control their bodies and their environments as much as possible will aid survivors in experiencing temporal safety [18]. Because survivors' bodies were literally owned by others, working towards ordering their actions may be especially difficult. A sense of eternal safety will also be important if survivors of chattel slavery are to embrace and learn to live their freedom, as fear of damnation resulting from fleeing bondage will likely haunt these patients. Imams can be instrumental in correcting misconstrued religious beliefs that were used to justify slavery. Helping patients adopt a less hierarchical version of Islam will also be helpful in combating remnants of pro-slavery thinking. Therapists should be aware that female survivors of chattel slavery may be hesitant in speaking with Imams because women in Mauritania are forbidden to receive religious instruction.

Helping survivors become aware of their humanity will also be necessary for healing to occur. Mental health professionals should assist patients in recognizing their emotions, sense of morality, talents, and ambitions. Mourning loss will be an important stage for therapists and survivors of chattel slavery to explore. Like mental health professionals caring for survivors of child abuse, therapists working with survivors of chattel slavery will need to walk alongside patients as they mourn what was never theirs to lose [18]. Patients' anger at the system of slavery in general and masters in particular can promote recovery, as long as this anger can be channeled in a constructive way. The desire for freedom, as well as for the equality, free choice, paid labor, and ability to act on preferences that it can bring, will be a great ally in the recovery of chattel slavery survivors.[2]

[2] "'When a slave runs away,' says Nasser, 'he's losing his roots. Slavery is his reality.' In such a context, 'it would take a person of enormous energy, with a built-in quest to find a new life, to stand up and walk away,' says Robert Pugh, a former US ambassador to Mauritania" (Skinner 43).

Assisting survivors in becoming self-sufficient will be very important in furthering their recovery. In individual therapy, mental health professionals can draw out patients' unique coping mechanisms and have them recount the various ways in which they resisted the system of slavery while still in bondage. Encouraging survivors of chattel slavery to take part in education, life skills, and occupational training programs will further their sense of self-efficacy. Vocational rehabilitation specialists will also be important in helping survivors of chattel slavery formulate and work towards personal goals and help them develop autonomy. Aiding survivors of chattel slavery learn life-skills, such as planning a daily schedule, will be especially important since former slaves have reported difficulties in getting out of bed and performing daily activities without their masters to direct their steps [11].

Aiding survivors in developing dialectical thinking is important, as this will help them adopt new beliefs and attitudes in a healthy manner [17]. For survivors of chattel slavery, slavery was and to some extent probably still remains a normal part of life. Challenging vestiges of patients' old belief systems and having them reconstruct worldviews that affirm the injustice of slavery will be painful. This is the irony of caring for survivors of chattel slavery—therapy may be the cause of just as much, or even more, cognitive upheaval than the original trauma [18]. Literacy and education classes will help survivors of chattel slavery cope with the cognitive dissonance that inevitably results from realizing that they once affirmed a system of life to which they can no longer ascribe.

In situations where race is used to justify chattel slavery, further cognitive restructuring should be done to address the assertion that dark skin indicates impurity [11]. Also, therapists should help survivors of chattel slavery in recalling events during which they witnessed the fallibility of their masters [11]. By simultaneously helping survivors discover their own identities as human beings and working with them to understand that they are not inferior, but rather are of equal standing with their masters, therapists can assist survivors of chattel slavery in countering feelings of otherness, degradation, and disenfranchisement [18, 21]. Once survivors accept that their former masters have no power over them, they can develop the ability to live apart from and uphold different beliefs than their masters. Such will further the process of empowerment and connection necessary for recovery [18].

Developing the ability to establish beneficial, appropriate connections with others will also be an important goal for survivors of chattel slavery. Individual therapy can assist survivors in learning how to trust and be known by another within a supportive, collaborative atmosphere. Therapists should be aware that the risk of transference and counter-transference is especially great because of the tremendous power differential between mental health professionals and survivors of chattel slavery [18]. A survivor may come to think of her therapist as her new mistress [22], making it difficult for the patient to enter a collaborative physician–patient relationship [18]. Conversely, mental health professionals may struggle with wanting to fulfill the savior-like role imposed on them by their patients [3, 24]. Because of possible rape histories and Mauritania's fundamentalist culture, female therapists should work with female survivors of chattel slavery whenever possible.

In addition to individual therapy, group therapy may provide survivors of chattel slavery with a space to engage in psychoeducation, open group discussion, cognitive restructuring, maladaptive interpersonal relationship work, and problem solving. Group therapy has been shown to reduce some childhood trauma symptoms [25] and help trauma survivors develop and maintain safe relationships, as well as explore how past trauma affects current relationships [23]. Group therapy may prove to be especially useful in helping survivors of chattel slavery combat common fears, including anxiety about the responsibility of living on one's own and the belief of damnation resulting from fleeing bondage. Patients may also fear that their masters will find them in the USA and punish them for escaping. Moreover, survivors of chattel slavery may suffer from knowing that without formal papers of manumission, they will never be considered free in their home country. Guilt from abandoning their own and their masters' families, the slave mentality, psychological symptoms, fatalism, expectations of a short life-expectancy and the consequent devaluing of future-focused thinking [22], and negative attitudes towards mental health treatment [22] are also significant barriers to healing. It has been shown that those with mental defeat or mental death have more severe PTSD and are more treatment-resistant [17]. Furthermore, those with mental death are reportedly less likely to have optimistic expectations about therapy and have more difficulty developing effective working relationships with therapists [17].

Social support systems, whether formal or informal, will be very important in helping survivors of chattel slavery gain a sense of connection and solidarity with others as equals. Having survivors of chattel slavery become involved in their communities and take part in social obligations—such as *zakat*[3]—will help them join a moral and social space in which their humanity and dignity are affirmed. Holding some form of public celebration in which survivors can declare their freedom and personal identity may serve as an important milestone for some patients.

[3] *Zakat* is tithing for the poor prescribed by Islam (Ruf 263).

During therapy sessions, language barriers, cross-cultural issues, transference, counter-transference, vicarious traumatization, patients' dishonesty [24], and the painful cognitive restructuring embedded in the therapy process itself will hinder recovery. The stressful asylum-seeking process, discrimination of all kinds, and re-victimization in the form of unhealthy relationships at best or new slavery at worst will delay the establishment of safety in the USA. In addition to having compromised abilities to defend their own interests, survivors of chattel slavery may not resist new slavery in the USA because it typically involves work with which they are familiar and may enjoy—domestic services, agricultural work, street peddling, and restaurant services. An absence of standard of care guidelines for this patient population, as well as resource limitations and difficulties in finding safe, affordable housing for slavery survivors will all likely impede the recovery process [3].

One of the greatest challenges that face both survivors of chattel slavery and their health professionals is residual religious-based messages yoked to the concept of slavery. Patterson asserts that masters' authority "rests on the control of those private and public symbols and ritual processes that induce (and seduce) people to obey because they feel satisfied and dutiful when they do so" [4]. In Mauritania, masters exploit Islam to justify and maintain current oppressive practices [6, 12]. *Bizan* and religious leaders teach *abid* that slavery is a duty that must be fulfilled in order to please Allah. Such indoctrination, evidenced in the common Mauritanian phrase, "the way to heaven is underneath the sole of your master's foot" [6], entangles masters with the concepts of mediator, savior, and God. Masters are not only mediators between secluded slaves and the world outside their masters' camps, but between earth and heaven. Thus, a former Mauritanian slave woman spoke [6]:

> We hear of abolition, but for most slaves it does not mean much. It is hard to ignore what they have been told all their lives, that without their master they cannot survive, that only he can ennoble them, give meaning to their life and lead them to heaven. They believe this; so how can they also believe that they must escape the situation that promises to give them so much? The slave lives in perpetual awe of his masters and is not aware of any other way of life.

The exploitation of faith and concepts of salvation are particularly dangerous for the minds and souls of slave women. Being female, they will have the least opportunity to learn what Islam truly asserts regarding God, their relationship with God, slavery, and the actual duties called for by Islam [10]. Ignorance, the need to hope for a better future in order to endure present suffering [8], and the willingness of many men and women throughout human history to preserve eternal rather than temporal life according to their belief systems [26] may be the most difficult barriers to successfully caring for the mental health of women with a history of chattel slavery.

Medical Treatment

Case Report: Physical Exam

> On initial visit, Ms. B's affect was numb and flat. She displayed little emotion, even when describing horrific events. Ms. B was unable to give a chronological history of life events, had no sense of linear time, and lacked spontaneous speech. Physical examination was difficult because of her fear and was terminated early during the abdominal/external pelvic exam due to a terror reaction. Ms. B's skin was significant for multiple scars and healed burn marks. The limited abdominal exam revealed a tender suprapubic mass and follow-up transabdominal pelvic ultrasound revealed an adnexal cystic mass. Ms. B was referred for exploratory laparoscopy. Prior to the procedure, she was given a tour of the operating suite and a detailed explanation of what she should expect on the day of surgery. During the procedure, she had a pelvic examination and pap smear under general anesthesia. Ms. B's primary care physician arranged to be in the preoperative area to give reassurance and in the recovery suite to provide support and monitor for posttraumatic stress disorder symptoms.

Providing medical care to women with a history of complex trauma, including chattel slavery, requires the establishment of trust and rapport through empathy, respect, patience, and active listening. Former slaves seeking health care in the USA may have never received any prior medical care and may be unfamiliar with bio-western medicine. Undergoing physical examinations, phlebotomy, routine screenings, and vaccinations may be foreign. In addition, survivors of chattel slavery may have difficulty answering questions routinely used to gather patient histories. Echolalia, monotonic speech, flat affect, paucity of rich language structures, difficulty expressing complex thought, and ignorance of age may be due to prolonged isolation, lack of social stimulation, and little practice with two-way dialogue. Medical providers should be familiar with and evaluate the former slave for physical sequelae of torture. Signs and symptoms can include sexual trauma, scars, musculoskeletal injuries, and head trauma.[4]

[4] The online course, *Caring for Torture Survivors*, provides an extended discussion (with illustrations) on mental and physical sequelae of torture, as well as how mental health, medical, and oral health professionals should approach such sequelae (www.bcrhhr.org).

The environment for the clinical encounter and physical exam should be made as comfortable and safe as possible. Selecting appropriate décor and limiting the number of medical instruments easily visible help in creating a safe atmosphere. Using trained, same-sex interpreters in caring for traumatized women who do not speak English is recommended. Health professionals at the Boston Center for Refugee Health and Human Rights have found telephone interpreter services very helpful. Survivors of chattel slavery are accustomed to lacking control over internal and external loci. Consequently, physicians may need to provide patients with encouragement in exercising control within clinical encounters. For instance, physicians should give patients explicit permission to terminate either the interview or examination whenever the patient feels uncomfortable. Moreover, patience and understanding is necessary as survivors learn to think about and perform multi-step tasks within and outside the clinic (i.e. giving voluntary informed understanding consent and medical adherence).

In addition to addressing the medical needs of patients, clinicians can serve an important function in the asylum seeking process, as affidavits documenting physical and psychological sequelae are often helpful in supporting asylum claims. Physicians who care for survivors of slavery will need to work closely with legal professionals, as the asylum-seeking process allows survivors to begin the acculturation process and assume the responsibilities and privileges corresponding with asylum. Specifically, gaining asylum gives survivors of chattel slavery legal and social standing, as well as the ability to work, which will be instrumental in satisfying patients' needs for empowerment and connection.

Case Report: Follow-Up

> Ms. B has made great strides despite the inadequacies of the medical community's understanding of how to effectively address her health needs. She has gained a full range of emotions and speech, her mental health symptoms have abated, and she continues to receive supportive care. With the help of an affidavit written on her behalf by her physician at the Boston Center for Refugee Health and Human Rights, Ms. B was granted asylum. She has begun to learn English and is now living in safe housing with two family members.

Agenda for Further Research

The above recommendations on caring for female survivors of chattel slavery have not been confirmed by research. Instead, these paradigms were developed from the limited information known about the socio-historical context of chattel slavery in Mauritania, as well as from best practice guidelines for patients with histories of other types of torture and trauma. Application and evaluation of these recommendations is necessary in order to establish sensitive and competent protocols that support the mental health and medical needs of all female survivors of chattel slavery coming to the USA.

Research should be directed at identifying the psychological symptoms and needs of chattel slavery survivors. Such research would ideally be used to accept or reject the possible relationships among mental defeat, mental death, slave mentality, and chronic PTSD proposed in this paper. Once the mental sequelae of chattel slavery is better understood, prospective studies should be performed in order to determine how to best care for the mental health of chattel slavery survivors. Data collection could include survivors' beliefs about mental health and medical treatment, as well as patient responses to various treatment approaches in various clinical settings.

Research should be preceded by consultations with institutions and professionals who have worked with survivors of chattel slavery.[5] Such consultations can provide information on how experienced professionals understand the psychological impact of chattel slavery from working with people with a history of such trauma. Consultations may also shed light on how experts have treated or supported survivors of slavery, what they have found to work and not work, and what questions they still have.

Because few survivors of chattel slavery have been identified in the USA, research endeavors may need to go beyond female survivors of chattel slavery to include male survivors, and perhaps men and women with histories of other forms of slavery. Broadening the subject pool may be necessary to ensure valid and generalizable data. Whether and when formal research should be done with survivors of slavery is a question that is beyond the scope of this paper. Such a decision involves a myriad of ethical dilemmas—typically surrounding the principles of beneficence and autonomy—that must be wrestled with in a serious

[5] Experts that may be helpful can be found at the Center for Refugee Health and Human Rights (http://www.bcrhhr.org), Iabolish (http://www.iabolish.org), Free the Slaves (http://www.freetheslaves.net), the Bellevue/NYU Program for Survivors of Torture (http://survivorsoftorture.org/survivors), the Department of Sociology and Anthropology at Georgetown University (http://www3.georgetown.edu/departments/sociology/about), the Program for Survivors of Torture and Severe Trauma: Center for Multi-Cultural Studies (http://ncttp.westside.com/wsContent/default.view?_pagename=VA-Program+for+Survivors), and the UUA Holdeen India Program (http://archive.uua.org/international/holdeen/panditbio.html).

manner.[6] If experts working with and knowledgeable about survivors of slavery agree that this population should be involved in research to help therapists learn how to best care for them, a retrospective study could be conducted to formally understand how survivors of slavery have responded to various interventions thus far. In addition, prospective research directed at determining which forms of mental health interventions are most effective could be performed. All the data collected from consultations, interviews, and research can be used to create best practice guidelines. These guidelines can be disseminated via the internet—discussed and improved by experts over time—and hopefully will aid health professionals to sensitively and competently care for survivors of chattel slavery worldwide.

Conclusion

Caring for former Mauritanian chattel slaves presents unique challenges. The trauma of chattel slavery, and particularly the mental health consequences of such trauma, will influence all encounters this patient population has with the medical community. Research is needed to sensitively and competently inform the best methods of care for the mental and physical health needs of female survivors of chattel slavery. Even before research is completed, health care professionals should continue to care for patients surviving slavery, bearing in mind the type of slavery endured, the gender of the patient, and the socio-political-cultural-religious context in which bondage was experienced.

[6] For instance, patients should ideally not be given treatment that is not proven safe and effective. Safety and effectiveness, however, typically require formal research. What happens when the patient population needing treatment cannot give voluntary understanding informed consent? Is it better for therapists to determine best treatment guidelines via formal research without such a stringent form of consent, or for therapists to continue to anecdotally create such guidelines until the high bar of voluntary informed understanding consent can be reached?

How Valid is the AHRQ Patient Safety Indicator "Postoperative Physiologic and Metabolic Derangement"?

Ann M Borzecki, MD, MPH, Marisa Cevasco, MD, MPH, Qi Chen, MPH, Marlena Shin, JD, MPH, Kamal MF Itani, MD, Amy K Rosen, PhD

BACKGROUND: The Agency for Healthcare Research and Quality Patient Safety Indicator postoperative physiologic and metabolic derangement (PMD) uses ICD-9-CM codes to screen for potentially preventable acute kidney injury (AKI) requiring dialysis plus diabetes-related complications after elective surgery. Data on PMD's accuracy in identifying true events are limited. We examined the indicator's positive predictive value (PPV) in the Veterans Health Administration (VA).

STUDY DESIGN: Trained abstractors reviewed medical records of 119 PSI software-flagged PMD cases. We calculated PPVs overall and separately for renal- and diabetes-related complications. We also examined false positives to determine reasons for incorrect identification, and true positives to determine PMD-related outcomes and risk factors.

RESULTS: Overall 75 cases were true positives (PPV 63%, 95% CI 54% to 72%); 73 of 104 AKI cases were true positives (PPV 70%, 60% to79%); only 2 of 15 diabetes cases were true positives (PPV 13%, 2% to 40%). Of all false positives, 70% represented nonelective admissions and 23% had the complication present on admission. Of AKI true positives, 37% died and 26% were discharged on dialysis; 55% had chronic kidney disease (≥ stage 3) present on admission. Cardiac surgery represented the largest category of AKI-associated index procedures (30%). AKI was most commonly attributed to perioperative renal hypoperfusion (84% of true positives), followed by nephrotoxins (33%) including contrast (11%).

CONCLUSIONS: Due to its low PPV, we recommend removing diabetes complications from the indicator and focusing on AKI. PMD's PPV could be significantly improved by using present-on-admission codes, and specific to the VA, by introduction of admission status codes. Many PMD-identified cases appeared to be at high risk based on patient- and procedure-related factors. The degree to which such cases are truly preventable events requires further assessment. (J Am Coll Surg 2011; 212:968–976. © 2011 by the American College of Surgeons)

Postoperative physiologic and metabolic derangement (PMD), an administrative data-based outcome, was developed by the Agency for Healthcare Research and Quality (AHRQ), as one of 20 adult patient safety indicators (PSIs).[1] This indicator uses ICD-9-CM codes to flag cases of "specified" postoperative physiologic and metabolic derangements among elective surgical discharges.[1] Specifically, cases are flagged based on the presence of either an acute kidney injury (AKI, formerly known as acute renal failure) secondary diagnosis code and a dialysis procedure code, or a code for a diabetes complication (ketoacidosis, hyperosmolarity, or hypoglycemic coma).

Similar to other PSIs, this indicator was designed to identify inpatient complications that are clinically significant and potentially preventable. Although postoperative AKI is known to be an important complication of surgery, less is known about the included postoperative diabetes complications. The incidence of postoperative AKI varies according to the AKI definition used, type of operation, surgical urgency, and population studied.[2,3] The risk of

Abbreviations and Acronyms

AHRQ = Agency for Healthcare Research and Quality
AKI = acute kidney injury
EMR = electronic medical record
ESRD = end-stage renal disease
IRR = inter-rater reliability
NSQIP = National Surgical Quality Improvement Program
PMD = postoperative physiologic and metabolic derangement
PPV = positive predictive value
PSI = patient safety indicator
VA = Veterans Health Administration

postoperative AKI is highest among patients undergoing cardiac and aortic operations, with an incidence between 1% and 15% based on metabolic parameters,[2] or 1% and 5% if a requirement for dialysis is specified.[3-5] Postoperative AKI requiring dialysis is associated with more than 2-fold increased lengths of stay and in-hospital costs[6,7] and mortality rates (both in-hospital and 30-day) in excess of 60%.[4,5] Although information specific to postoperative diabetes complications is lacking, limited data show that hospital-acquired diabetes complications are rare, occurring in 0.02% of discharged patients with diabetes, but are similarly associated with excess lengths of stay, costs, and mortality.[8] Postoperative AKI prevention entails avoiding perioperative renal hypoperfusion and limiting exposure to nephrotoxic agents.[9] For diabetes, prevention includes careful blood sugar monitoring and avoidance of sliding scales as the sole method of insulin delivery, especially in patients on preoperative insulin.[10]

Given that PMD uses administrative data, the indicator (and other PSIs) was originally developed to screen for possible patient safety problem areas for local quality improvement efforts.[1] However, increasing demand for easily applied quality measures has broadened their use. PMD is now a component of a composite PSI measure that the Centers for Medicare and Medicaid Services (CMS) are tracking as part of their pay-for-reporting program.[11-13] Hospitals that underperform or fail to report these measures receive reduced Medicare payments.

The increasing adoption of PSIs as quality and patient safety measures necessitates that users understand their strengths and limitations. Like the other PSIs, PMD was developed through a rigorous process including a consensus panel of clinical experts.[14] Additionally, rates of this PSI have been found to have strong positive correlations with other postoperative PSIs,[1] and its occurrence was associated with excess in-hospital lengths of stay, costs, and deaths.[15,16] Yet, few data exist regarding this indicator's ability to detect true events as identified by medical record review. A previous Veterans Health Administration (VA) study using 2001 data compared the PMD subset of flagged cases with AKI (based on PSI version 2.1) with chart-based data from the National Surgical Quality Improvement Program (NSQIP) (n = 62) and found a positive predictive value (PPV) of 54% and a sensitivity of 44%.[17] This resulted in indicator revisions such that diagnostic codes 586 ("renal failure unspecified") and 997.5 ("urinary complications") were added to the existing 584.x code ("acute renal failure"), which slightly increased both the PPV and sensitivity, to 63% and 48%, respectively. However, a number of questions about this indicator's validity remain. Only AKI-related complications were studied; there are no data on the criterion validity of the diabetes-related complications. The small number of NSQIP cases eligible for comparison may limit the generalizability of findings, and finally, there are no data on the degree to which PMD flagged cases are associated with process of care problems and therefore potentially preventable.

In this study, we examined the PPV of this indicator in the VA. We also investigated associated risk factors and perioperative processes of care to better understand the potential preventability of this PSI.

METHODS

This was a retrospective cross-sectional study using VA administrative and electronic medical record (EMR) data from October 1, 2002 through September 30, 2007. We obtained study protocol approvals from the Bedford VA Medical Center and the VA Boston Healthcare System Institutional Review Boards.

Data sources

We used hospital discharge information, (demographics, ICD-9-CM coded diagnoses and procedures, and discharge status) from the VA's National Patient Care Database Patient Treatment File.[18] Per earlier PSI work, we eliminated nonacute care (eg, long-term care).[15,19] We accessed VA EMR data using VistAWeb, a program enabling centralized access to EMR data from all VA facilities.[20]

PMD definition

See Appendix 1 (online only) for the full PMD definition including ICD-9-CM codes.[1,21] The numerator requires a secondary diagnosis code for AKI and a dialysis procedure code, or a secondary diagnosis code for a diabetes complication of ketoacidosis, hyperosmolarity, or coma. The denominator excludes discharges when the hospitalization was nonelective, the condition was present on admission, patients had advanced chronic kidney disease (stage 5) or end-stage renal disease (ESRD) present on admission, or

dialysis occurred before or on the same day as the first operation. Additionally, patients with diabetes complications are excluded if their principal diagnosis is diabetes; patients with AKI are excluded if they have a principal diagnosis of acute myocardial infarction, cardiac arrhythmia, cardiac arrest, shock, hemorrhage, or gastrointestinal hemorrhage.

Similar to PSI 11, postoperative respiratory failure, and PSI 13, postoperative sepsis, the denominator excludes nonelective hospitalizations because these complications are less likely to be preventable "in patients admitted for non-elective surgeries, or urgent/emergent conditions."[19] However, unlike nonfederal databases that include an admission type, the VA inpatient file lacks such a variable. (Neither source includes a surgery status field; admission type is intended as a proxy for surgery status.) So, previous PSI work in the VA involved developing an algorithm to characterize admission type using diagnostic related groups, admission date and time, and principal procedure date and time.[19,22]

Study population

Hospital sampling

The sampling method and final sample are described in detail elsewhere.[22] Briefly, we applied the PSI software (v. 3.1a) to the VA inpatient database to obtain individual PSI counts and composite scores (a combined measure that includes 11 PSIs).[23,24] Starting with 158 acute care hospitals, we selected a final sample of 28 hospitals, based on PSI counts, scores, and geographic location, which was intended to reflect the diversity of VA hospitals. The final sample included hospitals from 18 of the 21 VA regional health care networks.

Case identification

We identified the eligible pool of discharges based on presumed elective admission status using previously developed criteria,[19] and randomly selected 4 flagged cases of PMD from each sample hospital, yielding 112 cases. This total was chosen to ensure reasonably narrow confidence intervals (10% to 20%) based on power calculations using previously reported PPVs of similar indicators.[25] Due to relatively few cases of diabetes complications (n = 8), we opted to include all available flagged diabetes cases from our hospital sample, for a total of 119 cases (104 cases of AKI and 15 cases of diabetes complications).

Medical record abstraction

Two trained nurse abstractors conducted EMR reviews using a standardized data abstraction instrument and guidelines adapted from AHRQ-developed preliminary tools.[26] This instrument included initial questions about demographics and ascertainment of the event; if a case was deemed a false positive, abstraction ceased; for true positives, additional information was abstracted on risk factors, evaluation, management of the event, and patient outcomes.

To ensure consistency of abstracted information, we examined inter-rater reliability (IRR). The nurses independently abstracted the same records in groups of 5 until they achieved ≥90% agreement across all questions; thereafter they abstracted different records. Study physicians (AB) reviewed questions on which nurses disagreed, with resulting instrument revisions and/or guideline clarifications as appropriate. Study physicians also reviewed cases for clarification as required throughout the abstraction process. Another IRR assessment was performed on 5 charts toward the end of the abstraction process to check for drift in abstractor reliability. Additional details of the abstraction process are available elsewhere.[22]

Nurses agreed 100% on all questions pertaining to ascertainment of the event (identification of cases as true positives or false positives) on all rounds of IRR testing (kappa = 1.0). However, we required 2 early rounds of IRR assessment to achieve the prespecified observed agreement threshold. Observed agreement on an initial round of 5 charts was 85% (n = 60 questions), mainly due to disagreements with respect to the most likely causes of AKI and how to answer procedure-related questions for patients who had multiple operations before initiating dialysis. These questions were made more explicit, and observed agreement was 98% on the next IRR assessment round. Agreement on late IRR testing was 94%.

Analyses

We classified cases as true positives or false positives based on abstracted data, and analyzed AKI cases separately from diabetes complication cases. We calculated PPVs (true positives/flagged cases) and associated 95% CIs. Additionally, we conducted detailed examination of false positives to understand why they were flagged, as well as to determine how to improve the PSI. We determined whether false positives resulted from cases being coded inappropriately or from coding limitations (ie, despite correct coding, the case did not meet the clinical intent of the indicator) (Table 1).

We compared true positives and false positives with respect to selected demographics and assigned codes, using *t*-tests for continuous variables and chi-squares for categorical variables. We also examined true positives to determine the clinical consequences of PMD and factors contributing to its occurrence, and we performed descriptive analyses of relevant variables. Analyses were performed using SAS software, version 9.1 (SAS Institute Inc).

Table 1. Characteristics of Sample Patients

Variable	All AKI patients n = 104	TP AKI n = 73	FP AKI n = 31	All DM patients n = 15	TP DM n = 2	FP DM n = 13
Age, y, mean (SD)	67.8 (10.5)	69.0 (9.7)	65.2 (12.1)	56.4 (12.2)	55.0 (1.4)	56.6 (13.2)

African-American	13 (12.5)	10 (13.7)	3 (9.7)	3 (20.0)	–	3 (23.1)
Hispanic	8 (7.7)	4 (5.5)	4 (12.9)	1 (6.7)	–	1 (7.7)
Other/missing	9 (8.7)	6 (8.2)	3 (9.7)	1 (6.7)	1 (50.0)	–
ICD-9-CM codes - AKI diagnosis codes, n (%)*						
584.x only	76 (73.1)	53 (72.6)	23 (74.2)	–	–	–
Both 584 and 997.5	13 (12.5)	10 (13.7)	3 (9.7)	–	–	–
997.5 only	7 (6.7)	6 (8.2)	1 (3.2)	–	–	–
586 only	8 (7.7)	4 (5.5)	4 (12.9)	–	–	–

* ICD-9-CM codes: 584.x,"acute renal failure"; 997.5, "urinary complications" includes acute renal failure due to a procedure; 586,"renal failure unspecified." All diabetes patients had diabetic ketoacidosis codes (250.10 to 250.13).
Percentages represent column percents. Cases were flagged per the patient safety indicator algorithm.
There were no significant differences between TPs and FPs among AKI or diabetes patients. Diabetes patients were significantly younger than AKI patients ($p < 0.05$).
AKI, acute kidney injury; DM, diabetes mellitus; FP, false positive; TP, true positive.

RESULTS

PPV for PMD indicator

Of 86,321 eligible hospitalizations among sample hospitals, 185 were flagged for PMD (an observed rate of 2.1 per 1,000), which was comparable to the national VA flagged PMD rate (578 flagged cases per 268,552 eligible hospitalizations, or 2.1 per 1,000). Of the 119 reviewed cases, 75 were true positives, for a PPV of 63% (95% CI 54% to 72%). Of 104 AKI cases, 73 were true positives, for a PPV of 70% (95% CI 60% to 79%); of the 15 diabetes cases, only 2 were true positives, for a PPV of 13% (95% CI 2% to 40%).

Table 1 shows demographic and coding characteristics of all flagged cases, true positives, and false positives. Both true positive and false positive patients with AKI were older than patients flagged with diabetes complications (mean ± SD, 67.8 ± 10.5 years vs. 56.4 ± 12.2 years; $p < 0.001$). Of the AKI sample, 73% of cases were flagged based on a 584.x diagnosis code ("acute renal failure"), 8% based on a 586 code ("renal failure unspecified"), 7% based on a 997.5 code ("urinary complications," includes acute renal failure due to a procedure); the remainder had a combination of a 584x and a 997.5 code. All of the flagged diabetes cases had a code for diabetic ketoacidosis. See Appendix 1 for further information on code definitions.

False positive PMD cases

AKI cases

Of the 31 false positive AKI cases, 4 (13%) failed to meet coding criteria; they were all patients with end-stage renal disease (ESRD) present on admission, who received a 584.x code for unclear reasons. An additional 27 cases were coded appropriately, but failed to meet the indicator's clinical intent. Twenty-one cases were nonelective admissions (68%); 4 cases (13%) had ESRD present on admission; however, these were assigned less specific codes (586 or 997.5), so we did not consider them as coding errors. An additional 2 elective cases (6%) did have postoperative AKI requiring dialysis. However, 1 was an anticipated outcome of a procedure: a patient with a solitary kidney who underwent nephrectomy for a renal mass. In the other, the procedure was incidental to the development of AKI: a patient postcardiac transplantation with hepatitis C admitted for investigation of a cavitary lung nodule and elevated transaminases. He underwent a palate biopsy for a mouth ulcer and subsequently developed renal failure thought to be due to hepatorenal syndrome and/or from amphotericin B, which he was receiving for pulmonary aspergillosis.

Two nonelective cases would also have been excluded based on AKI being present on admission and having no preceding procedure. The 4 cases that failed to meet coding criteria would also have been excluded by other criteria because they all had ESRD present on admission (3 of these patients were actually admitted for dialysis access procedures).

Diabetes complications cases

Among the 13 false positive diabetes cases, there were no coding errors; all failed to meet the clinical intent of the

indicator. Ten were nonelective (69%); 9 of these were also present on admission (and unrelated to previous surgery). Two patients had ESRD present on admission (this is an exclusion criterion for both diabetes and AKI patients), and 1 patient had diabetic ketoacidosis incorrectly documented in the discharge summary as a secondary diagnosis on the current admission when it had occurred during a previous admission (and was unrelated to a procedure).

True positive PMD cases

AKI cases

Because only 2 of 75 true positives had diabetes complications, we present summary results only for the AKI true positives. See Appendix 2 online for details on the 2 true positive diabetes cases.

Outcomes

Median length of stay was 30 days (25th, 75th percentile: 15, 51 days, respectively). Nine patients underwent continuous hemofiltration, the remainder underwent standard intermittent hemodialysis. Nineteen true positive patients (26%) were discharged on dialysis. There were 27 in-hospital deaths (37%). The median time between the initial operation and initiation of dialysis was 7 days (25th, 75th percentile: 3, 15 days, respectively).

Procedure-related risk factors (Table 2)

Of the true positives, 30% of cases (n = 22) were associated with cardiac index procedures. This included 16 cardiac and 3 thoracic aorta procedures, all performed on cardiopulmonary bypass, and 3 coronary angioplasties; median on-pump time was 181 minutes, range 144 to 375 minutes, in the 10 cases in which this was documented. Twenty-one percent (n = 15) of associated index procedures were vascular, involving the abdominal aorta or lower extremities (12 of these involved abdominal aorta clamping; 4 were clamped suprarenally). Sixty-four true positive patients (88%) developed AKI after the first operating room (index) procedure; in 6 (8%) this followed a second procedure, and in 3 (4%), a third procedure. For all but 1 of the 9 true positive patients with AKI after a subsequent procedure, this was a nonelective procedure. Most (93%) index procedures were performed under general or epidural anesthesia. Thirty-seven noncardiac patients (51% of all patients and 73% of noncardiac patients) underwent an operation lasting longer than 3 hours. (All on-pump cardiac cases were longer than 3 hours.) Twenty noncardiac patients (27%) lost at least 1L of blood intraoperatively. Forty-one percent (n = 30) received at least 3 L of intravenous fluid intraoperatively (crystalloid, colloid; although this information was available on only 42 patients [58%]), and 48% (n = 35) received the equivalent of at least 1 unit of blood). (See Table 2 for further details.)

3	3 (4.1)

*Includes 3 thoracic aorta repairs (2 ascending repairs with aortic valve replacement, 1 descending – all done on pump); the remainder were coronary artery bypass grafts and/or valve repairs.
†Includes 6 open abdominal aortic aneurysm repairs, 6 bypass procedures involving the abdominal aorta; 1 endovascular abdominal aortic aneurysm repair and 2 lower extremity bypass procedures.
‡Includes 7 nephrectomies, including one patient with a single kidney.
§These were 3 coronary angioplasties.
‖In all but 3 of the 9 cases with acute kidney injury after a subsequent procedure, these procedures resulted from complications directly associated with the initial operation. The 3 cases were: an open cholecystectomy after a coronary artery bypass grafts /mitral valve replacement, a small bowel resection after a coronary angioplasty, and a lower extremity fasciotomy after esophagectomy.
PTCA, percutaneous transluminal coronary angioplasty.

Patient-related risk factors

Thirty-seven percent of patients had a history of diabetes present on admission; 23% had congestive heart failure. Although 33% had a diagnosis of chronic kidney disease documented per the preoperative anesthesia or admission note, 55% had an estimated glomerular filtration rate less than 60 mL/minute on admission (based on the modified Modification of Diet in Renal Disease [MDRD] formula); it was less than 30 mL/minute in 10% (Table 3).

Table 3. Patient-Related and Perioperative Risk Factors

Variable	True positives (n = 73)
BMI, mean (SD), kg/m^2	29.9 (7.5)
Conditions present on admission, n (%)	
Diabetes	27 (37.0)
Congestive heart failure	17 (23.3)
Documented chronic kidney disease	24 (32.9)

*Based on the modified Modification of Diet in Renal Disease (MDRD) equation.
†Received during admission, before diagnosis of acute kidney injury.
‡This included 3 coronary angiograms with angioplasties, 2 intraoperative arteriograms (both aortobifemoral bypasses with femoral embolectomies), 2 preoperative aorta and lower extremity angiograms, and 3 MRIs with gadolidium; the remainder were CT scans, including 2 CT angiograms. The contrast type was nonionic in 8 cases and unknown in 8 cases.
ACEIs/ARBs, angiotensin converting enzyme inhibitors/angiotensin receptor blockers; BMI, body mass index; GFR, glomerular filtration rate; NSAIDs, nonsteroidal anti-inflammatory drugs.

Contributing factors

The most common nephrologist-identified contributing causes were related to renal hypoperfusion (84%), most often due to perioperative hypotension (45%) or sepsis (34%). Although renal ischemia was often noted as a cause, it was only explicitly mentioned as due to renal artery or aorta occlusion in 4 vascular surgery cases. Exogenous nephrotoxins were implicated in 22% of cases; this was split between contrast (n = 8) and other drugs such as antibiotics (n = 8). Only 1 of 6 patients on an aminoglycoside antibiotic or vancomycin had this noted as a possible contributing factor. Virtually all patients had more than 1 presumed cause contributing to AKI (Table 4).

In terms of preventive measures, 8 of 18 patients who received intravenous or intra-arterial contrast before AKI onset had an estimated glomerular filtration rate less than 60 mL/minute; only 3 of these 8 patients (38%) had documentation of receipt of prophylaxis such as hydration with normal saline or sodium bicarbonate or use of n-acetylcysteine. (Two nonprophylaxed chronic kidney disease patients developed contrast-induced AKI, as did 2 prophylaxed chronic kidney disease patients who also received nonionic isomolar agents.)

DISCUSSION

This is one of the first studies to examine the criterion validity of the AHRQ PSI, PMD in its current form in any setting.[17] Although the overall indicator's PPV was 63%, we found that diabetes complications were rare and were associated with a very low PPV (13%). Conversely, AKI-related complications had a moderate PPV (70%). This latter value is comparable to the upper reported PPV range of other postoperative PSIs validated in non-VA settings.[27,28] Our PPV for the AKI-subset findings was slightly higher than that, supporting the previously reported value of 63% found in the VA using 2001 data.[17] Our findings also support the addition of the less specific renal failure codes (586 and 997.5) to the current version of the indicator.[17] Had we excluded them, our PPV would have been essentially unchanged at 71%, but we would have missed 10 true positives. To our knowledge, no other data exist with respect to the validity of coding for postoperative diabetes complications included in this PSI. There are also no data specific to diabetic ketoacidosis or hyperosmolar coding in any inpatient setting. However, a previous study found low coding rates and poor PPV for hypoglycemic diabetes complications.[29] Geraci and colleagues[29] were able to confirm only 35% (12 of 34) of coded hypoglycemic episodes in medical patients by chart review; conversely only 12 of 76 (16%) chart-identified hypoglycemic epi-

Table 4. Nephrologist-Presumed Causes of Postoperative Acute Kidney Injury

Other‖	7	9.6

*Multiple factors may be responsible for a given case. Causes were abstracted from nephrology notes. There is also overlap between some of the renal hypoperfusion causes (eg, hypotension may be associated with any of the listed causes).
†12 true positive patients had cross-clamping of the abdominal aorta; only 4 had it specifically noted as a contributing cause of acute kidney injury.
‡This included 6 cases of antibiotic presumed acute interstitial nephritis.
§These were all due to myoglobinuria, and most frequently associated with lower extremity reperfusion after revascularization procedures. In 2 cases, a statin and a fibrate were thought to contribute. These 2 cases were also counted under "Other nephrotoxins."
‖Seven cases specify the patient had a picture consistent with acute tubular necrosis but no additional details are given.

sodes were coded as such. This is noteworthy, given that CMS has adopted a related measure, "manifestations of poor glycemic control," which is applicable to all inpatient discharges, as one of its hospital-acquired conditions.[30]

Suggested coding improvements to the PMD indicator

With respect to false positives, coding errors were relatively rare, with most false positives representing cases that did not satisfy the PSI's clinical definition (ie, patients with nonelective hospitalizations or present-on-admission conditions such as ESRD and diabetic ketoacidosis). As mentioned, emergency admissions, a proxy for emergency procedures, are intended to be excluded. Because the VA lacks an admission status code, we used an algorithm designed to distinguish nonelective admissions, which incorrectly identified 21 flagged AKI cases and 10 diabetes-related cases as elective (26% overall).[19] However, even admission status is not a perfect proxy for procedure status; 3 AKI patients with nonelective admissions actually underwent elective procedures. Further, it is possible that some PMD cases associated with nonelective cases might be preventable. If we kept cases classified as false positives based solely on admission status, the PPV for diabetes-related complications would increase only to 20%. However, the AKI-related PPV would increase to 88% (95% CI 76% to 91%). Of note, even in settings that code data for admission status, such codes may not be always be applied properly. A non-VA study of the PSI "postoperative respiratory failure" (which similarly is intended to flag cases associated with elective admissions) found incorrect coding of elective status to be the most frequent reason for false positives.[28] So future research should examine the effect of expanding PSI denominator exclusions to additional principal diagnoses that are "suspicious for a nonelective presentation" (eg, sepsis).[28]

Although the VA does not code for present-on-admission status, in settings that have such coding, reported present-on-admission rates for PMD (AKI and diabetes complications combined) have ranged from 9% using chart validation at a single hospital[31] to 36% based on New York State data.[32] If the VA used present-on-admission codes, and these were applied correctly, 73% of diabetes cases but only 10% of AKI cases would have been excluded.

Based on our false positive review, we suggest some relatively straightforward modifications to improve this indicator's PPV. First, due to the low rate, poor PPV, and existing data showing infrequent coding of diabetes-related complications,[29] in addition to pathophysiologic differences, we believe the indicator should be restricted to AKI cases. Given CMS' related hospital-acquired condition measure, "manifestations of poor glycemic control," further efforts should be devoted to improving coding of diabetes complications. The PPV of the AKI cases in the VA could be improved by adoption of admission status and present-on-admission codes. Appropriate use of such codes would have eliminated all of our AKI false positives. VA adoption of an admission status code would also allow more meaningful VA and non-VA comparisons of PMD rates. Further, 3 false positives were patients with ESRD admitted for a principal procedure related to dialysis access (39.27, "arteriovenostomy for renal dialysis;" 39.41, "revision of arteriovenous shunt for dialysis;" and 39.93, "insertion of vessel-to-vessel cannula"). Such principal procedures could be excluded from the denominator.

We also had 1false positive patient who had his remaining kidney removed because of a renal mass. Although this patient was appropriately coded, postoperative AKI was an anticipated outcome of care, as opposed to a complication. However, there currently is no way to exclude such cases based on coding. One approach would be to add the term *anephric* to existing ICD-9-CM diagnosis codes, and exclude cases with this diagnosis and a principal procedure of a nephrectomy.

PMD preventability

PMD is intended to detect complications that are avoidable through good care. Although studies of other postoperative indicators provide empirical evidence of this, there are no data specific to PMD.[33] So, as a secondary study goal, we explored the preventability of true events through abstracted information on risk factors, processes of care, and causes. (Given we are recommending removal of diabetes cases from the indicator, this discussion is restricted to AKI prevention.) As expected, most of our AKI cases were due to acute tubular necrosis, representing the end result of multiple factors related to renal hypoperfusion or renal damage from nephrotoxins.[34] Because there is little that can be done to reverse postoperative AKI once a renal insult occurs,[35] management is primarily preventive (limiting perioperative exposure to renal hypoperfusion and nephrotoxins). However, there are few specific evidence-based methods for prevention, except perhaps with respect to contrast-induced nephropathy.[36,37] Preoperative evaluation is recommended to recognize and if possible modify predisposing factors; prediction models can help identify particularly high risk patients who may require more intensive perioperative monitoring of parameters including vital signs, fluid status, and cardiac hemodynamics.[3,4,9,34] These latter methods seem clinically intuitive, but there are no trials to support their use. Other measures, such as preoperative evaluation and modification of cardiac and pulmonary risks, and appropriate infection prophylaxis, may indirectly reduce AKI risk.

Although many of our patients appeared to be at high risk based on known procedure- (cardiac and abdominal aortic procedures) and patient-related risk factors (advanced age, chronic kidney disease, congestive heart failure, diabetes),[9,34] the extent to which these risk factors could have been modified preoperatively is unclear. Most patients had documentation of a preoperative assessment by anesthesia at a minimum and many were followed by cardiology, but it was beyond this study's scope to ascertain whether preoperative assessments resulted in changes in the management of comorbidities or choice of procedure that might have decreased risk.

In terms of processes of care related to nephrotoxin exposure, only 38% of patients with chronic kidney disease who received contrast were given any sort of prophylaxis including intravenous hydration. With respect to perioperative processes related to limiting hypoperfusion, although longer cardiopulmonary bypass on-pump and aortic cross-clamping times increase AKI risk,[2] it was not clear whether anything could have been done to shorten these times. We also did not have access to intraoperative anesthesia records, so we do not know whether patients experienced intraoperative blood pressure fluctuations, or the degree to which such information would help to assess preventability. We do know that all cardiac and vascular patients, as well as several other high-risk patients, were closely monitored perioperatively in the ICU. Finally, we did not abstract information on processes of care less directly related to AKI, such as infection prevention; we addressed this issue in detail in a study of the PSI "postoperative sepsis."[38]

Study limitations and strengths

We lack information on the indicator's sensitivity or specificity because abstracting cases that were not flagged by the PSI algorithm was beyond the scope and resources of this study. Additionally, this was a sample of mainly elderly men. In spite of this, our findings with respect to risk factors and outcomes were consistent with those in existing literature.[9,34] Though a few patients received contrast without appropriate prophylaxis, we cannot determine whether any other cases were associated with potential quality of care problems. This is partly because we used retrospective chart-based data, which rely on completeness of documentation, the relatively small sample size, the absence of a control group, and lack of certain data that are unavailable in VistAWeb. Further, the abstraction tool was designed to be as explicit as possible; the nurses were advised against drawing inferences about causation to maximize the reliability of findings.

In terms of study strengths, we randomly selected cases from a nationwide sample of VA hospitals. We performed IRR testing of data abstraction both early and late in the process, and attained high abstractor agreement. We also conducted a thorough examination of false positives and were able to identify ways to improve the PPV of the indicator. Also of note, PMD is part of the CMS-tracked PSI composite measure and overlaps with the diabetes-related hospital-acquired condition, both of which are being linked to sanctions.[12,30] Although this issue could potentially influence the accuracy of both coding and medical record documentation in Medicare-reimbursed settings, it is unlikely to have affected our findings because neither measure is currently tracked in the VA.

CONCLUSIONS

In its present state, PMD should continue to be used as a screen for patient safety events as opposed to a performance measure. However, to improve the usefulness of this indicator for detecting true events, we strongly recommend removing the diabetes-related complications from the indicator and focusing on AKI-related complications. The VA should also adopt admission status and present-on-admission codes. Further research regarding the extent to which PMD identifies events that are preventable through improved care is also necessary before it can be considered a definitive quality measure. Results of similar PMD validation efforts being conducted by AHRQ investigators in the non-VA setting should soon be available for comparison.

Appendix 1. Postoperative Physiologic and Metabolic Derangement Indicator: Detailed Definition & ICD-9-CM Codes

Definition	Cases of specified physiologic or metabolic derangement procedure per 1,000 elective surgical discharges with an operating room (OR) procedure*
Numerator	Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM codes for physiologic and metabolic derangements in any secondary diagnosis field. Includes the following: ● Acute renal failure (584.5–584.9 – acute renal failure, 586 – renal failure not otherwise specified, 997.5 – urinary complications, including acute renal failure complicating a procedure) accompanied by a procedure code for dialysis (39.95 - hemodialysis, 54.98 – peritoneal dialysis) *or* ● Diabetes (type 1 or 2) with: ○ ketoacidosis (250.10–250.13), or ○ hyperosmolarity (250.20–250.23), or ○ coma (250.30-250.33)
Denominator	All elective surgical discharges age 18 and over defined by specific DRGs and an ICD-9-CM code for an OR procedure.† Exclude cases with: ● A preexisting (principal diagnosis or secondary diagnosis present on admission, if known) of physiologic and metabolic derangements OR chronic renal failure‡ ● Acute renal failure where a procedure for dialysis occurs before or on the same day as the first OR procedure ● Both a diagnosis code of ketoacidosis, hyperosmolarity, or other coma (subgroups of physiologic and metabolic derangements coding) AND a principal diagnosis of diabetes ● Both a secondary diagnosis code for acute renal failure (subgroup of physiologic and metabolic derangements coding) and a principal diagnosis of acute myocardial infarction, cardiac arrhythmia, cardiac arrest, shock, hemorrhage, or gastrointestinal hemorrhage ● MDC 14 (pregnancy, childbirth and the puerperium)

*Reported as rates, risk-adjusted for age, sex and modified Diagnosis Related Groups (DRGs).

†Elective procedure defined by admit type. See PSI technical specifications for the complete list of eligible surgical DRG and operating room (OR) procedure codes. (Agency for Healthcare Research and Quality. Patient Safety Indicators: Technical Specifications. March 2003; Version 3.1 [March 12, 2007].) Eligible OR procedures include all procedures that are considered valid OR procedures by the DRG grouper; procedures such as a diagnostic cardiac catheterization are excluded, while a percutaneous coronary angioplasty is included.

‡The actual PSI SAS code specifies that this is advanced chronic renal failure (stage V) or end-stage renal disease.

MDC = Major Diagnostic Category; this is based on the principal diagnosis.

Appendix 2. True Positive Diabetes Complications Cases

Both cases were obese patients on short and long-acting insulin combined with oral agents prior to admission, admitted for major surgery, with endocrinologist-diagnosed probable diabetic ketoacidosis (DKA) noted on postoperative day (POD) 3. The first case did not receive perioperative basal insulin, the second case did.

Case 1 – This was a 54 year-old obese male, with a 30-year history of diabetes, admitted for a total knee replacement. He was on a sulfonylurea, glitazone, rapid-acting (glulisine) and long-acting insulin (glargine – 50U daily) prior to admission with reasonably-controlled sugars (A1c 7.6% on POD 3).

He was admitted the same day as the procedure. He took his usual medications the day before. He received IV ½ NS pre- and post-operatively without D5W. He did not receive any basal insulin or oral medications post-operatively till he developed DKA; he was covered only with regular insulin per sliding scale, starting with a glucose ≤200 mg/dl. He started to develop progressive elevation in his sugars late on POD 1 coinciding with advancing his diet. On POD 1 his sugars were up to 180 mg/dl, by POD 2 they were >300 mg/dl. On POD 3, he developed nausea and vomiting in the early am; serum glucose was 402 mg/dl, CO_2 was 9 meq/L, and urine was positive for ketones. Endocrinology was consulted; the patient was diagnosed with DKA, and transferred to the intensive care unit for IV insulin. (It took 4 days to clear the ketones.) No reason for the DKA was noted. Presumably the patient developed ketoacidosis because of insulin deficiency and this might have been avoided were he covered with basal insulin.

Case 2 – This was a 56 year-old obese male, with an 8-year history of diabetes, admitted for a right hemicolectomy. He was on a glitazone, intermediate (NPH, 40U am and 50U pm) and short-acting insulin (twice daily) prior to admission, with poorly controlled sugars (>300; A1c 12.0% on the day of admission). Endocrinology was involved in his perioperative care from POD 1 onward.

He was admitted the day before the surgery and was given IV ½ NS with D5W perioperatively. In hospital he received maintenance insulin, initially with NPH subcutaneously (sc), then with an insulin drip, and then with NPH twice daily supplemented with short-acting insulin sc with meals up until possible DKA was diagnosed in the setting of an acute gouty flare; his blood sugar at the time was 267 mg/dl. However, it is not clear he actually had DKA because he only had one urinalysis with a small amount of ketones and had a CO_2 of 28 meq/L. Per endocrinology's

recommendations, he was managed only with an increase in his NPH and regular insulin twice daily, and not with IV insulin. However, endocrinology never wrote a subsequent note to say he didn't have DKA. (The ketonuria may have been due to starvation, since he had just started a clear diet that day after a couple of days of fasting.) This case was coded appropriately, but one could argue the clinical evidence did not support the diagnosis of DKA.

How Valid is the AHRQ Patient Safety Indicator "Postoperative Hemorrhage or Hematoma"?

Ann M Borzecki, MD, MPH, Haytham Kaafarani, MD, MPH, Marisa Cevasco, MD, MPH, Kathleen Hickson, RN, MA, Sally MacDonald, RN, Marlena Shin, JD, MPH, Kamal MF Itani, MD, FACS, Amy K Rosen, PhD

BACKGROUND: Postoperative hemorrhage or hematoma (PHH), an Agency for Healthcare Research and Quality Patient Safety Indicator, uses administrative data to detect cases of potentially preventable postsurgical bleeding requiring a reparative procedure. How accurately it identifies true events is unknown. We therefore determined PHH's positive predictive value.

STUDY DESIGN: Using Patient Safety Indicator software (v.3.1a) and fiscal year 2003–2007 discharge data from 28 Veterans Health Administration hospitals, we identified 112 possible cases of PHH. Based on medical record abstraction, we characterized cases as true (TPs) or false positives (FPs), calculated positive predictive value, and analyzed FPs to ascertain reasons for incorrect identification and TPs to determine PHH-associated clinical consequences and risk factors.

RESULTS: Eighty-four cases were TPs (positive predictive value, 75%; 95% CI, 66−83%); 63% had a hematoma diagnosis, 30% had a hemorrhage diagnosis, 7% had both. Reasons for FPs included events present on admission (29%); hemorrhage/hematoma identified and controlled during the original procedure rather than postoperatively (21%); or postoperative hemorrhage/hematoma that did not require a procedure (18%). Most TPs (82%) returned to the operating room for hemorrhage/hematoma management; 64% required blood products and 7% died in-hospital. The most common index procedures resulting in postoperative hemorrhage/hematoma were vascular (38%); 56% were performed by a physician-in-training (under supervision). We found no substantial association between physician training status or perioperative anticoagulant use and bleeding risk.

CONCLUSIONS: PHH's accuracy could be improved by coding enhancements, such as adopting present on admission codes or associating a timing factor with codes dealing with bleeding control. The ability of PHH to identify events representing quality of care problems requires additional evaluation. (J Am Coll Surg 2011;212:946–953. © 2011 by the American College of Surgeons)

The Agency for Healthcare Research and Quality (AHRQ) Patient Safety Indicators (PSIs) were developed in response to demand for easily applied measures that could guide quality-improvement initiatives and monitor trends in patient safety.[1] Because they use hospital administrative discharge abstracts, they were originally intended as screens for potentially preventable inpatient complications, highlighting areas where quality of care should be investigated rather than being definitive measures. However, the National Quality Forum recently endorsed several PSIs as hospital performance measures, and the Centers for Medicare and Medicaid Services (CMS) are adding 4 individual PSIs and a composite PSI to measures tracked by their hospital reporting initiative.[2-4] Underperforming or nonreporting hospitals will receive reduced payments.

The increasing use of PSIs as a measure of quality and safety requires users to understand their strengths and lim-

Abbreviations and Acronyms

AHRQ = Agency for Healthcare Research and Quality
CMS = Centers for Medicare and Medicaid Services
EMR = electronic medical record
FP = False positive
OR = operating room
PHH = postoperative hemorrhage or hematoma
PPV = positive predictive value
PSI = Patient Safety Indicator
TP = true positive
VHA = Veterans Health Administration

itations, including whether they identify true events or preventable events. The current study focuses on PSI 9, ie, postoperative hemorrhage or hematoma (PHH), a component of the CMS-tracked composite measure. Although some blood loss is expected with most operations, this PSI is designed to capture bleeding after a surgical procedure that is presumably serious enough to require a subsequent reparative procedure. As such, the numerator requires both a diagnosis code of hemorrhage or hematoma and a procedure code for hemorrhage control or hematoma drainage.[5]

Like other PSIs, this indicator was developed using a consensus panel of clinical experts.[1] Additional work showed that hospital-level rates of this PSI were positively associated with rates of other PSIs representing postoperative complications,[6] and occurrence of this PSI was associated with excess hospitalization days, hospital costs, and in-hospital deaths.[7,8] However, relatively little is known about how well this indicator identifies true complications (ie, its criterion validity or agreement with medical record review). An earlier related indicator, "postprocedural hemorrhage or hematoma," from the Complications Screening Program had a moderate confirmation rate by chart review.[9] Complications Screening Program investigators also found frequently associated process of care problems, suggesting potential use of the current PSI as a quality of care measure.[10] Such use would be unwarranted if flagged cases do not identify true cases experiencing an event. Therefore, we examined the positive predictive value (PPV) of this indicator in the Veterans Health Administration (VHA). To better understand the type of events detected by this indicator and their potential preventability, we also examined circumstances surrounding this complication and associated risk factors.

METHODS

Study design

This was a retrospective cross-sectional study using VHA administrative and electronic medical record (EMR) data from fiscal year 2003 through 2007 (October 1, 2002 to September 30, 2007). We obtained Institutional Review Board approvals from the Bedford VA Medical Center and the VA Boston Healthcare System.

Data sources

We used hospital discharge information (ie, demographics, ICD-9-CM–coded diagnoses and procedures, and discharge status) from the VHA's National Patient Care Database Patient Treatment File.[11] Per earlier PSI work, we eliminated nonacute care (eg, long-term care).[7,12] We accessed VHA EMR data using VistaWeb, a program enabling centralized access to EMR data from all VHA facilities.[13]

PHH definition

The indicator is defined as "cases of hematoma or hemorrhage requiring a procedure per 1,000 surgical discharges with an operating room (OR) procedure."[6] The numerator requires both a secondary diagnosis code for hemorrhage or hematoma complicating a procedure and a procedure code for hemorrhage control or hematoma drainage. The denominator excludes discharges where the condition was present on admission, or the hemorrhage control or hematoma drainage procedure occurred before the first OR procedure, was the only OR procedure, or was part of the initial operative procedure (see Appendix 1, available online only, for the full PHH definition including ICD-9-CM codes).[5,6]

Study population

Hospital sampling

We applied the PSI software (v. 3.1a) to the inpatient database to obtain individual PSI counts and composite scores (ie, a combined measure that includes 11 PSIs).[14,15] From 158 acute care hospitals, we selected a representative sample of 28 hospitals based on individual PSI counts, composite rates, and geographic distribution (see Appendix 2, available online only, for sampling strategy and hospital characteristics). The observed PHH rate among sample hospitals was 3.8 per 1,000 (n = 614 cases), compared with a national VHA rate of 3.9 per 1,000 discharges at risk (n = 1,998 cases).

Case identification

We randomly selected 4 software-flagged cases of PHH per hospital. This total of 112 cases was based on power calculations using earlier reported PPVs and selected to ensure reasonably narrow confidence intervals (ie, 10% to 20%).[9]

Medical record abstraction

Two trained nurse-abstractors (KH, SM) conducted EMR reviews using a standardized data abstraction instrument

and guidelines adapted from AHRQ-developed preliminary tools.[16] The instrument included initial questions about demographics and ascertainment of the event; if a case was deemed a false positive (FP), abstraction ceased; for true positives (TPs), additional information was abstracted on risk factors, evaluation and management of the event, and patient outcomes.

To ensure consistency of abstracted information, we examined inter-rater reliability. The 2 nurses independently abstracted identical records in groups of 5 until they achieved ≥90% agreement across all questions, thereafter they abstracted different records. Study physicians (AB, HK) reviewed questions on which nurses disagreed, with resulting instrument revisions and/or guideline clarifications as appropriate. Study physicians also reviewed cases for clarification as required throughout the abstraction process. Additional inter-rater reliability assessment was performed on 5 charts toward the end of the abstraction process to check for abstractor reliability drift. Inter-rater reliability testing revealed 92% agreement (n = 58 questions) on the first 5 records and 93% on subsequent testing. Nurses agreed 100% on questions about event ascertainment (ie, identification of cases as TPs or FPs) on initial and subsequent inter-rater reliability testing ($\kappa = 1.0$).

Analyses

We categorized cases as TPs or FPs based on abstracted information and application of AHRQ's PHH definition. We calculated the PPV (ie, TPs/flagged cases) and associated 95% confidence intervals. Additionally, we examined FPs in detail to determine why they were flagged and gain insight into how the PSI might be improved. This included determining whether FPs resulted from inappropriate coding or limitations associated with coding (ie, the clinical intent of the indicator was not met despite correct coding) (see Appendix 1, available online only).

We compared selected demographics and assigned codes among TPs and FPs. For TPs, we examined clinical consequences of, and factors contributing to, the PHH occurrence, performing descriptive analyses of all variables.

To explore the relationship between processes of care and bleeding risk among TPs, we examined the association of bleeding risk with physician training status (resident versus attending) and procedure urgency (emergent versus nonemergent) using chi-square or *t*-tests as appropriate. Bleeding risk was defined by surgeon-estimated blood loss during the causative procedure, need for blood products intra- or postoperatively (yes/no), number of packed red blood cell units received during the hospitalization, or total number of units of all blood products received during the hospitalization. We also examined the association between bleeding risk and perioperative anticoagulant or antiplatelet use by defining mutually exclusive medication groups as follows: any receipt of IV heparin or warfarin, receipt of subcutaneous heparin (unfractionated or low molecular weight), receipt of antiplatelet agents, and no receipt of medication affecting hemostasis. We performed unadjusted logistic or linear regression as appropriate, with pairwise comparisons. We used SAS software, version 9.1 (SAS Institute Inc.) for analyses.

RESULTS

Of 112 flagged cases, 84 TPs met both coding and clinical criteria for a PPV of 75% (95% CI 66−83%). TP and FP patients were elderly (mean age 65 years or older), predominantly male (>96%) and white (>64%). Of the entire sample, 58% had a hematoma diagnosis code, 36% had a hemorrhage diagnosis code; and 6% had both. TPs were more likely to have a hematoma diagnosis or procedure code compared with FPs, although these differences were only significant for procedure codes (69% versus 50%; p = 0.18, and 80% versus 57%; p = 0.01, respectively) Thirty-six percent of FPs (n = 10) and 21% of TPs (n = 18) were discordant with respect to diagnosis and procedure codes, ie, they were assigned a hematoma diagnosis code and a hemorrhage procedure code or vice versa (not significantly different) (see Appendix 3, available online only, for TP and FP demographic and coding characteristics).

FP analysis

Four FPs (14%) failed to meet PHH coding criteria; in all 4 cases it was unclear why they received a 998.11 code (ie, Hemorrhage Complicating a Procedure code). Two of these had documented oozing during the index procedure without a discrete bleeding source. Although 3 of the 4 cases had appropriate procedure codes, these were for conditions unrelated to bleeding. Two cases had incision and drainage codes (86.04), one for a seroma, another for an abscess; the third case underwent exploratory laparotomy (code 54.12) for sepsis. These same codes are used for hematoma drainage.

An additional 24 cases did not fit the indicator's clinical intent. In 8 cases (29%), the postoperative complication was present on admission, resulting from a procedure performed before the index hospitalization; this included 5 hematomas and 3 hemorrhages. Six FPs (21%) had intraoperative bleeding controlled during the original procedure without subsequent bleeding or need for management. In 5 cases (18%), the postoperative hemorrhage or hematoma did not require a reparative procedure. In 3 other cases (11%), despite requiring management, the hematoma followed a noneligible procedure (ie, a diagnostic cardiac catheterization) (see Appendix 1, available online

Table 1. Hemorrhage-Hematoma Outcomes of True Positives (n = 84)

Outcome	
Return to OR for reparative/exploratory procedure, n (%)	69 (82.1)
Non-OR reparative procedure, n (%)*	16 (19.0)
Receipt of blood products during hospital stay, n (%)	54 (64.3)
RBCs, n (median, range)	51 (6U, 1–39U)
FFP, n (median, range)	30 (4U, 1–14U)
Platelets, n (median, range)	20 (2U, 1–7 U)
Cryoprecipitate, n (median, range)	5 (6U, 2–21U)
Lowest hematocrit, %, median (range)†	27.2 (12.2–42.2)
Moved to ICU, n (%)‡	11 (13.1)
Death, n (%)	6 (7.1)

*Acute airway compromise developed in 1 patient with a neck hematoma after carotid endarterectomy. The patient had a nonoperative hematoma evacuation at the bedside and then went to the OR for more definitive treatment.
†During the period after the index procedure until 7 days after discovery of the hemorrhage/hematoma or hospital discharge (whichever came first).
‡Does not include patients who were already admitted to the ICU for monitoring after the index procedure.
FFP, fresh frozen plasma; OR, operating room.

only, for explanation of eligible procedures). Two additional cases were present on admission and excluded for miscellaneous reasons: a patient with gastrointestinal bleeding post−bowel resection secondary to an arteriovenous malformation, and a patient admitted with an infected vascular graft that subsequently ruptured.

TP analysis

Outcomes

Sixty-nine TPs (82%) required at least 1 OR return to treat the hemorrhage or hematoma. Fifteen (18%) cases required a nonoperative procedure only, 11 of these were hematomas of the surgical wound treated with bedside incision and drainage. Nine TPs (11%) developed bleeding during the initial procedure and were treated intraoperatively, but then required an additional procedure for ongoing or recurrent hemorrhage or hematoma. Fifty-four TPs (64%) received blood products during the admission. Eleven TPs (12%) required ICU transfer because of bleeding consequences. Of 6 deaths (7%), 1 was directly attributed to bleeding (see Table 1).

Most hemorrhage/hematoma cases were discovered and addressed within 1 day of the index procedure (median 1 day; 25th, 75th percentile 0, 2 days). Up to 38% of cases were attributed to a possible technical problem occurring during the index procedure, such as suture unraveling, a vascular anastamosis defect, or localized vessel bleeding. The single most common physician-attributed bleeding cause was secondary to generalized oozing (n = 28; 33%); approximately one third (n = 10) of these also had an identified bleeding vessel. The cause was either unknown or not specifically documented in 42% of cases (see Fig. 1).

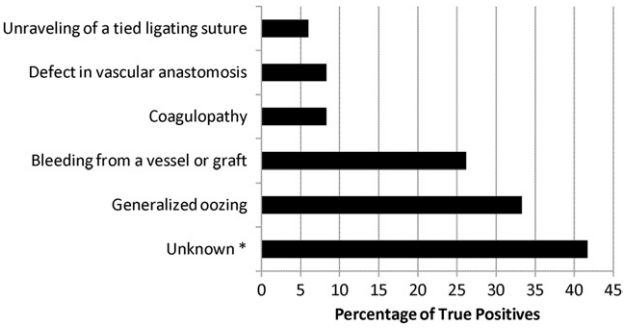

Figure 1. Physician-identified responsible factors for hemorrhage or hematoma. Multiple factors might be responsible for a given case. *Unknown, physician did not identify a cause for the bleeding.

Characteristics related to the index procedure

Of TP patients, 37% (n = 31) underwent an initial vascular procedure; 81% of these (n = 25) were associated with hematomas only. In contrast, only 42% of abdominal procedures (the next largest procedure category) were associated with hematomas only. Most index procedures (56%) were performed by a physician-in-training with documentation of attending supervision in >90%. Fourteen percent of procedures were emergent; 17% (n = 14) lost at least 1 L blood intraoperatively (see Table 2).

We found no substantial association between physician training status (resident versus attending) or procedure urgency and estimated blood loss during the index procedure, need for blood products during or after the procedure, or number of units received (data not shown, available from authors).

Coagulation-related factors

Only 6 TPs (7%) had medical conditions predisposing to bleeding present on admission (ie, primary hematologic disorder, advanced liver disease, or renal failure). In terms of potential medication-related coagulopathy, 35 TPs (43%) were on antiplatelets or anticoagulants before admission. Only 22% of patients on antiplatelets and none on anticoagulants had documentation that these were held before admission. Forty-three TPs (51%) received anticoagulants or antiplatelets in-hospital before the identified bleed (see Table 3).

Five patients on IV heparin had a partial thromboplastin time >150 seconds at some point perioperatively before the identified bleed. However, the physician attributed the bleeding specifically to coagulopathy in only 2 of these cases. Four of 9 patients on warfarin perioperatively had a therapeutic or supratherapeutic international normalized ratio (>2.0); however, only 1 of these patients who was also

Table 2. Characteristics of the Index Procedure

†Includes 1 splenectomy and 3 laparoscopic procedures.
‡Includes 3 minor cardiac procedures: 1 pacemaker, 1 implantable defibrillator placement, and 1 percutaneous coronary angioplasty.
§Two incision and drainages, and 1 each of breast reduction, facial rhytidectomy, and submental liposuction, and pedicle graft attachment.
OR, operating room.

on IV heparin with a partial thromboplastin time >200 seconds had coagulopathy identified as the bleeding cause. The perioperative platelet count was <100 in 18 TP patients and <50 in 3 patients. Of 30 patients with generalized oozing or coagulopathy identified as contributing to their bleeding, 9 were on an anticoagulant, 3 were on an antiplatelet (none were on clopidogrel), and 7 had a platelet count <100 (only 1 had a platelet count <50).

There was a trend toward higher intraoperative blood loss in patients on either an antiplatelet only or no medication affecting hemostasis versus those on anticoagulants, plus a trend toward greater need for blood products in patients receiving an antiplatelet versus the other medication groups. However, these differences were not significant in pairwise comparisons.

DISCUSSION

This is the first study to examine the criterion validity of the AHRQ PSI, PHH. We found that PHH has a moderate PPV (75%) when applied to VHA data. This estimate is consistent with related measures in the non-VHA setting and compares favorably with the upper range of reported PPVs of other recently validated PSIs representing postoperative complications (ie, 44% for postoperative venous thromboembolism to 83% for postoperative respiratory failure).[17,18] A precursor of the current PSI, which specified either a hemorrhage or hematoma secondary diagnosis code or a procedure code, was associated with a PPV of 78%.[9,19] Another study found a PPV of 75% comparing an ICD-9-CM diagnosis code of 998.1 (Hemorrhage or Hematoma Complicating a Procedure) to a clinical definition of postoperative hemorrhage after coronary artery bypass grafting (ie, return to surgery or blood product transfusion of ≥6 U).[20]

Table 3. Coagulation-Related Factors

Variable	True positives (n = 84)
Conditions present on admission, n (%)	
Coagulopathy (nonmedication-related)*	2 (2.4)
Advanced liver disease	2 (2.4)
End-stage renal disease	2 (2.4)
On anticoagulant or antiplatelet agent prior to admission, n (%)	37 (44.0)
Anticoagulant only (warfarin)	5 (6.0)
Antiplatelet only (aspirin or clopidogrel)	24 (28.6)
Anticoagulant and antiplatelet agent†	8 (9.5)
On anticoagulant or antiplatelet agent after admission and before bleed, n (%)‡	43 (51.2)
IV heparin or warfarin§	16 (19.0)
SC heparin (unfractionated or LMWH)	18 (22.2)
Antiplatelet agent only	9 (11.1)
Lowest perioperative temperature <96.8°F, n (%)‖	14 (16.7)
Lowest platelet count, $\times 10^3/mm^3$, median (range)¶	164 (4–531)
Highest PTT, seconds, median (range)¶	35.4 (21.8–240)
Highest INR, median (range)¶	1.28 (0.89–17.0)

*Two patients with possible idiopathic thrombocytopenic purpura versus myelodyplasia with preoperative platelet counts of 71 and 114.
†One of 8 patients on an anticoagulant and antiplatelet was on LMWH.
‡These were mutually exclusive groups (see text description). An additional 8 patients on anticoagulants were also on antiplatelets—3 in the IV heparin/warfarin group and 5 in the subcutaneous heparin group. Four patients in the antiplatelet only group were on both clopidrogel and aspirin; none were on only clopidogrel.
§Included 7 patients on IV heparin, 3 on warfarin, 6 on both. Patients who received only intraoperative heparin are not included.
‖Intraoperative temperatures were rarely available in the electronic medical record. We therefore used the time period starting at the index procedure until 24 hours postprocedure.
¶This was the most extreme value documented during the time period after the index procedure until discovery of the postoperative hemorrhage/hematoma.
INR, international normalized ratio; LMWH, low molecular weight heparin; PTT, partial thromboplastin; SC, subcutaneous.

Identification of true events—coding limitations and how to improve the indicator

Although 25% of cases were FPs, most were coded correctly but did not fulfill the indicator's clinical intent due to ICD-9-CM coding limitations. Our FP review suggests some basic modifications to the PSI algorithm and ICD-9-CM coding system could increase identification of flagged cases and the PPV.

With respect to cases resulting from a procedure performed before the current admission, although the indicator's PPV could be improved by adopting present on admission codes, which the VHA currently does not use, ignoring such cases could potentially result in loss of important data. The PSIs were intentionally designed to only use information from the index admission because of limitations of the dataset on which they were developed (ie, lack of linkage to information occurring outside the index admission).[1] Other researchers have advocated linking inpatient data to identify 30-day readmissions for PHH.[21] Because many procedures occur in the outpatient setting, outpatient linkage is also important. If we used a 30-day linkage to inpatient or outpatient data, 7 of the 8 present on admission cases would have been considered as TPs (the PPV would increase to 81%); we would have still identified 3 cases that were FPs (2 local surgical infections and the arteriovenous malformation case).

This indicator is intended to identify bleeding that was missed or not fully controlled during the initial procedure, as well as to identify postoperative bleeding serious enough to require a reparative procedure. Many of our FPs had intraoperative or postoperative bleeding but no subsequent reparative procedure, yet had procedure codes associated with the index procedure suggesting hemorrhage control (eg, 39.98, Control of Hemorrhage Not Otherwise Specified). Codes dealing with hemorrhage/hematoma diagnosis or control could be made more specific by associating a time factor with them (ie, intraoperative versus postoperative, or using a different code for bleeding control during the initial procedure versus a subsequent reparative procedure).

To decrease misidentification of cases that are not bleeds, the codes intended to represent hematoma drainage could be made more specific, for example, 86.04 (Other Incision And Drainage of Skin and Subcutaneous Tissue) or 54.12 (Reopening of Recent Laparotomy Site). The PPV impact of such enhancements, including data source linkage and coding changes, requires additional study because of potential trade-offs between sensitivity and specificity.

Additionally, we had 3 hematoma case requiring drainage associated with noneligible procedures (ie, diagnostic angiograms). However, angiography associated with an intervention such as angioplasty is eligible. Therefore, consideration should be given to including such diagnostic procedures.

Clinical implications/preventability

Although this indicator identifies clinically important events, because most TPs required at least one OR return and blood product transfusion, PHH and the other PSIs were also designed to identify complications resulting from quality of care problems. Theoretically, some PHH cases should be avoidable through appropriate perioperative care. Two studies of related indicators support this idea; the Complications Screening Program revealed potential quality problems in 37% of postprocedural hemorrhage or hematoma cases among Medicare patients[22]; a more recent pediatric study estimated that up to 57% of postoperative hemorrhage or hematoma cases were potentially preventable.[23] Because both studies used implicit review, the reproducibility of their findings is unclear.

Although not our main study aim, we abstracted data on risk factors, processes of care, and provider-identified causes to explore the preventability of events. Consistent with existing literature, we found that PHH was most commonly associated with vascular procedures.[21] This is not surprising considering the direct manipulation of large vessels and frequent concurrent use of systemic heparin. Preexisting nonmedication-acquired coagulopathies, which are known to be associated with increased bleeding risk, were rare among our sample.[24]

Up to 38% of procedures were associated with physician-documented potential technical problems. We investigated technical expertise and complication risk by examining trainee status and bleeding risk, but found no association; although we lacked adequate documentation on year of postgraduate training to be able to examine this further. The degree to which iatrogenic coagulopathy contributed to bleeding is unclear. Although medications affecting hemostasis must have played a role in some cases, fewer than half of TP patients received any anticoagulant or antiplatelet agent perioperatively, and few patients had abnormal clotting parameters or had coagulopathy explicitly cited as a bleeding cause. We also found no evidence of increased risk with respect to bleeding risk in patients receiving perioperative anticoagulants or antiplatelets.

Study limitations

Our study has a few limitations. This was a sample of male patients predominantly. However, patient sex should not affect physician documentation or complication coding. We cannot report on sensitivity, specificity, or negative predictive value; this was beyond the current study's scope and resources. Additionally, the ability to detect complications

depends not only on coding accuracy and completeness, but also on completeness of physician documentation. Tying sanctions to PSI rates, as CMS is doing, might impact both coding and medical record documentation. Although PHH is not among the individual CMS-tracked PSIs, it is part of the composite PSI. However, the VHA is less subject to financial incentives than other health care systems. Therefore, this should not have meaningfully affected findings.

Although several procedures were associated with potential technical problems and a few patients on anticoagulants had supratherapeutic clotting parameters, we cannot determine the actual number of cases associated with quality of care problems. This is due in part to lack of established evidence-based processes of care, possible physician documentation issues, the study's retrospective nature, the relatively small sample size, and lack of a control group. In addition, the nurse-abstractors were advised against drawing inferences about causation to maximize the reliability of findings. It was not our intent to make judgments about preventability.

Our findings are strengthened by the fact that cases were randomly drawn from a nationally representative sample of VHA hospitals. We assessed inter-rater reliability of abstraction at different time points and achieved a high level of abstractor agreement at each review. We thoroughly examined FPs and identified opportunities for improving this indicator's PPV.

CONCLUSIONS

In its current form, given its moderate PPV, it is reasonable to use PHH to screen for patient safety events. Additional indicator refinement is required using methods mentioned previously (eg, more specific diagnostic and procedure codes; data source linkage where feasible). Additional investigation about whether PHH identifies remediable quality of care problems is also necessary before it can be considered a definitive quality measure. This indicator is currently being validated in the non-VHA setting by AHRQ investigators. We await their results for comparison with our findings.

Appendix 1. Postoperative Hemorrhage or Hematoma: Detailed Definition and ICD-9-CM Codes

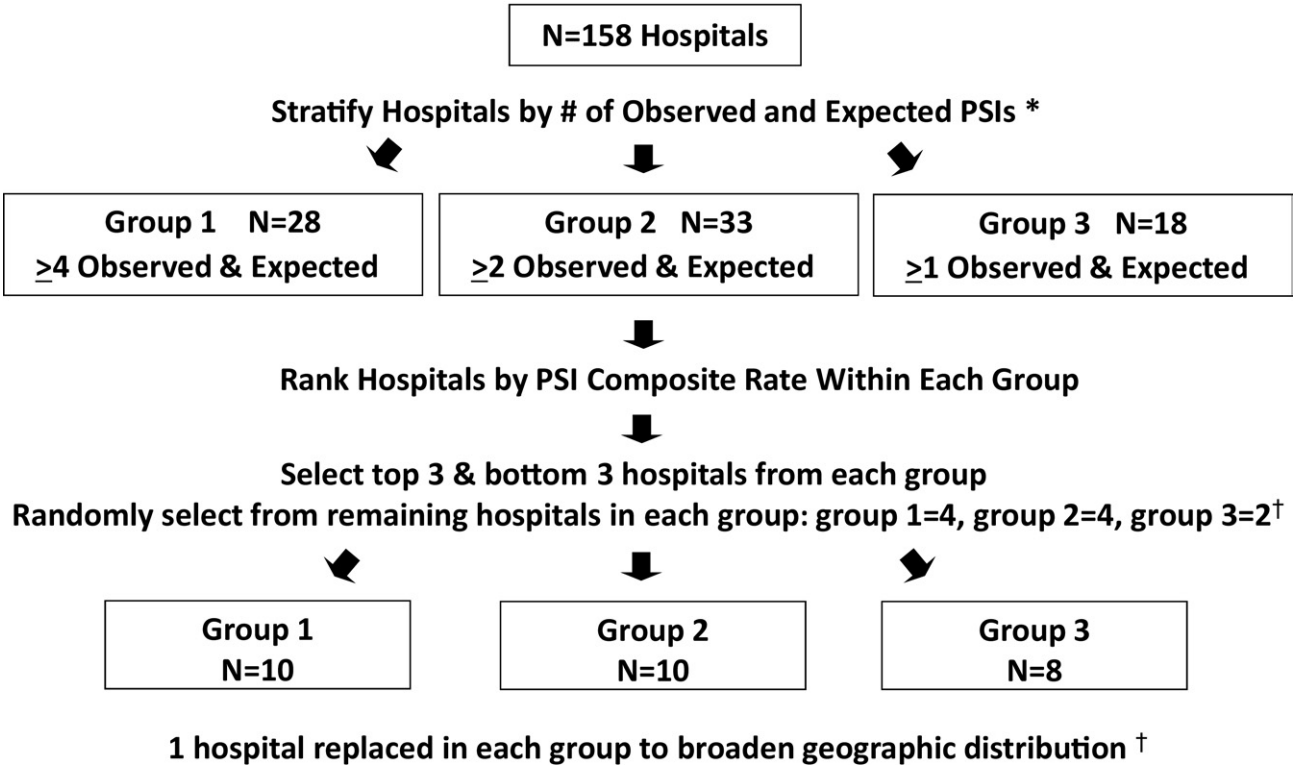
Definition	Cases of hematoma or hemorrhage requiring a procedure per 1,000 surgical discharges with an operating room procedure*	
Numerator	Discharges among cases meeting the inclusion and exclusion rules for the denominator with both of the following: ICD-9-CM code for postoperative hemorrhage (998.11) or postoperative hematoma (998.12) in any secondary diagnosis field† ICD-9-CM code for postoperative control of hemorrhage or for drainage of hematoma in any procedure code field	
Denominator	All surgical discharges 18 years and older defined by specific DRGs and an ICD9-CM code for an operating room procedure‡ Exclude cases: With preexisting condition (principal diagnosis or secondary diagnosis present on admission, if known) of postoperative hemorrhage or postoperative hematoma Where the only operating room procedure is postoperative control of hemorrhage or drainage of hematoma Where a procedure for postoperative control of hemorrhage or drainage of hematoma occurs before the first operating room procedure. MDC 14 (pregnancy, childbirth and the puerperium)	
Control of postoperative hemorrhage ICD-9-CM procedure codes	28.7	Control of Hemorrhage After Tonsillectomy and Adenoidectomy
	38.8x	Other Surgical Occlusion of Vessels (various sites)
	39.41	Control of Hemorrhage Following Vascular Surgery
	39.98	Control of Hemorrhage Not Otherwise Specified
	49.95	Control of (Postoperative) Hemorrhage of Anus
	57.93	Control of (Postoperative Hemorrhage of Bladder
	60.94	Control of (Postoperative) Hemorrhage of Prostate
Drainage of hematoma ICD-9-CM procedure codes	18.09	Other Incision of External Ear
	54.0	Incision of Abdominal Wall
	54.12	Reopening of Recent Laparotomy Site
	59.19	Other Incision of Perivesicle Tissue
	61.0	Incision and Drainage of Scrotum and Tunica and Vaginalis
	69.98	Other Operations on Supporting Structures of Uterus
	70.14	Other Vaginotomy
	71.09	Other Incision of Vulva and Perineum
	75.91	Evacuation of Obstetrical Incisional Hematoma of Perineum
	75.92	Evacuation of Other Hematoma of Vulva or Vagina
	86.04	Other Incision with Drainage of Skin and Subcutaneous Tissue

*Reported as rates, risk-adjusted for age, sex, and modified DRGs.

†Per the ICD-9-CM codebook, these codes are actually for hemorrhage or hematoma "complicating a procedure." Therefore, intraoperative bleeds would be coded identically.

‡See PSI technical specifications for the complete list of eligible surgical DRG and operating room (OR) procedure codes.[5] Eligible OR procedures include all procedures that are considered valid OR procedures by the DRG grouper; procedures such as a diagnostic cardiac catheterization are excluded, but percutaneous coronary angioplasty is included.

Appendix 2. Hospital Sampling Strategy



*The expected PSI count of a specific facility was calculated as the national VHA PSI rate multiplied by the facility's PSI denominator. Group 1 included facilities with at least four safety-related events in both the expected and observed numerators of each PSI; group 2 had at least two events; group 3 had at least 1 event.
†We randomly selected 4 remaining hospitals for groups 1 and 2, and 2 for group 3. We then replaced 1 of the chosen facilities in each group to improve geographic diversity. The final sample (n = 28) included hospitals representing 18 of the VHA's 21 regional health care networks; 32% were from the South, 29% from the West, 21% from the Northeast, and 18% were from the Midwest. Median number of hospital beds was 155 (range 62 to 360 beds). Eighty-nine percent were major or very major teaching hospitals.[25]

Appendix 3. Characteristics of Sample Patients

Variable	All flagged cases (n = 112)	True positives (n = 84)	False positives (n = 28)
Age, mean (SD)	66.8 (11.7)	67.5 (11.9)	64.5 (10.9)
Sex, male, n (%)	109 (97.3)	81 (96.4)	28 (100)
Race, n (%)			
White	77 (68.8)	54 (64.3)	22 (78.6)
Black	11 (9.8)	10 (11.9)	1 (3.6)
Hispanic	8 (7.1)	7 (8.6)	1 (3.2)

*See Table 1 for a description of codes.
†Significant difference ($p < 0.05$) between true positives and false positives.

How Valid is the AHRQ Patient Safety Indicator "Postoperative Respiratory Failure"?

Ann M Borzecki, MD, MPH, Haytham MA Kaafarani, MD, MPH, Garth H Utter, MD, MSC, FACS, Patrick S Romano, MD, MPH, Marlena H Shin, JD, MPH, Qi Chen, MPH, Kamal MF Itani, MD, FACS, Amy K Rosen, PhD

BACKGROUND: The Agency for Healthcare Research and Quality Patient Safety Indicator postoperative respiratory failure (PRF) uses administrative data to screen for potentially preventable respiratory failure after elective surgery based on a respiratory failure diagnosis or an intubation or ventilation procedure code. Data on PRF accuracy in identifying true events is scant; a recent study using University HealthSystem Consortium data found a positive predictive value (PPV) of 83%. We examined the indicator's PPV in the Veterans Health Administration.

STUDY DESIGN: We applied the Patient Safety Indicator software (v.3.1a) to fiscal year 2003–2007 VA discharge data. Trained abstractors reviewed medical records of 112 software-flagged PRF cases. We calculated the PPV and examined false positives to determine reasons for incorrect identification and true positives to determine clinical consequences and potential risk factors of PRF.

RESULTS: Seventy-five cases were true positive (PPV 67%; 95% CI, 57–76%); 13% were identified by a diagnosis code, 53% by a procedure code, 33% by both. Of false positives, 19% represented coding errors, 76% represented nonelective admissions. Of true positives, 28% of patients died, 56% had an American Society of Anesthesiologists level higher than II. Of associated index procedures, 53% were abdominal/pelvic, and 56% lasted >3 hours.

CONCLUSIONS: Based on our and University HealthSystem Consortium's findings, PRF should continue to be used as a screen for potential patient-safety events. Its PPV could be substantially improved in the Veterans Health Administration through introduction of an admission status code. Many PRF-identified cases appeared to be at high risk, based on patient and procedure-related factors. The degree to which such cases are truly preventable events requires additional assessment. Postoperative pulmonary complications are an important contributor to surgical risk, occurring in an estimated 6.8% of all surgical patients.[1] Guidelines exist for assessing perioperative pulmonary risk and recommend preventive strategies for high-risk patients.[2] Respiratory failure—usually defined as unplanned intubation or prolonged ventilation—is considered to be the most serious of the respiratory complications because of its high morbidity, mortality, and associated costs.[3]

Given the potential preventability, seriousness, and association with high resource use, respiratory failure is an attractive result with which to measure quality of surgical care. Postoperative respiratory failure (PRF), administrative data-based outcomes, has been developed by the Agency for Healthcare Research and Quality (AHRQ), as part of its Patient Safety Indicators (PSIs) module.[4] Because its reliance on administrative data, the AHRQ developers cautioned that PRF (PSI 11 and other PSIs) should be used as a screen for potential safety problems, highlighting areas in which quality of care should be investigated as opposed to being used as a definitive patient safety measure.[4] However, based on evidence of its validity to date, PRF was recently endorsed by the National Quality Forum as a hospital performance measure.[5-8] It also is a component of a com-

Abbreviations and Acronyms

AHRQ = Agency for Healthcare Research and Quality
EMR = electronic medical record
IRR = inter-rater reliability
OR = operating room
PPV = positive predictive value
PRF = postoperative respiratory failure
PSI = Patient Safety Indicator
UHC = University HealthSystem Consortium
VHA = Veterans Health Administration

posite PSI measure that the Centers for Medicare and Medicaid Services are tracking as part of their hospital reporting initiative.[9,10]

The PRF indicator is defined as cases of acute respiratory failure per 1,000 elective surgical discharges.[4] The numerator requires either an acute respiratory failure diagnosis code or an intubation or mechanical ventilation procedure code.[11] Recent risk-adjusted rates of this indicator in the nonfederal setting range from 5.3 to 15.8 events per 1,000 discharges, depending on the subgroup studied.[12] Previous work has demonstrated the face,[13] construct (through its association with related measures),[4] and predictive validity of this indicator (ie, its ability to predict an outcome such as death).[5,6] For example, hospital-level PRF rates were highly correlated with rates of other PSIs representing postoperative complications, and the occurrence of PRF was associated with >5-fold increased lengths of stay and costs, and >40-fold increased death rates in the Veterans Health Administration (VHA).[5,6] However, there are relatively few data on its criterion validity (ie, its agreement with an accepted standard, such as medical record information). To this end, we and other groups are conducting chart validation studies of PRF (as well as several of the other PSIs).

The purpose of this study is to build on a recent study performed in the nonfederal setting, using University HealthSystem Consortium (UHC) data. This study found a high positive predictive value (PPV) of 83% for the PRF indicator, signifying it has good accuracy for identifying true events.[7] However, this study also raised concerns that many PRF cases were likely not preventable.[7] Given potential differences with respect to patient case-mix and coding practices, it is important to examine if similar findings exist in other health care systems before conclusions can be made about the indicator's performance. Here we examined the validity of this indicator in the VHA, specifically its PPV. Additionally, we examined potential risk factors for and circumstances surrounding this complication to better understand the nature of events detected by this indicator and their potential preventability.

METHODS

This was a retrospective observational study using VHA administrative and electronic medical record (EMR) data from fiscal year 2003 through 2007 (October 1, 2002 to September 30, 2007). The study protocol was approved by the Bedford VA Medical Center and the VA Boston Healthcare System Institutional Review Boards.

Data sources

Data sources included the VHA's National Patient Care Database Patient Treatment File and the EMR. The Patient Treatment File contains administrative information on all VHA discharges, including demographics, diagnoses (principal and secondary ICD-9-CM codes), surgical and nonsurgical procedures (ICD-9-CM codes), and summary information (eg, admission/discharge dates, discharge status).[14] Because the PSIs were designed to screen for patient-safety events in nonfederal acute care hospitals, per previous work we eliminated the nonacute portion of care (eg, rehabilitation or long-term care), yielding a hospital discharge file containing only acute care.[6,15] We accessed the VHA's EMR data using VistAWeb, a program that allows centralized access to EMR data from all VHA facilities.[16]

PRF definition

Table 1 presents the full PRF definition and specific ICD-9-CM codes.[4,11] As shown, the numerator requires either a secondary diagnosis code for acute respiratory failure or an intubation or mechanical ventilation procedure code. The denominator excludes discharges when the condition was present on admission, or when a tracheostomy procedure was the only procedure or was performed before the first operation. It also excludes patients with major respiratory or circulatory disorders based on their principal diagnosis because of their higher risk for respiratory failure and lower likelihood of preventability.

The denominator also excludes nonelective hospitalizations, reflecting the logic that postoperative respiratory failure is less likely to be preventable "in patients admitted for non-elective surgeries, or urgent/emergent conditions."[15] In nonfederal administrative databases, admission type (eg, elective) serves as a proxy for surgery status because admission type is available but surgery status is not. However, the VHA Patient Treatment File lacks an admission type (or surgery status) field. Because of this, we previously developed an algorithm based on expert clinical opinion to distinguish between elective

Table 1. Postoperative Respiratory Failure Detailed Definition and ICD-9-CM Codes

Definition	Cases of acute respiratory failure per 1,000 elective surgical discharges with an OR procedure*
Numerator	Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM codes for: Acute Respiratory Failure (518.81 or 518.84) in Any Secondary Diagnosis Field, or Reintubation or Mechanical Ventilation Procedure as Follows: 96.04 (Insertion of Endotracheal Tube) ≥1 Day after the Major OR Procedure Code 96.70 (Continuous Mechanical Ventilation of Unspecified Duration) or 97.71 (Continuous Mechanical Ventilation for <96 hours) ≥2 Days after the Major OR Procedure Code 96.72 (Continuous Mechanical Ventilation for ≥96 hours) ≥0 Days after the Major OR Procedure Code
Denominator	All elective surgical discharges aged 18 years and older defined by specific DRGs and an ICD-9-CM code for an OR procedure† Exclude cases: With pre-existing (principal diagnosis or secondary diagnosis present on admission, if known) acute respiratory failure With an ICD-9-CM diagnosis code of neuromuscular disorder Where a procedure for tracheostomy is the only OR procedure or tracheostomy occurs before the first OR procedure MDC 14 (pregnancy, childbirth, and puerperium) MDC 4 (diseases/disorders of respiratory system) MDC 5 (diseases/disorders of circulatory system)

*Reported as rates, risk-adjusted for age, sex, and modified diagnosis related group.
†Elective procedure defined by admit type. See PSI technical specifications for the complete list of eligible surgical DRG and OR procedure codes.[4,11] Eligible OR procedures include all procedures that are considered valid OR procedures by the DRG grouper; procedures such as a diagnostic cardiac catheterization are excluded, but a percutaneous coronary angioplasty is included.
OR, operating room; DRG, diagnosis related group; MDC, major diagnostic category; MDC is based on the principal diagnosis.

and nonelective hospitalizations using diagnosis related groups (DRGs) adapted from a nonelective DRG list originally used with California hospitalization data, admission date and time, and principal procedure date and time.[15] Cases with admissions or procedures occurring after hours or on weekends are classified as nonelective, as are DRGs, suggesting management of acute conditions (eg, trauma-related DRGs).

Study population

Hospital sampling

We applied the PSI software (v. 3.1a) to the VHA inpatient database to obtain individual PSI counts and composite scores (ie, a combined measure that includes 11 PSIs).[17,18] We selected hospitals to obtain a reasonably sized sample that would be representative of the diversity of VA hospitals. Starting with 158 acute care hospitals, we categorized facilities into 3 groups based on their observed and expected individual PSI counts, exclusive of PSI 5 (ie, Foreign Body Left During Procedure) and PSI 8 (ie, Postoperative Hip Fracture), which had low rates across most hospitals and obstetric PSIs. We ranked hospitals by PSI composite score and chose the top 3 and bottom 3 from each group. We then randomly selected from the remaining hospitals within each group to achieve a final sample of 28 hospitals (Fig. 1). The final sample included hospitals representing 18 of the VHA's 21 regional health care networks; 21% were from the Northeast, 32% the South, 18% the Midwest, and 29% from the West. Eighty-nine percent were major teaching hospitals (ie, resident-to-bed ratio >0.25).[19] Median number of hospital beds was 155 (range 62 to 360 beds).

Case identification

We used criteria developed by Rivard and colleagues to identify the eligible pool based on presumed elective admission status[15] and randomly selected 4 flagged cases of PRF from each of the 28 hospitals, yielding a total of 112 cases. This number was based on power calculations using earlier reported PPVs and selected to ensure reasonably narrow confidence intervals (ie, 10% to 20%).[20] Because 1 hospital had only 1 flagged case, we randomly selected 1 case each from 3 other hospitals in group 3 (Fig. 1).

Instrument development/chart abstraction

We modified a data abstraction instrument and guidelines from preliminary versions developed by AHRQ-funded investigators.[21] The instrument included questions about demographics, case ascertainment and exclusions, patient and procedure-related risk factors, evaluation, and management. (A revised version of a preliminary AHRQ tool with similar questions was used in the UHC study.) We added questions on perioperative fluid management and patient risk factors, with additional modifications occurring iteratively through clinician review, pre-pilot testing by 2 trained nurse-abstractors, and formal pilot testing with inter-rater reliability (IRR) assessment. For IRR measurement, the 2 nurse-abstractors independently reviewed identical records in groups of 5 until they achieved ≥90%

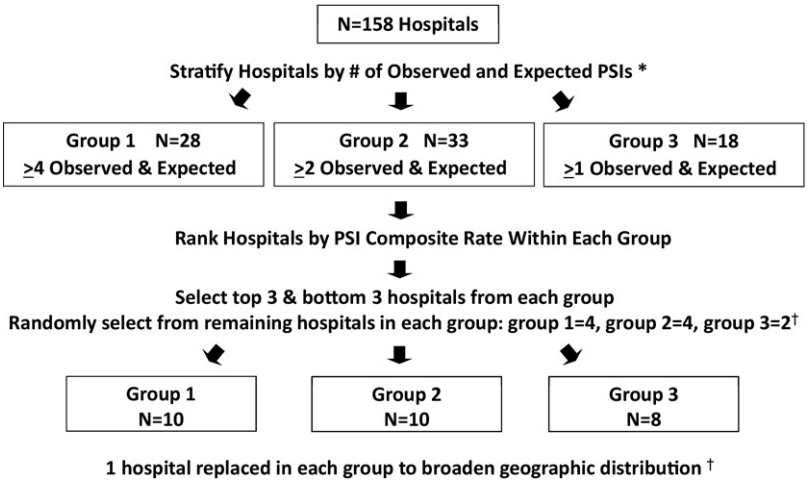

Figure 1. Hospital sampling strategy. *The expected Patient Safety Indicator (PSI) count of a specific facility was calculated as the national Veterans Health Administration PSI rate multiplied by the facility's PSI denominator. Group 1 included facilities with at least 4 safety-related events in both the expected and observed numerators of each PSI; group 2 had at least 2 events; group 3 had at least 1 event. †We randomly selected 4 remaining hospitals for groups 1 and 2, and 2 for group 3. We then randomly replaced 1 of the chosen facilities in each group to improve geographic diversity.

observed agreement across all questions, after which abstraction proceeded on different records. Abstraction disagreements were classified as being the result of an abstraction error (eg, the nurse abstracted an item incorrectly, such as noting the wrong value for weight or height) or an instrument problem (eg, a question was ambiguous, such as "what was the estimated blood loss during the procedure?" The response to which might vary based on whether the surgeon's, anesthetist's, or nurse's estimate was used). Nurse-abstractors corrected abstraction errors by reviewing the medical record together. They reviewed instrument-related issues with study clinicians (AB, HK), resulting in additional abstractor training, with instrument revisions and/or guideline clarifications as appropriate. Another IRR assessment was performed with 5 charts toward the end of the abstraction process to check for drift in abstractor reliability. Study physicians (AB, HK) also reviewed cases for clarification as necessary on an ongoing basis. This occurred with 6 cases; these tended to be cases in which abstractors could not determine why the patient remained ventilated postoperatively.

Once the initial criteria for inter-rater agreement were met, abstractors entered information directly into an electronic form hosted on a secure server on the VHA intranet, from which data were extracted into a relational database for subsequent analysis.

IRR testing revealed 90% agreement (n = 49 questions) on the initial 5 records and 91% on subsequent testing. Nurse-abstractors agreed 100% on questions pertaining to ascertainment of the event (ie, identification of cases as true positives [TPs] or false positives [FPs]) on initial and subsequent testing ($\kappa = 1.0$).

Analyses

Based on abstraction results and application of AHRQ's PRF definition, we categorized cases as TPs or FPs. Following UHC study methods, we calculated the PPV (ie, TPs/flagged cases) and associated 95% confidence intervals in 2 ways: based on whether the ICD-9-CM codes that resulted in the case being flagged were appropriate (coding criteria) and whether the case represented PRF from a clinical perspective (clinical criteria).[7] With respect to the second issue, we also classified FPs based on whether they failed to meet numerator or denominator criteria (Table 1). By classifying FPs as due to either coding inaccuracies or failure to meet the indicator's clinical intent, we hoped to gain insights into how to improve the PSI. Our characterization of cases differed slightly from the UHC study because we considered nonelective cases as FPs based on clinical criteria as opposed to coding criteria.

We compared TPs and FPs with respect to selected demographics and assigned codes using *t*-tests or chi-square as indicated. We also examined TPs to determine the clinical consequences of PRF and factors contributing to its occurrence, and performed descriptive analyses of relevant variables. Analyses were performed using SAS software, version 9.1 (SAS Institute Inc.).

Table 2. Characteristics of Sample Patients

Variable	All flagged cases (n = 112)	True positives (n = 75)	False positives (n = 37)
Age, y, mean (SD)	68.6 (10.2)	68.5 (9.9)	68.9 (10.9)
Sex, male, n (%)	111 (99.1)	74 (98.7)	22 (100)
Race, n (%)			
White	79 (70.5)	52 (69.3)	27 (73.0)
African American	15 (13.4)	11 (14.7)	4 (10.8)
Hispanic	5 (4.5)	4 (5.3)	1 (2.7)
Other/missing	13 (11.6)	8 (10.7)	5 (13.5)
ICD-9-CM codes, n (%)*			
Diagnosis code only	13 (11.6)	10 (13.3)	3 (8.1)
Procedure code only	65 (58.0)	40 (53.3)	25 (67.6)
Both diagnosis and procedure codes	34 (30.4)	25 (33.3)	9 (24.3)
Procedure codes, n (%)			
96.04	51 (45.5)	41 (54.7)	10 (27.0)†
96.70	1 (0.9)	0	1 (2.7)
96.71	10 (8.9)	6 (8.0)	4 (10.8)
96.72	37 (33.0)	18 (24.0)	19 (51.4)†

Percentages represent column percents. Cases were flagged per the Patient Safety Indicator algorithm.
*See Table 1 for a description of codes.
†Significant difference (ie, $p < 0.05$) between true positives and false positives.

RESULTS

Of 64,293 eligible hospitalizations among sample hospitals, 871 were flagged for PRF (ie, an observed rate of 13.5 per 1,000), compared with 2,850 flagged cases per 201,192 eligible hospitalizations nationally in the VHA (14.2 per 1,000). Of the 112 reviewed cases, 105 were TPs by coding criteria, for a PPV of 94% (95% CI 88–97%). When accounting for both coding and clinical criteria, the number of TP cases decreased to 75, for a PPV of 67% (95% CI 57–76%). Table 2 shows demographic and coding characteristics of all flagged cases, TPs, and FPs. The TP and FP groups were elderly (mean age 69 years) and predominantly male and white. Of the entire sample, 58% of cases were flagged based on a procedure code only, 12% were flagged based on a diagnosis code only, and 30% had both a diagnosis and procedure code. TP cases differed from FP cases with respect to assigned procedure codes; a 96.04 procedure code (Insertion of an Endotracheal Tube ≥1 Day after the Major Operating Room [OR] Procedure) was more common among TPs; a 96.72 procedure code (Continuous Mechanical Ventilation for ≥96 Hours 0 or More Days after the Major OR Procedure) was more common among FP cases (55% versus 27%, and 51% versus 24% respectively; $p < 0.05$).

FP analysis

Of the 7 patients (6%) that did not meet coding criteria, 2 remained on the ventilator immediately postoperatively for <96 hours; 4 had postoperative ventilation codes but no medical record documentation that they were on a ventilator; 1 patient was coded as if he had an OR procedure when he did not. An additional 30 patients did not fit clinical criteria; 28 of these did not satisfy denominator criteria because they were nonelective hospital admissions. Two additional patients did not fulfill the numerator criteria, as the patient was kept on the ventilator postoperatively for airway protection. Of the nonelective admissions, 5 would also have been excluded by other criteria, such as being intubated for respiratory failure before the first operation.

TP analysis

Outcomes

Median length of stay was 21 days (25^{th}, 75^{th} percentile 12, 36 days). Thirteen TP patients (17%) underwent tracheostomies; 2 TP patients were discharged with tracheostomies. No one was discharged on a ventilator. There were 21 deaths (28%).

Procedure-related risk factors

Of the TP cases, 53% (n = 40) involved abdominal/pelvic procedures; the next largest category was head and neck procedures at 16% (n = 12) (see Table 3 for additional details). Sixty-five TP patients (87%) had respiratory failure after the first OR procedure; in 6 (8%) this followed a second procedure and in 4 (5%) it followed a third procedure. Of the 10 TP patients (13%) who had respiratory failure after a nonelective procedure, in all but 1 this was a procedure resulting from a complication

Table 3. Procedure-Related Risk Factors

Duration of operation, minutes, median, (range)	235 (35–795)
No. of OR procedures before respiratory failure (median, range)	1 (1–3)

Although the indicator is intended to exclude patients with principal diagnoses of circulatory or respiratory disorders, the 5 cases involving the chest and 6 vascular cases (5 carotid and 1 femoral anastomosis) all received an appropriate noncirculatory or respiratory-related principal diagnosis. (Patients with cerebrovascular disease get assigned to a major diagnostic category of "nervous system.")

*Includes 5 carotid vascular procedures.

†Includes 4 esophagectomies and 1 video-assisted thoracoscopic surgery.

‡Includes 1 splenectomy, 4 laparoscopic procedures, and 8 nephrectomies.

§Includes 1 femoral anastomosis revision; other procedures are orthopaedic.

‖Penile prosthetic implant.

¶Procedure status was obtained from the operative report.

#18 epidurals and 1 peripheral nerve block.

**One patient received only local anesthetic for a carotid angioplasty.

associated with the initial elective procedure. Fifty-three (71%) patients received general anesthesia only. Nineteen TP patients (25%) received regional anesthesia; 18 received an epidural, the majority of whom retained it for postoperative pain control, and 1 received a peripheral nerve block. Forty-two cases (56%) underwent an operation lasting >3 hours (see Table 3). Twenty percent lost at least 1 L blood intraoperatively. Thirty-one percent (n = 23) received at least 3 L IV fluid intraoperatively (crystalloid, colloid, and blood products combined; although this information was available for only 46 patients [61%]).

Table 4. Patient-Related Risk Factors

Variable	True positives (n = 75)
BMI, mean (SD)	27.7 (6.1)
Conditions present on admission

ASA, American Society of Anesthesiologists; BMI, body mass index; CHF, congestive heart failure; SVT, supraventricular tachycardia.

Patient-related risk factors

Sixty-one percent (n = 46) had at least 1 pre-existing condition recognized as a risk factor for respiratory complications (eg, obstructive sleep apnea, COPD, smoking, alcohol use, or congestive heart failure), with COPD and smoking being most common at 32% and 40%, respectively.[2] Sixty percent had at least 1 risk factor for cardiac complications, with diabetes, and chronic kidney disease being the most common.[22] All but 8 TP patients (11%) had at least 1 substantial comorbidity (see Table 4 for additional details on individual comorbidities). The American Society of Anesthesiologists' class was higher than II in 82% of TP cases in which it was documented. Thirty-three percent were obese (ie, body mass index ≥30). Of 57 cases with a documented preoperative albumin level, it was <3.0 in 16% (n = 9).

Contributing factors

Seventy-nine percent of cases (n = 59) were initially extubated after the procedure but were reintubated later; 20%

(n = 15) remained intubated at the conclusion of the procedure (1 case of respiratory failure did not involve ventilation). Mean interval between the preceding operation and reintubation was 3.6 ± 5.2 days (median 2.0, 25th, 75th percentile 0, 4 days).

The most common provider-identified contributing factors included fluid overload (45%), pneumonia (43%), and atelectasis (31%), with these commonly co-occurring (see Fig. 2). Seventy-one percent had more than one contributing cause to respiratory failure. Eight cases represented primarily cardiac causes (ie, ischemia/infarction/atrial dysrhythmia with rapid ventricular response and congestive heart failure) as the cause of respiratory failure. Five cases represented cardiopulmonary arrests; of the 3 autopsies, 1 was a primary cardiac cause (ie, a massive myocardial infarction) and 2 were primarily respiratory (ie, a massive pulmonary embolism and aspiration). Upper airway causes of PRF were relatively rare (only 3 were due to upper airway edema); oversedation as the sole cause of PRF did not occur in any cases.

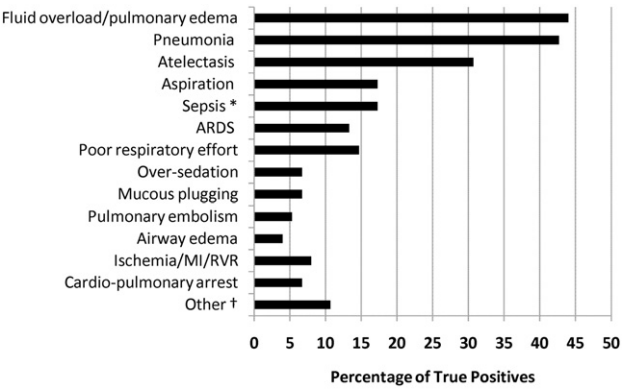

Figure 2. Physician-identified responsible factors for postoperative respiratory failure. Multiple factors can be responsible for a given case. *Sepsis unrelated to pulmonary process. †Includes COPD exacerbations or underlying COPD (n = 2), bronchospasm (n = 1), altered mental status (n = 1), thick secretions (n = 2). Ischemia/MI/RVR, myocardial ischemia/infarction/rapid ventricular response with congestive heart failure.

DISCUSSION

This is 1 of only 2 studies, to our knowledge, that examine the criterion validity of the AHRQ PSI, PRF in its current form, and the first to do so in the VHA.[7] We found that PRF has a modest PPV when applied to VHA data. Based on coding criteria, 94% of cases met its technical definition and 67% (95% CI 57–76%) met coding and clinical criteria, thereby representing true postoperative respiratory failure events. The majority of FPs represented patients with nonelective hospitalizations; incorrect coding was the next most common category. The in-hospital death rate for the TPs was markedly elevated (ie, 28%). PRF was most commonly associated with abdominal/pelvic procedures. A majority of the procedures were done under general anesthesia alone and were >3 hours long. Patient-related respiratory and cardiac comorbidities that can contribute to postoperative respiratory failure, such as COPD; current smoking; congestive heart failure history; and earlier MI, were common. Most cases represented reintubations after the initial operation, with volume overload, pneumonia, and atelectasis as the most common contributing conditions.

Identification of true cases

Comparison with other studies

The UHC study, involving 609 cases from 18 nonfederal academic medical centers, had a similar observed rate of PRF among sample hospitals at 14.7 per 1,000. The UHC investigators also found that 94% of cases met coding criteria, although a higher percentage, 83% (95% CI 77–89%), met both coding and clinical criteria.[7] As noted, our PPV results based on coding criteria are not directly comparable because the UHC data includes admission status codes (ie, FPs resulting from nonelective cases were considered as due to coding errors). The UHC study additionally had minor differences in classification of PRF cases based on investigators' interpretation of the indicator (ie, they considered patients with cardiac arrests as clinical FPs). Had we likewise categorized our patients, the PPV in this study would have dropped to 64%.

Comparison with older data on related measures reveals PPVs similar to our current findings both in the VHA and Medicare setting. We previously compared the original AHRQ PRF definition, defined solely by a diagnosis code for respiratory failure, with chart-based complication data from the National Surgical Quality Improvement Program.[23] The related National Surgical Quality Improvement Program clinical definition was "on the ventilator for more than 48 hours postoperatively." This work resulted in AHRQ-adopted revisions to the previous indicator. By capturing cases with either a diagnosis code for respiratory failure or intubation or ventilation procedure codes with associated timing specifications, the PSI's PPV decreased from 74% to 68%, and its sensitivity improved from 19% to 63%. The Complications Screening Program study, a sentinel patient-safety study using hospital discharge data from the early 1990s developed the indicator "Postoperative Pulmonary Compromise."[24] Although this indicator differed because it included no ventilation codes and only diagnostic codes for pulmonary congestion, pulmonary insufficiency, and acute pulmonary edema, its PPV was 72% (33 of 46) among Medicare beneficiaries.[4,20,24]

Coding-related strengths of indicator

Our current findings support the previous modifications to the AHRQ PRF indicator. Had we imposed the original PRF requirement of a diagnosis code of respiratory failure only, we would have detected just 46% of TPs. Consistent with UHC data, we found that it was rare for this indicator to identify cases of respiratory failure that were present on admission. None of our flagged cases had respiratory failure present on admission, compared with 0.8% of UHC cases.[7] Therefore, unlike some of the other PSIs, this indicator does a good job distinguishing complications or conditions that are present on admission from complications occurring during the hospital stay. Although the VHA does not code for present on admission status, in settings that have present on admission coding, reported rates have been similarly low, ranging from 1% using single institutional data[25] to just <7% using California and New York state data.[26]

Coding-related limitations of indicator

Because patients undergoing emergency procedures are at higher risk for nonpreventable events, they are intended to be excluded. Because there is currently no way to identify emergency procedures from administrative data, emergency admissions are considered a proxy for emergency procedures. The VHA has an additional limitation because admission status is not identified in the administrative database. Using a previously developed algorithm with face validity,[15] we incorrectly identified 28 flagged cases as elective admissions (25%). However, one might argue that PRF associated with nonelective admissions is still important to capture because some of these cases might be preventable. Had we retained cases classified as FPs based only on admission status, our PPV would have been 88% (95% CI 81–94%; ie, more comparable with the UHC findings).[7] Notably, even in UHC member hospitals that code data with respect to admission status, incorrect admission status coding was still the most frequent reason for FPs, occurring in 5% of cases.[7]

The indicator also excludes patients undergoing noninvasive ventilation (bilevel positive airway pressure/continuous positive airway pressure) unless they also have an acute respiratory failure diagnosis. In our sample, 1 TP patient received bilevel positive airway pressure postoperatively and remained on the ventilator prophylactically after a second surgery. This was flagged as PRF because of the ventilation associated with the second procedure, even though the clinical event was associated with the first. The effect on PPV of adding noninvasive ventilation (ie, procedure code 93.90) to the PRF definition requires additional study.

Additionally, the indicator makes no distinction between respiratory failure from a primarily pulmonary versus cardiac cause. One could argue that this distinction is of little clinical value because both cardiac and respiratory complications are common, potentially preventable, and serious, as they can result in respiratory failure, cardiopulmonary arrest, and death.

Apparent coding-related errors were seen in 6% of our flagged cases and 10% of UHC cases.[7] In the UHC study, after accounting for incorrect coding of hospitalization status, coding errors were most commonly due to a diagnosis code of acute respiratory failure not supported by medical record documentation; in our sample, coding errors were most commonly due to inappropriate coding for ventilation procedures. Although diagnostic terms can frequently be vague and subject to interpretation, procedure coding should be more straightforward. Although it might be difficult to determine the exact number of hours for which a patient was ventilated, it is unclear why FP patients who were not ventilated postoperatively received a mechanical ventilation code as if they were.

Are true cases preventable?

An important issue with respect to use of any potential quality measure is whether the identified adverse events are associated with process or systems failures and are therefore preventable. In theory, respiratory failure should be preventable through appropriate preoperative, intraoperative, and postoperative care. Additional support for this aspect of construct validity comes from the Complications Screening Program study; implicit physician review revealed potential quality problems in 27% of postoperative pulmonary compromise cases (n = 44) and only 2% of controls.[27]

As noted, guidelines exist for preoperative pulmonary (and cardiac) screening of patients undergoing elective procedures.[2,22] The goal is to determine their complication risk, manage modifiable risk factors preoperatively (eg, optimize lung/cardiac function through appropriate medication use in a patient with symptomatic COPD), and provide appropriate perioperative and postoperative management.

Although not our primary goal, we tried to get some idea of preventability by abstracting data on risk factors and processes of care. As in the UHC TP group, both patient- and procedural-related risk factors were very common. Compared with the UHC sample, VHA cases involved older patients with an especially high prevalence of COPD and smoking; despite this, essentially all TP patients in both samples had an American Society of Anesthesiologists class higher than I (among those for whom it was documented). Although the indicator excludes patients with a principal diagnosis of major respiratory or circulatory diseases, a large percentage of patients in both our and the UHC study had considerable respiratory or circulatory co-

morbidities impacting their risk. In both studies, TPs were commonly associated with procedures of at least moderate to high risk, of relatively long duration, and done under general anesthetic only.

The degree to which these risk factors could have been modified and the patient's risk decreased is uncertain. This is due in part to missing information in the EMR, as well as few existing strategies showing a benefit in either the preoperative, intraoperative, or postoperative setting.[28] With respect to preoperative management, although the majority of patients had at least documentation of a preoperative anesthesia assessment, because of resource limitations it was outside the scope of this study to determine whether patients had a change in preoperative comorbidity management or type of anesthesia used based on a preoperative assessment. Although volume overload was a common contributing cause, we found limited information with respect to intra- or postoperative fluid management (due to missing anesthesia reports or nursing flow sheets). In addition, information on use of postoperative preventive strategies (eg, lung expansion modalities) was frequently not documented in the EMR. Faced with similar findings because many of their cases appeared to be at high risk based on patient and procedural factors, the UHC investigators concluded that most of the identified cases were likely not preventable.[7]

Study strengths

Our cases were randomly drawn from a nationally representative sample of Veterans Affairs hospitals. Unlike the UHC study, we performed IRR testing of abstraction both early and late in the abstraction process and achieved high agreement between the registered nurses on abstracted data elements. In addition, our study clinicians were able to re-review cases when there were questions or concerns. In addition, unlike the UHC study, we also report on provider-identified circumstances surrounding the respiratory failure.

Study limitations

Similar to the UHC study, we are unable to report on sensitivity or specificity because we did not abstract cases that were not flagged by the PSI algorithm. This is because of difficulties in identifying an adequately representative sample that would not exceed time and staff resources available for chart abstraction. Our team does plan to examine PRF's negative predictive value among high-risk groups. Our study is also limited because our sample was relatively small, elderly, predominantly male, and had a high comorbidity burden. Despite this and the problems related to the VHA's lack of an admission status code, our findings with respect to risk factors were consistent with those of the UHC study, which had a larger population (507 TP patients) that was slightly younger and with more female patients (46% of TP patients). We cannot draw any conclusions as to the number of cases associated with potential quality of care problems or make recommendations to address these. This is partly a result of the retrospective nature of the study, relatively small sample size, lack of a control group, and missing data, such as anesthesia reports, which are often not available in VistAWeb.

How to improve the indicator

The PPV of the PRF indicator could be improved considerably in the VHA through introduction of an admission status code. This would also enable more accurate comparisons of VHA and non-VHA PRF rates. The UHC investigators have suggested that in non-VHA settings, misidentification of nonelective admissions could be improved by excluding cases that are suspicious for nonelective conditions based on principal diagnoses (eg, acute pancreatitis). Additional refinement would entail adding noninvasive ventilation codes. The UHC study additionally recommended excluding head and neck operations because they found several FP patients who were intubated for airway protection. Among our FP patients (including nonelective admissions), we had only 2 such patients. We also had 3 TP patients who were ventilated because of acute respiratory failure due to airway edema. Therefore, the trade-offs of any such modification will need to be carefully considered.

CONCLUSIONS

Based on both the UHC study and our findings, we think it is reasonable to use this indicator in its current form as a screen for postoperative respiratory failure events. Even with coding improvements that would enhance the identification of true complications, we have concerns about using this indicator for pay-for-performance. This is because of the lack of current evidence that such events are actually preventable through improvements of care. Additional study on whether identified events are avoidable is required, as is development of evidence-based methods to prevent such complications.

Summary. Stroke prevention in atrial fibrillation is of paramount importance given its associated morbidity and mortality. The many challenges of warfarin limit its effective use in real-world clinical practice. We are entering an exciting therapeutic era as new classes of anticoagulants, including direct thrombin inhibitors, factor Xa inhibitors and novel vitamin K antagonists, are being evaluated for possible use in this patient population. If proven to be as efficacious as warfarin and safer, expanded use of these novel agents to lower risk subgroups may be justified. It is imperative that providers be aware of the many advantages and potential challenges posed by use of these novel agents in routine clinical care. An understanding of individual pharmacokinetic profiles and potential drug-drug and drug-disease interactions will translate into improved effectiveness in real-world practice.

Keywords: anticoagulation, atrial fibrillation, direct thrombin inhibitors, factor Xa inhibitors, novel anticoagulants, stroke prevention.

Introduction

Atrial fibrillation (AF) is the most common significant cardiac rhythm disorder in the world. In the United States alone, it currently affects an estimated 2.5 million people a year and is estimated to increase to approximately 8 million individuals by the year 2020 [1,2]. The increasing incidence is due to multifactorial causes and is attributed largely to the aging of the population, the rates of hypertension, obesity, diabetes mellitus and heart failure and increased survival with chronic cardiovascular disease. The morbidity and mortality associated with AF are substantial. Atrial fibrillation-related strokes are associated with a 30-day mortality of 24% [3]. The Framingham Heart Study has shown that the attributable risk of stroke for patients with AF increases from 1.5% at age 50–59 years to 23.5% at age 80–89 years [4]. It is projected that by the year 2050, more than half of the patient population with atrial fibrillation will be older than 80 years of age [5]. Older individuals are also at the highest risk of serious bleeding from anticoagulant therapy, highlighting the critical balance between risk and benefit.

Currently, the vitamin K antagonist, warfarin, is the mainstay of anticoagulant therapy for patients with atrial fibrillation [6]. Developed over 60 years ago, warfarin has been the most effective treatment to prevent ischemic stroke in patients with atrial fibrillation, decreasing the stroke risk by two-thirds when compared with placebo [7]. Despite its efficacy, warfarin remains under-used in clinical practice [8,9]. In fact, only 50–60% of those eligible AF patients are anticoagulated with warfarin, due to its high risk profile and complex pharmacokinetics and pharmacodynamics [10]. Maintaining its narrow therapeutic range in a real-world patient population is challenging due to warfarin's variable dose response, diet and medication interactions, and frequent monitoring. Analyses from clinical trial data have identified a minimum threshold of time in the therapeutic range (TTR) of at least 60% to maximize the benefit of warfarin [11,12]. In addition, warfarin has a slow onset of action, a long duration of action and a long elimination half-life, which makes it difficult to manage peri-procedural interventions. Due to these dosing complexities, warfarin is associated with a high rate of adverse events, which creates barriers to more widespread use [13,14].

Despite 60 years of experience with warfarin for stroke prevention in atrial fibrillation, many questions remain to be answered. Current investigation of novel anticoagulants, the mechanisms underlying thrombosis and propagation of atrial fibrillation, the role of genetics, stroke risk stratification, and the comparative effectiveness of different treatment strategies

across diverse subgroups, will further our understanding and inform optimal management of this enlarging patient population. In this review, we will provide an update and overview of promising new anticoagulant therapies and highlight areas of current uncertainty in the prevention of stroke in atrial fibrillation.

Novel oral anticoagulants

There are currently over 20 novel anticoagulants in development and more than half of them are oral agents. The new oral anticoagulants primarily focus on inhibiting a specific factor in the coagulation pathway by directly binding to the factor. Various binding mechanisms are employed depending on which factor is the target, including factors (Fs) II, V, VII, IX, X and XI. The agents that are most advanced in clinical research and closest to approval for various indications, are the direct thrombin (FIIa) inhibitors and the direct FXa inhibitors [15–18].

Direct thrombin (FIIa) inhibitors

Oral, direct thrombin inhibitors (DTIs) are synthetic, small molecules that interact directly with thrombin, blocking both free and clot bound thrombin [16]. Blocking directly at FIIa is a desirable strategy because it is the final step in blood coagulation. Thrombin plays a central role as a procoagulant by converting fibrinogen to fibrin, activating other substrates (FV, FVIII, FXI and FXIII) and activating platelet protease activated receptors [19]. It is also the most potent agonist of platelet aggregation. By binding directly to the active site of thrombin and minimally to plasma proteins, DTIs produce a predictable anticoagulant response [16,19].

The first oral DTI, ximelagatran, developed and studied over 5 years ago, was a prodrug of melagatran. It had predictable pharmacokinetics and anticoagulant response, required no monitoring and had minimal drug or food interactions. Ximelagatran was the first oral DTI to undergo clinical testing, showing that it was at least as effective as warfarin for stroke prevention in atrial fibrillation [20,21]. It was ultimately removed from the market due to its association with hepatic toxicity. Nevertheless, ximelagatran established a cautious precedent for inhibition of thrombin as a viable single target for anticoagulants.

Dabigatran etexilate

Dabigatran etexilate is the oral DTI that has been most extensively studied to date and is currently approved for prevention of venous thromboembolism (VTE) after total hip or knee replacement surgery in Europe and Canada. The US Food and Drug Administration recently approved the use of dabigatran for stroke prevention in AF [22,23]. Dabigatran etexilate is a prodrug that is rapidly converted to its active form, dabigatran. Dabigatran etexilate is a twice daily oral medication, with an onset of action of about 2 h. It has an elimination half-life of 12–17 h, which may be prolonged in renal insufficiency, as it is primarily eliminated through renal routes [24,25]. Dabigatran does not require routine monitoring and may avoid major cytochrome (CYP) P450 drug interactions

Table 1 Pharmacokinetic and pharmacodynamic characteristics of new agents and stage of development [16,24–32,65]

	Dabigatran	AZD0837	Rivaroxaban	Apixaban	Edoxaban	Betrixaban	YM-150	Tecarfarin

because it is metabolized through conjugation [23–32]. (Table 1) It is, however, a P-glycoprotein (P-gp) substrate and implications of potential drug interactions will be discussed later in the paper. Dabigatran has recently been evaluated in a number of phase III clinical trials, including VTE prevention after orthopedic surgery, VTE treatment, and stroke prevention in AF [33–38]. Subsequent to a phase II evaluation in 502 patients with atrial fibrillation, two doses of dabigatran were chosen to be compared with warfarin in the Randomized Evaluation of Long-term anticoagulation therapY (RE-LY) trial [37]. This multicenter, prospective, open-label, randomized trial included patients with non-valvular atrial fibrillation at moderate to high risk of stroke or systemic embolism [38,39]. Patients were excluded for a number of reasons, but most notably, a history of heart valve disorders, stroke within 14 days or severe stroke within 6 months, conditions associated with an increased risk of bleeding, severe renal impairment (Cockcroft Gault creatinine clearance (Clcr) ≤30 mL min^{-1}) or active liver disease. The primary objective was to demonstrate dabigatran as non-inferior to warfarin in preventing stroke and systemic embolism. Over 18 000 patients worldwide were randomized to dabigatran etexilate 110 mg twice daily, dabigatran etexilate 150 mg twice daily or warfarin (target international normalized ratio (INR) goal 2.0–3.0).

The mean age of patients enrolled in RE-LY was 71 years and approximately two-thirds were men [38]. Stroke risk was assessed using the $CHADS_2$ risk scoring scheme, assigning 1 point each for congestive heart failure, hypertension, age ≥75 years and diabetes mellitus, and two points for history of prior stroke or transient ischemic attack (TIA) [40]. The mean $CHADS_2$ score was 2.1, with roughly equal proportions distributed among the respective $CHADS_2$ categories: 0–1, 2 and 3–6 [38]. The median duration of follow-up was 2 years, and 99.9% of patients achieved complete follow-up of at least 1 year. The mean TTR for the warfarin group was 64%. Dabigatran 110 mg twice daily was found to be non-inferior to warfarin in preventing stroke or systemic embolism (1.54% vs. 1.71% per year, $P = 0.30$) and superior in terms of major bleeding (2.87% vs. 3.57% per year, $P = 0.003$). Dabigatran 150 mg twice daily was found to be superior to warfarin in preventing stroke or systemic embolism (1.11% vs. 1.71% per year, $P < 0.001$) and non-inferior to warfarin in terms of major bleeding ($P = 0.32$). Both dabigatran doses resulted in fewer intracranial hemorrhages compared with warfarin ($P < 0.001$), and there were no signals of hepatic toxicity. Gastrointestinal bleeding was significantly increased with the dabigatran 150 mg dose and discontinuation rates were higher in both dabigatran groups compared with warfarin at 1 and 2 years. Consistent with other dabigatran phase III clinical trials, the most common reason for discontinuation was gastrointestinal symptoms, particularly dyspepsia (11.8%, 110 mg dose; 11.3%, 150 mg dose; 5.8%- warfarin; $P < 0.001$ for both). A higher rate of clinical myocardial infarction was observed with both doses, but neither was significant compared with warfarin (0.82 for the 110 mg dose, 0.81 for the 150 mg dose, vs. 0.64 for warfarin; $P = 0.09$ and 0.12, respectively), and overall vascular mortality was reduced.

Although results of this trial were impressive, several unanswered questions remain, warranting further investigation in this patient population, particularly regarding optimal dose selection. The US FDA recently approved the 150 mg twice daily dose and did not approve the 110 mg twice daily dose. A 75 mg twice daily dose was also approved based on pharmacokinetic extrapolations, to be used in patients with renal insufficiency. A recent analysis of RE-LY reassuringly showed similar results in patients with previous TIA or stroke for secondary prevention [41]. RELY-ABLE, a long-term follow-up study of RE-LY trial participants, will look at outcomes up to 28 months. It is estimated to be completed in late 2011 [42].

AZD0837

In addition to dabigatran etexilate, AZD0837 is another oral DTI in development that has shown promise in phase II testing in the AF population. AZD0837, a prodrug that is rapidly converted to its active form, has an average elimination half-life of 9 h and is eliminated through both the renal and hepatic routes [16]. It is currently being developed and studied as both a twice daily immediate-release regimen and a once daily extended-release formulation [43]. AZD0837 has undergone two phase II trials, one with each of the formulations in development. The first phase II trial was a randomized, parallel, dose-guiding study that compared AZD0837 150 mg twice daily or 350 mg twice daily with dose-adjusted warfarin (INR 2.0–3.0) [43]. Patients with atrial fibrillation at moderate risk, with one additional risk factor for stroke, were studied over 3 months at 20 sites within Europe. Results showed that the 150 mg dose had a similar safety profile as warfarin and was more tolerable than the 350 mg dose. Few major bleeding events occurred, with no difference in overall frequency between groups, but a higher rate of minimal bleeding events occurred with the 350 mg dose. More patients discontinued treatment in the 350 mg dose group, primarily due to gastrointestinal adverse effects. There was a low incidence of elevated liver enzymes in this population; however, a 10% increase in serum creatinine with both AZD0837 doses was noted. The elevations were transient, reversed after discontinuation and were not related to a decrease in glomerular filtration rate (GFR) [43]. The other completed phase II, dose-guiding study, investigated AZD0837 150, 300 and 450 mg once daily extended-release formula, and a 200 mg twice daily regimen, compared with dose-adjusted warfarin (INR 2.0–3.0) [44]. Results indicated that overall bleeding events were less common in the AZD 150, 300 and 200 mg groups compared with warfarin and similar to warfarin in the 450 mg group. The proportion of patients with adverse effects was similar between the AZD0837 and warfarin groups; however, the AZD0837 groups had higher discontinuation rates compared with warfarin. Similar to the earlier phase II trial, the most

common adverse effects associated with AZD0837 were gastrointestinal disorders. These adverse effects were less frequent in the lower AZD0837 doses. There was a slight increase in liver enzymes in the AZD0837 groups, and an increase of approximately 10% in serum creatinine, as noted in the earlier phase II trial.

Factor Xa inhibitors

Oral, FXa inhibitors bind directly to the active site of FXa and block the interaction with its substrate [16]. Factor Xa is strategically located at the convergence of the intrinsic and extrinsic pathways, effectively inhibiting thrombin generation from both sources. In addition, by not blocking thrombin directly, traces of thrombin may be able to escape neutralization, facilitating hemostasis and potentially providing an increased safety profile [16,19]. Furthermore, it may be advantageous to block more proximally in the coagulation cascade, thereby minimizing the amplification of thrombin generation that occurs downstream [16,19].

Rivaroxaban

Rivaroxaban is an oral FXa inhibitor currently in use in Europe and Canada for VTE prevention in the orthopedic population [45–49]. It is a potent, selective and reversible FXa inhibitor that inhibits free FXa both in solution and within a clot [16]. Rivaroxaban has a time to peak concentration of about 3 h and is partially metabolized through the CYP450 system. Two-thirds of the drug is renally eliminated, with a half-life of 9–13 h, and it does not require routine monitoring. It has been evaluated in phase III clinical trials for VTE prophylaxis in the orthopedic population, for VTE treatment, and for stroke prevention in AF [42,50].

Results of ROCKET-AF (Rivaroxaban once daily Oral direct factor Xa inhibition Compared with vitamin K antagonism for prevention of stroke and Embolism Trial in Atrial Fibrillation) were recently presented at the annual scientific sessions of the American Heart Association [51]. ROCKET-AF is a randomized, double-blind, double-dummy study with over 14 000 participants worldwide. The study compared rivaroxaban 20 mg once daily, or 15 mg once daily for Clcr 30–49 mL min^{-1}, with warfarin (target INR 2.0–3.0). A distinct difference between ROCKET-AF and previous trials is the medical complexity of the study population. Fifty-five percent of participants had a history of stroke, 62% had heart failure, and 87% had a $CHADS_2$ score of 3 or greater. Rivaroxaban was found to be non-inferior to warfarin in this high-risk population for prevention of stroke and systemic embolism. It did not achieve superiority in the intention-to-treat analysis, 2.12% for rivaroxaban vs. 2.42% for warfarin (hazard ratio (HR), 0.88; 95% confidence interval (CI), 0.74 to 1.03). Importantly, rates of hemorrhagic stroke were decreased with rivaroxaban, 0.26% vs. 0.44% (HR, 0.58; 95% CI, 0.38–0.89). Overall rates of major bleeding were similar, 3.60% vs. 3.45% (HR, 1.04; 95% CI, 0.90–1.20). Of note, the TTR achieved in this trial was 57.8% [50,51].

Apixaban

Apixaban, another oral FXa inhibitor in development, is currently emerging from phase III testing in orthopedic surgery, with ongoing trials for several indications including VTE treatment and atrial fibrillation [52,53]. Apixaban is administered twice daily and has an elimination half-life of 8–15 h [16,19,24]. It is eliminated through various pathways, with only 25% through the kidneys, suggesting an advantage for those with renal impairment. Although apixaban is metabolized through CYP3A4 to several metabolites, apixaban is not thought to directly inhibit or induce CYP450 and therefore has a low potential for major drug interactions [16]. Apixaban is currently being studied in two trials for stroke prevention in atrial fibrillation. ARISTOTLE (Apixaban for the Prevention of Stroke in Subjects With Atrial Fibrillation) will randomize over 18 000 patients with non-valvular AF to apixaban 5 mg twice daily or dose-adjusted warfarin (INR 2.0–3.0) [42,54]. This double-blind, parallel arm, event-driven, non-inferiority trial is expected to be completed in 2011. The Apixaban Versus Acetylsalicylic Acid to Prevent Stroke in Atrial Fibrillation Patients Who Have Failed or Are Unsuitable for Vitamin K Antagonist Treatment (AVERROES) trial was recently stopped early due to evidence of clear benefits of apixaban compared with aspirin among individuals with atrial fibrillation who either failed or were unsuitable for warfarin [52]. AVERROES included 5600 patients randomized to receive apixaban 5 mg twice daily or aspirin 81–324 mg once daily. Preliminary data were presented at the European Society of Cardiology Congress 2010 [55,56]. The study showed that apixaban led to a statistically significant reduction in the risk of stroke or systemic embolic events (relative risk (RR), 0.46; 95% CI, 0.33–0.64) and a reduction in cardiovascular hospitalizations, with no statistically significant increase in bleeding rates (RR, 1.14; 95% CI, 0.74–1.75). Although these results, compared with aspirin, are not unexpected, the AVERROES trial provides evidence that patients deemed to be at too great a risk for warfarin can be safely treated with apixaban.

Edoxaban

Edoxaban (DU-176b) is an orally active, small-molecule, reversible FXa inhibitor. It is rapidly absorbed, reaching a maximum concentration about 1–2 h after oral administration. Edoxaban has an elimination half-life of 9–11 h and 35% is renally excreted [16]. Favorable results have been reported from phase II studies of edoxaban for VTE prophylaxis in patients after total knee arthroplasty and total hip replacement [57,58]. In addition, edoxaban has recently completed phase II testing in atrial fibrillation. This study of over 1100 patients demonstrated a safety and tolerability profile similar to that of warfarin [59]. The doses from this trial, 30 and 60 mg once daily, are now being studied in a phase III, randomized,

double-blind, double-dummy trial, ENGAGE AF-TIMI 48 (Effective aNticoaGulation with factor xA next Generation in Atrial Fibrillation). An estimated 20 500 patients are to be enrolled from 1400 clinical sites worldwide. The planned treatment duration is 24 months and the study expects to conclude in early 2012 [42].

Betrixaban and YM150

Betrixaban and YM150 are two oral FXa inhibitors that have recently completed phase II testing in the AF population; however, neither agent has entered phase III trials yet. Betrixaban has a rapid onset of action and an elimination half-life of 19 h, allowing once daily dosing. It offers several potential advantages over other anticoagulants, including biliary elimination, therefore completely avoiding renal clearance. It has a low potential for major drug interactions because it is not a substrate for CYP450 [16,60–62]. In addition, the agent is being developed in conjunction with an intravenous antidote to neutralize the anticoagulant effects of betrixaban, as well as those of other FXa inhibitors [63].

Betrixaban recently completed EXPLORE-Xa, a dose-finding phase II trial in AF patients with one additional risk factor [64]. Three doses, 40, 60 and 80 mg, were compared with warfarin. Patients were an average of 74 years of age and had a mean $CHADS_2$ score of 2.2. There were fewer incidences of major and clinically relevant non-major bleeding with the 40 mg dose compared with warfarin (one vs. four patients). The 60 and 80 mg doses had bleeding rates similar to warfarin. No differences in liver function enzymes were noted. The only adverse effect that was more common with betrixaban compared with warfarin was gastrointestinal complaints, particularly with the two higher doses.

YM150 has minimal pharmacokinetic or pharmacodynamic data available to date. However, it is reported to be well tolerated in phase I studies with predictable pharmacokinetics in healthy young and elderly volunteers [16]. YM150 has undergone phase II, dose-finding studies in VTE prevention, as well as in atrial fibrillation. A phase II study in patients with non-valvular AF has been completed, in which YM150 was compared with warfarin. Patients are being recruited for a second phase II study, in which YM150 will be compared with warfarin in non-valvular AF patients, with a primary outcome of major bleeding [42]. This study, OPAL-2, is expected to be completed in late 2010.

Novel vitamin K antagonist: tecarfarin

The novel oral anticoagulants currently being studied in atrial fibrillation are not exclusively direct thrombin or FXa inhibitors. A new vitamin K antagonist in development, tecarfarin, is a selective, non-competitive inhibitor of vitamin K epoxide reductase (VKOR). It is developed to be similar to warfarin but is metabolized by esterases instead of the CYP450 system [65]. With a more predictable pharmacological profile and its potential lack of drug interactions, it is assumed to have clinical, real-world advantages over warfarin. Tecarfarin was evaluated in an open-label, phase II study of 66 AF patients to determine the safety, tolerability and effect of tecarfarin on TTR [66]. The TTR with tecarfarin was high; only 10% of patients had a TTR of $<45\%$. The mean interpolated TTR was 71.4% over the initial 3 weeks of tecarfarin therapy, resulting in a median daily dose of 15.6 mg per patient to maintain an INR of 2–3. This TTR is higher than typically observed with warfarin in clinical trials; however, patients were monitored intensively, with INRs drawn at least two to three times per week for the first 3 weeks. Although circumventing CYP450 metabolism is a true scientific advance, tecarfarin will still be subject to dietary vitamin K fluctuation and variability secondary to the variants in the VKOR complex subunit 1 (*VKORC1*) gene. In the absence of a warfarin control, more clinical data are needed on this agent.

Anticipated issues outside of the clinical trial setting

Risk stratification in diverse patient populations

Clinical trial participants are often younger with overall fewer chronic medical conditions compared with patients seen in routine practice. Low- to high-risk $CHADS_2$ scores range from 0 to 6 [40]. Trial participants in recent trials have had a mean $CHADS_2$ score of approximately 2.1 for RE-LY and 3.48 for ROCKET-AF. This is important not only from a stroke risk perspective, but also from a bleeding perspective, as bleeding risk has been shown to increase with $CHADS_2$ score [67–69]. The efficacy and safety of these novel agents will need to be closely monitored in the older and more medically complex patient populations.

Conversely, as newer agents with potentially improved safety profiles emerge and those barriers we currently face to the effective use of warfarin dissipate, the expansion of anticoagulant drugs to the lowest risk patients may be justified. The estimated yearly stroke risk among individuals with a $CHADS_2$ score of 0 is approximately 2% [40]. The recently published European Society of Cardiology guidelines for the management of atrial fibrillation incorporate risk modifiers (female gender, age 65–74 years, vascular disease) to consider among patients with a CHADS2 score of 0 or 1 to comprise a $CHADS_2VASc$ score. Anticoagulant therapy is recommended if two or more of these modifiers are present and anticoagulant therapy or aspirin if only one is present. If the risk of major hemorrhage is reduced with novel agents, then the threshold for their use will probably also be reduced, providing they are cost effective.

Reversibility and anticoagulant half-life

The oral FIIa and FXa inhibitors offer many advantages over warfarin, but also have potential limitations, one of which is the absence of a reversal agent. Their short half-lives, compared with warfarin, provide assurance that drug concentrations will decline relatively rapidly when therapy is discontinued in

patients with normal renal function. Nevertheless, reversibility in emergent situations, such as trauma, life-threatening bleeding, emergent surgery, or in patients with severe renal insufficiency, is unclear. Limited animal studies have shown that the anticoagulant effects of dabigatran and rivaroxaban may be reversed by infusions of recombinant FVIIa or prothrombin complex concentrates [71,72]. Of particular interest is the development of a specific modified FXa protein, lacking catalytic and membrane binding activities, that can competitively neutralize a FXa inhibitor [63,73]. The clinical value of all of these approaches remains to be determined in future clinical trials. In addition, the development of a reliable and valid laboratory assay to measure residual anticoagulant effects would be desirable.

With regard to the shorter half-lives of these drugs, adherence will be a key issue for effective use in clinical practice [74]. Respective of the faster onset of action, thrombotic risk associated with interruption is likely to be less of an issue, but post-procedural bleeding may increase if hemostasis is not fully achieved prior to resumption of these drugs. For dabigatran, it is recommended to discontinue the drug 'one to 2 days prior to invasive or surgical procedures for patients with a Clcr $\geq$50 mL min^{-1} or 3–5 days if Clcr $<$ 50 mL min^{-1}' [25]. It is also recommended to perhaps discontinue it 'earlier than 5 days in those patients undergoing major surgery or requiring complete hemostasis' [25]. Such recommendations must be guided by further clinical experience.

Table 2 Common P-gp transporters (list is not all inclusive) [79–81]

P-gp substrates	Atorvastatin
	Cyclosporine
	Digoxin
	Loperamide
	Quinidine
	Indinavir, nelfinavir, ritonavir
	Dexamethasone, hydrocortisone
	Vinblastine, vincristine
	Daunorubicin, doxorubicin, etoposide
P-gp inhibitors	Amiodarone
	Ceftriaxone
	Clarithromycin, erythromycin
	Cyclosporine
	Diltiazem
	Dipyridamole
	Hydrocortisone
	Ketoconazole, itraconazole
	Nicardipine, nifedipine
	Propranolol
	Quinine
	Quinidine
	Ritonair, saquinavir, nelfinavir
	Tamoxifen
	Tacrolimus
	Verapamil
P-gp inducers	Rifampin
	Clotrimazole
	Phenytoin
	Phenobarbital
	St. John's Wort

Drug interactions

An additional potential advantage that the emerging FIIa and FXa inhibitors may possess over warfarin is a decreased number of drug interactions. Warfarin's numerous food and drug interactions often lead to non-therapeutic INRs and decreased TTR. Newer agents have few, if any, interactions with food. However, they are not completely free of drug interactions. From the available data, almost all of the agents, excluding dabigatran, tecarfarin and potentially betrixaban, are metabolized to some degree by the CYP450 enzyme system. As numerous medications are metabolized via this pathway, it could be the source of potential medication interactions. Furthermore, the structure, location and activity of CYP450, particularly 3A4, overlap with the P-glycoprotein (P-gp) transport system, which may lead to additional drug interactions [75]. P-gp is an intracellular drug transport system that plays an important role, particularly in drug absorption and distribution [76]. The P-gp system is widespread, expressed on the surfaces of the gastrointestinal tract, brain, liver, kidney and capillaries, and acts as an efflux pump, preventing the uptake of foreign substances [76]. The activity of this extensive transport system is controlled in part through genetic factors; however, foods and medications can also influence its activity. Medications that inhibit P-gp will increase absorption of a substrate, thus increase its serum concentrations (area under the curve [AUC]), and medications that induce P-gp will have the opposite effects, decreasing serum concentrations [75] (Table 2). Because of its pharmacokinetic importance and potential implications in drug interactions, P-gp transport screening is often incorporated into the drug discovery process [76].

Dabigatran etexilate, rivaroxaban, apixaban and edoxaban are P-gp substrates [15,77]. Current data show that dabigatran yielded no clinically relevant interaction when given concurrently with the P-gp substrates, atorvastatin and digoxin. However, it resulted in significant decreases in AUC when given with the P-gp inducer, rifampin, and therefore the combination should be avoided in patients [22,77]. When given with the P-gp inhibitors, such as ketoconazole, verapamil, clarithromycin, quinidine and amiodarone, the AUC of dabigatran increased; however, it did not result in changes in the extent of absorption, maximum concentration, time to peak concentration or half-life. Therefore, if these particular agents are given with dabigatran, no dose adjustments are recommended at this time [22,77]. (Table 1) However, increased monitoring of renal function should be employed if amiodarone is given with dabigatran. The use of azole antifungals or HIV-protease inhibitors is a contraindication for rivaroxaban, and most likely also for apixaban. Most of these drugs are strong inhibitors of both CYP3A4 and P-glycoprotein, resulting in significant increases in AUC and changes in pharmacodynamic effects of the anticoagulant [77]. Additionally, the

concomitant use of a potent P-gp inhibitor is a protocol-specified exclusion criterion in the ENGAGE AF-TIMI 48 trial and the need for verapamil or quinidine mandates a protocol-directed 50% reduction of the edoxaban dose [78]. Increases in AUC concentrations of the novel anticoagulants from potential P-gp drug interactions may increase the risk of hemorrhage and therefore warrant caution. Phase IV registries will help to elucidate the potential hazards of these drug-drug and drug-disease interactions in real-world practice.

Conclusion

Stroke prevention in atrial fibrillation is entering an exciting therapeutic era, with new classes of targeted anticoagulants that avoid the many pitfalls of the current vitamin K antagonists. It is hoped that these promising new drugs will be at least as efficacious as warfarin and safer. Their ease of management will improve patients' quality of life and alleviate the workload of healthcare providers. All of these attributes may encourage providers to treat more patients with atrial fibrillation, many of whom are currently considered unsuitable for warfarin.

Disclosure of conflict of interests

K.P. Cabral states that she has no conflict of interest. J. Ansell is a consultant for Boehringer Ingelheim, Ortho McNeil, and Bristol Myers Squibb. E.M. Hylek is on the Advisory Board of Boehringer-Ingelheim, Bristol-Myers Squibb, Daiichi Sankyo, Merck, Pfizer and Sanofi-Aventis; and research for Bristol-Myers Squibb and Ortho McNeil. None of these achieve the level of 'significant'.

Excess Costs Attributable to Postoperative Complications

Kathleen Carey[1,5], Theodore Stefos[2,5], Shibei Zhao[1], Ann M. Borzecki[1,3,5], and Amy K. Rosen[4,5]

Abstract

This article estimates excess costs associated with postoperative complications among inpatients treated in Veterans Health Administration (VA) hospitals. The authors conducted an observational study on 43,822 hospitalizations involving inpatient surgery in one of 104 VA hospitals during fiscal year 2007. Hospitalization-level cost regression analyses were performed to estimate the excess cost of each of 18 unique postoperative complications. The authors used generalized linear modeling techniques to account for the heavily skewed cost distribution. Costs were measured using an activity-based cost accounting system and complications were assessed based on medical chart review conducted by the VA 'National Surgical Quality Improvement Program. The authors found excess costs associated with postoperative complications ranging from $8,338 for "superficial surgical site infection" to $29,595 for "failure to wean within 24 hours in the presence of respiratory complications." The results obtained suggest that quality improvement efforts aimed at reducing postoperative complications can contribute significantly to lowering of hospital costs.

Keywords

hospitals, quality, patient safety, cost

In the decade since publication of the Institute of Medicine's landmark report "To Err is Human" (Kohn, Corrigan, & Donaldson, 2000), the quality and safety of hospital inpatient care in the United States has come under increased public scrutiny. Despite widespread interest, considerable effort expended, and a degree of measured progress, the pace of quality improvement has fallen short of the Institute of Medicine recommendations, and patient safety recently has been cited as an area in urgent need of attention (Agency for Healthcare Research and Quality [AHRQ], 2010). Mounting pressure to improve the quality and safety of hospital inpatient care is complicated by recent high-cost growth in hospital services. In the current environment of economic constraints, efficiency in both quality improvement and health care delivery is becoming an increasingly important goal.

Concern over adverse events and complications in U.S. hospitals has also stimulated a growing body of research. Some studies have used medical chart abstraction to demonstrate the extent of such events (Bates et al., 1995; Brennan et al., 1991; Classen, Pestonik, Evans, & Burke, 1991; Thomas et al., 2000), and a few have addressed their cost burden, which has been found to be substantial (Bates et al., 1997; Dimick et al., 2004; Dimick, Pronovost, Cowan, & Lipsett, 2003; Peng, Kurtz, & Johannes, 2006; Shannon et al., 2006; Thomas et al., 1999). For example, recent studies of Pennsylvania hospitals found that excess costs because of central line–associated bloodstream infections were $26,839 (Shannon et al., 2006), and for patients with hospital-acquired infections overall, charges were four times higher than for patients without hospital-acquired infections (Peng et al., 2006).

Some broader based studies of medical error costs have drawn on administrative data; a number of these have measured adverse events using the patient safety indicators (PSIs) developed by the AHRQ in response to the need for more standardized measures of patient safety. These studies also have demonstrated the high cost of safety lapses. For example, the average difference in 90-day expenditures between patients who had one of 14 PSIs and those who did not was $36,000 among 22,477 Medicare surgeries in 2000 (Encinosa & Hellinger, 2005), and ranged from $646 to $28,000 for 161,004 commercially insured surgeries in 2001-2002 (Encinosa & Hellinger, 2008). A study of the general patient population in 994 U.S. hospitals in 2000 found average excess charges of $9,000 to $58,000 for patients experiencing a PSI (Zhan & Miller, 2003), and an analysis of 2002 Medicare patient data estimated the extra payment for five adverse events measured using PSIs at $300 million per year (Zhan, Friedman, Mosso, & Pronovost, 2006). A recent large-scale study using administrative data on a 40-state sample from the period 1998 to 2006 developed coding rules for identifying hospital-acquired infections, and found excess costs in the range of $33,000 to $46,000 for hospitalizations involving surgery (Eber, Laxminararyan, Perencevich, & Malani, 2010). Finally, a study of PSI adverse events in Veterans Health Administration (VA) hospitals in 2001 found excess costs in the range of $5,000 to $40,000 per hospitalization (Rivard et al., 2008).

New Contribution

While all postoperative complications are not the result of medical error, complications are considered valid indicators of the general quality of inpatient care

(Lawthers et al., 2000; Weingart et al., 2000). They have been found to be among the most frequent of inpatient adverse events, as well as the most costly (Thomas et al., 1999), since complications following surgery can lead to increased days of hospitalization, greater intensity of services, more ancillary services, and/or extra medications. We sought to estimate the excess costs of postoperative complications in surgical inpatients treated in VA hospitals during fiscal year 2007. Our study is unique in that it simultaneously (a) assesses the occurrence of complications through measures obtained via chart abstraction rather than through imperfect algorithms applied to administrative data, (b) relies on hospitalization-level cost estimates as opposed to charge or reimbursement data, (c) examines a broad set of postoperative complications occurring in a large number of hospitals, and (d) compares excess costs obtained using administrative data with excess costs obtained using medical record data. In this study, we conceptualize costs as the resources that hospitals expend to produce their services. While other research perspectives may be valuable, we maintain that under current U.S. health care reform it is essential to achieve a significant slowing of cost growth at the point of health care delivery and that a focus on the hospital's prospects for cost control is highly pertinent to the ongoing policy discussion.

Method

This is an observational study on a sample of 47,040 hospitalizations among patients who underwent inpatient surgery in one of the 104 acute-care VA hospitals during fiscal year 2007 (October 1, 2006, to September 30, 2007). The unit of observation is the unique hospitalization. Patient-level cost regressions are performed on binary variables indicating the presence of a surgical complication, controlling for severity, demographics, and facility-level variables.

Data and Variables

The VA has two distinct systems for determining the cost of a hospitalization. The VA Health Economics Resource Center takes a top-down approach that allocates the VA national budget using coefficients from a Medicare cost function linking cost-adjusted charges to patient demographic and hospitalization information (Chapko et al., 2009; Wagner, Chen, & Barnett, 2003). In contrast, the bottom-up Decision Support System (DSS) is an activity-based costing system that creates relative value units at the local departmental level to determine the cost of intermediate products that are in turn summed to the level of the individual hospitalization (Barnett, 2003; Chapko et al., 2009), independent of patient mix, market conditions, or socioeconomic characteristics. While both systems capture costs from the hospital's perspective at the level of the hospitalization, the greater patient specificity accounted for in the DSS approach is more likely to be better suited to gauging high patient costs because of specific complications experienced by unique patients than the Health Economics Resource Center costs (which are averaged over patients sharing the same characteristics). For

this reason, we used the DSS costs in this study. The dependent variable was the log of the DSS measured cost of the hospitalization.

The key independent variable was a binary indicator of whether the patient experienced one of 19 postoperative complications. Data were obtained from the VA National Surgical Quality Improvement Program (VASQIP), which VA commenced in 1991 in response to Congressional mandate for VA to compare its risk-adjusted surgical outcomes with those of private hospitals. Program founders believed that postoperative outcomes were particularly relevant for measuring general quality of surgical care, since a surgical operation is a predictable event with an expected outcome in most cases. While they were not particularly focused on preventability, they believed that good science promotes good management, and targeted 30-day adverse outcomes as a means toward quality improvement (Henderson & Daley, 2009). The VASQIP uses a comprehensive medical record review to collect data that include 19 distinct postoperative complications. The VASQIP assesses a systematic random sample of VA major noncardiac surgeries, accounting for approximately 70% of VA major surgeries, and 25% of VA surgeries overall (Henderson & Daley, 2009). The complication variables are generic in nature, because the program was intended to cover a broad scope of surgical specialties. Medical record data are considered the "gold standard" for measuring adverse events and complications, because they are obtained directly from patients' medical charts (Best et al., 2002).

We followed previous literature for estimating the excess cost associated with PSIs in VA by controlling for severity, demographics, and facility-level variables commonly associated with variation in patient cost (Rivard et al., 2008). This required that we merge the VASQIP data with the VA Patient Treatment File (PTF), an inpatient administrative file containing information on all VA hospitalizations. Because the VASQIP data were organized at the surgical procedure level and the PTF data were organized at the hospitalization level, we merged only those records in which VASQIP surgery dates fell between PTF admission and discharge dates.

We used the Elixhauser comorbidity index, constructed using PTF data, as a proxy for illness severity (Elixhauser, Steiner, Harris, & Coffey, 1998). This index was constructed in two steps. First, for all hospitalizations in the database, we estimated a fixed effects regression of the natural logarithm of costs on age and binary variable indicators for 27 comorbid conditions. The fixed effects represented unique clinical classifications measured by diagnosis-related groups. Second, we summed the regression coefficients for the comorbid conditions that were significant at the 5% level ($p < .05$) for each hospitalization according to whether or not the comorbid condition was present during the hospitalization.

Demographic control variables in the cost regressions included four age categories and gender, obtained from the PTF. Facility-level controls were indicator variables constructed from the American Hospital Association 2007 Annual Survey Database for major teaching facilities and indicator variables for facilities located in metropolitan areas. Major teaching status was defined by membership in the Council of Teaching Hospitals. Metropolitan areas were defined using the Census Bureau's Core Based

Statistical Areas as urban areas with populations of 50,000 or more. Finally, we included hospital level and diagnosis-related group fixed effects.

Analytic Technique

The assumptions underlying estimators generated by ordinary least squares regression are generally not met in analyses of individual hospitalization costs, which usually exhibit significant positive skewness and heteroscedasticity, violations likely amplified in cases characterized by postoperative complications. Researchers often address this problem with log transformation of costs. However, raw dollars is normally the scale of interest, and retransformation is not straightforward, since the expected value of the log of dependent variable y conditional on independent variable x is not likely to be equal to the log of the expected value of y conditional on x. Suitable retransformation techniques have been developed (Duan, Manning, Morris, & Newhouse, 1983) but significant bias in inference can arise if heteroscedasticity is not characterized and applied to the retransformation process (Manning, 1998; Mullahy, 1998). We took an alternative approach to estimation by using generalized linear modeling (GLM), which provides appropriate estimators of mean values when the distribution of data is nonnormal. GLM models have the practical advantage of providing estimates of the conditional mean directly, without requirement of retransformation (Basu & Manning, 2009).

We estimated GLMs corresponding to each of the unique complications, using a gamma-distributed log-linked structure, selected on the basis of the Modified Park Test (Manning & Mullahy, 2001). For each model, we evaluated the excess cost because of the complication by first assuming that every hospitalization had the complication associated with it and predicting the cost associated with that hospitalization. We then assumed that no hospitalization in the sample had the complication and predicted the cost. The excess cost associated with the complication was calculated as the difference between the predicted cost with the complication and the predicted cost without the complication (Encinosa & Hellinger, 2005, 2008; Rivard et al., 2008; Zhan & Miller, 2003). We estimated models using PROC GENMOD, SAS Version 9.1.

Results

Of the 47,040 observations (unique hospitalizations), we omitted 1,930 observations for which the patient experienced more than one complication. This exclusion permitted us to avoid confounding estimates of excess cost across the range of specific complications studied. This left 45,110 observations, of which 44,911 had complete data. From these, we excluded 610 observations on hospitalizations for which the patient was transferred to another hospital. Of the remaining 44,301 hospitalizations, 479 resulted in death. Table 1 presents descriptive statistics on the sample of 44,301 observations, which included patients who died in hospital and on the sample of 43,822 observations on hospitalizations for patients who were alive at discharge.

Table 1. Descriptive Statistics[a]

Variable	Mean or Proportion (Standard Deviation)	
	All Hospitalizations	Alive at Discharge
Dependent		
Cost of hospitalization (dollars)	25,461 (30,760)	25,865 (26,592)
Independent		
Age		
18 years and younger (%)	3.19	3.22
8-39 years (%)	55.32	55.53
40-64 years (%)	21.74	21.72
65 years or older (%)	19.75	19.52
Female gender (%)	5.14	5.18
Comorbidity index	0.09 (0.14)	0.08 (0.13)
	N = 44,301	*N* = 43,822

a. Excludes transfer patients.

For analysis purposes, we excluded the complication "coma lasting longer than 24 hours," because only four hospitalizations had this complication and the patient died in all four cases. Table 2 presents the remaining 18 postoperative complications, their VASQIP definitions, the percentage of hospitalizations in which the complication was present and for which the patient was transferred to another hospital or died, and the frequencies of events. Frequencies are listed for the two samples used in the analyses: all hospitalizations on nontransferred patients and hospitalizations on nontransferred patients discharged alive. The events are relatively infrequent, in the latter group ranging from 0.34 per 1,000 for "cardiac arrest requiring CPR" (cardiopulmonary resuscitation) to 8.28 per 1,000 for "superficial surgical site infection."

Model results for the 18 complication indicators associated with excess costs are presented in Table 3. For the sample of all hospitalizations, the coefficients of the complication variables are positive and highly significant, with two exceptions: "peripheral nerve injury" and "cardiac arrest requiring CPR." The former complication exhibits no statistical significance, likely because of low frequency of occurrence. The latter complication is negatively and significantly associated with cost. As the majority of patients in this group (77.4%) died, this result suggests that death occurred early in the hospitalization, such that relatively low costs were incurred. Among the 16 complications that were significantly related to cost, the calculated excess costs ranged from $8,234 for "progressive renal insufficiency" to $28,779 for "failure to wean from ventilator within 48 hours." The directions and associations of the covariates (not shown) were as expected. Cost rose with age and increased level of the comorbidity index.

The final two columns of Table 3 list the coefficients and excess costs for hospitalizations in which the patient was discharged alive. The results are generally similar to

Table 2. Postoperative Complications: Descriptions and Frequencies

VASQIP Variable Label	Percentage of Hospitalizations (With Complications) That Ended in Transfer or Death		Mean Number of Events per Thousand Surgical Patient Hospitalizations Excluding Transfers	
	Transfer	Death	All Hospitalizations[a]	Alive at Discharge[b]

Table 4. Excess Costs: VASQIP and PSI Estimates Compared

VASQIP Measures		PSI Measures[a]		
Variable	Excess Cost Estimate: Regression Method ($)	Variable	Excess Cost Estimate: Regression Method ($)	Excess Cost Estimate: Case Matching Method ($)[b]
Failure to wean	29,595	Respiratory failure	12,360	50,953
Reintubation	12,104			
Pulmonary embolism	13,411	Pulmonary embolism/ deep vein thrombosis	11,620	9,237
Deep vein thrombosis	13,918			
Sepsis	23,422	Sepsis	17,172	40,080
Wound dehiscence	16,688	Wound dehiscence	22,154	24,236

Note: PSI = patient safety indicator; VASQIP = VA National Surgical Quality Improvement Program.
a. From Rivard et al. (2008), inflated to 2007 dollars using the Bureau of Labor Statistics producer price index for hospital services.
b. Case matching approach was included in Rivard et al. (2008) in addition to the regression approach to replicate the methods of Zhan and Miller (2003).

failure," however, excess costs were higher among patients who died, suggesting some unmeasured degree of severity for these complications. Finally, patients with "cardiac arrest requiring CPR" who were discharged alive did not incur significant excess costs.

In Table 4, we compare our estimates with those of aforementioned earlier research on excess cost in VA that used PSIs to measure adverse events (Rivard et al., 2008). Table 4 lists excess cost estimates of those postoperative PSI events that correspond to VASQIP complications among patients discharged alive. In 2007 dollars, our excess cost estimate for "failure to wean" was 139% higher than the regression-estimated PSI excess cost for postoperative respiratory failure but within 2% of the regression-estimated PSI excess cost for postoperative respiratory failure in the case of "reintubation." For "pulmonary embolism" and "deep vein thrombosis," our estimates were approximately 18% higher than the comparable PSI regression-estimated excess cost, and for "sepsis," approximately 36% higher. Our results for "wound dehiscence," on the other hand, were substantially lower (approximately 25%) than the PSI regression-estimated excess cost.

Discussion

Assessing the costs associated with adverse patient events is complicated by difficulties in measuring the incidence of these events, as well as the lack of standardized data for a comprehensive national evaluation of patient safety (AHRQ, 2010). Moreover, the development of valid and feasible measures of the cost of health care events has

proven to be very difficult (Lipscomb, Yabroff, Brown, Lawrence, & Barnett, 2009). This article addresses both of these challenges by drawing on high-quality, standardized measures of the incidence and cost of inpatient postoperative complications collected nationally by the VA.

Our analysis contributes new information to understanding comparative costs, which varied considerably over a broad range of complications. We found excess costs associated with postoperative complications in VA to be considerable, ranging from 3% to 120% higher (for "cardiac arrest requiring CPR" and "failure to wean," respectively) than inpatient costs in the absence of complications among patients discharged alive. The low cost associated with cardiac arrests suggests that survivors are likely to be relatively healthy respondents who have a transient postoperative arrhythmia. While studies of PSIs have generally found sepsis more expensive than postoperative respiratory complications at least in part because of longer hospital stays, it is possible that the higher costs seen among this sample in patients with "failure to wean" was because they were sicker going into the procedure, that is, more likely to be undergoing emergency surgery, with less time to optimize preexisting conditions, than those suffering some of the other complications.

Comparison of VASQIP events with those of corresponding postoperative PSIs revealed considerable discrepancies in both magnitude and direction of estimated excess costs. Hence, our results do not provide evidence that using measures derived from algorithms applied to administrative data are good substitutes for those using the more labor-intensive chart-abstracted complication rates when estimating excess cost. At the same time, it should be borne in mind that the VASQIP and PSI definitions are not precisely comparable, and this may account for some of the discrepancy between the two measures. PSIs are defined using ICD-9 coding, whereas VASQIP complications are defined by clinical definitions applied by nurse abstractors based on reviews of physician documentation as well as laboratory and radiologic data (Romano et al., 2009). Moreover, because of lack of Present on Admission (POA) coding in VA administrative data, our PSI calculations do not account for POA, which may explain some of the differences, particularly with "deep vein thrombosis" and "pulmonary embolism" (Houchens, Elixhauser, & Romano, 2008). VASQIP measures, on the other hand, provide a gold standard for examination of the issue, and accordingly, can distinguish between complications that arose following surgery and complications that were present on admission. Finally, the previously cited Rivard et al. (2008) study using PSIs differed from the present study in that it used Health Economics Resource Center rather than DSS costs. Nevertheless, further study using PSIs would be worthwhile, because even though identification of adverse events using administrative data has some limitations, efficiency in their construction (yielding millions of observations compared with thousands for the more expensive approach) may outweigh the lower reliability of screening for adverse events. Moreover, with POA data elements available, the validity of PSIs constructed using administrative data is improved.

Our estimates are informative in prioritizing efforts to improve quality of care in VA hospitals and also in determining whether financial incentives are well aligned versus misaligned with improvement. Results suggest that directing efforts toward

reducing complications such as cerebral vascular accidents, systemic sepsis, acute renal failure, and failure to wean, each of which incurred excess costs of greater than $20,000, might have high value. However, that postoperative complications have high costs must be interpreted in light of the fact that not all complications reflect deficiencies in care. High complication rates can be reflective of underlying severity of disease in the patient population (Silber & Rosenbaum, 1997). There is also some evidence that hospitals known for quality may have higher rates of adverse events because they pay more attention to documenting this (Isaac & Jha, 2008). Moreover, the cost per event is not in itself sufficient to render it high priority, as some complications bring about greater patient harm than others. Quality improvement efforts must consider the cost-effectiveness of reducing particular complications. Such evaluation requires estimates of the frequency and morbidity associated with these events, the total attributable cost, and also the cost of the prevention activities themselves. Many complications cannot be avoided, and among those that can, prevention may not be cost-effective for events that are very rare or exceedingly costly to prevent. Nevertheless, the results of our study are informative in demonstrating the range of potential returns to investment in quality improvement in VA hospitals.

There are limitations to this study. The excess costs that we measured were only those incurred during the inpatient stay. However, the excess costs extend beyond the initial hospitalization, so that any interventions undertaken will appear to be more cost-effective if postoperative costs following discharge are taken into account (Encinosa & Hellinger, 2008). From a methodological perspective, it should be borne in mind that this is an observational study using data from a single year. No method can completely identify causality from observational data. Without a randomized controlled experiment, conclusions regarding the effect of variables of interest on outcomes are subject to parameter estimate bias to the extent of correlation between measured variables of interest and omitted variables that are significantly associated with outcomes. Finally, our study was of VA hospitals only, using VA-specific cost measures, so that excess costs observed here do not necessarily generalize to nonfederal U.S. hospitals.

As U.S. hospitals respond to concern over patient safety by investing in quality improvement efforts, knowledge of the relative cost-saving potential of reducing various inpatient complications becomes increasingly important. Future research should continue to refine the measurement of patient safety and cost as well as improve understanding of the relative potential for prevention across the range of adverse events.

Declaration of Conflicting Interests

Positive Predictive Value of the AHRQ Patient Safety Indicator "Postoperative Sepsis": Implications for Practice and Policy

Marisa Cevasco, MD, MPH, Ann M Borzecki, MD, MPH, Qi Chen, MPH, Patricia A Zrelak, PhD, CNRN, CNAA-BC, Marlena Shin, JD, MPH, Patrick S Romano, MD, MPH, Kamal MF Itani, MD, FACS, Amy K Rosen, PhD

BACKGROUND: Patient Safety Indicator (PSI) 13, or "Postoperative Sepsis," of the Agency for Healthcare Quality and Research (AHRQ), was recently adopted as part of a composite measure of patient safety by the Centers for Medicare and Medicaid Services (CMS). We sought to examine its positive predictive value (PPV) by determining how well it identifies true cases of postoperative sepsis.

STUDY DESIGN: Two retrospective cross-sectional studies of hospitalization records that met PSI 13 criteria were conducted, one within the Veterans Administration (VA) Hospitals from fiscal years (FY) 2003 to 2007, and one within community hospitals between October 1, 2005 and March 31, 2007. Trained abstractors reviewed medical records from each database using standardized abstraction instruments. We determined the PPV of the indicator and performed descriptive analyses of cases.

RESULTS: Of 112 cases flagged and reviewed within the VA system, 59 were true events of postoperative sepsis, yielding a PPV of 53% (95% CI 42% to 64%). Within the community hospital sector, of 164 flagged and reviewed cases, 67 were true cases of postoperative sepsis, yielding a PPV of 41% (95% CI 28% to 54%). False positives were due to infections that were present on admission, urgent or emergent cases, no clinical diagnosis of sepsis, or other coding limitations such as nonspecific shock in postoperative patients.

CONCLUSIONS: PSI 13 has relatively poor predictive ability to identify true cases of postoperative sepsis in both the VA and nonfederal sectors. The lack of information on diagnosis timing, confusion about the definition of elective admission, and coding limitations were the major reasons for false positives. As it currently stands, the use of PSI 13 as a stand-alone measure for hospital reporting appears premature. (J Am Coll Surg 2011;212:954–961. © 2011 by the American College of Surgeons)

In 2003, the Agency for Healthcare Research and Quality (AHRQ) developed a formal set of Patient Safety Indicators (PSIs) to screen administrative databases for gaps in patient safety. Specifically, the PSIs are ICD-9-CM-based algorithms that use hospital discharge data to screen for safety-related inpatient events. Initially, the PSIs were designed for case-finding and quality improvement activities. However, the PSIs are increasingly being used to assess hospital performance and as part of pay-for-performance programs.[1,2] Nine states use PSIs for public reporting on hospitals; the National Quality Forum formally endorsed 10 PSIs for hospital performance measures, and the Centers for Medicare and Medicaid Services have adopted 4 PSIs and 1 composite measure to compare quality and safety across hospitals.[3,4]

Despite the increasing use of PSIs in assessing hospital performance, validation studies investigating the positive predictive value (PPV) of these indicators demonstrate wide variability in their accuracy to detect true events com-

PPV = positive predictive value
PSI = Patient Safety Indicator
VA = Veterans Health Administration

pared with the "gold standard" of medical record review. PPVs ranging between 44% and 91% have been documented for various PSIs.[5-11] This variation has been attributed to ambiguity in coding guidelines, differences in coding practices between hospitals, and the inability of ICD-9 CM codes to distinguish between diagnoses that were present on admission versus those that developed after admission.[6]

In this study, we focused on PSI 13, postoperative sepsis, and determined its PPV in both the Veterans Health Administration (VA) and the nonfederal sector. Rates of postoperative sepsis will continue to be investigated because they are part of the AHRQ PSI composite measure used by the Centers for Medicare and Medicaid Services to compare quality and safety across hospitals. It is a significant complication, associated with a 21.9% excess mortality, 10.2 extra days in the hospital, and nearly $60,000 in excess charges.[12] Many cases of postoperative sepsis may be prevented through appropriate use of perioperative antibiotics, good surgical site preparation, and sterile surgical techniques.[13]

This is the first study to investigate the PPV of the postoperative sepsis PSI and the first study to directly compare the PPV of a single PSI in 2 different health care systems. In this article, we examine the PPV of PSI 13, characterize the type of events incorrectly captured by this PSI, and assess which perioperative events may contribute to postoperative sepsis. Results from this study will have important implications for hospital reporting, pay-for-performance, and other uses of this specific PSI.

METHODS

PSI definition

PSI 13, postoperative sepsis, captures all discharges of patients age 18 or older who underwent an elective operating room procedure with a postoperative length of stay greater than 3 days and at least 1 of 21 ICD-9-CM diagnosis codes with sepsis as a secondary diagnosis (Table 1). Excluded from this definition are patients admitted with a principal diagnosis of infection or sepsis, a secondary diagnosis of infection or sepsis POA, patients admitted for a nonelective hospitalization (used as a proxy for urgent or emergent surgical intervention), patients with cancer or immunocompromised states, and all obstetric admissions (pregnancy, childbirth).

Table 1. ICD-9-CM Sepsis Diagnosis Codes Present in Any Secondary Diagnosis Field

ICD-9-CM sepsis diagnosis code	Definition
0380	Streptococcal septicemia
0381	Staphylococcal septicemia
03810	Staphylococcal septicemia
03811	Methicillin-susceptible *Staphylococcus aureas* septicemia
03812	Methicillin-resistant *Staphylococcus aureas* septicemia
03819	Other staphylococcal septicemia
0382	Pneumococcal septicemia
0383	Septicemia due to anerobes
78552	Septic shock
78559	Shock without mention of trauma
9980	Postoperative shock
99591	Systemic inflammatory response syndrome due to infectious process without organ dysfunction
99592	Systemic inflammatory response syndrome due to infectious process with organ dysfunction
Septicemia due to	
03840	Gram-negative organism, unspecified
03841	Hemophilus influenza
03842	*Escherichia coli*
03843	Pseudomonas
03844	Serratia
03849	Septicemia due to other gram-negative organisms
0388	Other unspecified septicemia
0389	Unspecified septicemia

VA methods

For the VA analysis, we applied AHRQ PSI software (v.3.1.a) to VA fiscal years 2003 to 2007 administrative data to identify patients with suspected postoperative sepsis. The required Institutional Review Board approvals from the Bedford VA Medical Center and the VA Boston Healthcare System were obtained to conduct this study.

Hospital selection

We randomly selected 28 of 150 acute care VA hospitals to obtain a manageable number of hospitals for individual medical record review while capturing variation in coding across facilities. Our sampling scheme was designed to generate a sample of hospitals with a range of observed and expected safety events. The scheme of randomization and selection has been simultaneously published by our group.[11] Twenty-one percent of sampled

hospitals were in the Northeast, 32% were in the South, 18% were in the Midwest, and 29% were in the West. Eighty-nine percent were major teaching hospitals (resident-to-bed ratio $>$ 0.25). The median number of hospital beds was 155 (range 62 to 360 beds).

Case selection

We randomly selected 4 medical records flagged with postoperative sepsis from each of the 28 hospitals, for a total of 112 medical records. Based on previously reported PPV estimates, 112 cases per PSI were selected to ensure reasonably narrow PPV confidence intervals ($\pm$ 10% to 20%).

Medical record abstraction and inter-rater reliability

To determine rates of true and false positives for the PSI, 2 trained nurses conducted a retrospective chart review using standardized chart abstraction tools and guidelines developed by AHRQ. These were modified for the VA's electronic medical record and to achieve inter-rater reliability (IRR) measurement standards of greater than 90% observed agreement. Specifically, medical records were reviewed for occurrence of postoperative sepsis; demographic characteristics, comorbidities, and risk factors of the sampled patients; and patient outcomes after the event, such as transfer to a higher level of care, development of end organ dysfunction, or death. The presumed source(s) of infection leading to sepsis, the presence or absence of positive blood cultures, and the procedures performed during the hospital stay were also abstracted from the medical record. Perioperative processes were noted, including administration of preoperative antibiotics and postoperative glycemic control. Nurse training included several sessions discussing the rationale of PSI 13, the likely sources of information needed from the electronic medical record, and a systematic chronology for chart abstraction. We also conducted IRR testing to ensure standardized and reliable abstraction. Before independent abstraction, a series of medical records were reviewed by both nurses, and IRR was measured as the percentage of agreement on 40 selected key clinical questions. IRR testing ultimately revealed 95% agreement after 3 rounds of 5 records each.

Community hospital methods

The study was approved by the federal Office of Management and Budget and by the Institutional Review Board at the University of California, Davis Medical Center (UCDMC). Each participating hospital was provided with a Notice of Data Use, indicating that all collected data would be considered confidential unless otherwise compelled by law. As in the VA analysis, AHRQ PSI software version 3.1.a was used.

Hospital selection

Hospitals were recruited for participation in the study through the AHRQ Quality Indicators LIST-SERV. Forty-seven hospitals representing 29 states agreed to participate on a voluntary basis and without financial compensation. They included not-for-profit, nonreligious hospitals (78%), hospitals with a religious affiliation (4%), and for-profit hospitals (4%). Large hospitals with more than 400 beds constituted more than one-third of participants (36%), small hospitals with fewer than 200 beds constituted 21% of participants, and no participant had fewer than 50 beds.

Case selection

Discharges between October 1, 2005 and March 31, 2007 were used to extract a sample of medical records that met PSI 13 criteria. The number of postoperative sepsis cases varied among hospitals, and the sampling fraction at each hospital was adjusted to achieve a target sample size of 240 cases (recognizing that some records would be unavailable or ineligible for abstraction).

Medical record abstraction

A data abstraction instrument was developed as noted above. Study staff pretested the abstraction instrument at UC Davis Medical Center and 2 nonprofit hospitals in the Sacramento region. Additional input was obtained from national experts as needed. The entire instrument and corresponding guidelines are available online at http://qualityindicators.ahrq.gov/validationpilot.htm.

Analysis

Positive predictive value

We calculated PPV as the rate of true positives divided by the total number of medical records reviewed and derived 95% confidence intervals about that estimate.

True positive analysis

For patients with confirmed postoperative sepsis, we performed descriptive analyses of multiple continuous and categorical variables including demographic characteristics (age, sex, race or ethnicity), comorbidities, relevant risk factors, and the nature of the surgical procedure and outcomes. All statistical analyses were performed using SAS version 9.1 (SAS Institute, Inc.).

False positive analysis

All false positive cases underwent further detailed review to better understand why they were incorrectly flagged by the PSI algorithms. However, the authors did not have access to the original records, so cases that were reclassified as "nonelective" were designated as false positive even if the record was correctly coded.

Table 2. Characteristics of True Positive Patients

Characteristic	VA sample (n = 59)	Community hospital sample (n = 67)
Demographics and comorbid conditions		
Male gender, n (%)	57 (97)	48 (78)
Age, y, mean	64	65
Current cigarette smoker, n (%)	19 (32)	19 (29)
Diabetes, n (%)	22 (37)	14 (21)
Type of case, n (%)		
Cardiothoracic	12 (20)	12 (18)
Vascular	11 (19)	6 (9)

VA, Veterans Health Administration

RESULTS

VA hospitals

Within the 28 selected hospitals, 33,548 cases met the eligibility criteria for postoperative sepsis during the study period, and 218 cases were flagged by PSI 13. Of the 112 reviewed cases, 59 were confirmed as postoperative sepsis, yielding a PPV of 53% (95% CI 42% to 64%).

True positive analysis

The sample was 97% male (n = 57), with a mean age of 63.8 years. Seventy-six percent of patients were white, 9% were African American, and 7% were Hispanic. The average body mass index was 30.0 kg/m^2. Thirty-seven percent of patients had diabetes and 32% were smokers. There was no IV drug abuse documented among these patients, no patient had a chronic indwelling IV catheter in place on admission, and 2 patients used steroids within the month before admission.

The majority of cases were cardiothoracic (n = 12), vascular (n = 11), or general surgery (n = 11). Thirty-three cases (56%) were labeled as clean, 16 cases (27%) were clean-contaminated, and 1 case was contaminated (the remainder were missing case classification information). Preoperative antibiotics were given in 48 cases (81%). Eleven patients (19%) either did not receive antibiotics or documentation was absent. If hair removal was necessary, a razor was used in 20 instances (34%) and clippers in 15 (25%).

Average blood glucose level at 6:00 AM on postoperative day 1 was 154 mg/dL. A single patient with blood glucose over 200 mg/dL had no antiglycemic ordered; otherwise patients were appropriately treated with oral hypoglycemic agents or intravenous or subcutaneous insulin.

Regarding the source of infection, 59% of cases were attributed to pneumonia, 29% to a urinary tract infection, 22% to a catheter-related bloodstream infection, and 15% to a surgical site infection. These diagnoses were not mutually exclusive. Blood cultures were positive in 26 patients (44%), but 6 patients (10%) did not have blood cultures sent despite having a documented diagnosis of sepsis (Table 2).

Patient outcomes

The average length of stay was 32 days. Slightly more than half the patients required a transfusion of packed red cells or plasma (n = 31), and 16 (27%) patients required transfer to a higher level of care due to postoperative sepsis. All-cause in-hospital mortality was 35% (n = 21) (Table 3).

False positive analysis

Of 53 false positive cases, 16 (30%) patients had an infection present on admission and 12 (23%) were emergent admissions. Seven (13%) cases of sepsis were diagnosed after admission but before the index procedure. Twelve patients (23%) had postoperative sepsis listed as a possible diagnosis in the medical record but no antibiotics were ever administered, no imaging was notable for an infection, nor were any blood cultures sent. Other false positives represented limitations of the ICD-9-CM coding system in that some patients who had postoperative hemorrhagic shock (n = 3) or cardiogenic shock (n = 3) were assigned a diagnosis code of 998.0 (postoperative shock) in the absence of a more specific code to describe their condition (Table 4).

Community hospitals

From the 49 selected hospitals, we identified 164 cases of postoperative sepsis. Of these, 67 cases were true events of

Table 3. Patient Outcomes

Consequences of postoperative sepsis	VA sample	Community hospital sample
Positive blood cultures, n (%)	44 (26)	30 (45)
Move to higher level of care, n (%)	27 (16)	Not abstracted
Blood product transfusion, n (%)	53 (31)	33 (22)
Length of stay, d, mean	32	27
All-cause mortality, n (%)	21 (35)	19 (28)

VA, Veterans Health Administration

Table 4. Characteristics of False Positives

Characteristic	VA sample (n = 53)		Community hospital sample (n = 97)	
	n	%	n	%
Infection present on admission	16	30	27	28
Nonelective admission	12	23	41	43
Not confirmed by medical record	12	23	27	28
Diagnosis after admission but before index procedure	7	13	Not evaluated	
Other coding-related inaccuracies	6	11	0	
Incompleteness of the medical record	0		2	2

VA, Veterans Health Administration

postoperative sepsis, yielding a PPV of 41% (95% CI 28% to 54%).

True positive analysis

The sample was 48% male (n = 32), with a mean age of 65 years. Twenty-one percent of patients had diabetes and 29% were smokers. Four patients had used oral steroids within the 60 days before admission. One patient had chronic liver disease and 10 patients had chronic pulmonary disease.

The majority of cases were cardiothoracic (n = 12, 18%), general surgery (n = 12, 18%), or vascular surgery (n = 6, 9%). Preoperative antibiotics were given in 64 patients (96%) within 60 minutes of incision time. The remaining 3 patients had antibiotics given within 15 minutes of the 1-hour standard. If hair removal was necessary, the use of a razor was noted in 25% of cases.

Average blood glucose at 6:00 AM on postoperative day 1 was 111 mg/dL. Regarding source of infection, 54% were attributed to pneumonia, 46% to a catheter-related bloodstream infection, 12% to a urinary tract infection, and 2% to a surgical site infection. These diagnoses were not mutually exclusive (Table 2).

Patient outcomes

The average length of stay was 27 days. Greater than 92% of patients developed some evidence of systemic infection or end organ dysfunction, including a temperature greater than 38° C (92% of patients); systolic blood pressure ≤ 95 mmHg (92% of patients); postoperative blood glucose greater than 180 mg/dL (61% of patients); and low urine output (50% of patients). Twenty-two patients received a blood product transfusion. All-cause in-hospital mortality was 28% (n = 19). Deaths attributed to sepsis based on clinical documentation in the medical record represented 14% (n = 9) of patients (Table 3).

False positive analysis

Of 97 false positive cases, 43% were nonelective admissions, 28% had infection or sepsis present on admission, and 28% had no documentation of bacteremia, septicemia, sepsis, or systemic inflammatory response syndrome. The majority of patients admitted with infection or sepsis were readmissions from an earlier procedure or complications from a previous inpatient stay (Table 4).

DISCUSSION

One of the most important goals of developing the PSIs was to accurately identify potentially preventable complications of medical care. This goal, representing the criterion validity of the indicator, can be assessed by determining the PPV of each PSI. We found that the PPV of PSI 13 was low in both the VA and nonfederal sectors: specifically, 53% (95% CI 42% to 64%) in the VA sector and 41% (95% CI 28% to 54%) in the nonfederal sector. Recent studies have demonstrated PPVs between 44% and 91% for other PSIs.[5-11] Our PPV estimates for PSI 13 are at the low end of this range. The similarity of these estimates, despite the lack of financial incentives in the VA system, suggests that factors inherent to coding, such as ambiguous codes, play an important role in the accuracy of this PSI based on administrative databases.[6]

Investigation of the false positive cases confirmed that the low criterion validity of PSI 13 stems primarily from diagnosis timing and coding issues. In the VA sample, nearly one-third of false positives were cases of sepsis that were present on admission. Similarly in the nonfederal sector, 28% of false positives were present on admission. These findings are consistent with previous studies that showed that introducing a "present on admission flag" (as many state health data agencies and the Centers for Medicare and Medicaid Services have done) could substantially decrease the high false positive rate for several PSIs.[6] By eliminating cases that had sepsis present on admission, the PPV of the indicator would improve to 67% and 56% in the VA and nonfederal sectors, respectively. However, these values are arguably still poor. So, implementation of a present on admission flag alone is insufficient to improve the criterion validity of this indicator.

Other reporting and coding issues contributed to poor criterion validity. Patients with urgent or emergent operations accounted for a significant percentage of false positive cases (23% in the VA sector and 43% in the nonfederal sector), although abstractors often reported some confusion about the distinction between elective and nonelective procedures. Some patients were incorrectly coded as having

sepsis when there was no clinical diagnosis of sepsis (23% in the VA sector and 28% of the nonfederal sector). Some of these latter cases stemmed from coding the "rule out" or "versus" diagnoses of sepsis referred to in a physician's note when a postoperative patient experienced hypotension or other signs of end organ dysfunction (cardiogenic shock, hemorrhagic shock, hypovolemia, intravascular volume depletion, acute renal failure, etc). Although this coding practice is well justified, it decreases the specificity of this PSI.

Coding issues and missing information about diagnosis timing are not solely to blame for the low PPV of this indicator. One inherent difficulty with this PSI is that there are varying clinical definitions of sepsis. Providers may have different thresholds and methods of diagnosing a patient as septic. For the purpose of this study, we relied solely on physician documentation of sepsis within the medical record, regardless of whether the physician adhered to a standardized definition of sepsis. Depending on the threshold of the physician, patients with the same clinical state may not be given the same diagnosis. Moreover, a revised consensus definition of sepsis was published during the study period, which likely contributed to variation in the classification of sepsis.[14] This ambiguity may have contributed to the high number of "rule out" sepsis diagnoses that were incorrectly captured under this PSI. It is important to note that 2 organisms typically associated with community-acquired infections (*H. influenza* and *Pneumococcus sp.*) are included in the list of 21 ICD-9-CM codes that are used to capture postoperative sepsis. This highlights that some cases of postoperative sepsis captured under this indicator may be due to community-acquired organisms, making it difficult to attribute all cases of postoperative sepsis to nosocomial infections.

Another concern about PSI 13 is that it potentially describes events also captured by PSI 7 (central venous catheter-related bloodstream infections). In our study, approximately one-quarter of the VA patients and nearly half of the nonfederal patients had sepsis attributed to an infected vascular catheter. PSI 7 was developed to capture infections due to central venous catheters, but does not exclude postoperative cases of sepsis.[15] Under the current PSI classification system, cases of postoperative sepsis stemming from a central venous catheter could be assigned both PSI 7 and 13. Although this does not diminish the criterion validity of either PSI 7 or 13, hospitals have the potential to be penalized more than once for the same complication.

A final potential shortcoming of this indicator is that the prevalence of postoperative sepsis is low, making this PSI less reliable for judging hospital performance than some of the more common PSIs. However, PSI 13 does detect clinically consequential events, as demonstrated by the high rates of bacteremia, systemic inflammatory response syndrome, and mortality seen in both sets of true positive patients. This meets an important goal of the AHRQ Patient Safety Indicators, which is to identify patients for whom there is a potential opportunity to improve clinical outcomes.[16] In the VA sample, nearly 50% of patients were bacteremic, 27% required transfer to a higher level of care such as an ICU, and all-cause mortality was 35%. Similarly, for the nonfederal sector, 92% of patients developed evidence of end organ dysfunction and all-cause mortality was 28%. These high rates of adverse outcomes are reflected in the mean length of stay—32 days for true positive cases within the VA and 27 days for true positive cases within the nonfederal sector. Moreover, a recent study within the VA system demonstrated that relative costs per inpatient hospitalization were 2.28 times greater for patients with sepsis relative to patients without sepsis. This difference in risk-adjusted costs amounted to nearly $28,000 (Vaughan-Sarrazin and colleagues. Costs of post-operative sepsis: the business case for quality improvement to reduce postoperative sepsis in VA hospitals. Personal communication, 2011).

Although we are limited by the retrospective nature of this study, analysis of the true cases of postoperative sepsis suggests that at least some infections leading to postoperative sepsis may be preventable. Nosocomial pneumonia was cited as the most frequent cause of infection in both the VA and nonfederal sectors. We know that judicious postoperative pain control, limiting the use of nasogastric tubes, good oral hygiene, preoperative optimization of COPD, keeping the head of bed at greater than 30 degrees in intubated patients, and expeditious weaning to extubate have been associated with lower rates of nosocomial pneumonia. We also know that hospital-acquired pneumonia can increase a patient's hospital stay by more than 1 week, resulting in up to a 3-fold increase in mortality.[17] Similar logic may be applied to the other causes of postoperative sepsis identified in this study, such as catheter-related bloodstream infections, urinary tract infections, and surgical site infections. With respect to surgical site infection, it is striking that razors were used in 20 operative cases in the VA sector (34%) and 17 cases in the nonfederal sector (20%), despite consensus guidelines established in 1999 dictating the use of clippers.[18] Although this study did not investigate postoperative processes of care, it does suggest the need for vigilance to prevent these postoperative infections.

Study limitations

There are some inherent limitations to our study. The patient populations were different in the VA and nonfederal sectors, making direct comparisons difficult. Similarly, the data were abstracted from 2 different but overlapping time periods.

However, these differences in populations and time may be perceived as a relative strength of the study because the poor criterion validity of the PPV remained constant across dissimilar populations and time periods.

Another limitation is that the data elements collected and abstraction methods were not identical. For instance, within the VA sample, we were unable to obtain specific information on the timing of antibiotic administration and whether antibiotics were redosed intraoperatively. These data points are available only on paper-based anesthesia records maintained at each VA hospital. On the other hand, the nonfederal data abstraction instrument was not subject to IRR testing, nor were clinicians available to review ambiguous cases. As a result, PPV was underestimated in the community hospital sample, because any case reclassified by the abstractor as a nonelective admission was automatically labeled as false positive, even if the patient was correctly coded as having postoperative sepsis. Some shortcomings were noted in both abstraction tools; for instance, neither instrument specified whether urinary tract infections were catheter-associated. This information would have been useful when considering the perioperative processes of care that contributed to postoperative sepsis.

In the VA study, 112 cases were abstracted from a total of 218 cases that qualified for PSI 13. In the nonfederal hospitals, 164 cases that qualified for PSI 13 were reviewed. The decision to limit the VA study to 112 cases was based on the ability to allocate trained nurse-reviewers for data abstraction. However, both the VA and nonfederal studies were designed to generate confidence intervals of similar width, so this difference should not detract from the findings.

Two final limitations of this study should be noted. Using the medical record as the gold standard to determine whether the PSI coding algorithm identifies true events relies on the completeness of physician documentation. Lastly, we are unable to report on sensitivity, specificity, or negative predictive value of this PSI because we did not abstract charts of patients not flagged by the PSI 13 algorithm. Future research efforts could examine these issues because this PSI may be missing clinically significant events.

In conclusion, PSI 13 has relatively poor predictive ability to identify postoperative sepsis in both the VA and community hospital sectors, although its predictive value would be substantially higher with information on diagnosis timing (as now required by the Centers for Medicare and Medicaid Services and many state health data agencies) and greater clarity about elective admissions. Despite the low PPV of this PSI, it does identify clinically significant events, representing opportunities for real quality improvement. However, as it currently stands, the use of PSI 13 on a stand-alone basis for hospital safety profiling, public reporting and pay-for-performance measures appears premature.

Positive Predictive Value of the AHRQ Patient Safety Indicator "Postoperative Wound Dehiscence"

Marisa Cevasco, MD, MPH, Ann M Borzecki, MD, MPH, David A McClusky III, MD, Qi Chen, MPH, Marlena H Shin, JD, MPH, Kamal MF Itani, MD, FACS, Amy K Rosen, PhD

BACKGROUND: The Agency for Healthcare Research and Quality patient safety indicator (PSI) 14, or "postoperative wound dehiscence," is 1 of 4 PSIs recently adopted by the Centers for Medicare & Medicaid Services to compare quality and safety across hospitals. We determined how well it identifies true cases of postoperative wound dehiscence by examining its positive predictive value (PPV).

STUDY DESIGN: A retrospective cross-sectional study of hospitalization records that met PSI 14 criteria was conducted within the Veterans Health Administration hospitals from fiscal years 2003 to 2007. Trained abstractors used standardized abstraction instruments to review electronic medical records. We determined the PPV of the indicator and performed descriptive analyses of cases.

RESULTS: Of the 112 reviewed cases, 97 were true events of postoperative wound dehiscence, yielding a PPV of 87% (95% CI 79% to 92%). Sixty-one percent (n = 59) of true positive cases had at least 1 risk factor, such as low albumin level, COPD, or superficial wound infection. False positives were due to coding errors, such as cases in which the patient's abdomen was intentionally left open during the index procedure.

CONCLUSIONS: PSI 14 has relatively good predictive ability to identify true cases of postoperative wound dehiscence. It has the highest PPV among all PSIs evaluated within the Veterans Health Administration system. Inaccurate coding was the reason for false positives. Providing additional training to medical coders could potentially improve the PPV of this indicator. At present, this PSI is a promising measure for both quality improvement and performance measurement; however, its use in pay-for-performance efforts seems premature. (J Am Coll Surg 2011;212: 962–967. © 2011 by the American College of Surgeons)

Postoperative wound dehiscence is a serious surgical complication. Up to 3% of laparotomy incisions are associated with dehiscence, and more than half of repaired laparotomy dehiscences will go on to form incisional hernias, entering many patients into a cycle of surgical repair, reherniation, and acute and chronic wound complications.[1] Postoperative wound dehiscence is associated with an additional 9 days of hospitalization, $40,000 in excess charges, and 10% in-hospital attributable mortality.[2] Despite the high morbidity and mortality associated with this complication, its incidence has remained relatively unchanged over time.[3]

Postoperative wound dehiscence is defined by the Agency for Healthcare Quality and Research (AHRQ) as "reclosure of postoperative disruption of abdominal wall" in a patient who has undergone an abdominopelvic operating room procedure. Postoperative wound dehiscence may be prevented through appropriate surgical technique, optimizing modifiable patient risk factors prior to elective surgery and close monitoring of perioperative conditions.[4] Surgeon experience level and technical factors have also been shown to affect the rate of wound dehiscence.[5] Patient characteristics such as age, pulmonary disease, malnourishment, steroid use, diabetes mellitus, and obesity are each independently associated with increased rates of wound dehiscence. Perioperative conditions such as wound infection, intra-abdominal infection, and hypotension have also

been associated with increased rates of postoperative wound dehiscence.[6]

Wound dehiscence is a significant complication of surgical care, occurs at a clinically meaningful rate, and may be prevented by good processes of care.[7] Because of these factors, particularly its potential preventability, postoperative wound dehiscence was selected as a patient safety indicator (PSI 14) by AHRQ. The PSIs were developed in 2003 to improve methods for identifying potential gaps in patient care related to patient safety. Originally intended for use in quality improvement initiatives, the PSIs are currently applied in ways inconsistent with this purpose. At present, more than 100 organizations are using the PSIs for national, state, and regional public reporting and hospital profiling. More recently, the Centers for Medicare & Medicaid Services added 4 individual PSIs and a composite PSI measure to their Hospital Compare Web site.[8] PSI 14 was 1 of 4 individual indicators adopted. Increasing interest in these activities, including their use by the Centers for Medicare & Medicaid Services, makes it essential that the PSIs accurately reflect hospital safety performance. Research regarding their validity is urgently needed.

We therefore conducted a study to determine the positive predictive value (PPV) of PSIs within the Veterans Health Administration (VHA). Although several of the PSIs have undergone extensive validation in both the federal and private sectors, this is the first study, to our knowledge, that explicitly evaluated the validity of this PSI using medical record data as the "gold standard." We also characterized the type of events incorrectly captured by this PSI and assessed which perioperative events may have contributed to postoperative wound dehiscence. Results from this study will have important implications for hospital reporting, pay for performance, and other uses of this specific PSI nationwide.

METHODS

Study design

We conducted a retrospective observational analysis of VHA inpatient administrative data that met criteria for PSI 14. We applied the AHRQ PSI software (version 3.1a) to VHA fiscal years 2003 to 2007 (October 1, 2003 through September 30, 2007) administrative data to identify cases with suspected postoperative wound dehiscence. The required IRB approvals from the Veterans Administration (VA) Boston Healthcare System and Bedford VA Medical Center were obtained to conduct this study.

PSI 14, "postoperative wound dehiscence," captures all discharges of patients who underwent an abdominopelvic operating room procedure and subsequent "reclosure of postoperative disruption of abdominal wall" (ICD-9-CM code 54.61). Excluded from this definition are patients who underwent reclosure procedures performed on the same day as the original surgery, those with a length of stay less than 2 days, patients with immunocompromised states, and all obstetric admissions (eg, pregnancy, childbirth).[7]

Hospital selection

We randomly selected 28 of 158 acute care VA hospitals to obtain a manageable number of hospitals for individual medical record review while capturing variation in coding across facilities. Our sampling scheme was designed to generate a sample of hospitals with a range of observed and expected safety events; previous work describes the sampling methodology in greater detail.[9] Twenty-one percent of sampled hospitals were from the Northeast, 32% were from the South, 18% were from the Midwest, and 29% were from the West. Eighty-nine percent were major teaching hospitals (ie, resident-to-bed ratio >0.25). The median number of hospital beds was 155 (range 62 to 360 beds).

Case selection

We randomly selected 4 medical records flagged with postoperative wound dehiscence from each of the 28 hospitals for a total of 112 medical records. Based on previously reported PPV estimates, 112 cases per PSI were selected to ensure reasonably narrow PPV CIs ($\pm$10% to 20%).

Medical record abstraction and inter-rater reliability (IRR)

To determine rates of true and false positives for the PSI, 2 trained nurses conducted a retrospective chart review using standardized chart abstraction tools and guidelines developed by AHRQ. These were modified to be suitable for the VHA's electronic medical records and to achieve IRR measurement standards of greater than 90% observed agreement. Specifically, medical records were reviewed for the occurrence of postoperative wound dehiscence; in addition, demographic characteristics were abstracted. For true positives, nurses also abstracted information on comorbidities; risk factors of the sampled patients; and patient outcomes following the event such as number of reparative surgeries, postoperative wound infection, or death. Additional variables abstracted included the type of surgical incision; surgical technique, and type of suture used to close

the fascia; presence of infection within the abdomen or pelvis; level of training of the person performing the procedure; and whether retention sutures were placed.

Nurse training included several sessions discussing the rationale of PSI 14, the likely sources of information needed from the electronic medical record, and a systematic chronology for chart abstraction. We also conducted IRR testing to ensure standardized and reliable abstraction. Prior to independent abstraction, a series of medical records were reviewed by both nurses, and IRR was measured as the percentage of agreement on 48 clinical questions. IRR testing ultimately revealed 96% agreement after 4 rounds of 4 records each.

Analysis

PPV

We calculated PPV as the rate of true positives divided by the total number of medical records reviewed and derived 95% CIs.

True positive analysis

For patients with confirmed postoperative wound dehiscence, we performed descriptive analyses of multiple continuous and categoric variables, including demographic characteristics (age, gender, race/ethnicity), comorbidities, risk factors, nature of the surgical procedure, and outcomes. All statistical analyses were performed using SAS version 9.1 (SAS Institute Inc).

False positive analysis

All false positive cases underwent further detailed review to better understand why they were incorrectly flagged by the PSI algorithms.

RESULTS

From the 28 selected hospitals, 191 of 29,721 eligible patients were flagged as having PSI 14. This generated an observed rate of wound dehiscence of 6.4 per 1,000 discharges, which is comparable to the national VHA rate of 6.2 per 1,000 discharges at risk. Of these 191 patients, 112 were chosen for detailed review (see case selection outlined earlier). Ninety-seven cases were true positives, yielding a PPV of 87% (95% CI 79% to 92%).

True positive analysis

The sample was 99% male (n = 96), with a mean age of 67.2 ± 11 years. Seventy-two percent were white, 7% were African American, and 7% were Hispanic. Twenty-eight percent of patients (n = 27) had COPD, 14% (n = 14) were obese (ie, body mass index >30), and 9% (n = 9) used systemic steroids. Twenty-three percent of patients (n = 23) had a preoperative albumin level of <3 g/dL (Table 1).

Table 1. True Positive Characteristics

	True positives (n = 97)
Demographics and comorbid conditions	
Male sex, n (%)	96 (99)
Mean age, y	67 ± 11
COPD, n (%)	27 (28)
Body mass index >30, n (%)	14 (14)
Systemic steroids, n (%)	9 (9)
Albumin <3 g/dL, n (%)	23 (23)
Procedure characteristics, n (%)	
Sigmoidectomy	11 (11)
Small bowel resection	6 (6)
Right hemicolectomy	6 (6)
Other	74 (77)*
Wound dehiscence characteristics, n (%)	
Evisceration	41 (43)
Fluid drainage	27 (28)
Wound infection	9 (9)
Coughing	12 (13)
Visceral leak	5 (5)
Postoperative course, n (%)	
1 additional surgery	82 (84)
≥2 surgeries	13 (13)
Median length of stay, d	26
All-cause mortality, n (%)	11 (11)

*Other procedures included left hemicolectomy, total proctocolectomy, low anterior resection, abdominoperineal resection, Hartman takedown procedure, colostomy revision, abdominal aortic aneurysm repair, right hepatectomy, paraesophageal hernia repair, radical cystectomy with ileal conduit, and open appendectomy.

Characteristics related to the index procedure

Of the 55 separate ICD-9-CM procedure codes listed as the index procedure, the most frequent were codes for sigmoidectomy (n = 11 [11%]), partial small bowel resection (n = 6 [6%]), and right hemicolectomy (n = 6 [6%]) (Table 1). Overall, one-third of the index cases involved interventions upon the small bowel, colon, and/or rectum. Twenty-five percent of index procedures were considered emergent or urgent.

During the index procedure, the majority of incisions were midline vertical (95%). The most common method of abdominal wound closure involved primary continuous closure (n = 70 [72%]) using a large polydiaxone suture (n = 67 [69%]). Interrupted techniques using absorbable (n = 12 [12%]) and nonabsorbable (n = 5 [5%]) sutures were also noted. Internal retention sutures of the Smead-Jones technique were placed in 3% (n = 3) of index pro-

cedures, and true retention sutures were placed in 1% (n = 1) of index procedures. All 4 of these procedures with retention suture placement involved a perforated hollow viscus in an obese patient who presented with fluid leaking from the wound. For patients for which this information was recorded, an attending physician performed closure in 31% (n = 26) of cases and a physician-in-training performed the closure in 69% (n = 56).

Characteristics related to the wound dehiscence

Sixty-three percent (n = 61) of wound dehiscences were diagnosed within 7 days after the index procedure. Clinically evident evisceration of abdominal contents was noted in 41 patients (43%), and 28% of patients (n = 27) had large amounts of fluid draining from the wound. Excessive coughing and/or physical exertion was noted in 13% of patients (n = 12), and a visceral leak was found in 5% of patients (n = 5). A wound infection was found in 9% of patients (n = 9) (Table 1). Of those 9 patients, 3 had a perforated hollow viscus, but the skin had been closed with either staples (n = 2) or running monocryl suture (n = 1). Wound dehiscence was attributed to fascial tearing in 32% of patients, necrotic fascia in 12%, breakage of suture material in 11%, intra-abdominal infection in 9%, and unraveling of a tied suture in 2% of patients.

Postoperative course

The majority of patients (84%) underwent only 1 additional procedure following wound dehiscence. Thirteen patients required 2 or more additional operations, including 1 patient who underwent a total of 6 subsequent procedures during a single hospitalization. The median length of stay was 26 days, and the overall mortality rate was 11% (Table 1).

False positive analysis

Of 15 false positives, 7 (47%) were patients in which the fascia was intentionally left open during the initial procedure. Three patients (20%) returned to the operating room because of concern for postoperative wound dehiscence, but only a superficial fluid collection without fascial dehiscence was involved. An additional 3 false positives (20%) were patients in which a second procedure was performed for a reason other than wound dehiscence (eg, postoperative hemorrhage, planned reinternalization of a ventriculoperitoneal shunt). Finally, 2 operations addressed the sequelae of prior abdominal surgical interventions (eg, colostomy takedown, ventral hernia repair) but were incorrectly coded (Table 2).

Table 2. Characteristics of False Positives

	False positives (n = 15), n (%)
Abdomen intentionally left open	7 (47)
Superficial fluid collection	3 (20)
Other reason (eg, bleeding)	3 (20)
Addressed sequelae of prior surgery	2 (13)

DISCUSSION

We found a PPV of 87% for PSI 14 within the VHA system. This is higher than the PPV of 72% previously reported for PSI 14 when comparing VHA administrative data with chart-abstracted data derived from the VA's National Surgical Quality Improvement Program.[10] It is also higher than the reported PPV range of 34% to 75% for the pediatric postoperative wound dehiscence indicator (pediatric quality indicator 11).[11] The PPV of PSI 14 also compares favorably with the PPVs of other PSIs. It has the highest PPV among all PSIs evaluated in the VA system.[9,12,13] It is also superior to the published PPVs of all other PSIs validated in the private sector other than PSI 15, accidental puncture and laceration, which had a PPV of 91%.[14-19]

The relative value of a PPV of 87% primarily depends on its intended use. Eighty-seven percent may be considered sufficiently high when broadly identifying opportunities for patient safety improvement. Alternatively, 87% is arguably unsatisfactory if the data are being used to determine pay-for-performance parameters or for disciplinary measures. It is within this latter context that an analysis of false positives is instructive, both as a reminder of the limitations of ICD-9-CM–based triggers and as a means of improving the PSI.

Our review of false positive cases highlighted potential sources of coding error. Seven, or 47%, of the false positives were patients in which the fascia was intentionally left open owing to intra-abdominal contamination or concern for development of compartment syndrome. Clinical descriptors that highlighted the intent not to close the abdomen were apparent, in the indications for surgery, postoperative diagnosis, or operative note. For instance, one operative report noted that the "abdominal fascia was intentionally left open following the first surgery." Similarly, a second report stated, "during the first operative surgery the fascia was not closed." However, these 7 false positives were each inappropriately coded as ICD-9-CM 54.61, "reclosure of postoperative disruption of abdominal wall." Although the patients did have a subsequent operation to close the abdomen, this procedure was a planned takeback, not the result of a postoperative wound dehiscence.

This coding error may be due in part to the fine level of distinction required to correctly assign an ICD-9-CM

code. Although there is no specific code for "delayed primary closure," the 7 false positives incorrectly coded as ICD-9-CM 54.61 should have been coded as ICD-9-CM 54.62, "delayed closure of granulating abdominal wound." A trained medical coder should be able to differentiate the 2 situations. Although this clinical scenario is relatively uncommon in a typical VA medical center, failure to differentiate a postoperative wound dehiscence from an intentional open abdomen could prove troublesome if PSI 14 is evaluated within hospitals at which this practice is more commonplace, such as a trauma center. This suggests a need for increased attention to coding practices and better training of coders.

An additional 20% of cases were associated with a fluid-draining wound infection or seroma requiring operative drainage. These patients were also incorrectly coded as ICD-9-CM 54.61, instead of ICD-9-CM 86.04, "other incision with drainage of skin and subcutaneous tissue." In all cases, the fascia remained intact, although wound dehiscence was initially suspected in each case. Because fluid leakage may precede wound dehiscence, its presence in the face of a second operation understandably serves as a source of confusion. In our detailed chart analysis, clinicians filtered through the operative report to eventually determine that the fascia remained intact. This level of analysis may be untenable for the average medical coder. Moreover, some clinicians use "wound dehiscence" to signify that the superficial portion of the wound involving subcutaneous tissue is open. Although not a reason for false positives in this study, this nonspecificity of clinical terms may further confound abstractors' ability to correctly code for postoperative wound dehiscence. Ultimately, this coding error may be hard to avoid without specialized instruction.

Despite these coding errors, the PPV of PSI 14 is the highest of any PSI validated in the VA setting. This is largely because other VA-validated PSIs had a high percentage of false positives from diagnoses that were actually present on admission but not coded as such because of the lack of a present on admission code in the VA administrative database. Wound dehiscence is more likely to occur within the immediate postoperative period, as opposed to other PSIs, such as pressure ulcer, which may develop after a patient has been discharged from the hospital or sometime prior to admission.

Although the PPV of PSI 14 is relatively high, it is also important to consider whether it can identify clinically significant opportunities for quality improvement.

Several descriptive characteristics of our true positives suggest that this is the case. Within this group, the median length of stay was nearly 1 month (26 days) and 11% of patients died. These data are consistent with previously published reports noting that hospitalizations associated with postoperative wound dehiscence were associated with increased morbidity and mortality (eg, VA patients hospitalized with this PSI experienced approximately 4 times the number of in-hospital deaths, nearly 4-fold greater median length of stay, and 3 times increased cost compared with similar hospitalizations without this indicator).[20]

Although we are limited by the retrospective nature of this study, analysis of the true cases of postoperative wound dehiscence suggests that at least some cases may be preventable. Twenty-three percent of patients had a preoperative albumin level of less than 3 g/dL, suggesting the opportunity to improve perioperative nutrition in elective cases. Twenty-eight percent of patients had a diagnosis of COPD, another known risk factor for wound dehiscence. Ensuring that care of patients with COPD includes both preoperative inhalers and postoperative vigilance with pulmonary toilette may also help reduce the risk of this complication. Moreover, 9% of true positives had a wound infection. This highlights the importance of minimizing surgical site infections by using proper surgical techniques and implementing surgical infection prevention measures. Also striking is that physicians-in-training performed nearly 70% of fascial closures among patients with wound dehiscence. It is not uncommon for attending surgeons to scrub out after the critical part of the procedure and leave fascial closure to the residents. Increased vigilance by the attending surgeon during closure may reduce rates of postoperative dehiscence.

Study limitations

There are some inherent limitations to our study. We are unable to report on sensitivity, specificity, or negative predictive value of this PSI because we did not abstract the charts of patients not flagged by the PSI 14 algorithm. Future research efforts should examine these issues because the PSI may be missing clinically significant events. Additionally, using the medical record as the gold standard to determine whether the PSI coding algorithm identifies true events relies on the accuracy and completeness of physician documentation. We also did not collect information on surgical infection prevention measures; therefore, we do not know the extent to which these contributed to wound infections. Finally, this was a retrospective observational study with potential for selection, observation, and confounding biases.

CONCLUSIONS

PSI 14 has good predictive ability to identify true instances of postoperative wound dehiscence in the VA system. Its predictive value could be improved by eliminating coding

errors, such as those related to cases in which the patient's fascia was intentionally left open. This PSI identifies clinically significant events representing opportunities for real quality improvement and highlights perioperative conditions and patient risk factors that may be optimized to decrease the incidence of postoperative wound dehiscence. As it currently stands, PSI 14 appears to be a promising measure for use beyond quality improvement and screening, particularly if efforts to decrease coding mistakes are implemented; however, use for pay-for-performance may be premature.

Validity of the AHRQ Patient Safety Indicator "Central Venous Catheter-Related Bloodstream Infections"

Marisa Cevasco, MD, MPH, Ann M Borzecki, MD, MPH, William J O'Brien, MS, Qi Chen, MPH, Marlena H Shin, JD, MPH, Kamal MF Itani, MD, FACS, Amy K Rosen, PhD

BACKGROUND: "Central venous catheter-related bloodstream infections" (CR-BSIs) is one of the patient safety indicators (PSI 7) developed by the Agency for Healthcare Research and Quality (AHRQ) to screen for potential safety events. We sought to investigate the validity of this PSI using the medical record as the gold standard.

STUDY DESIGN: We conducted a retrospective cross-sectional study of all hospitalization records that met the criteria for PSI 7 within Veterans Health Administration (VA) hospitals from fiscal years 2003 to 2007. Trained abstractors used a standardized abstraction tool to review electronic medical records for the presence of a CR-BSI and the clinical circumstances surrounding the event. We determined the validity of this PSI by calculating its positive predictive value (PPV), and analyzed both true and false positive cases.

RESULTS: Of 112 reviewed cases, 42 were true events of CR-BSIs, yielding a PPV of 38% (95% CI 29% to 47%). Seventy cases were false positives; these were attributed to correct ICD-9-CM codes but had diagnoses that fell outside the scope of the indicator (n = 28, 40%), coding inaccuracies (n = 21, 30%); and present on admission (POA) diagnoses (n = 21; 30%). Among the 42 patients with CR-BSIs, catheters were left in place for an average of 11 days, and 20% (n = 8) were placed in the femoral position.

CONCLUSIONS: PSI 7 has relatively poor predictive ability for identifying true events. Coding-related issues were the main reason for the low PPV. Implementing POA codes and using more specific ICD-9-CM codes would improve its validity. As it currently stands, PSI 7 should not be used as a pay-for-performance measure, but should be limited to use in internal quality improvement efforts. (J Am Coll Surg 2011;212:984–990. © 2011 by the American College of Surgeons)

Central venous catheter-related bloodstream infections (CR-BSIs) are associated with significant morbidity and mortality, prolonged hospitalization, and increased medical costs. They have an attributable mortality rate as high as 25%, are associated with up to a 14-day increase in length of stay, and an incremental in-hospital cost of $45,000 per patient.[1-5] CR-BSIs affect more than 80,000 patients per year in the United States alone.[6]

Vascular catheter-related infections are preventable.[6] Evidence-based processes of care for preventing CR-BSIs include proper hand hygiene, use of maximal barrier precautions, and chlorhexidine gluconate for insertion site preparation.[5,7] Daily review of catheter necessity, prompt removal of unnecessary lines, and avoiding the femoral vein as the insertion site are also associated with a decreased rate of infection.[5,7] One notable initiative at the University of Michigan Health and Hospital Association (MHA) Keystone ICU Project nearly eliminated CR-BSIs by implementing these measures. They decreased baseline rates of CR-BSIs from a mean of 7.7 and median of 2.7 per 1,000 catheter days, to 1.3 and 0, respectively, at 18 months postimplementation.[6] Significantly, 3 years later these rates remained at a mean of 1.1 and a median of 0.[6]

Abbreviations and Acronyms

AHRQ = Agency for Healthcare Research and Quality
CR-BSI = central venous catheter-related bloodstream infection
IRR = inter-rater reliability
PICC = peripherally inserted central venous catheter
POA = present on admission
PPV = positive predictive value
PSI = patient safety indicator
VA = Veterans Health Administration

Because CR-BSI is a significant complication of inpatient hospitalization that may be prevented through specific processes of care, the Agency for Healthcare Research and Quality (AHRQ) chose it as a patient safety indicator (PSI). The PSIs, first released in March 2003, were designed to identify areas of concern and potential preventability that occur during inpatient admissions. The free PSI software provides hospitals with a way to assess the incidence of adverse events that occur during inpatient hospitalizations using administrative data (ICD-9-CM codes) found in the discharge record. Currently, there are 20 hospital-level PSIs that cover a spectrum of surgical, medical, and obstetric adverse events.[8] PSI 7, previously known as "selected infections due to medical care," was renamed "central venous catheter-related bloodstream infections" to clarify the intent of the indicator.[9]

The PSIs were developed for internal review and quality improvement projects, but are increasingly used to assess hospital performance, compare facilities, and as pay-for-performance measures.[8,10] More than 100 organizations use PSIs for public reporting and hospital profiling. A very similar measure, vascular catheter-associated infection, is included among the list of hospital-acquired conditions for which hospitals will no longer receive reimbursement from Centers for Medicare and Medicaid Services (CMS).[11] Despite these recent policies, there are currently no data on the validity of this PSI or its related hospital-acquired conditions measure. Moreover, this policy was enacted despite studies of other PSIs showing wide variability in positive predictive values (PPVs), a measure of their accuracy against the gold standard of medical record review.[12-17]

As part of a larger study, we investigated the PPV of PSI 7 within the Veteran's Health Administration (VA). This is the first study, to our knowledge, that investigates the PPV of this PSI using the medical record as the gold standard. We also investigated the types of events incorrectly captured by the PSI algorithm in order to better understand the reasons behind its failure. Finally, we sought to gain insight into the circumstances surrounding true events of CR-BSI, with the goal to recommend improvements in processes of care.

METHODS

Study design

This was a retrospective chart review based on a computerized random sample of VA administrative data that met criteria for PSI 7. AHRQ software version 3.1a was applied to fiscal year 2003 to 2007 (October 1, 2002 to September 30, 2007) inpatient administrative data to identify patients coded as having a CR-BSI. Institutional Review Board approvals were obtained from the VA Boston Healthcare System and the Bedford VA Medical Center.

Definition of PSI 7

PSI 7, central venous catheter-related bloodstream infections, included all medical or surgical discharges of patients aged 18 years or older with an ICD-9-CM code of 999.3(infection following infusion, injection, transfusion or vaccination); or 996.62 (infection or inflammatory reaction to a vascular device, implant or graft, in any secondary diagnosis field). Discharges were excluded if the length of stay was less than 2 days, if the patient was immunocompromised, or had a cancer diagnosis. Discharges were also excluded if ICD-9-CM codes 999.3 or 996.62 were found in the principal diagnosis field, suggesting that the condition was present on admission (POA).[8]

Hospital selection

Twenty-eight VA hospitals were randomly selected from the network of 158 acute care VA hospitals. This ensured sufficient exposure to interfacility coding variability while maintaining a manageable number of hospitals for individual medical record review. Our hospital sample included facilities with a range of observed and expected patient safety events. Details of our sampling scheme have been previously published.[13]

Case selection

Four medical records flagged with PSI 7 were randomly selected from each of the 28 hospitals, to generate a sample size of 112 medical records. One hundred twelve cases were selected to ensure reasonably narrow PPV confidence intervals (± 10% to 20%).

Medical record abstraction

Two trained nurses conducted a retrospective chart review of the 112 cases. Standardized chart abstraction tools and guidelines developed by AHRQ for "selected infections due to medical care" were modified to be specific to CR-BSI; these were then adapted to the VA's electronic medical

record and designed to generate inter-rater reliability (IRR) measurement standards of greater than or equal to 90% observed agreement. The tool also directed the nurses' chart review, and facilitated identification of both true and false positive cases.

Nurse training included several sessions discussing the rationale of PSI 7, the likely sources of information needed from the electronic medical record, and a systematic chronology for chart abstraction. We also conducted IRR testing to ensure standardized and reliable abstraction; this was performed at the start, and later in abstraction to rule out abstractor drift. The nurses achieved 91% observed agreement after an initial round of 5 records. Observed agreement on late IRR testing on 5 records was similarly 91%. Further details of the chart abstraction are described elsewhere.

Analysis

Positive predictive value (PPV)

Medical records were reviewed to detect the occurrence of a CR-BSI. PPV was calculated as the rate of true positives divided by the total number of medical records reviewed. We also derived 95% confidence intervals around that estimate.

True positive analysis

We performed descriptive analyses of all patients with confirmed CR-BSIs as documented in the medical record. Specifically, we relied on clinician documentation of an infection from a central venous catheter, such as a triple lumen, Hickman, peripherally inserted central catheter (PICC), or portacath. We excluded infections from peripheral venous catheters, arterial lines, or vascular grafts. We also investigated multiple continuous and categorical variables including demographic characteristics, comorbidities, site of central line placement, indication for placement, diagnosis of CR-BSI, and patient outcomes. All statistical analyses were performed using SAS version 9.1 (SAS Institute, Inc).

False positive analysis

We performed detailed analysis of all cases that were not true instances of CR-BSI to understand the reason behind their inappropriate capture by the PSI 7 algorithm.

RESULTS

From the 28 selected hospitals, 467,434 cases met the eligibility criteria for PSI 7, and 1,033 cases were flagged as having a CR-BSI. This yields an observed rate of 2.2 per 1,000 discharges, comparable to a rate of 2.0 per 1,000 discharges in the overall VA population. Of these 1,033 cases, 112 were chosen for detailed medical record review as described above. Forty-two cases were true cases of CR-BSI, yielding a PPV of 38% (95% CI 29% to 47%). The remaining 70 cases were false positives.

Table 1. Characteristics of True Positives

Variable	True positives n=42
Demographics and comorbid conditions	
Male gender, n (%)	41 (99)
Age, y, mean	61 ± 10
Diabetes, n (%)	17 (41)
Systemic steroids, n (%)	6 (14)
Presenting conditions, n (%)	
Urinary tract infection	8 (19)
Pneumonia	5 (12)
Gastroenteritis	4 (10)
Pancreatitis	3 (7)
Cellulitis	3 (7)
Clostridium difficile infection	2 (5)
Other*	3 (7)

*Includes 1 patient with a small bowel perforation, 1 with bacterial meningitis, and 1 with a surgical site infection.

True positive analysis

Patients were 98% male (n = 41) with a mean age of 60.6 ± 10.3 years. Seventeen patients (41%) had diabetes, and 6 (14%) patients had been on intravenous or oral steroids within the previous month (Table 1). None of the other patients had received any other type of immunosuppressive drug within the past month and none of the patients underwent radiation therapy.

A total of 23 patients (55%) were noted in the medical record as having 1 or more infectious or inflammatory conditions POA. Specifically, 15 patients had 1 such condition and 8 were noted as having 2 or more. Eight patients had a urinary tract infection POA, 5 were admitted with pneumonia, and 4 patients had gastroenteritis. Three patients were admitted with pancreatitis, 3 had cellulitis, and 2 were admitted with a *Clostridium difficile* infection. One patient was admitted with a small bowel perforation, 1 with bacterial meningitis, and 1 with a surgical site infection (Table 1). (Of note, an infection POA does not exclude a case from being reviewed for a CR-BSI per the definition of PSI 7).

Of the 3 patients who had central lines POA, these were all peripherally inserted central venous catheters (PICCs) for administration of total parenteral nutrition. None of these 3 patients had blood cultures drawn on admission because there was no suspicion of infection. Two of these PICCs were subsequently considered to be the source of the CR-BSI that developed during the hospitalization; the third patient had a second line placed that was considered to be the source.

Table 2. Characteristics of Catheter-Related Bloodstream Infections

Characteristic	True positives (n=42)
Infectious organism, n (%)	
Gram-positives	
Methicillin-sensitive *Staphylococcus aureus*	12 (29)
Methicillin-resistant *Staphylococcus aureus*	6 (14)
Coagulase-negative *Staphylococcus* species	5 (12)
Enterococcus species	5 (12)
Vancomycin-resistant *Enterococcus faecalis*	1 (2)
Gram negatives and *Candida*	
Eschericia coli	3 (7)
Pseudomonas aerigunosa	2 (5)
Candida species	3 (7)
Source of blood culture, n (%)	
Peripheral	17 (41)
Central	14 (33)
Not specified	11 (26)
Site of catheter placement, n (%)	
Internal jugular vein	12 (29)
Subclavian vein	10 (24)
Femoral vein	8 (19)
Peripherally inserted central venous catheter	12 (29)
Emergent or urgent lines, n (%)	14 (43)
Catheter tip, n (%)	
Sent for culture	30 (71)
Positive for organisms	16 (38)
Blood cultures sent within 48 h of central line placement, n (%)	4 (11)
Lines changed over a wire, n (%)	3 (16)
Duration catheters in place, mean, d	11 ± 9
Symptoms or clinical signs, n (%)	
Fever greater than 38.0°C	36 (86)
Leukocytosis or bandemia*	20 (48)
Rigors or chills	10 (24)
Hypotensive†	8 (19)
Transfer to higher level of care, n (%)	7 (17)
Death attributed in part to CR-BSI, n (%)	6 (14)

*Leukocytosis defined as the presence of a white blood cell count greater than 12,000; bandemia defined as greater than 10% band forms.
†Documented systolic blood pressures of less than 90 mmHg.
CR-BSI, catheter-related bloodstream infection.

All 42 true positive cases had positive blood cultures drawn after placement of their central line. The majority of infections were due to gram-positive organisms (Table 2). Seventeen patients had positive blood cultures (41%) obtained from peripheral lines, and 14 patients had positive blood cultures (33%) drawn from the central line; of this latter group, 7 patients had blood cultures drawn from both central and peripheral sources. In the remaining 11 patients (26%) with positive blood cultures, the source of the sample was not documented. In addition, 30 patients had catheter tips sent for culture, of which 16 (53%) were positive for infection. Eleven percent of all true cases (n = 4) had positive blood cultures that were sent within the first 48 hours of central line placement (Table 2).

Of the catheters associated with infection, 12 (29%) were placed in the internal jugular vein, 12 (29%) were PICCs (including the 2 PICCs that were POA), 10 (24%) were in the subclavian position, and 8 (19%) were in the femoral vein. Of the 41 patients for whom documentation was available, 19 (46%) had the infected catheter removed and a new catheter placed the same day. Eighteen catheters (43%) were placed in an urgent or emergent situation; 6 (33%) of these were femoral venous catheters. Catheters were in place for a mean duration of 11 days (median 11 days; range 2 to 56 days) (Table 2).

All patients manifested at least 1 symptom or laboratory indicator of a CR-BSI, such as a fever greater than 38.0°C, leukocytosis or bandemia, rigors or chills, or hypotension with systolic blood pressures of less than 90 mmHg. CR-BSIs resulted in 7 patients being transferred to a higher level of care, such as an ICU. Six patients' deaths were attributed in part to a CR-BSI (Table 2).

False positive analysis

Seventy patients were false positive. Of these, 40% (n = 28) of patients received a correct ICD-9-CM code, but this code did not capture the clinical intent of the indicator. Specifically, 19 patients (27%) were diagnosed with thrombophlebitis, 5 patients (7%) had an infected vascular polytetrafluoroethylene femoral-popliteal bypass graft, and 4 (6%) had cellulitis at a peripheral IV site, all of which would be coded for using ICD-9-CM code 996.62. An additional 30% (n = 21) were inaccurately coded as having a CR-BSI. Reasons for inaccurate coding included negative work-up for a CR-BSI (n = 12, 17%), or no documentation of central line, no evidence of infection or inflammation at an injection site, or infection or inflammation of a vascular device (n = 9, 13%). Finally, 30% (n = 21) of patients had a CR-BSI POA (Table 3).

DISCUSSION

The PPV of PSI 7 is 38%, indicating a poor ability to identify CR-BSIs. Recently evaluated PSIs have demonstrated PPVs between 44% and 91%, so PSI 7 ranks lowest among all PSIs evaluated to date.[12-17]

Importantly, 40% of false positives were cases that were coded correctly but represented diagnoses that were not clinically sensitive to the intent of the indicator. Specifically, there were 19 cases of superficial thrombophlebitis

Table 3. Reasons for False Positives

Reason	False positives (n=70)	
	n	%
Inaccurately coded, n (%)		
Negative rule-out	12	17
No documentation of central line or infection/ inflammation at IV site	9*	13
Outside of the scope of the indicator, n (%)		
Superficial thrombophlebitis	19	27
Infected vascular graft	5	7
Cellulitis at IV site	4	6
Present on admission, n (%)	21	30

*This includes 4 cases associated with a nonvascular catheter infection (urinary tract infections) and 1 case of nonvascular "injection/aspiration," ie, paracentesis.

from a peripheral IV, 5 cases of infected vascular bypass grafts, and 4 cases of cellulitis from a peripheral IV that were correctly captured under ICD-9-CM code 996.62, "infection or inflammatory reaction to a vascular device, implant or graft." These diagnoses do not represent a CR-BSI and are outside the scope of this PSI. A more specific ICD-9-CM code for CR-BSI, 993.1, has subsequently been developed for use on data captured after 2007. This code was designed to capture only an infection from central venous catheters, including triple lumens, Hickmans, PICCs, or portacaths, and excludes infections from peripheral venous catheters, arterial lines, or vascular grafts.[18] (Because our sample contained data from 2003 to 2007, we do not know how well this new code performs.)

Code 996.62 was also recently modified to exclude cases captured by 999.31.[18] In our study, if we were to eliminate those non-CR-BSI cases captured by the older versions of these ICD-9-CM codes, our PPV would become 63% (95% CI 54% to 72%), arguably still a low PPV, but relatively improved. This scenario highlights the vagueness of many administrative codes, as well as the importance of validation studies such as ours, which show the potential improvement that can be achieved by making ICD-9-CM codes more specific. This also underscores the fact that quality measures based on administrative codes should be interpreted cautiously, especially when chart validation is lacking.

Similar to many of the PSIs, diagnoses that were POA played a large role in limiting the potential usefulness of this indicator. Thirty percent (n = 21) of patients had a CR-BSI on admission, suggesting that a POA flag in the administrative data would increase the indicator's PPV. This has already been implemented in private hospitals and is in the early stages of adoption by the VA system. Introduction of a POA flag, in addition to using the updated ICD-9- CM codes, would generate a PPV of 81% (95% CI 73% to 88%), more in line with previously published results for other PSIs.

Coding inaccuracies are a final important component limiting the potential value of this indicator. Thirty percent of false positives (n = 21) were cases that were incorrectly coded. Of these, medical record review revealed that 12 had negative work-ups for CR-BSIs. Of the remaining 9 cases, there was no documentation of central line placement, no evidence of infection or inflammation at an injection site, or infection or inflammation secondary to a vascular device. It is unclear how these medical records were given ICD-9-CM codes of 999.3 or 996.62, particularly because chart review did not reveal any diagnosis (such as thrombophlebitis or infected vascular bypass graft) that would qualify them for such a code. The attention to detail required for ascertaining this may be untenable for the average medical coder, who is often charged with reviewing up to 15 inpatient medical records per day (B Cirrone, personal communication, November 22, 2010). Coders may not have the time to carefully peruse the complete medical record, progress notes may be contradictory, and discharge summaries may be incomplete or nebulous.

It is also important to note variations in the definitions of CR-BSI. The Centers for Disease Control and Prevention, in their *Guidelines for the Prevention of Intravascular Catheter-related Infections*, provides 3 different definitions of CR-BSI.[5] Two surveillance definitions were developed for use in quality of care and hospital performance measures; these include "laboratory-confirmed BSI" and "catheter-associated BSI." A third definition, "catheter-related BSI," was developed for clinical purposes only and provides the most stringent criteria, including positive cultures from the catheter tip and central and peripheral lines (Table 4).[5] Not only do the definitions of CR-BSI significantly differ, they may be used differently across hospitals and clinicians.[19] To obtain accurate rates of CR-BSIs, particularly when comparing facilities, it is important to know what definition of CR-BSI was used to arrive at the diagnosis. The ICD-9-CM codes (996.62 and 999.31) are not specific enough to differentiate between the CDC definitions of laboratory-confirmed BSI, catheter-associated BSI, or CR-BSI. Additionally, the indicator itself does not specify a definition of CR-BSI, and it may not be realistic to expect a code-based algorithm to differentiate between these 3 definitions.

A separate concern regarding this indicator is that it potentially flags events also captured under PSI 13 (postoperative sepsis) potentially penalizing hospitals twice for the same event. For example, another study described by

Table 4. Centers for Disease Control Definitions of Catheter-Related Bloodstream Infections

Definitions intended for surveillance measures
Catheter-associated BSI • Vascular access device that terminates at or close to the heart or one of the great vessels, and • BSI is considered to be associated with a central line if the line was in use during the 48-h period before development of the BSI. If the time interval between onset of infection and device use is > 48 h, there should be compelling evidence that the infection is related to the central line.

Laboratory-confirmed BSI (patients need to meet 1 of 2 criteria)
• Criterion 1: Patient has a recognized pathogen cultured from 1 or more blood cultures, and the pathogen cultured from the blood is not related to an infection at another site.
• Criterion 2: Patient has at least 1 of the following signs of symptoms: fever (>38.0° C), chills, or hypotension, and at least 1 of the following:
  • Common skin contaminant* cultured from 2 or more blood cultures drawn on separate occasions
  • Common skin contaminant cultured from at least 1 blood culture from a patient with an intravenous line, and the physician institutes appropriate antimicrobial therapy
  • Positive antigen test on blood and signs and symptoms with positive laboratory results are not related to an infection at another site.

Definition intended for clinical research measures

Catheter-related BSI
• Bacteremia/fungemia in a patient with an intravascular catheter with at least 1 positive blood culture obtained from a peripheral vein, clinical manifestations of infections (ie, fevers, chills, and/or hypotension), and no apparent source for the BSI except the catheter.
• One of the following should be present:
  • Positive culture whereby the same organism is isolated from the catheter segment and peripheral blood;
  • simultaneous quantitative blood cultures with a ≥ 5:1 ratio CVC versus peripheral;
  • differential period of CVC culture versus peripheral blood culture positivity of >2 hours.

*Common skin contaminant includes diphtheroids, *Bacillus* spp, *Propionibacterium* spp, coagulase-negative staphylococci, or micrococci.
BSI, bloodstream infection; CVC, central venous catheter.

our group found that 13 cases of postoperative sepsis were attributed to a CR-BSI.[20] In this study, 3 of those same 13 cases were captured herein, resulting in these patients' adverse events contributing to 2 distinct PSIs. (The remaining 10 sepsis cases were not captured by this study because we chose distinct samples of 112 flagged cases per PSI for review (ie, 3 cases ended up in both samples).

Finally, it is important to ascertain whether some of the true cases of CR-BSIs are preventable. Seventy-five percent of femoral lines were placed during a code or medical emergency, when access to the subclavian or internal jugular veins is likely limited by other caregivers intubating the patient or performing chest compressions. In this setting, it may be difficult to avoid cannulating the femoral vein for central access.

On the other hand, we found that the mean duration of catheter placement ultimately associated with an infectious complication was 11 days, 2 days longer than the mean duration seen in other studies. Whether this indicates that central venous catheters in our study remained sterile longer or clinicians were less vigilant about working up a CR-BSI is a source of conjecture. However, it does highlight the importance of prompt removal of nonessential catheters, particularly because the mean duration of noninfected catheterization is approximately 6 days (median 4 days; range 1 to 29 days).[21] This suggests that there may be at least some room for improvement in terms of reducing the rate of CR-BSIs and in replacing emergently placed femoral catheters as soon as possible.

Our study has several strengths. This is the first study to evaluate the accuracy of PSI 7 in identifying CR-BSI in any setting. The VA system is unique in that it is not subject to financial incentives, nor is it currently tracking PSI rates, so there are no penalties or benefits for not coding or clinically documenting PSIs. Additionally, our sample was randomly drawn from a nationally representative group of VA hospitals, ensuring broad geographic representation and diversity of inpatient clinical encounters. IRR testing occurred twice during the data abstraction process and achieved a high level of agreement on both occasions. Last, physicians (AB) were available to clarify clinical issues with the nurse-abstractors as necessary throughout the abstraction process to maximize accuracy and reliability of our findings.

There are certain limitations to our study. Our population was predominately older male veterans, which may limit its generalizability. As a retrospective observational study, there is potential for selection, observation, and confounding biases. We were not able to investigate all aspects of central line placement such as use of chlorhexidine gluconate, maximal barrier protection, or hand hygiene; this information was not commonly included in the medical record. Also, we were unable to report sensitivity, specificity, or negative predictive value because we did not investigate cases that were not flagged for a CR-BSI. Finally, we relied on the completeness and accuracy of the medical record.

Future efforts should focus on investigating the validity of this indicator in more up-to-date datasets that include recently revised ICD-9-CM codes, such as 993.1, and POA codes. It would also be instructive to investigate the rate of true cases not receiving an ICD-9-CM code for CR-BSI (ie, the negative predictive value) to get a sense of how many cases of CR-BSI are not captured by administrative codes.

CONCLUSIONS

We determined that at least in the VA system, PSI 7 has poor predictive ability, with a PPV of 38%. Implementing POA codes and using newly revised ICD-9-CM codes would improve its PPV to 81%. Nonetheless, even with a moderate predictive ability of 81%, the use of PSI 7 in pay-for-performance metrics is premature; its utility for internal quality improvement or measurement should be viewed positively. Despite this, there is some evidence that the rate of CR-BSIs in this population may be at least modestly reduced, particularly through clinician vigilance regarding duration of catheterization.

Impact of a New Gender-Specific Definition for Binge Drinking on Prevalence Estimates for Women

Pollyanna R. Chavez, PhD, David E. Nelson, MD, MPH, Timothy S. Naimi, MD, MPH, Robert D. Brewer, MD, MSPH

Background: Binge drinking accounts for more than half of the 79,000 deaths due to excessive drinking in the U.S. each year. In 2006, the Behavioral Risk Factor Surveillance System (BRFSS) lowered the threshold for defining binge drinking among women from ≥5 drinks to ≥4 drinks per occasion, in accordance with national recommendations.

Purpose: To assess changes in binge-drinking prevalence among women.

Methods: The relative and absolute change in binge drinking among U.S. adult women was assessed using pooled BRFSS data from the 2 years before (2004–2005) and after (2006–2007) the implementation of the new gender-specific definition. Analyses were conducted in 2008–2009.

Results: Binge-drinking prevalence among women increased 2.6 percentage points (from 7.3% in 2004–2005 to 9.9% in 2006–2007), a 35.6% relative increase. The percentage of women who reported consuming exactly 4 drinks in 2006 (3.6%) was similar to the increase in the prevalence of binge drinking among women that was observed from 2005 to 2006 (absolute change=2.9 percentage points).

Conclusions: The new gender-specific definition of binge drinking significantly increased the identification of women drinking at dangerous levels. The change in prevalence among women was primarily due to the change in the definition and not to actual changes in drinking behavior. The new gender-specific definition of binge drinking can increase the usefulness of this measure for public health surveillance and support the planning and implementation of effective prevention strategies (e.g., increasing alcohol excise taxes).

(Am J Prev Med 2011;40(4):468–471) Published by Elsevier Inc. on behalf of American Journal of Preventive Medicine

Introduction

Binge drinking is responsible for more than half of the estimated 79,000 deaths and two thirds of the 2.3 million years of potential life lost annually due to excessive alcohol use in the U.S.[1] It is also a risk factor for many health and social problems.[2] Since the Monitoring the Future Study[3] began using a 5-drink measure for high school students in 1975, most national surveys have defined binge drinking as consuming 5 or more drinks on an occasion (or in a row) for both women and men.[4,5] The Harvard School of Public Health College Alcohol Study used a gender-specific measure of ≥5 drinks for men, and ≥4 drinks for women, because of gender differences in the risk of alcohol-related harms at these levels.[6–8] The use of a 4-drink threshold for defining binge drinking in women is justified also because women generally have a smaller stature than men and because of physiologic differences that affect the absorption and distribution of alcohol (e.g., women absorb alcohol more rapidly than men).[9]

Recognizing these differences, in 2004 the National Institute on Alcohol Abuse and Alcoholism (NIAAA) Advisory Council endorsed the use of a 4-drink threshold for defining binge drinking in women.[10] The National Epidemiologic Survey on Alcohol and Related Condi-

[a]In 2006, the BRFSS changed the threshold to define binge drinking among women from consuming ≥5 drinks on an occasion to ≥4 drinks on an occasion in the past 30 days.
BRFSS, Behavioral Risk Factor Surveillance System

tions Survey also began using 4 drinks to define binge drinking among women that year,[11] and the Behavioral Risk Factor Surveillance System (BRFSS) did so in 2006. The present study assessed the impact of the new definition on BRFSS estimates of binge drinking among women and examined whether any changes in prevalence were attributable to the new definition or to actual changes in drinking behavior of women.

Methods

Data for the present study came from the 2004–2007 BRFSS (more details available at www.cdc.gov/brfss).[12] The number of respondents ranged from 303,822 in 2004 to 430,912 in 2007, and median state response rates ranged from 50.6% to 52.7%. Data analyses were conducted in 2008–2009 using SAS-callable SUDAAN. All data were weighted to produce population-based national estimates.

Current drinkers were defined as those who reported consumption of alcohol in the past 30 days. To assess binge drinking, in 2004 and 2005 current drinkers were asked: *Considering all types of alcoholic beverages, how many times during the past 30 days did you have 5 or more drinks on an occasion?* In 2006 and 2007, the definition of binge drinking varied by gender: *Considering all types of alcoholic beverages, how many times during the past 30 days did you have [5 (for men)/4 (for women)] or more drinks on one occasion?*

To assess whether changes in binge-drinking prevalence among women were due to the adoption of a 4-drink threshold, the prevalence of binge drinking among women was compared to that of men (for whom no definition change occurred). In addition, data from another BRFSS question on the maximum number of drinks consumed by women during a drinking occasion were used to assess (1) the prevalence among women of consuming a maximum of 4 or more drinks (≥4) or 5 or more drinks (≥5) in 2005 and 2006 (before and after the new binge definition for women), and (2) the prevalence of consuming exactly 4 drinks in 2006 (when the new gender-specific binge-drinking definition was implemented).

Results

There were no significant changes in binge-drinking prevalence from 2004 to 2005, or from 2006 to 2007 among men and women (Table 1). Therefore, data were pooled for 2004–2005 and 2006–2007 and the two time periods compared. Binge-drinking prevalence for women increased from 7.3% to 9.9% (absolute increase=2.6%; relative increase=35.6%) during this time, whereas no increase was seen in binge drinking among men (Table 2).

The largest absolute increases in prevalence among women were generally among those with the highest baseline levels of binge drinking, including those aged 25–34 years, whites, those with incomes ≥$75,000, college graduates, and those who were employed (Table 2). The largest relative increases in binge-drinking prevalence were among women aged ≥45 years, those with household incomes ≥$75,000, and college graduates. Among women of childbearing age (18–44 years), binge prevalence increased from 11.3% to 14.5%.

Using data from the maximum number of drinks question, the percentage of women consuming ≥4 drinks increased slightly from 9.0% (95% CI=8.8%, 9.3%) to 9.5% (95% CI=9.2%, 9.8%) from 2005 to 2006. Furthermore, the percentage of women who reported consuming exactly 4 drinks in 2006 was 3.6% (95% CI=3.4%, 3.8%), which was similar to the increase in binge-drinking prevalence observed from 2005 to 2006 (absolute change=2.9 percentage points, 95% CI = 2.7, 3.0).

Discussion

Lowering the BRFSS threshold for defining binge drinking among women from ≥5 drinks to ≥4 drinks per occasion, in accordance with national standards,[10] increased the absolute prevalence of this behavior among U.S. women by approximately 3 percentage points, which corresponded to a one-third relative prevalence increase. Given the evidence and rationale for lowering the threshold in the first place, the new binge-drinking definition improves the ability of the BRFSS to identify women drinking at levels that increase their risk and result in impairment-level blood alcohol concentrations.[10] In addition, these analyses demonstrated that the increased prevalence was attributable to the change in the binge-drinking threshold.

The larger relative increases in binge-drinking prevalence following the adoption of the new definition among women in older age groups, with higher income levels, or with more education probably reflects the greater sensitivity of this definition for indentifying women who were drinking just below the 5-drink threshold as well as the

[a]Binge drinking among women was defined as consuming ≥5 drinks on an occasion in the past 30 days.
[b]Binge drinking among women was defined as consuming ≥4 drinks on an occasion in the past 30 days.
[c]Asian, American Indian/Alaska Native, Native Hawaiian/Pacific Islander, multiracial, other

distribution of binge-drinking intensity (i.e., the number of drinks per binge) in these populations. For example, a recent CDC study concluded that the average number of drinks per binge was lower for women than men (6.9 vs 8.3); declined with increasing age (from 9.8 to 6.4 drinks); and was lower for college graduates (6.5 drinks) and those with a household income ≥$35,000 (6.8 drinks).[13]

The current study has several limitations. BRFSS data are self-reported, and alcohol measures in particular are subject to recall bias and underestimation.[14] The 2004−2007 BRFSS surveys were land-line based, and binge drinking is more common among people who exclusively use cell phones, such as those aged 18–24 years.[15,16] The prevalence of binge drinking based on both the old and new definitions among women could not be assessed within the same year. However, indirect methods (e.g., comparison of alcohol consumption by women at the 4-drink level before and after this definitional change) strongly suggest that the increased prevalence was due to this definitional change.

These results, along with prior biological evidence of gender differences in the metabolism of alcohol,[9] suggest that changing the operational definition of binge drinking for women from 5 to 4 drinks should be considered in other settings, such as in alcohol screening protocols in primary care settings. Evidence-based prevention strategies for binge drinking, such as increasing alcohol excise taxes,[17] limiting alcohol outlet density,[18] and maintaining and enforcing age-21-years minimum legal drinking-age laws[19,20] should be widely adopted.

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the CDC.

No financial disclosures were reported by the authors of this paper.

INTRODUCTION

This update examines and summarizes the most recent data on prevention, testing, and treatment of HIV infection for the general internist. Our aims were: (1) to describe the most recent data on HIV prevention; (2) to discuss the recommendations and emerging evidence for routine HIV screening, particularly in community-based settings; (3) to interpret the most recent data on initiation and selection of antiretroviral therapy; and (4) to facilitate the application of these findings to the clinical practice of the generalist.

We performed a PUBMED search of from March 2008 through April 2010, using the Medial Subject Heading (MeSH) term "HIV," limited to English language articles focusing on human subjects. Additionally, the authors each reviewed studies published between March 2008 and April 2010 in the major internal medicine and HIV journals. We also performed targeted searches using the search terms "HIV prevention" and "HIV testing." Articles were included after review by consensus among a group of experts, all practicing HIV clinicians and researchers, if they met the following criteria: (1) offered novel findings in HIV prevention, HIV testing, or initiation of antiretroviral therapy; and (2) had the potential for direct clinical relevance to the practicing generalist. We narrowed down our selection by group consensus with the goal of presenting the eight to ten most relevant papers published since March 2008.

PREVENTION

Celum et al. Acyclovir and Transmission of HIV-1 from Persons Infected with HIV-1 and HSV-2. NEJM. 2010. 362:427-439

In HIV-1 infected populations, the seroprevalence of HSV ranges from 60-90%[1], and studies suggest that HSV may increase HIV transmission. In coinfected cells, HSV proteins bind HIV and promote transcription[2–5]. HSV reactivation is associated with increased HIV levels in blood and the genital tract,[6–9] and rates of sexual HIV transmission are markedly higher from persons with genital ulcers.[10] Additionally, several randomized clinical trials (RCTs) demonstrate that anti-HSV therapy decreases plasma HIV levels.[6,11–14]

This study is an RCT designed to evaluate the effect of daily acyclovir therapy on HIV transmission.[15] The investigators enrolled HIV serodiscordant heterosexual couples from seven sites in southern Africa and seven sites in eastern Africa. For each couple, the HIV-infected partner was seropositive for HSV, had CD4 cell count ≥250 cells/mm^3, no AIDS-related conditions, no current antiretroviral therapy, and no persistent genital ulcers. The HIV-negative partner was eligible whether HSV-negative or positive. The intervention group received acyclovir 400 mg twice daily, and the control group received an identical-appearing placebo. The primary outcome was HIV incidence. HIV sequencing was used to classify the transmission as 'linked' or 'unlinked.'

There were 3,360 discordant couples included in the final analysis. In 68% of couples, the woman was HIV-infected. The median CD4 count was 462 cells/mm^3. Sixty-eight percent of HIV-negative partners had HSV-2. There were 132 new HIV infections, corresponding to an incidence of 2.7 per 100 person-years (95% CI: 2.3 to 3.2). Eighty-four linked transmissions were included in the analysis, 41 in the acyclovir group and 43 in the placebo group (HR 0.92; 95% CI: 0.60–1.41).

The Bottom Line: Suppressive doses of acyclovir given for up to 2 years did not reduce HIV transmission, despite significantly decreased HIV viremia and symptomatic genital ulcers.

Wawer et al. Circumcision in HIV-Infected Men and Its Effect on HIV Transmission to Female Partners in Rakai, Uganda: A Randomised Controlled Trial. Lancet 2009.374:229-37

The World Health Organization (WHO) recommends male circumcision as a male HIV prevention strategy[16] on the basis of several recent RCTs that reduced HIV transmission from females to their male partners[17–19].

This study enrolled 922 HIV-infected uncircumcised men aged 15–49 years of age who were randomized to receive

Accepted November 4, 2010
Published online December 8, 2010

either immediate circumcision or circumcision delayed for 24 months[20]. One hundred sixty HIV-negative female partners were also enrolled. The primary outcome was the rate of acquisition of HIV among female partners, including all couples with at least one follow-up visit for the female partner. Seventeen of 92 (18%) women in the intervention group and 8 of 67 (12%) in the control group had incident HIV infection during the study period. Over 24 months, the cumulative probability of HIV infection was 21.7% (95% CI: 12.7–33.4) for women in the intervention group and 13.4% (95% CI: 6.7–25.8) for those in the control group. In a Cox proportional hazards regression analysis, the adjusted hazard ration (HR) was 1.49 (95% CI: 0.62–3.57; p=0.368). There were no significant differences in HIV incidence by participant characteristics or by women's self-reported risk behaviors.

The Bottom Line: The trial was stopped early because of ineffectiveness: male circumcision of HIV-infected men did not reduce transmission of HIV to female partners of HIV-infected men in this study over a 24-month period.

Van Damme et al. Lack of Effectiveness of Cellulose Sulfate Gel for the Prevention of Vaginal HIV Transmission. NEJM. 2008. 359:463-472

More than half of all adults living with HIV/AIDS in sub-Saharan Africa are women.[21] Most strides that have been made in HIV prevention (condoms, circumcision) depend largely on male cooperation. Topical microbicides offer the possibility of initiation by women. Cellulose sulfate is an entry inhibitor with in-vitro activity against HIV and demonstrated safety and tolerability. This was a randomized, double-blind, placebo-controlled trial[22] of cellulose sulfate gel for prevention of HIV.

Women who were 18 or older, had a negative HIV-antibody test and reported three or more acts of vaginal intercourse/week and three or more different partners in the previous 3 months were recruited from five sites in Africa and India. The intervention group received 6% cellulose sulfate gel and controls an identical placebo (the pH of the compounds were different). The primary outcome was incident HIV infection.

Among 1,398 women, at the prespecified interim analysis point, there were 24 new HIV infections in the cellulose sulfate group and 11 among those receiving placebo (HR: 2.23, 95% CI: 1.05–5.03, p=0.02), prompting early termination of the trial. While this suggested increased risk of HIV transmission among women using cellulose sulfate, the interim analysis did not include an additional six incident cases that had not been entered in the database. Analysis including these cases yielded HR: 1.61 (95 CI: 0.86–3.01, p=0.13). An additional pre-planned analysis censoring data from participants who interrupted cellulose or placebo use (most often due to pregnancy) yielded a HR 2.02 (95% CI 0.97–4.18, p=0.05).

In summary, there was a higher incidence of HIV in the cellulose sulfate group: however, this did not reach significance in the primary effectiveness analysis. It was noted by the investigators that there were non-differential pregnancy rates in the two groups. Given the contraceptive profile of cellulose sulfate, non-adherence might have been a factor in the observed results.

The Bottom Line: Cellulose sulfate is not effective in the prevention of vaginal HIV transmission.

Rerks-Ngarm et al. Vaccination with ALVAC and AIDSVAX to Prevent HIV-1 Infection in Thailand. N Engl J Med. 2009. 361:2209-2220

This was a multicenter community-based, randomized double-blind, placebo-controlled trial in Thailand to evaluate the efficacy of vaccines to prevent HIV.[23] The vaccine protocol consisted of a primer of a recombinant canarypox vector vaccine (ALVAC-HIV) (four injections) and two booster injections of a recombinant glycoprotein 120 subunit vaccine (AIDSVAX B/E). A total of 16,402 HIV-uninfected persons aged 18–30 years were enrolled. HIV testing was performed at baseline, 24 weeks, 26 weeks, and every 6 months for 3 years of follow-up. The primary outcomes were HIV infection and early HIV viremia.

There were 132 new HIV infections, 56 in the vaccine group and 76 in the placebo group over a total of 52,985 person-years of follow-up in the intention-to-treat analysis. This result translated to an observed efficacy of 26.4% (95% CI: -4.0–47.9, p=0.08). A modified intention-to-treat analysis excluded seven persons found to be HIV-infected at baseline. In this group, there were 125 new HIV infections, 51 in the vaccine group and 74 in the placebo group over 52,985 person-years of follow-up, corresponding to an observed vaccine efficacy of 31.2% (95% CI: 1.1–52.1, p=0.04). A per-protocol additional analysis included only those who received all scheduled vaccinations in the series, maintained eligibility in the study, and had not acquired HIV by the fourth vaccination. Among this group, there were 86 new HIV infections, 36 in the vaccine group and 50 in the placebo group in 36,720 person-years of follow-up corresponding to an observed vaccine efficacy of 26.2% (95% CI: -13.3–51.9, p=0.16).

The Bottom Line: While the intention to treat analysis demonstrated only a trend towards efficacy, after excluding those with HIV at baseline, there was a significant reduction in HIV incidence in the vaccination group. Future studies must address the immune mechanisms involved as well as whether vaccine efficacy varies over time and in certain populations.

EXPANDING HIV TESTING

Bokhour et al. Barriers and Facilitators to Routine HIV Testing in VA Primary Care. J Gen Intern Med. 2009 24:1109–14

Implementing expanded HIV testing in primary care requires an understanding of the context into which broad testing will be introduced. Bokhour and colleagues conducted focus groups with patients (N=28) and health-care providers (N=13) from primary care clinics at two US Veterans Administration facilities to better understand issues in the expansion of HIV testing.[24] Patients in the four focus groups were HIV-negative men aged 35–88 years, predominantly low income, with a range of educational backgrounds. The two provider focus groups consisted of men (N=6) and women (N=7), and included physicians, nurse practitioners, and a registered nurse.

Semi-structured group interviews led to several recurrent themes. Both patients and health-care providers felt that HIV testing should be routine. Many felt that routine testing could reduce stigma. Concerns were expressed about special written consent forms and the anxieties that they may cause. Though "normalizing" the HIV testing was a consistent theme, results showed that patients wanted to be aware that HIV testing was being done and that it should be explicitly offered, with the option to decline. They also pointed out the need for clear and prompt communication of results.

The Bottom Line: Veteran patients are likely to accept routine testing, but attention to issues of stigma and clear communication about results are important for both patients and providers. To help with patient-centered discussions, the authors developed "Six R's" for routine testing: (1) Raise the topic; (2) Reassure the patient that the offer is routine; (3) provide Rationale for the test; (4) Respond to questions; (5) Request the test; and (6) tell the patient when and how they will get Results.

Arbelaez et al. Emergency Provider Attitudes and Barriers to Universal HIV Testing in the Emergency Department. J Emerg Med. 2009 Oct 13. (Epub ahead of print)

The Centers for Disease Control and Prevention (CDC) HIV testing guidelines include emergency departments (EDs) as target locations for expanded routine HIV testing.[25] This research study surveyed ED providers before and 6 months after institution of an ED-based HIV testing program to understand attitudes toward testing and how they might change with experience.[26]

One hundred eight providers (43% nurses, 29% resident physicians, 17% attending physicians, 7% nursing assistants, and 4% physician assistants) completed both pre- and post-surveys. Before starting the HIV testing intervention in the ED, many providers identified barriers to HIV testing such as inadequate resources (70%), inadequate time (51%), and concerns about assuring follow-up (50%). After experience with the intervention, two of these barriers were more frequently reported than at baseline: inadequate time (62%) and follow-up care (59%). In multivariate modeling, female providers, providers who felt they had sufficient time to test, and providers reporting sufficient legal understanding of testing issues were more likely to favor HIV testing in the ED. While most providers favored HIV testing in general (86%), fewer supported doing it in the ED (56%), and still fewer expressed willingness to offer it themselves (37%).

The Bottom Line: For HIV testing in the ED to be substantially adopted, provider perceptions about barriers must be addressed, including concerns about inadequate time and legal ramifications of testing.

Myers et al. Routine Rapid HIV Screening in Six Community Health Centers Serving Populations at Risk. J Gen Intern Med. 2009. 24:1269–74

Federally qualified community health centers (CHC) are a crucial part of the health-care delivery system for predominantly underserved populations. In late 2006 the National Association of Community Health Centers supported the expansion of point-of-care HIV testing programs across North Carolina, South Carolina, and Mississippi. Myers and colleagues conducted a before-and-after analysis of data from six CHCs who adopted routine rapid HIV screening.[27] Efforts included redesign of patient flow, written protocol development, clinic in-service trainings, on-site technical assistance, follow-up support, and dissemination of patient educational materials.

During the year prior to program rollout, approximately 3% (N=3,078) of patients seen for care were tested for HIV. During the 13 months after rollout, 16,148 were offered testing, and 10,769 (66%) accepted. Thirty-nine persons tested positive on rapid test results, of whom 20 were confirmed HIV-positive and 17 were new HIV diagnoses. Rates of infection were lower than expected by the investigators, but still higher than thresholds disseminated by the CDC for identifying health-care settings eligible for routine testing. Twelve of the 17 newly diagnosed patients were successfully linked to HIV care. Patients who were white were significantly less likely than African-Americans or Latinos to be HIV tested, as were the oldest patients (those aged 55–64 years). While false positives occurred at rates to be expected for the rapid tests, staff were not fully prepared for false positives, and had to develop procedures for understanding and communicating the inherent uncertainty of the initial, preliminary rapid test results.

The Bottom Line: Routine point of care testing markedly increased screening rates in community health centers.

WHAT TO START IN ANTIRETROVIRAL NAÏVE PATIENTS

Table 1 summarizes the current (2009) US Department of Health and Human Services (DHHS) recommendations on which combinations of antiretroviral medications to initiate in the naïve patient.[28]

WHEN TO START ANTIRETROVIRAL THERAPY

Mari Kitahata et al. Effect of Early Versus Deferred Antiretroviral Therapy for HIV on Survival. N Engl J Med. 2009. 360:1815-1826

When to Start Consortium Timing of Initiation of Antiretroviral Therapy in AIDS-Free HIV-1-Infected Patients: A Collaborative Analysis of 18 HIV Cohort Studies. Lancet. 2009. 373:1352–63

When to start antiretroviral therapy (ART) has been an ongoing controversy.[29,30] The decision regarding when to start therapy has to balance anticipated benefits with potential side effects, impact on quality of life, and risk of therapeutic burnout and virologic resistance. Potential benefits of starting early include: modulation of the inflammatory response, lowering of the viral set point, higher rates of immune reconstitution, and use of treatment as prevention.[31,32]

Kitahata, writing for the NA-ACCORD investigators, investigated the effects of starting therapy at different levels of CD4 counts[33]. The NA-ACCORD group consists of 22 clinical cohorts in North America. They identified antiretroviral naïve

Table 1. Antiretroviral Regimens Recommended for Treatment-Naïve Patients. Adapted from Table 5a, Panel on Antiretroviral Guidelines for Adults and Adolescents. Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents, Available at: http://aidsinfo.nih.gov/contentfiles/AdultandAdolescentGL.pdf, Page 39

Preferred Regimens: (Regimens with optimal and durable efficacy, favorable tolerability and toxicity profile, and ease of use)

Non-nucleoside reverse transcriptase inhibitor -based regimen
efavirenz/tenofovir/emtricitabine†
Protease inhibitor-based regimens
atazanavir/ritonavir + tenofovir/emtricitabine†
darunavir/ritonavir (once daily) + tenofovir/emtricitabine†
Integrase strand transfer inhibitor -based regimen
raltegravir + tenofovir/emtricitabine†
Preferred regimen for pregnant women
lopinavir/ritonavir (twice daily) + zidovudine/lamivudine†

Alternative Regimens:
(Regimens that are effective and tolerable but have potential disadvantages compared with preferred regimens. An alternative regimen may be the preferred regimen for some patients.)

Non-nucleoside reverse transcriptase inhibitor -based regimens
efavirenz + (abacavir or zidovudine)/lamivudine†
nevirapine + zidovudine/lamivudine†
Protease inhibitor-based regimens
atazanavir/ritonavir + (abacavir or zidovudine)/lamivudine†
fosamprenavir/ritonavir (once or twice daily) + either [(abacavir or zidovudine)/lamivudine†] or tenofovir/emtricitabine†
lopinavir/ritonavir (once or twice daily) + either [(abacavir or zidovudine)/lamivudine†] or tenofovir/emtricitabine†
saquinavir/ritonavir + tenofovir/emtricitabine†

Acceptable Regimens:
(Regimens that may be selected for some patients but are less satisfactory than preferred or alternative regimens.)

Non-nucleoside reverse transcriptase inhibitor -based regimen
efavirenz + didanosine + (lamivudine or emtricitabine)
Protease inhibitor-based regimen
Atazanavir + (abacavir or zidovudine)/lamivudine†

Comments:
Efavirenz should not be used during the first trimester of pregnancy or in women trying to conceive or not using effective and consistent contraception.
Atazanavir/ritonavir should not be used in patients who require >20 mg omeprazole equivalent per day.
Nevirapine:
- Should not be used in patients with moderate to severe hepatic impairment
- Should not be used in women with pre-ARV CD4 >250 cells/mm^3 or men with pre-ARV CD4 >400 cells/mm^3

Abacavir:
- Should not be used in patients who test positive for HLA-B*5701
- Use with caution in patients with high risk of cardiovascular disease or with pretreatment HIV-RNA >100,000 copies/mL

Once-daily lopinavir/ritonavir is not recommended in pregnant women.

Efavirenz + didanosine + emtricitabine or lamivudine has only been studied in small clinical trials.
Atazanavir/ritonavir is generally preferred over unboosted atazanavir. Unboosted atazanavir may be used when ritonavir boosting is not possible.

†*lamivudine may substitute for emtricitabine or vice versa. Abbreviations: ARV=antiretroviral*

patients who began therapy at CD4 counts greater than 500 cells/mm^3, at CD4 counts between 350 and 500 cells/mm^3, and patients who chose to defer therapy between 1996 and 2006. The main outcome was survival comparing earlier therapy (at either greater than 500 cells/mm^3 or between 350 and 500 cells/mm^3) with deferred therapy. At both levels, deferred treatment was associated with increased death rates [500 cells/mm^3: RR 1.94; 95% CI, 1.37 to 2.79, 350–500 cells/mm^3: RR: 1.69; 95% confidence interval (CI), 1.26 to 2.26].

Evidence supporting starting ART above 350 cells/mm^3 was also recently released by the ART-Cohort Collaboration.[34] They found an increased hazard of death (HR 1.28, 95% CI 1.04–1.57) for starting ART in the 250–350 cells/mm^3 CD4 count range versus 350–450 cells/mm^3. It should be noted that patients with a history of injection drug use were excluded from this study, which may account for the lower hazard ratio. The ART-CC study did not observe a benefit of starting above 450 cells/mm^3, and it is unclear why there is a discrepancy at this higher range. Even larger differences were seen for comparisons with lower CD4 counts at time of treatment initiation.

Because both of these studies are based on observational cohort data, the potential for unmeasured confounders exists. ART initiation is no doubt strongly associated with health status, physician expectations, and patient health seeking behaviors. Both studies adjusted for or excluded patients with a history of injection drug use as a major potential confounder. The NA-ACCORD investigators performed a sensitivity analysis that found a large confounder effect would be needed to reduce or negate their findings. However, an effect of this magnitude was uncovered by the Women's Health Initiative trial of hormone replacement therapy in primary prevention of coronary heart disease compared to prior observational cohort studies.[35] An RCT of ART, the Strategic Timing of AntiRetroviral Treatment (START) trial, is underway and may help to establish the validity of the guidelines.

The Bottom Line: Antiretroviral therapy should be initiated once the CD4 declines below 500 cells/mm^3 and may be beneficial at CD4 counts above 500 cell/mm^3.

Summary and Implications for Practice

Prevention.

- Much work remains to be done, particularly regarding methods initiated and controlled by women, as well as prevention of transmission between serodiscordant couples. Further work is needed to evaluate sexual transmission prevention strategies among men who have sex with men.
- These studies highlight the importance of continuing to recommend condom use as a proven HIV prevention strategy.
- Further research on optimal vaccination regimens, immune responses to vaccination, and the safety and efficacy of vaccinations in specific target populations is still needed.

Testing.

- Routine point of care testing can markedly increase screening rates.
- Attention to issues of stigma and clear communication about results are important for both patients and providers.
- Provider perceptions must be addressed, including concerns about inadequate time and legal ramifications.

Initiation of Treatment. The studies presented both favor earlier treatment in the 350–500 cells/mm^3 range and possibly above. The combined data have led to a change in DHHS Guidelines[28]:

- As before, ART should be initiated if the CD4 count is less than 350 cells/mm^3 or in cases of pregnancy, HIV-

associated nephropathy, and hepatitis B virus (HBV) coinfection when treatment of HBV is indicated.

- Now, the expert panel recommends starting therapy between 350–500 cells/mm^3 and is divided on therapy at CD4 counts above 500 cells/mm^3 with 50% in favor and 50% viewing it as optional.
- It is important to note that most patients are diagnosed with a CD4 under 350 cells/mm^3. Increased adoption of routine testing may identify those with HIV at earlier CD4 counts.

Detecting Patient Safety Indicators: How Valid Is "Foreign Body Left During Procedure" in the Veterans Health Administration?

Qi Chen, MPH, Amy K Rosen, PhD, Marisa Cevasco, MD, MPH, Marlena Shin, JD, MPH, Kamal MF Itani, MD, FACS, Ann M Borzecki, MD, MPH

BACKGROUND: The Agency for Healthcare Research and Quality (AHRQ) developed patient safety indicator (PSI) 5, "Foreign body left during procedure," to flag accidental foreign bodies in surgical and medical procedures. This study examined how well this indicator identifies true foreign body events in the Veterans Health Administration (VA).

STUDY DESIGN: This was a retrospective study within 28 selected VA hospitals from fiscal year 2003 to 2007. Trained abstractors reviewed medical charts flagged by PSI 5 and determined true foreign body cases. We calculated the positive predictive value (PPV) of this indicator and performed descriptive analyses of true positive and false positive cases.

RESULTS: Of the 652,093 eligible cases, 93 were flagged by PSI 5 (0.14 per 1,000). Forty-two were true positives, yielding a PPV of 45% (95% CI 35% to 56%). False positives were due to a foreign body that was present on admission (57%) or coding errors (43%). True foreign bodies were associated with surgical (n = 23) and medical (n = 19) procedures. The most common type of surgical foreign body was a sponge (52%). Overall, approximately 40% of foreign bodies were related to a device failure or malfunction (30% surgical vs 53% medical foreign bodies). Postoperative complications included pain (24%), infection (12%), adhesions (5%), and bowel obstruction (5%).

CONCLUSIONS: The reported rate of foreign body events as detected by PSI 5 is low in the VA, but occurs in both surgical and medical procedures. Despite widespread implementation of surgical counts, quality improvement efforts should focus on novel ways to eliminate this "never event" from operations. Future studies are needed to better understand the preventability of medical procedure-associated foreign bodies and particularly, device failure-related foreign bodies. (J Am Coll Surg 2011;212:977–983. © 2011 by the American College of Surgeons)

According to the National Quality Forum (NQF), a "foreign body" unintentionally left in a patient during a procedure is one of the serious reportable events (ie, NQF "never events").[1] It is a rare event, with an estimated incidence rate of 1 in 5,000 operations,[2,3] but has a reported mortality rate as high as 11% to 35%.[4] Risk factors associated with this event include incorrect counts, surgical team transitions, multiple procedures,[5] unplanned changes in the operation, the emergent nature of procedure, and high body mass index.[6] Theoretically, foreign body events can be eliminated by instituting standardized processes of care such as surgical counts of sponges and instruments before and at the end of each operation. However, despite widespread adoption of standardized processes, foreign body events still occur.

Given its potential preventability, the Agency for Healthcare Quality and Research (AHRQ) developed patient safety indicator (PSI) 5, "Foreign body left during procedure," to detect foreign body events using adminis-

POA = present on admission
PPV = positive predictive value
PSI = patient safety indicator
VA = Veterans Health Administration

trative data. This indicator is defined as discharges with ICD-9-CM codes for foreign body left in during a procedure in any secondary diagnosis field of surgical and medical discharges. ICD-9-CM codes for foreign body used in this PSI include 998.4 (foreign body accidentally left during a procedure not elsewhere classified), 998.7 (acute reaction to foreign substance accidentally left during a procedure not elsewhere classified), and external cause of injury codes (E-codes) E871.x (foreign object left in body during procedure).[7] Similarly, the Centers for Medicare and Medicaid Services (CMS) is currently using an administrative data-based measure (hospital acquired conditions, also known as CMS "never events") to track rates of foreign bodies associated with surgical procedures.[8] However, PSI 5 is the only indicator that flags both surgical and medical foreign bodies.

The accuracy of PSI 5 in identifying true events is unknown. Such information is necessary if this measure is to be used to improve the quality of care. The purpose of this study was to evaluate the positive predictive value (PPV) of this indicator in the Veterans Health Administration (VA) (ie, to evaluate the degree to which the PSI flagged case represents a true foreign body based on data obtained from the medical record). To our knowledge, this is the first study to validate this indicator. We also aimed to examine clinical circumstances and outcomes associated with these true foreign body events.

METHODS

Study design

This was a retrospective observational study using VA inpatient administrative data and electronic medical record (EMR) data from VA fiscal years 2003 to 2007 (from October 1, 2002 to September 30, 2007).[9,10] The required Institutional Review Board approvals from the Bedford VA Medical Center and the VA Boston Healthcare System were obtained for this study.

Study population

We applied the PSI software, version 3.1a, to the VA inpatient dataset to obtain counts of individual PSIs and composite rates. We then selected 28 of 158 VA acute-care hospitals using a stratified sampling method to obtain a diverse sample of VA hospitals. Full details of sampling are provided elsewhere.[9]

PSI 5 technical specifications (v. 3.1)

The denominator of this indicator includes all medical and surgical discharges of patients age 18 or older except for patients with ICD-9-CM codes for foreign body left in during procedure (998.4, 998.7, or E871.x) in the principal diagnosis field or secondary diagnosis present on admission. The numerator includes any discharges with ICD-9-CM codes for foreign body in any secondary diagnosis field among cases meeting the inclusion and exclusion rules for the denominator.[7]

Medical record abstraction

Two trained nurses used standardized abstraction instruments modified from AHRQ-developed instruments to review selected EMRs for the occurrence of a foreign body event and to obtain patient demographics.[9,10] If a foreign body event occurred (ie, a true positive), records were further abstracted for risk factors, clinical circumstances surrounding the procedure associated with the foreign body, and patient outcomes. If no foreign body event occurred (ie, a false positive), abstraction stopped once the reason for exclusion was determined. To assess inter-rater reliability (IRR), both nurses reviewed the same records in groups of 5 until they achieved an average observed agreement of at least 90% across all questions (n = 41) in all records, after which abstraction proceeded independently. IRR was also assessed on 5 charts toward the end of the abstraction process to make sure abstractor reliability did not drift. Further details of the abstraction process are available elsewhere.[9]

Specific to this PSI, we performed 2 early rounds of IRR assessment in order to have enough records to adequately evaluate all questions. Average observed agreement for these 2 rounds combined was 96%. Agreement on late IRR testing was 98%.

Analysis

We calculated PPV as the rate of true positives divided by the total number of flagged cases and derived 95% confidence intervals. We also examined the PPVs of ICD-9-CM codes 998.4, 998.7, and the group of E-codes separately, due to concerns regarding the validity of E-codes in previous.[11,12] We reviewed demographics (age, sex, race and eth-

Table 1. Positive Predictive Values (PPVs) Based on Different Foreign Body ICD-9-CM Codes

ICD-9-CM code(s)	True positives flagged by this code(s), n	False positives flagged by this code(s), n	Positive predictive value, %	95% CI
Overall	42	51	45	35–56
Overall without E871.x	36	37	49	37–61
998.4 only	22	20	52	36–68
998.7 only	1	5	17	0–64
E871.x only	6	14	30	12–54

nicity) in the total sample of 93 patients. Specific to false positives, we examined the type of foreign bodies and the reasons why they were incorrectly flagged by the PSI algorithms. For true positives, we performed descriptive analyses of continuous and categorical variables, including characteristics of foreign bodies, nature of the procedures, risk factors, and patient outcomes, based on whether the foreign body was associated with a surgical or a medical procedure. All statistical analyses were performed using SAS version 9.1 (SAS Institute, Inc).

RESULTS

Across all VA hospitals, a total of 290 foreign body cases out of 2,342,690 eligible discharges were flagged by PSI 5 (0.12 per 1,000); within the 28 selected hospitals, 93 of 652,093 eligible discharges were flagged (0.14 per 1,000). Of the 93 flagged cases, 42 were true positives, yielding a PPV of 45% (95% CI 35% to 56%). ICD-9-CM code 998.4 had a higher PPV (52%) than both ICD-9-CM code 998.7 (17%) and the E-codes (30%), although the confidence intervals overlapped. The overall PPV increased to 49% when we excluded E-codes (Table 1).

Demographics

Flagged patients had an average age of 67 years (SD 11 years) and a median length of stay of 7 days (range 1 to 91 days). Ninety-two patients were male and 73% were white. Demographic characteristics were similar in true positives and false positives (Table 2).

Reasons for false positives

Of the 51 false positives, 29 (57%) were foreign bodies that were present on admission (POA) and 22 (43%) had no documentation of an accidental foreign body event in the EMR during the index hospitalization. Of these 22 cases, 5 false positives represented intentional foreign bodies; 2 (4%) of these had laparotomy pads intentionally left in and 3 had "feeding tubes" (ie, percutaneous endoscopic gastrostomy tubes) inserted. We did not find any evidence of foreign bodies in the other 17 cases. Foreign bodies that were POA included sponges, pads, and fragments of guidewires, drains, and leads— similar to the foreign body types in true positives.

To better understand the accuracy of each individual ICD-9-CM code (998.4, 998.8, and E871.x), we further analyzed the false positive cases flagged by 998.7 or E871.x separately. Of the 5 false positives flagged only by ICD-9-CM code 998.7 ("acute reaction to foreign substance accidentally left during a procedure not elsewhere classified"; Table 1), 2 were POA, and the other 3 were "feeding tubes" that did not cause any postoperative complications. Fourteen false positives were flagged only by external cause-of-injury code E871.x, "foreign object left in body during procedure." (Note that "accidentally or unintentionally" is not incorporated into this definition.) Of these 14 false positives, 10 patients had no evidence of an accidental foreign body, and 1 patient had 3 laparotomy pads intentionally left in an open abdomen to ensure hemostasis during surgery. (Note that the other patient who had laparotomy

Table 2. Patient Demographics (n = 93)

Variable	All flagged cases (n = 93)	True positives (n = 42, 45%)	False positives (n = 51, 55%)

pads intentionally left in was flagged by ICD-9-CM code 998.4.)

True positive analyses

Of the 42 true positives, 23 foreign bodies (55%) were related to a surgical procedure; 15 (61%) of these were related to an abdominopelvic procedure. Twenty-one surgical foreign bodies were associated with the original operation, and the other 2 foreign bodies (drain fragments) occurred during postoperative drain removal. Sponges were the most common type of foreign body left behind during surgical procedures (n = 12, 52%); the remainder were instrument or device fragments (Foley tips, drill tips, a steel fragment from a resectoscope, and drain fragments). All surgical procedures had documentation of correct surgical counts (sponge, instrument, and sharp counts) except 4, which documented a disagreement in counts (1 in the final sponge count and 3 in the final instrument count). Intraoperative radiologic survey was performed in these 4 discrepant count cases, and in 3 other cases based on surgeon's concern. Overall, 9 foreign bodies (39%) were discovered at the time of procedure (7 by intraoperative radiologic survey, 1 by surgeon's manual exploration of surgical site, and 1 drain fragment that was discovered immediately after drain removal). Of the 8 foreign bodies that were detected during the original operation, 4 were discovered before skin closure and 4 afterwards. However, only 2 foreign bodies were removed before the patient left the operating room; the rest (n = 6) were left in the patient and scheduled for removal in subsequent procedures based on the surgeon's decision (eg, the patient was hemodynamically unstable and required additional stabilization before object retrieval). Among the other 14 true positives (61%) who had foreign bodies discovered postoperatively, 7 were discovered during investigation of symptoms, 6 were discovered during routine postoperative screening in patients with no symptoms, and 1 was discovered incidentally during a subsequent operation. Seven of the surgical foreign bodies (30%) were related to device failure or malfunction (an instrument broke during the procedure or a device fragment was accidentally left in patient) (Table 3).

The remaining true positives (n = 19) were related to a medical procedure, including cardiac catheterization (n = 12), central line placement (n = 3), and pacemaker placement (n = 2). The most common types of foreign bodies were guidewires or guidewire fragments (n = 13, 68%). Ten of these (53%) were related to device failure or malfunction. Eleven foreign bodies (58%) were discovered at the time of procedure (the physician found part of the instrument was missing when he or she pulled it out) (Table 4).

Patient symptoms related to retained foreign bodies included pain (n = 10), infection (n = 5), adhesions (n = 2), and bowel obstruction (n = 2) (Table 5). Two patients died during the index hospitalization, but neither death was due to the retained foreign body.

Table 3. Characteristics of Foreign Body and Procedure in Surgical Procedure Related True Positives (n = 23)

Variable	n	%
Type of surgical foreign body		
Sponge or gauze	12	52
Instrument or device fragments (Foley tips, drill tips, and a steel fragment from a resectoscope)	7	30
Drain fragments	2	9

*1) The basket used to retrieve kidney stone; 2) A piece of tape from camera drape during esophagectomy.
†Three radiology studies were performed before skin closure, 4 were after.
‡1) Video-assisted thoracic surgery converted to thoracotomy; 2) unplanned splenectomy; 3) laparoscopic converted to open cholecystectomy.

DISCUSSION

"Unintentionally retained foreign body" was a rare event in the VA. The reported rate of this safety event by PSI 5 was 0.14 per 1,000 cases in the 28 sample hospitals and 0.12 per 1,000 cases across all VA hospitals. As the first study to examine the accuracy of the AHRQ PSI 5, "foreign body left during procedure," we found that the PPV (45%) of this indicator was relatively low compared with other examined PSIs.[9,10]

Table 4. Characteristics of Foreign Body and Procedure in Medical Procedure Related True Positives (n = 19)

Variable	n	%
Type of medical foreign body		
Guidewire or guidewire fragment	13	68
Other instrument fragments	5	26
Stent	1	5

Procedure was performed on weekend or weekday night	3	16
Foreign body related to device failure or malfunction	10	53

*We collected only the ranking of physicians in medical procedures.

The reasons for false positives were due to conditions being POA (57%) and coding errors (43%). Such a high rate of POA conditions highlights the need to implement POA codes in the VA; the frequency of coding errors underscores existing concerns about coding accuracy, particularly the validity of E-codes.[11,12] Presumably because of such concerns, only codes 998.4 and 998.7 are used for the CMS hospital-acquired condition measure, "foreign object obtained after surgery." This measure also assumes that POA coding is in place and being implemented correctly.[8] Assuming appropriate POA coding and using only the 998.x codes, the PPV of PSI 5 in our study would have increased to 80%, a more moderate PPV.

Our detailed review of false positive cases raised some additional concerns about coding. First, it is unclear whether VA coders are familiar with how to use these foreign body codes. For example, we found that 1 patient had 3 laparotomy pads intentionally left in the open abdomen to ensure hemostasis, but it was coded as an accidental foreign body event. It might be difficult for a coder to determine whether a foreign body was intentionally or unintentionally left in a patient if he or she did not have a strong clinical and/or surgical background or the medical record did not provide explicit details about the scenario. Second, implementation of POA codes in the VA would undoubtedly improve the validity of PSI 5 for detecting true in-hospital events. However, one might argue that from the perspective of measuring performance, it is also important to capture foreign bodies that are POA, because they might reflect true complications of care that occurred during a previous admission or in the outpatient setting. For example, in our false positive review, we found a patient who underwent low anterior resection of the rectosigmoid at Hospital A. After discharge he developed low-grade fevers and left upper quadrant abdominal pain. On return to the hospital 1 month later for a follow-up examination, an abdominopelvic CT showed a retained sponge in his left upper quadrant. He was admitted and brought to the operating room to remove this foreign body. After implementing POA codes in the VA, this case would not be flagged as a foreign body event. However, it is a true safety event that occurred in Hospital A, and should be counted when we evaluate the performance of this facility.

In the true positive review, despite seemingly universal compliance with manual counting protocols for sponges in VA, we still found 12 cases of sponges left in a patient during an operating room procedure when pre- and post-sponge counts supposedly "agreed." This highlights the issue of "false correct counts" (final counts erroneously thought to be correct), suggesting human error in surgical counts. Previous studies have also found other types of human errors in surgical counts.[5,6,13,14] For example, Greenberg and colleagues[14] found that 1 in 8 operations involved at least 1 counting discrepancy (defined as "any instance in which a subsequent count does not agree with a previous one") while they were observing procedures in the operating room, and 41% of these discrepancies were due to miscounting (disagreements between pre- and post-counts that are due to an error in counting). Study authors

suggested that technological solutions may be needed to reduce such surgical count errors. They subsequently conducted a clinical trial with cost-effectiveness analysis, showing that bar-coding of sponges can improve the detection of miscounted and misplaced sponges in operations at an acceptable cost.[15,16] Although more research needs to be done, technological solutions may be one way to reduce foreign body events, at least in surgical settings.

Although surgical foreign bodies, such as sponges left behind, may be eliminated either by standardized counting or introduction of some of the available technologies to track sponges, we found that almost 40% of all foreign bodies (both surgical and medical foreign bodies) were related to a device failure or malfunction. For example, one patient had a Foley catheter placed before arthroscopic shoulder surgery. The Foley balloon broke and a missing portion (about 0.25 × 0.25 inch) was accidentally left in the patient. Device-related foreign body events occurred more often in medical (n = 10) than surgical (n = 7) procedures. Although previous studies have shown the general public health burden of adverse events associated with medical devices,[17-19] none of these have focused on foreign body events. This study was the first to examine device-associated foreign bodies; our results underscore a concern about the preventability of this type of foreign body event. Although operator inexperience may be one of the reasons for device failure or malfunction, it is hard to determine if a sheared-off guidewire occurred due to physician error or other factors. It will be difficult to prevent such device-associated foreign body events if we cannot clearly identify the reason for device failures.

This was also the first study to examine foreign body events related to medical procedures. Although quality improvement efforts should focus on both medical and surgical procedures, further research is necessary to determine the degree to which these medical foreign body events (and as noted, those associated with device failure) are preventable. Until such information is available, any public reporting of foreign body events, as CMS is doing, should be limited to events associated with surgical procedures.[8]

Notably, the timing of the foreign body event is one of the key components in defining a true event. In this study, 2 foreign bodies discovered after surgical site closure but before leaving the operating room were deemed to be true positives based on the AHRQ definition. Surgical studies usually do not recognize this type of scenario as a true event, because the patient was still in the operating room and therefore the procedure was not officially completed.[6,13,14,20] These 2 cases highlight the discrepancy between the surgical and AHRQ definitions of foreign body. Further discussion and clarification may be needed to ensure that the definition of a foreign body event is consistent across coders, surgeons, and health service researchers, especially in comparing provider performance.

As with any study, there are some inherent limitations. We do not report the sensitivity, specificity, or negative predictive value of this PSI because we did not examine patients who were not flagged by PSI 5. Furthermore, all the data used in this study were abstracted from the EMR, where providers may not completely document all relevant clinical details related to the hospitalization. However, as discussed earlier, the strengths of this study are that it is the first to examine the PPV of this PSI, examine foreign body events occurring outside the operating room, and report on foreign body events associated with device failures. There are study design strengths as well: we selected a nationwide representative sample of VA hospitals; we performed explicit review of the EMR to collect data; high abstractor agreement was obtained in IRR tests; false positives were reviewed to identify ways to improve the validity of this PSI; and we examined true positives in detail to try to determine the preventability of this safety event.

CONCLUSIONS

Based on the reported rate of PSI 5, a foreign body unintentionally left in a patient is a rare event in the VA. However, it occurs in both surgical and medical procedures. Because both NQF and CMS have defined a surgical foreign body as a "never event," quality improvement efforts should focus on novel ways of eliminating unintentionally retained foreign bodies. Although medical procedure-associated foreign bodies are also considered as "never events" by NQF, future studies are needed to better understand the preventability of medical foreign bodies, and particularly device failure-related foreign bodies.

Circulating Testosterone and SHBG Concentrations Are Heritable in Women: The Framingham Heart Study

A. D. Coviello, W. V. Zhuang, K. L. Lunetta, S. Bhasin, J. Ulloor, A. Zhang, D. Karasik, D. P. Kiel, R. S. Vasan, and J. M. Murabito

Sections of Preventive Medicine and Epidemiology (A.D.C., R.S.V.), Endocrinology, Diabetes, and Nutrition (A.D.C., S.B., J.U., A.Z.), and General Internal Medicine (J.M.M.), Department of Medicine, Boston University School of Medicine, and Department of Biostatistics (W.V.Z., K.L.L.), Boston University School of Public Health, Boston, Massachusetts 02118; Institute for Aging Research (D.K., D.P.K.), Hebrew SeniorLife, Harvard Medical School, Boston, Massachusetts 02131; and Framingham Heart Study (K.L.L., R.S.V., J.M.M.), Framingham, Massachusetts 01702

Context: Many factors influence the concentration of circulating testosterone and its primary binding protein, SHBG. However, little is known about the genetic contribution to their circulating concentrations in women, and their heritability in women is not well established.

Objective: Our objective was to estimate the heritability of circulating total testosterone (TT), free testosterone (FT), and SHBG in women in families from the Framingham Heart Study.

Methods: Women in the Framingham Heart Study who were not pregnant, had not undergone bilateral oophorectomy, and were not using exogenous hormones were eligible for this investigation. TT was measured using liquid chromatography tandem mass spectrometry and SHBG using an immunofluorometric assay (Delfia-Wallac), and FT was calculated. Heritability estimates were calculated using variance-components methods in Sequential Oligogenic Linkage Analysis Routines (SOLAR) and were adjusted for age, age^2, body mass index (BMI), BMI^2, diabetes, smoking, and menopausal status. Bivariate analyses were done to assess genetic correlation between TT, FT, and SHBG.

Results: A total of 2685 women were studied including 868 sister pairs and 688 mother-daughter pairs. Multivariable adjusted heritability estimates were 0.26 ± 0.05 for FT, 0.26 ± 0.05 for TT, and 0.56 ± 0.05 for SHBG ($P < 1.0 \times 10^{-7}$ for all). TT was genetically correlated with SHBG [genetic correlation coefficient (ρG) $= 0.31 \pm 0.10$] and FT ($\rho G = 0.54 \pm 0.09$), whereas SHBG was inversely correlated with FT ($\rho G = -0.60 \pm 0.08$).

Conclusion: Circulating TT, FT, and SHBG concentrations in women are significantly heritable, underscoring the importance of further work to identify the specific genes that contribute significantly to variation in sex steroid concentrations in women. The strong shared genetic component among pairs of TT, FT, and SHBG concentrations suggests potential pleiotropic effects for some of the underlying genes. **(*J Clin Endocrinol Metab* 96: E1491–E1495, 2011)**

Sex steroids are essential for normal sexual differentiation and reproductive health across the lifespan. Sex steroids influence many age-related chronic diseases in women including osteoporosis (1), metabolic syndrome (MetS) (2, 3), type 2 diabetes (T2DM) (2, 4, 5), and cardiovascular disease (CVD) (6, 7). The relationship between sex steroids and chronic disease is affected by changes in hormone profiles in women, particularly with menopause.

Testosterone and its primary binding protein, SHBG, mediate sex-hormone-sensitive phenotypes in women. Higher circulating testosterone has been associated with incident T2DM (4) and CVD (8). Lower SHBG has been associated with MetS and T2DM (4, 9, 10), whereas higher SHBG has been associated with greater risk for hip fracture (1).

Although circulating testosterone and SHBG are affected by many environmental factors including obesity, smoking, insulin resistance, and T2DM (11), they are believed to be at least partially heritable. In men, heritability estimates range from 25–75% for testosterone and 30–50% for SHBG (12–14). In contrast, little is known about the genetic influences of circulating sex hormones in women. One study estimated the heritability of total testosterone at 39% and SHBG at 56% in postmenopausal sisters and twins (15). The purpose of this investigation was to estimate the heritability of circulating total and free testosterone and SHBG in adult women in families from the Framingham Heart Study (FHS), a multigenerational population-based study.

Subjects and Methods

Study population

The FHS design and participants have been described in detail previously (16). In brief, the FHS recruited a population-based sample of men and women residing in Framingham, MA, in 1948 (n = 5209) with the purpose of prospectively studying CVD. In 1971, children of the original cohort and their spouses were recruited as a second generation (the Offspring Study). In 2002, children of the Offspring cohort were recruited as a third generation. Women from Generation 2 and Generation 3 aged 19 and above with sex steroid hormone measurements were eligible for this study. Women taking estrogens, progestins, and androgens or who were pregnant or had undergone bilateral oophorectomy were excluded. All participants signed informed consent before participation in the FHS. The study was approved by the institutional review board at Boston University Medical Center.

All blood samples were collected in the morning, usually between 0730 and 0930 h after participants fasted approximately 10 h overnight. Samples were aliquoted, frozen, and stored at −80 C. Samples used for testosterone and SHBG measurements were not thawed previously.

Assay measurements

Total testosterone was measured by liquid chromatography tandem mass-spectrometry (17). Mass spectrometry was performed using TSQ Thermo-Finnigan Quantum Ultra (Thermo Fisher Scientific, Waltham, MA). The functional limit of detection, defined as the lowest concentration detected with less than 20% coefficient of variation, was 2 ng/dl. Cross-reactivity with other steroids including dehydroepiandrosterone/dehydroepiandrosterone sulfate, androstenedione, and estradiol was negligible. SHBG was measured with a two-site directed immunofluorometric assay with sensitivity of 0.5 nM and less than 0.1% cross-reactivity with other circulating proteins (Delfia-Wallac, Inc., Turku, Finland). Free testosterone was calculated from total testosterone and SHBG using the law of mass action equations (18).

Statistical analysis

Serum hormones were transformed by rank normalization to minimize skew. Covariates considered in the analysis included age, age^2, body mass index (BMI), BMI^2, T2DM, smoking, and menopausal status. Covariates were defined as follows: T2DM, fasting blood sugar of at least 126 mg/dl or use of diabetes medications; current smoking, yes/no; and postmenopause, at least 1 yr without menses. SAS version 9.1 (SAS Inc., Cary, NC) was used. SOLAR (Sequential Oligogenic Linkage Analysis Routines) statistical software was used to estimate heritability (19). All family relationships including first-degree relatives (mother-daughter, sister-sister pairs) and extended family relationships (aunt-niece, cousins) were analyzed. Heritability estimates were adjusted for the same covariates across all models. Heritability estimates for free and total testosterone were also adjusted for SHBG to assess for genetic influences independent of SHBG. Bivariate analyses were used to examine the genetic correlation between circulating testosterone and SHBG and were adjusted for the above covariates.

Results

The 2685 women studied included first-degree relatives (868 sister-sister, 688 mother-daughter pairs) and extended family relationships (Table 1). The older, predominantly postmenopausal Generation 2 women had higher BMI (28 ± 6 *vs.* 26 ± 6 kg/m^2) and more T2DM (10 *vs.* 2%) than the younger, predominantly premenopausal Generation 3. SHBG was higher in Generation 3, whereas free testosterone was slightly higher in Generation 2.

Heritability estimates (Tables 2 and 3)

Total and free testosterone as well as SHBG showed strong heritability after adjusting for age, BMI, T2DM, current smoking, and menopausal status (Table 2). Both total and free testosterone showed heritability estimates of 0.26 (SE = 0.05). SHBG heritability was estimated at 0.56

TABLE 1. Characteristics of women from the Offspring and Generation 3 cohorts of the FHS

	Offspring Generation 2	Generation 3
Sample (n)	1071	1614
Age (yr)	62 ± 10	41 ± 8
BMI (kg/m^2)	28 ± 6	26 ± 6
Postmenopause (%)	80	10
Smoker (%)	12	16
Diabetes (%)	10	2
Total testosterone (ng/dl)	32.1 ± 21.8	27.9 ± 15.3
Free testosterone (pg/ml)	3.6 ± 2.4	2.9 ± 1.9
SHBG (nmol/liter)	74.2 ± 38.8	87.2 ± 46.6

TABLE 2. Heritability of total and free testosterone and SHBG in adult women from the FHS Generations 2 and 3: univariate analysis

	Total testosterone	SHBG	Free testosterone
n	2671	2677	2671
h^2 (SE)	0.263 (0.053)	0.556 (0.052)	0.259 (0.052)
P value	1.00×10^{-7}	7.29×10^{-30}	3.25×10^{-8}
SHBG-adjusted analysis[a]			
n	2671		2671
h^2 (SE)	0.246 (0.053)		0.203 (0.052)
P value	3.00×10^{-7}		1.24×10^{-5}

Covariates included age, age^2, BMI, BMI^2, menopausal status, diabetes, and current smoking. h^2, Heritability estimate.

[a] Total and free testosterone heritability estimates adjusted for circulating SHBG in addition to age, age^2, BMI, BMI^2, menopausal status, diabetes, and current smoking.

(SE = 0.05). Heritability estimates of circulating free and total testosterone remained significant after adjustment for SHBG: free testosterone heritability was 0.20 (SE = 0.05) and total testosterone heritability was 0.25 (SE = 0.05).

Bivariate analyses (Table 3) showed significant genetic correlation between total testosterone and SHBG [genetic correlation coefficient (ρG) = 0.31; SE = 0.10; $P = 3.32 \times 10^{-3}$] after adjustment for age, BMI, T2DM, current smoking, and menopausal status. Total and free testosterone were also highly genetically correlated (ρG = 0.54; SE = 0.09; $P = 1.69 \times 10^{-3}$) as would be expected because free testosterone, a small fraction of total testosterone concentrations, is calculated from total testosterone and SHBG. SHBG was inversely genetically correlated with free testosterone (ρG = −0.60; $P = 1.93 \times 10^{-8}$), suggesting that specific genes may have opposite effects on their circulating concentrations. Estimates of environmental influences on circulating SHBG and free testosterone were inversely correlated as well (environmental correlation, ρE = −0.37; SE = 0.05; $P = 2.23 \times 10^{-8}$), suggesting that environmental influences may affect SHBG and free testosterone in opposite directions.

The derived phenotypic correlation, ρP, between SHBG and free testosterone is −0.44 (Table 3), which is consistent with the correlation of the two hormones circulating concentrations (Pearson correlation = −0.41, $P < 0.0001$).

TABLE 3. Heritability of total and free testosterone and SHBG in adult women from the FHS Generations 2 and 3: bivariate analysis

	Total testosterone and SHBG	Total testosterone and free testosterone	SHBG and free testosterone
n	2677	2671	2677

Covariates included age, age^2, BMI, BMI^2, menopausal status, diabetes, and current smoking. ρE, Environmental correlation; ρG, genetic correlation; ρP = phenotypic correlation; Ho, null hypothesis.

Discussion

We have shown that total and free testosterone and SHBG are moderately to highly heritable (26–56%) in white women of European ancestry in the FHS. Furthermore, circulating total testosterone and SHBG are genetically correlated, suggesting that the two are influenced by common genes or that genetic influences on SHBG may indirectly influence total testosterone given that SHBG is testosterone's primary binding protein. Free testosterone and SHBG are inversely genetically correlated, suggesting that genes may influence them in opposite directions, which is consistent with the inverse correlation of their circulating concentrations. Given the importance of testosterone and SHBG for both reproductive and nonreproductive health in women, further analyses of the genetic influences of circulating testosterone and SHBG are needed to elucidate risk factors for the diseases influenced by these hormones, particularly osteoporosis, MetS, T2DM, and CVD.

Women experience a rapid decline in estrogen production at the time of menopause. In contrast, testosterone declines at a relatively stable rate across the menopause (20). The menopausal transition is associated with changes in metabolism and body fat distribution consistent with the MetS. Furthermore, there is an increase in osteoporosis (1) and CVD (21) after menopause traditionally thought to be due to estrogen deficiency. However, estrogen and estrogen/progestin treatment in clinical trials have not shown a benefit in CVD risk or mortality and have suggested possible increased risk for CVD and stroke (7). The role of testosterone independent of estrogens in osteoporosis, CVD, and metabolic disorders is not clear. Some studies (including the FHS) (22) have shown that higher testosterone levels are associated with increased prevalence of CVD and T2DM (2, 4). Prospective studies have found higher testosterone to be associated with increased risk of T2DM (4) and CVD (8). Postmenopausal women in the WISE (Women's Ischemia Syndrome Evaluation) study being evaluated for ischemia with a history

of irregular menses and elevated free testosterone had a higher burden of angiographic coronary artery disease and were more likely to have a myocardial infarction or cardiovascular-related death (23). There are very limited data on the genetic influences of circulating testosterone in otherwise healthy women.

SHBG tightly binds testosterone in women. SHBG production and clearance are affected by many factors including age, adiposity, smoking, hormone use, liver disease, insulin resistance, and T2DM, resulting in variable circulating SHBG levels (11). SHBG was thought to function only as a carrier protein for sex hormones, but it has been proposed that SHBG binds to its own receptor and exerts biological effects as well (24, 25). Lower SHBG has recently been shown to predict incident T2DM in women (9–10). SHBG concentrations are higher in premenopausal women compared with postmenopausal women due to the stimulation of SHBG production by the liver in response to higher estrogen levels. Thus, the lower SHBG levels coincident with lower estrogen levels after menopause may be related to the greater metabolic and cardiovascular risk observed after the menopausal transition.

Our adjusted heritability estimate for SHBG of 56% suggests a significant genetic component and is in the range estimated in the San Antonio Heart Study in men and women and extends the observation in the Australian study of postmenopausal sisters to premenopausal women as well (12, 15). Additionally, SHBG had a strong inverse genetic correlation with free testosterone, suggesting that the two share common genes that influence their circulating levels. The candidate gene approach has been used to identify regions of interest that may influence circulating hormone levels in conjunction with disease states. A *SHBG* single-nucleotide polymorphism, rs179994, has been associated with T2DM (odds ratio = 0.94; 95% confidence interval = 0.91–0.97; $P = 2 \times 10^{-5}$) (10). Further study of the genetic factors influencing circulating SHBG levels are warranted to determine whether these genes influence susceptibility to chronic diseases, particularly T2DM and CVD.

The use of mass spectrometry, a state of the art method for measuring testosterone in the low concentrations prevalent in women, is a significant strength of this study. The multigenerational design of the FHS is also a significant strength. Our findings are based on the FHS population, which is Caucasian of European ancestry. Future studies of the genetic influences of circulating sex steroid profiles in women should be conducted in populations of varied racial and ethnic backgrounds.

Summary

Circulating testosterone and SHBG levels are highly heritable in women of white, European ancestry, suggesting strong genetic influences. Further study to elucidate the genetic loci that contribute to the determination of circulating hormone profiles is important given that circulating sex hormone profiles are associated with increased risk for significant chronic disease in women including osteoporosis, T2DM, and CVD. The candidate gene approach is limited by the assumptions underlying the choice of the genes to be analyzed. Genome-wide association scans may be a more fruitful approach for identifying genetic regions that influence sex hormone and SHBG levels that are not encumbered by the bias of *a priori* assumptions about which genes will be important in mediating their synthesis or action. There is evidence of potential pleiotropic genetic effects with single genes affecting both testosterone and SHBG. Understanding pleiotropic genetic effects on circulating hormone concentrations may have important implications for the development of hormone-targeted therapy for chronic diseases.

Abstract

Little is known about how different types of substances affect oral health. Our objective was to examine the respective effects of alcohol, stimulants, opioids, and marijuana on oral health in substance-dependent persons. Using self-reported data from 563 substance-dependent individuals, we found that most reported unsatisfactory oral health, with their most recent dental visit more than 1 year ago. In multivariable logistic regressions, none of the substance types were significantly associated with oral health status. However, opioid use was significantly related to a worse overall oral health rating compared to 1 year ago. These findings highlight the poor oral health of individuals with substance dependence and the need to address declining oral health among opioid users. General health and specialty addiction care providers should be aware of oral health problems among these patients. In addition, engagement into addiction and medical care may be facilitated by addressing oral health concerns.

Keywords: Oral health; Substance dependence; Dental care

1. Introduction

Poor oral health is a common problem among individuals with substance dependence, yet this topic has been largely neglected in the addiction literature (Reece, 2009). Individuals with heavy substance use are at increased risk for poor oral health for a variety of reasons, including limited access to dental care (Johnson, Hearn, & Barker, 2008; Khocht, Schleifer, Janal, & Keller, 2009; Sheridan, Aggleton, & Carson, 2001; ter Horst, Molendijk, Brouwer, & Verhey,

1996), poor dietary (Laslett, Dietze, & Dwyer, 2008; Morio, Marshall, Qian, & Morgan, 2008; Titsas and Ferguson, 2002) and oral hygiene habits (Barbadoro, Lucrezi, Prospero, & Annino, 2008; Friedlander, Marder, Pisegna, & Yagiela, 2003; Morio et al., 2008), negative attitudes about oral health and health care (Robinson, Acquah, & Gibson, 2005), and direct physical effects of the substance on oral health. There are several mechanisms by which drugs can directly affect oral health, including increased xerostomia (dry mouth) due to hyposalivation (lack of salivary flow), poor diet and self-care leading to higher rates of dental caries, enamel erosion, and periodontal disease (Friedlander et al., 2003; Hamamoto and Rhodus, 2009; Morio et al., 2008; Versteeg, Slot, van der Velden, & van der Weijden, 2008).

Prior research suggests that individuals who abuse methamphetamines (Curtis, 2006; Donaldson and Goodchild, 2006; Hamamoto and Rhodus, 2009; Morio et al., 2008; Shetty et al., 2010), alcohol (Araujo, Dermen, Connors, & Ciancio, 2004; Hornecker, Muuss, Ehrenreich, & Mausberg, 2003; Khocht et al., 2009; Manarte, Manso, Souza, Frias-Bulhosa, & Gago, 2009), opioids (Sheedy, 1996; Steinmiller and Greenwald, 2007), marijuana (Versteeg et al., 2008), and cocaine (Brand, Gonggrijp, & Blanksma, 2008) are at increased risk of poor oral health outcomes, including enamel erosion and caries. It is not clear, however, whether these consequences are substance specific or due to substance dependence in general. Suboptimal oral health and periodontal disease are associated with health consequences localized to dental issues, such as tooth loss (Martin, Page, Loeb, & Levi, 2010), and more pervasive physical health problems (Slots, 2003), including cerebrovascular disease (Wu et al., 2000), low birth weight (Cruz et al., 2009; Moliterno, Monteiro, Figueredo, & Fischer, 2005), pulmonary infection (Mojon, 2002), diabetes (Demmer, Jacobs, & Desvarieux, 2008), and potentially cardiovascular disease (Humphrey, Fu, Buckley, Freeman, & Helfand, 2008). Given the deleterious impact of poor oral health on both local and systemic health outcomes, it is critical to identify populations at increased risk in an effort to develop tailored interventions to improve overall health in this population.

Despite its prevalence and consequences, there have been few studies that compare and contrast the oral health of patients who use different substances. Most studies that have examined oral health among substance users are cross-sectional or case studies and have assessed only one type of substance (Araujo et al., 2004; Hornecker et al., 2003; Khocht et al., 2009; Manarte et al., 2009; Morio et al., 2008; Versteeg et al., 2008; Shetty et al., 2010) and include small samples (Araujo et al., 2004; Johnson et al., 2008; Khocht et al., 2009; Morio et al., 2008; Robinson et al., 2005; Sheedy, 1996). Many studies and reviews that have addressed the issue of substance use and oral health were conducted internationally, with little work focused in the United States, where the stigma of substance use and perceptions of and access to treatment for oral health may be different (Barbadoro et al., 2008; Blanksma and Brand, 2004; Cho, Hirsch, & Johnstone, 2005; Johnson et al., 2008; Laslett et al., 2008; Molendijk, Ter Horst, Kasbergen, Truin, & Mulder, 1996; Pilinova, Krutina, Salandova & Pilin, 2003; Reece, 2007; Robinson et al., 2005; Sheridan et al., 2001; ter Horst et al., 1996). Understanding how specific types of substances affect oral health can potentially help target interventions to certain groups at risk. Thus, the purpose of this study is to examine whether substance use, including alcohol, stimulants, opioids, and marijuana, is associated with oral health status among people with substance dependence.

2. Materials and methods

2.1. Design

We analyzed data on self-rated oral health and substance use collected prospectively from participants enrolled in a randomized trial testing the effectiveness of chronic care management in the primary care setting in Boston from September 2006 to September 2008. This study was approved by the Boston University Medical Campus Institutional Review Board. All subjects provided informed consent, and procedures were followed in accordance with the Helsinki Declaration of 1975. A certificate of confidentiality was obtained from the National Institute on Alcohol Abuse and Alcoholism to further protect participants' privacy. We hypothesized that different types of substances would differentially affect oral health.

2.2. Sample

The sample included 563 men and women who reported using a variety of substances and had enrolled in the Addiction Health Evaluation and Disease Management study. All subjects had current alcohol and/or drug dependence by *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* criteria (American Psychiatric Association, 2000) assessed using the Composite International Diagnostic Interview Short form (Gigantesco and Morosini, 2008) and were willing to establish or continue primary medical care at the study location. Participants were included if they reported past 30-day drug use or heavy alcohol use (defined as ≥4 standard drinks for women, ≥5 for men at least twice; or >14 drinks per week for women, >21 drinks per week for men, in an average week in the past month). Approximately 74% of the subjects were recruited from a detoxification center, 9% from ambulatory care/outpatient settings, 1% from the hospital emergency department or inpatient setting, and 16% from other sources. Subjects were at least 18 years of age, spoke English or Spanish, and were without indication of cognitive impairment at screening (assessed using the Mini Mental State Examination score greater than 20; Klein et al., 1985). For this analysis, data were taken from an interview conducted at study entry prior to randomization; thus, any intervention effects would not impact survey responses.

2.3. Measures

2.3.1. Independent variables: Types of substances used

The four main independent variables of interest represented use of a particular type of substance: heavy alcohol (yes/no), stimulants (yes/no), opioids (yes/no), and marijuana (yes/no). All subjects in this study met criteria for substance dependence; however, for this analysis, we are analyzing different types of substance use. Thus, the term *substance use* is used to refer to these variables. Heavy alcohol use was assessed using the timeline follow-back measure and defined as drinking five or more drinks at least 1 day in the past 30 days (if male) or four or more drinks at least 1 day in the past 30 days (if female; National Institute on Alcohol Abuse and Alcoholism, 2005). Other drug use was assessed using the Addiction Severity Index (McLellan, Luborsky, Woody, & O'Brien, 1980). Stimulant use was defined as using cocaine or amphetamines at least 1 day in the past 30 days. Individuals who used heroin, methadone, or other opioid analgesics, either without a doctor's prescription, in larger amounts than prescribed, or for a longer period than prescribed, at least 1 day in the past 30 days were considered opioid users. Marijuana use was defined as using marijuana or cannabis at least 1 day in the past 30 days.

2.3.2. Dependent variables: Oral health indicators

Our primary outcome was self-reported oral health status ("How would you describe the health of your teeth and gums?"; Jones et al., 2004). Subjects rated this item on a 5-point Likert scale, which was then dichotomized into *satisfactory* oral health, defined as "excellent," "very good," or "good," versus *unsatisfactory*, defined as "fair" or "poor" (Cunha-Cruz, Hujoel, & Kressin, 2007; Jones, Spiro, Miller, Garcia, & Kressin, 2002). Four secondary self-reported outcomes related to oral health were also evaluated. Health of teeth and gums compared to 1 year ago was dichotomized as *worse*, defined as "somewhat" or "much" worse, versus *the same*, "somewhat" or "much" better. Tooth or gum pain in the past 3 months was dichotomized as *pain* ("some," "quite a bit," or "a great deal") versus *no pain* ("little" or "none"). The time since last dentist visit was dichotomized as *recent* (<1 year ago) versus *distant* (≥1 year ago, never been to the dentist, or "don't know"). The number of permanent teeth removed because of tooth decay, gum disease, or infection was dichotomized as 0–5 versus 6 or more (Kapp, Boren, Yun, & LeMaster, 2007) The rationale for this dichotomy was that individuals could have had all four wisdom teeth or bicuspids extracted for orthodontic treatment and still have excellent oral health.

2.4. Covariates

The analyses controlled for sociodemographic and other variables that could affect oral health, including age, gender, education, being a current smoker, race/ethnicity, health insurance, and income. Health status was assessed using one item of a general rating of health on a 5-point Likert scale ranging from "excellent" to "poor", analyzed as a continuous variable (Ware, Kosinski, & Keller, 1996). In addition, oral health can also be influenced by lifestyle, including dietary and hygiene habits. Individuals in prison (Walsh, Tickle, Milsom, Buchanan, & Zoitopoulos, 2008) or who have experienced homelessness (De Palma and Nordenram, 2005; Gibson et al., 2003) may be at an increased risk for worse oral health due to poorer lifestyle habits and access to care. Thus, we included covariates of ever spending time in prison and recent homelessness, the latter defined as spending at least one night in a shelter or on the street in the last 3 months. Polysubstance use was also included and defined as using two or more of the above substances (heavy alcohol, stimulants, opioids, or marijuana) in the last 30 days.

2.5. Statistical analyses

Descriptive statistics were used to assess the bivariate relationship between subject characteristics and the primary outcome of unsatisfactory oral health. Two sample *t* tests and chi-square tests were used as appropriate to assess the bivariate associations. We evaluated the association between the types of substances used and each oral health outcome using separate logistic regression models. The multivariable logistic regression models were fit to evaluate the associations between types of substances used and worse oral health outcomes after adjustment for sociodemographic characteristics, health status, and lifestyle variables. Adjusted odds ratios (AORs) and 95% confidence intervals (CIs) are reported. To minimize the potential for collinearity, we assessed correlation between pairs of independent variables and covariates to identify pairs of variables that were correlated (i.e., $r > .50$). Polysubstance use was moderately correlated with stimulant use ($r = .66$). Polysubstance use was expected to be an important factor and potential confounder; therefore, we fit adjusted models with and without this covariate. Adjustment for polysubstance use attenuated the odds ratios for the main independent variables with oral health status. Thus, we present results controlling for polysubstance use as the final models. All analyses were conducted using two-sided tests and a significance level of .05. Analyses were performed using SAS software (version 9.1; SAS Institute, Cary, NC).

3. Results

The majority of our sample was male (73%), currently smoking (88%), less than 50 years of age (88%; mean age = 38), with an annual income less than $50,000 (74%), had at least a high school education (76%), and had some form of health insurance (79%; Table 1). Almost half were White (47%), 32% Black, 13% Hispanic, and 8% other racial/ethnic background. Most were incarcerated at least once during

their lives (78%), and many noted homelessness in the past 3 months (59%). Most reported heavy alcohol (78%), stimulant use (68%), opioid use (67%), and polysubstance use (81%). About half used marijuana in the last month (49%).

Overall, the majority of the sample reported unsatisfactory oral health (60%), with the most recent dental visit being more than 1 year ago or not able to recall (52%; Table 2). However, most reported the same or better oral health compared with 1 year ago (64%), little or no tooth/gum pain (63%), and having less than six teeth removed (71%).

3.1. Primary outcome: Oral health status

In unadjusted analyses, there were no significant associations between heavy alcohol use, stimulant use, opioid use, or marijuana use and unsatisfactory self-rated oral health. The findings were similar in adjusted analyses, where those with heavy alcohol use (AOR = 1.31, 95% CI = 0.79–2.15) and opioid use (AOR = 1.09, 95% CI = 0.66–1.79) had nonsignificant higher odds of unsatisfactory self-reported oral health; those with stimulant use (AOR = 0.85, 95% CI = 0.49–1.47) and marijuana use (AOR = 0.69, 95% CI = 0.45–1.06) had nonsignificant lower odds of unsatisfactory oral health (Table 3). In multivariable models, individuals who were older (AOR = 2.86, 95% CI = 1.41–5.80), currently smoking (AOR = 1.99, 95% CI = 1.13–3.50), and had a worse overall health status rating (AOR =

Table 2
Self-reported oral health outcomes (n = 563)

Item	n (%)
How would you describe the health of your teeth and gums?	
Fair or poor	335 (60)
Good, very good, or excellent	228 (40)
Compared with 1 year ago, how would you rate the health of your teeth and gums today?	
Somewhat or much worse	201 (36)
The same, somewhat, or much better	362 (64)
During the past 3 months, how much pain or distress have your teeth or gums caused you?	
Some, quite a bit, or a great deal	209 (37)
A little bit or none	354 (63)
About how long has it been since you last saw a dentist?	
More than 1 year ago, never, don't know	292 (52)
1 year ago or less	271 (48)
How many of your permanent teeth have been removed because of tooth decay or gum disease?	
6 or more	161 (29)
5 or fewer	387 (71)

Note. Bold indicates $p < .05$.

[a] Separate models were fit for each outcome, each adjusting for age, education, gender, race/ethnicity, smoking, health insurance, income, health status, lifetime incarceration, homelessness, and polysubstance use.

1.66, 95% CI = 1.37–2.01) had significantly higher odds of unsatisfactory oral health status (not shown).

3.2. Secondary outcomes

In adjusted analyses, opioid use was the only substance significantly related to a worse oral health rating compared with 1 year ago (AOR = 1.72, CI = 1.04–2.82; Table 3). None of the substance types were significantly associated with tooth/gum pain, time since last dental visit, or number of teeth removed. Overall, in adjusted analyses across secondary outcomes, marijuana use was associated with lower odds of worse oral health outcomes, although none of these associations were statistically significant.

4. Discussion

Overall, most of these individuals with substance dependence reported unsatisfactory oral health status, consistent with previous literature (Araujo et al., 2004). Contrary to our hypothesis, we did not detect an association between type of substance and self-reported oral health status. Of note, however, is that the reference group for each comparison is people with substance dependence who do not use the particular substance of interest (e.g., those with heavy alcohol use vs. those without heavy alcohol use but who use other substances), and thus, our findings should not be interpreted or generalized to represent the impact of a particular substance compared with no other substance use. Our results did reveal that opioid use is associated with worse self-rated oral health compared with 1 year ago. This is consistent with research that has found an association between opiate use and poor oral health (Nathwani and Gallagher, 2008; Reece, 2007; Sheedy, 1996; Titsas and Ferguson, 2002). The association could be due to direct effects of opioids, or it could be that people with worsening oral health use opioids for relief (although this seems less likely given the absence of an association between opioid use and dental pain). Of note, however, is that opioid use is reported for the previous 30 days, and worse oral health is compared with 1 year ago. Subjects may be disappointed in their continued substance use, which may have affected their reports of worsening oral health status.

The association between use of methamphetamines or cocaine and poor oral health is well established in the literature (Brand et al., 2008; Curtis, 2006; Donaldson and Goodchild, 2006; Hamamoto and Rhodus, 2009; Shetty et al., 2010). Similarly, research indicates there is an association between alcohol dependence or marijuana use and poor oral health (Araujo et al., 2004; Hornecker et al., 2003; Khocht et al., 2009; Manarte et al., 2009; Versteeg et al., 2008). These findings from other studies are in contrast to ours. One possibility regarding stimulants is that although the prevalence of cocaine use was substantial in our sample, the prevalence of methamphetamine use was not. If more effects on oral health would be seen from the latter, then that could explain the absence of effect. However, one would have expected effects from cocaine itself. Another possible explanation for different findings is that most of the prior studies relied on oral examination to evaluate oral health outcomes. Our findings, that no individual substance type was related to overall oral health status, may be a function of individual subjectivity in the assessment of their oral health. Although methamphetamine use is associated with poor oral health compared with no methamphetamine use, it may not be associated with poor oral health more than other substances in people with dependence. Similarly, given the large percentage of polysubstance use in our sample, we may not have been able to disentangle the effects of specific substances on oral health.

Twenty-nine percent of our sample had six or more teeth removed. This is substantially more than the 8.5% of adults in the general population who have had six or more teeth removed, according to the Behavioral Risk Factor Surveillance Survey data from 2004 (Kapp et al., 2007). This finding

confirms other research documenting worse oral health status among substance-dependent populations (Reece, 2009).

Although not the focus of this analysis, we noted that some covariates behaved as we expected, supporting their inclusion in the adjusted models. The association between smoking and worse oral health is not surprising, given the previous literature confirming their correlation (Friedlander et al., 2003; Morio et al., 2008). The persistent association between lower self-rated health status and oral health across several models suggests that oral health may influence physical health or vice versa. A longitudinal study examining health status over time could better determine that causal pathway. Future research should also compare self-reported oral health of this population to the general population to understand the extent to which oral health is worse among individuals with substance dependence.

These findings should be interpreted within the limitations of our analysis. All of our oral health outcomes are self-reported and thus subject to recall and other potential biases; we did not conduct a clinical dental health examination. We believe there is value in understanding patients' perceptions of their oral health, given that subjective assessment can affect health behaviors (Baker, 2009; Kneckt, Syrjala, & Knuuttila, 1999). For number of teeth removed, which can be considered a less subjective measure, there is evidence that self-report is highly correlated with the number of teeth found missing on clinical examination and thus can be considered reasonably reliable (Pitiphat, Garcia, Douglass, & Joshipura, 2002). We included a measure of recent homelessness in our analysis; however, an estimate of long-term homelessness may have been more appropriate considering its chronic impact on lifestyle, dietary habits, and oral health care. Our definition of substance use was defined within the last 30 days, which may not entirely capture the effects on oral health, given that long-term exposure of a particular substance would have more of an impact on these outcomes. Given our reference group in adjusted analyses, we are not able to assess the independent effects of a particular substance compared with people who did not use any substances. Instead, our results indicate the effects of a substance on oral health, above and beyond the effects of other substances. Finally, we do not have data to compare to non-substance-using populations, and thus, it is difficult to tease out the effects of substance use and other sociodemographic characteristics. We attempted to do so in our adjusted model, controlling for age, education, gender, race/ethnicity, smoking, health insurance, income, health status, lifetime incarceration, homelessness, and polysubstance use.

Despite these limitations, this study is among the first to assess the differential effects of varying types of substance use on self-rated oral health outcomes. Our findings suggest that addiction treatment providers, as well as medical and dental clinicians, should consider dental and addiction problems as associated comorbidities, requiring the development of treatment plans that address both substance use and potential oral health problems. These results suggest that type of substance had little effect on oral health outcomes. However, the overall poor rating of oral health in our sample indicates that the health of teeth and gums is a significant issue among individuals who use alcohol and/or drugs, in general. Thus, interventions for poor oral health could be tailored toward this population.

Despite the association between substance use and oral health and national recommendations for improving oral health among such vulnerable populations (Department of Health and Human Services, 2000), few interventions have been targeted to individuals with substance dependence. One intervention aimed at improving knowledge, attitudes, and behavior of individuals with alcohol dependence found that the intervention group who attended a lecture had significant improvement in oral health behaviors after 1 year, including frequency of tooth brushing (Barbadoro et al., 2008). Although conducted in Italy, this study has implications for rehabilitation programs in the United States, where such educational workshops can be incorporated into treatment. Clinicians should pay particular attention to oral health among opioid users. Given our findings, and the correlation between oral and general health status, oral health warrants increased attention and public health efforts among substance users. In addition, general health and specialty addiction care providers should be aware of oral health problems among patients with substance dependence. Finally, engagement into addiction and medical care, often a challenge in this population, may be facilitated by addressing oral health concerns.

Stroke Prevention in Atrial Fibrillation: Current Status and Near-Future Directions

Raffaele De Caterina, MD, PhD,[a] Elaine M. Hylek, MD, MPH[b]

[a]Institute of Cardiology and Center of Excellence on Aging, "G. d'Annunzio" University, Chieti, Italy; [b]Department of Medicine, Boston University School of Medicine, Boston, Mass.

ABSTRACT

Prevention of atrial fibrillation-related stroke is an important part of atrial fibrillation management. However, stroke risk is not homogeneous and varies with associated morbidities and risk factors. Risk stratification schemes have been developed that categorize patients' stroke risk into classes based on a combination of risk factors. According to the calculated level of risk, guidelines recommend patients with atrial fibrillation receive antithrombotic therapy either as a vitamin K antagonist or aspirin. Despite recommendations, however, many patients with atrial fibrillation do not receive adequate thromboprophylaxis. We will discuss some of the underlying reasons, in part related to the drawbacks associated with vitamin K antagonists. These highlight the need for new anticoagulants in atrial fibrillation. The novel oral anticoagulants in development may overcome some of the limitations of vitamin K antagonists and address their underuse and safety concerns.

KEYWORDS: Anticoagulants; Antithrombotic therapy; Atrial fibrillation; Stroke; Thromboembolism

Atrial fibrillation, the most common sustained cardiac arrhythmia,[1] increases the risk of stroke and thromboembolism by 5-fold.[2] Strokes in atrial fibrillation are generally more severe and associated with greater mortality and disability than strokes from other causes.[3] Therefore, prevention of stroke and thromboembolism is an important part of atrial fibrillation management. However, stroke risk varies widely. Stroke risk-stratification schemes categorize patients' stroke risk into classes based on the presence of risk factors.[4] On this basis, guidelines until now have recommended that patients with atrial fibrillation receive some form of antithrombotic therapy, either as a vitamin K antagonist or aspirin. However, such current treatments are suboptimal, and despite recommendations, many patients do not receive adequate thromboprophylaxis. We discuss the reasons why guidelines are not adhered to in clinical practice and recent important advances.

Efficacy and Safety of Current Antithrombotic Therapy

Antithrombotic therapy is well established in the prevention of atrial fibrillation-related stroke.[5] Adjusted-dose warfarin reduced the risk of stroke by 64% compared with no antithrombotic treatment.[6] Aspirin alone reduced stroke by 22% compared with placebo.[6] Adjusted-dose warfarin reduced stroke risk by 38% versus aspirin.[6] The Atrial fibrillation Clopidogrel Trial with Irbesartan for prevention of Vascular Events (ACTIVE W) trial also has shown warfarin to be approximately 40% more efficacious than combined aspirin plus clopidogrel.[7,8] Many patients, however, receive aspirin because they are considered "unsuitable" for vitamin K antagonist therapy. In such patients, according to the ACTIVE A,[9] aspirin plus clopidogrel reduced the rate of major vascular events, in particular stroke, versus aspirin

alone (relative risk 0.72; 95% confidence interval [CI], 0.62-0.84), but with an increased risk of major hemorrhage (relative risk 1.56; 95% CI, 1.28-1.89), and therefore with uncertain clinical benefit.[9]

Despite proven efficacy, vitamin K antagonists also cause more major bleeding. Compared with aspirin, vitamin K antagonists were associated with a 70% and 128% increase in the relative risk of major extracranial and intracranial hemorrhage, respectively,[6] a risk higher in the first 90 days of therapy among patients with the highest stroke risk.[10] Although contemporary risk of bleeding with better international normalized ratio control may be lower than before,[11] balancing the risk of stroke and bleeding among older individuals with several comorbidities is a continuing clinical challenge.[6]

CLINICAL SIGNIFICANCE

- Prevention of stroke in atrial fibrillation is an important part of atrial fibrillation management. Guidelines here mostly recommend a vitamin K antagonist, but are largely disattended.
- We discuss current gaps in knowledge, reasons why guidelines are not adhered to, and the need for new anticoagulants.
- We also highlight results so far obtained with novel anticoagulants in trials just completed.

Problems with Current Antithrombotic Therapies and Uncertainties with Current Risk Prediction Schemes

Guidelines for antithrombotic therapy in patients with atrial fibrillation are based on predicted stroke risk (Table 1). The most widely adopted risk stratification scheme has been $CHADS_2$,[12] based on a cumulative scoring system focusing on 5 major risk factors: **C**ongestive heart failure, **H**ypertension, **A**ge ≥75 years, and **D**iabetes, each scoring 1; and history of prior **S**troke or TIA, scoring 2 to reflect its increased weight.[12] A score of 0 indicates low risk, a score of 1 indicates moderate risk, and a score of 2 or more indicates high risk.[13] The definitions of low, moderate, and high risk of stroke used in the American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) 2006 joint guidelines[14] and the American College of Chest Physicians guidelines[15] also are based on the presence or absence of these same risk factors in addition to impaired left ventricular function. However, because of variations in the criteria used by different risk stratification schemes, the proportion of patients categorized as low, moderate, or high risk may range from 7% to 42%.[16,17] In addition, less well-validated risk factors, such as female gender, age 65 to 74 years, and vascular disease, were not formally incorporated in older schemes. A new expanded version of $CHADS_2$ (CHA_2DS_2VASc) that includes these factors has recently been developed.[18] **A**ge ≥ 75 years is assigned 2 points (A_2), **a**ge 65 to 74 years is assigned 1 point (A), **v**ascular disease (prior myocardial infarction, peripheral arterial disease, complex aortic plaque) is assigned 1 point, and female gender (**s**ex) is assigned 1 point. Compared with existing schemes, it seems to have a slightly better predictive value for stroke and thromboembolism, with only 15% of patients in the moderate risk group. Furthermore, at 1 year no thromboembolic events were recorded for patients with a CHA_2DS_2VASc score of 0, thus probably allowing the identification of patients at "truly" low risk.[18] This scheme has been adopted by the newest ESC Guidelines as an add-on to the $CHADS_2$ score in patients in whom the latter is ≤ 1.[11]

Vitamin K Antagonists or Aspirin for Moderate Stroke Risk

The 2006 ACC/AHA/ESC guidelines recommended either a vitamin K antagonist or aspirin for individuals with a $CHADS_2$ score of 1,[14] in whom "risk of bleeding complications, ability to safely sustain adjusted chronic anticoagulation, and patients' preferences should be assessed."[14] This recommendation reflected concern for inducing harm from vitamin K antagonists among individuals with a relatively low risk of stroke, but assumed that aspirin is safer and that the choice of aspirin may be an appropriate balance between risk and benefit in such patients. Recent evidence, however, has shifted the focus toward anticoagulants for patients at moderate risk. The Birmingham Atrial Fibrillation Treatment of the Aged Study (BAFTA) randomized individuals aged more than 75 years, in whom the referring physicians needed to be uncertain as to which therapy provided the best benefit/risk balance, to either warfarin or aspirin. Fatal and nonfatal disabling stroke or systemic arterial embolism occurred at 1.8%/year for warfarin versus 3.8%/year for aspirin (hazard ratio [HR] 0.48; 95% CI, 0.28-0.80), with no difference in rates of major hemorrhage (1.9 vs 2.2, respectively).[19] In an analysis of ACTIVE W, reporting risks and benefits of vitamin K antagonists versus aspirin plus clopidogrel in relation to stroke risk ($CHADS_2$ score = 1 vs $CHADS_2$ >1)[20] and stroke rates for those with a $CHADS_2$ score of 1 were 1.25% and 0.43% per year on aspirin plus clopidogrel and oral vitamin K antagonists, respectively ($P = .01$). In patients with a score > 1, rates were 3.15% per year on aspirin plus clopidogrel and 2.01% on vitamin K antagonists ($P = .01$).[20] The rates of major bleeding for patients with a $CHADS_2$ score of 1 were comparable (1.36% on vitamin K antagonists vs 2.09% on aspirin plus clopidogrel, $P = .11$). The use of vitamin K antagonists gave a lower net risk (vascular events plus major bleeding) with vitamin K antagonists compared with aspirin plus clopidogrel (2.97% vs 5.25% per year; $P = .001$).[20] Therefore, as in 2 other recent trials,[21,22] patients with a $CHADS_2$ score of 1 apparently derive a modest (<1% per year) but significant benefit with vitamin K antagonists, with no in-

crease in major hemorrhage.[20] Because of this, the 2010 ESC guidelines further restrict the uncertainty between vitamin K antagonists and aspirin indications only to patients with a CHA_2DS_2VASc score of 1 and, even in this case, with a preference for vitamin K antagonists.[11]

Underuse of Vitamin K Antagonists in Clinical Practice

Despite overwhelming evidence of the benefits of vitamin K antagonists on stroke risk in patients with atrial fibrillation, registries suggest that vitamin K antagonists are underused in clinical practice. In the National Anticoagulation Benchmark Outcomes Report, retrospectively evaluating practices in hospitalized patients with atrial fibrillation (n = 945), of 86% of patients eligible for warfarin, only 55% actually received it.[23] This proportion was similar for both academic and community hospitals. In the Euro Heart Survey on atrial fibrillation, only 67% of patients eligible for vitamin K antagonists were actually prescribed them, and 7% of eligible patients did not receive any form of antithrombotic treatment.[24] Three new large atrial fibrillation registries, the Global Anticoagulation Registry in the FIELD, the Outcomes Registry for Better Informed Treatment of Atrial Fibrillation, and the RECORD-AF registry,[13,25] will shed further light on the patterns of use of vitamin K antagonists (and novel anticoagulants) worldwide.

Inherent Challenges of Vitamin K Antagonists

Some of the problems connected with the underuse of vitamin K antagonists are due to the intrinsic limitations of vitamin K antagonist. These include a narrow therapeutic window;[26,27] marked variability in dose-response, and the influence of environmental (eg, drug and food interactions) and genetic factors making it difficult for the patient to remain within the recommended optimal international normalized ratio of 2.0 to 3.0, necessitating regular monitoring and dose adjustments.[28,29] The management of vitamin K antagonists is further complicated by their delayed onset of action, with a complete effect not achieved until functional vitamin K-dependent coagulation factors (F II, VII, IX, and X) are cleared,[29] thus sometimes requiring bridging therapy with a parenteral anticoagulant.[29] Vitamin K antagonists also have a slow offset of action, related to their long half-lives (36-42 hours for warfarin) and the time required for the synthesis of new, functional coagulation factors.[28]

A number of physician-related factors also influence the use of vitamin K antagonists.[30,31] These include a perception of the presence of a potential contraindication, their underrating, a perceived risk of bleeding, and low patient compliance.[30] There is a continuing reluctance among physicians to prescribe vitamin K antagonists to the elderly, particularly patients aged >80 years,[32] in whom hypertension, renal impairment, and diabetes are known to increase bleeding with vitamin K antagonist therapy.[31] Cognitive impairment also decreases time in the therapeutic range, which is a good measure of anticoagulation quality,[33] thereby correctly increasing physicians' concerns.[31] Although newer guidelines recommend the adoption of bleeding risk stratification schemes, such as the HAS-BLED score (a score by which **H**ypertension (**H**) is given 1 point, **A**bnormal renal and liver functions (**A**) are given 1 point each, **S**troke (**S**) is given 1 point, **B**leeding (**B**) is given 1 point, **L**abile INRs (**L**) is given 1 point, **E**lderly (**E**, age >65 years) is given 1 point, **D**rug or alcohol abuse (**D**) are given 1 point each, up to a maximum of 9 points),[11] it is uncertain how these will separate the bleeding risk from the thromboembolic risk.

Novel Oral Anticoagulants: Latest Developments

The limitations of vitamin K antagonists have highlighted the need for new oral anticoagulants that may overcome their drawbacks while maintaining or improving therapeutic benefit. Ideally, such drugs would have predictable pharmacokinetic and pharmacodynamic profiles; limited or no drug/food interactions; a fast onset of action, removing the need for bridging therapy; and a fast offset of action to allow temporary discontinuation of anticoagulant therapy if required (eg, for surgery).[34] They also would have the potential to be given at a fixed dose with no monitoring or dose adjustment, thus being more convenient for patients and physicians.[34] Such anticoagulants might overcome the barriers to vitamin K antagonist use, leading to improved patient management.

Established vitamin K antagonists act on multiple targets of the coagulation cascade, with different and variable half-life. To make the drug effects more predictable, efforts have focused primarily on the direct inhibition of a single coagulation factor, in particular FIIa (thrombin) and FXa.[35] The potential of novel oral anticoagulants for stroke prevention in atrial fibrillation was first demonstrated with the direct thrombin inhibitor ximelagatran in the stroke prevention with the oral direct thrombin inhibitor ximelagatran compared with warfarin in patients with non-valvular atrial fibrillation (SPORTIF) trials.[36-38] However, its use was associated with liver toxicity,[39] which led to the termination of its clinical development.[40]

Studies on several new oral anticoagulants have been recently completed or are currently undergoing phase III clinical trials in patients with atrial fibrillation. These studies aim at demonstrating non-inferiority compared with vitamin K antagonists or superiority compared with aspirin in patients for whom vitamin K antagonists are contraindicated or not tolerated.

Oral Direct Thrombin Inhibitors

Dabigatran etexilate. The recently published phase III Randomized Evaluation of Long-term anticoagulation therapY (RE-LY) study[41] was a prospective, multicenter, parallel-group, non-inferiority trial evaluating the efficacy and safety of 2 fixed doses of dabigatran etexilate (110 mg and 150 mg twice per day [bid]), in a blinded fashion, compared with open-label

warfarin in patients with atrial fibrillation at increased risk of stroke. Dabigatran 150 mg bid was superior to warfarin for the primary efficacy outcome of stroke and systemic embolism (1.11% vs 1.69% per year, $P < .001$), with a similar rate of major bleeding (3.11% vs 3.36% per year, $P = .31$), whereas dabigatran 110 mg bid was non-inferior to warfarin for the primary efficacy outcome (1.53% vs 1.69% per year, $P = .34$), with a significantly lower rate of major bleeding (2.71% vs 3.36% per year, $P = .003$).[41] Both dabigatran doses also had lower rates of intracranial hemorrhage, including hemorrhagic stroke and subdural or subarachnoid hemorrhage,[41] and no evidence of hepatotoxicity. A higher rate of myocardial infarction was observed with both doses of dabigatran, but neither was significant compared with warfarin (0.82 for the 110 mg dose and 0.81 for the 150 mg dose vs 0.64 for warfarin; $P = .09$ and 0.12, respectively). Overall vascular mortality was reduced with dabigatran.[41] Dyspepsia was reported by approximately 11.5% of participants assigned to either dose of dabigatran versus 5.8% for warfarin ($P < .001$).

Dabigatran is now the first oral anticoagulant with the potential to replace vitamin K antagonists for the long-term prevention of thromboembolism in patients with atrial fibrillation, having been recently approved by the US Food and Drug Administration at the dosage of 150 mg bid and by the Canadian regulatory authorities at both dosages tested in the RE-LY study. Further safety analysis of dabigatran will be carried out in the RELY-ABLE trial (NCT00808067, estimated completion date: July 2011).

Oral Direct Factor Xa Inhibitors

Rivaroxaban. Rivaroxaban has been assessed in the phase III Rivaroxaban Once daily oral direct FXa inhibition Compared with vitamin K antagonism for prevention of stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF) (NCT00403767). This was a randomized, double-blind, double-dummy, multicenter, event-driven study to test the non-inferiority of rivaroxaban (20 mg/d or 15 mg/d in patients with renal impairment [creatinine clearance of 30-49 mL/min]) compared with adjusted-dose warfarin in subjects with non-valvular atrial fibrillation at high risk of stroke. The primary safety outcome was the composite of major and non-major clinically relevant bleeds. As reported at the 2010 American Heart Association Scientific Sessions (http://www.theheart.org/article/1148785.do), the trial met the non-inferiority end point, with overall rates of bleeding for rivaroxaban similar to those for warfarin, but with less intracranial hemorrhage. A comparison of the characteristics and main outcomes of RELY and ROCKET-AF is shown in Table 2.

Apixaban. Apixaban for the prevention of stroke in subjects with atrial fibrillation (ARISTOTLE, NCT00412984) is a phase III randomized, double-blind, double-dummy study testing the non-inferiority of apixaban versus warfarin for the composite of stroke and systemic embolism in approximately 18,000 patients with atrial fibrillation. Patients are required to have at least 1 additional risk factor for stroke, including age ≥ 75 years, previous stroke, transient ischemic attack or systemic embolism, and diabetes. The study will be complete in April 2011.

Apixaban has already been assessed in the phase III Study of Apixaban in Patients with Atrial Fibrillation (AVERROES, NCT00496769), a randomized, double-blind, double-dummy study to assess the superiority of apixaban 5 mg bid versus aspirin (81-324 mg/d) for the prevention of stroke in 5600 patients with atrial fibrillation and at least 1 additional risk factor for stroke, who had failed or were considered unsuitable for vitamin K antagonist treatment for reasons including poor anticoagulation control, adverse events, and the need for other treatments that may interact with vitamin K antagonists. The primary efficacy outcome was the time to first ischemic stroke, hemorrhagic stroke, or systemic embolism. In April 2010, the Data and Safety Monitoring Board recommended early study termination because of clear benefit in favor of apixaban. The median duration of follow-up was 1.5 years. The primary outcome was stroke or systemic embolism. There were 52 primary outcome events in those randomized to apixaban (1.6%/year) and 112 primary outcome events in those randomized to aspirin (3.5%/year) (HR 0.46; 95% CI, 0.33-0.64; $P < .001$). Mortality rates were 3.4%/year for those randomized to apixaban and 4.4%/year for those randomized to aspirin (HR 0.79; 95% CI, 0.61-1.01; $P = .06$). There were 46 major bleeds (1.4%/year) in the apixaban group and 43 major bleeds (1.3%/year) in the aspirin group (HR 1.08; 95% CI, 0.71-1.63; $P = .73$). There were 13 intracranial bleeds in the apixaban group and 12 intracranial bleeds in the aspirin group.[42] Thus, a clear superiority of apixaban over aspirin was shown in terms of efficacy, with comparable safety.

Edoxaban (DU-176b). The Global Study to Assess the Safety and Effectiveness of DU-176b vs Standard Practice of Dosing with Warfarin in Patients with Atrial Fibrillation (ENGAGE AF-TIMI 48, NCT00781391) is a randomized double-blind, double-dummy study in subjects with atrial fibrillation and a high risk of stroke ($CHADS_2$ score ≥ 2). The study will evaluate the efficacy and safety of 2 doses of edoxaban (30 or 60 mg/d, with halved doses for moderate renal impairment or low body weight) compared with warfarin. The primary study hypothesis is that at least 1 dose regimen of edoxaban will be non-inferior to warfarin in reducing the composite of stroke and systemic embolism. The trial is estimated to be completed in March 2012.

Other agents, such as the direct thrombin inhibitor AZD0837 (13) and the direct FXa inhibitors betrixaban (NCT00742859) and YM-150 (NCT00448214), are in phase II clinical development in the atrial fibrillation setting.

Other Oral Anticoagulants Under Development

Two other classes of oral anticoagulants are now in earlier stages of development. Tecarfarin, now in phase 2 devel-

Table 2 Comparison of RE-LY and ROCKET-AF Results*

	RE-LY[46]		ROCKET AF*
Comparisons	Dabigatran 110 mg bid vs warfarin	Dabigatran 150 mg bid vs warfarin	Rivaroxaban 20 mg qd vs warfarin
Study design	Dabigatran doses assigned in a double-blind fashion; warfarin given open-label; blinded adjudication of outcomes		double-blind, double-dummy
Sample size	18,113 patients, 3 arms (dabigatran 110 mg bid, dabigatran 150 mg bid, or dose-adjusted warfarin (titrated to an INR of 2.5).		14,000 patients, 2 arms: 20 mg qd (or 15 mg in patients with moderate renal impairment at screening) or to dose-adjusted warfarin (titrated to an INR of 2.5).
Quality of warfarin comparison (% TTR)	64 (mean)		58 (median)
Mean age (y)	71		73
Mean $CHADS_2$ score	2.1		3.5
Prior use of VKAs (%)	50%		63%
Primary outcome	Stroke and systemic embolism		Stroke and systemic embolism
Primary end point, HR (95% CI), non-inferiority, *P* value*	0.91 (0.74-1.11) <.001	0.66 (0.53-0.82), <.001	0.79 (0.66-0.96) <.001

opment, is a vitamin K antagonist metabolized through the esterase pathways,[43] overcoming the limitations related to warfarin metabolism through cytochrome P450, namely, the many drug-drug interactions.

TTP889 is a selective, small-molecule, orally available, partial FIXa inhibitor, which can be administered with fixed once per day dosing, with a reported half-life of 21 to 25 hours.[44] Preclinical data support the concept of upstream coagulation inhibition of FIXa (more upstream than FXa) as a viable and possibly highly efficient way to prevent thrombosis.

CONCLUSIONS

The choice of antithrombotic therapy for patients with atrial fibrillation currently depends on the appropriate classification of an individual patient's predicted risk of stroke. Most recent guidelines overall recommend oral anticoagulants (vitamin K antagonists) for most patients with atrial fibrillation, even at moderate risk of stroke. On the other hand, there is a clear underuse of vitamin K antagonists and a strong need for safer and more convenient antithrombotic drugs. The new oral anticoagulants in development, with fewer food and drug interactions and predictable pharmacology, have no requirement for routine coagulation monitoring and may provide equally or more effective, yet safer, alternative options.

Summary

Statins have important pleiotropic effects and have been shown to reduce vascular inflammation. Some evidence suggests that statins may have a role in the primary prevention of atrial fibrillation (AF), whereas little is know on the role of statins in patients with existing AF. We performed a meta-analysis of the literature to assess the effect of statins on the recurrence of AF after electrical cardioversion or ablation. MEDLINE and EMBASE databases were searched up to January 2010. Relative risks (RR) and 95% confidence intervals (CIs) were then calculated and pooled using a random-effects model. Statistical heterogeneity was evaluated through the use of I^2 statistics. Sixteen studies were included in our systematic review. Statins did not reduce the risk of AF recurrence after ablation (four studies including 750 patients; RR, 1.04; 95% CI, 0.85–1.28, p=0.71; I^2 = 34%). Conversely, the use of statins was associated with a significantly reduced risk of AF recurrence after electrical cardioversion (12 studies including 1790 patients; RR, 0.78; 95% CI, 0.67–0.90, p=0.0003; I^2 = 34%). This reduction was not statistically significant when the analysis was restricted to randomised controlled trials (RCTs) only (five studies, 458 patients, RR, 0.76; 95% CI, 0.48–1.20). In conclusion, statins may lower the risk of AF recurrence after electrical cardioversion, but not ablation. However, this finding should be considered with caution, and larger RCTs are warranted to confirm our preliminary results.

Introduction

AF is the most common arrhythmia encountered in clinical practice with an increasing prevalence during the last few decades (1). Prevalence of AF is increasing with age (1, 2) and these patients have a higher prevalence of hypertension and a larger waist circumference than non- AF patients (2). On the other hand, presence of hypercholesterolaemia seems to be less common in AF patients (2, 3). AF is associated with a significant increase in the risk of cardiovascular morbidity and cardiovascular overall mortality (4) representing a major public health problem (1). Although control of the ventricular response is an acceptable treatment in certain subgroups of patients, restoration and maintenance of sinus rhythm remains a widely used strategy in many patients (4). This strategy offers several potential benefits, such as the prevention of electrical and structural remodelling of the atria, improved haemodynamic function, amelioration of symptoms, and improvement in the quality of life (4).

Although some recent studies indicate increased efficacy of pharmacological cardioversion using combination therapy (5), electrical cardioversion is the most commonly used method for sinus rhythm restoration in patients with persistent AF. Despite the use of antiarrhythmic agents for sinus rhythm maintenance, a considerable proportion of patients relapse to AF (1, 6–9).

Catheter ablation has been proposed as an effective therapeutic option for AF that is resistant to pharmacologic rhythm or rate control, with successful long-term maintenance of sinus rhythm in the absence of treatment with anti-arrhythmic drugs reported in many patients (10). However, the recurrence rate of AF after catheter ablation has been reported to range between 30 and 40%, depending on the ablation strategy and the type of AF (10, 11).

Factors associated with relapse include older age, atrial dilation, and longer duration of the arrhythmia. Recently, experimental and clinical studies have demonstrated an association between AF and inflammation, suggesting a role of inflammation both in the genesis and in the recurrence of AF (12–14). A number of studies and a meta-analysis indicate a positive association between C-reactive protein (CRP) levels and AF recurrence (15).

Hydroxymethylglutaryl coenzyme-A reductase inhibitors (statins) have anti-oxidant effects (16) and they decrease inflammatory markers independent of their action on lipids (17). Both experimental and clinical studies have demonstrated that statins pre-

vent remodelling and reduce the incidence of AF (18). Clinical trials and a recently published meta-analysis of the literature have suggested that statins reduce the incidence of AF after cardiac surgery (19). On the other hand, evidence on the role of statins in preventing AF recurrence after electrical cardioversion or ablation is less compelling (20).

Therefore we performed a systematic review and a meta-analysis of the literature to assess the effect of statins on recurrence of AF after electrical cardioversion or ablation.

Methods

A protocol was prospectively developed, detailing the specific objectives, criteria for study selection, approach to assess study quality, outcomes, and statistical methods.

This systematic review was performed according to the guidelines for Quality of Reporting of Meta-analysis (PRISMA, MOOSE) (21, 22).

Study identification

We tried to identify all published studies that evaluated the role of statins on recurrence of AF after electrical cardioversion or ablation using the MEDLINE (1966 to January 2010, week 4) and EMBASE (1980 to January 2010, week 4) electronic databases. The search strategy was developed without any language restriction, and used the subject headings and key words presented in Appendix 1 (see supplementary material online available at www.thrombosis-online.com). We supplemented our search by manually reviewing the reference lists of all retrieved articles for additional published or unpublished trials and by searching the abstracts of the American Heart Association (AHA) (from 1999 to 2009) and the European Society of Cardiology (ESC) (from 2005 to 2009) Scientific Meetings. Abstracts presented at the ESC Scientific Meetings and at AHA Scientific Sessions were searched at http://spo.escardio.org/abstract-book/search.aspx and at www.ahajournals.org, respectively.

Study selection

Study selection was performed independently by two reviewers (FD, MG), with disagreements resolved through discussion and by the opinion of a third reviewer (LG), if necessary. Studies were included if they met the following criteria: 1) separate data for patients on treatment with statins and controls were available; 2) recurrence of AF was objectively documented. Both observational and experimental studies were included.

Studies not including a control group drawn from the same population, animal studies, *in vitro* studies, or trials that exclusively reported other clinical outcomes were excluded. Case reports, editorials, commentaries, letters, review articles, guidelines or secondary prevention trials were also excluded from the analysis.

To assess the agreement between reviewers for study selection, we used the kappa (κ) statistic, which measures agreement beyond chance (23).

When more than one publication from the same patient cohort existed, then the study with the most complete data set was included in the systematic review.

Data extraction

Two reviewers (FD, MG) independently extracted data on study (year of publication, design, study centre) and patients characteristics (number of subjects enrolled, mean age, variation in age, gender and race). Furthermore, the following characteristics were collected: (i) total follow-up duration for randomised controlled trials (RCTs) and cohort studies; (ii) total number of patients with AF recurrence (iii) molecule and regimen of statins.

In case necessary data were not provided in the manuscript, the corresponding author was contacted for additional data request.

Study validity assessment

Two unmasked investigators (FD, MG) independently completed the assessment of study validity. For RCTs, we planned quality assessment by means of Jadad's scale, which evaluates the following three study characteristics: method of randomisation, method of blinding, and follow-up (24). To stratify RCTs, we applied the following cut-offs: a total of five points defined high quality studies; three and four points defined medium quality studies; two or less points defined low quality studies.

Although in observational studies the use of quality scoring systems or quality scales is controversial (22), study quality was assessed by the following items for cohort studies: type of study (prospective or retrospective); patient selection (consecutive patients without potential bias of selection); control group (consecutive enrolment or matched for age and sex). For each fulfilled item one point was given. A scoring system was adapted to identify two quality categories as follows: a total of three points defined high quality studies; two or less points defined low quality studies. The total number of patients lost to follow-up (less than 5% of patients, more than 20%, or between 5 and 20%) was also ascertained as an additional quality item.

Statistical analysis

Relative risk (RR) and 95% confidence intervals (CIs) of AF recurrence after catheter ablation and electrical cardioversion were cal-

culated. The data were pooled using a random-effects model (the DerSimonan and Laird method) (25). Separate analyses for patients undergoing catheter ablation and electrical cardioversion were performed. For treatment effects that were statistically significant, we determined the absolute risk reduction and NNT to prevent a recurrence. Statistical heterogeneity was evaluated using the I^2 statistic, which assesses the appropriateness of pooling the individual study results (26). The I^2 value provides an estimate of the amount of variance across studies due to heterogeneity rather than chance. $I^2 < 30\%$ indicates mild heterogeneity, 30–50% moderate, and > 50% severe heterogeneity. When heterogeneity was present, we repeated the analysis removing one study at a time to assess the source of heterogeneity. Presence of publication bias was explored using funnel plots of effect size against standard error (27). The software Review Manager (RevMan, version 5.0.16 for Windows, Oxford, UK; The Cochrane Collaboration, 2008) supported the analysis.

As a sensitivity analysis, we planned to analyze separately RCTs considering the effect of treatment with statins.

Results

Study identification and selection

We identified 1,475 potentially relevant studies from the following databases: 1,356 from EMBASE and 119 from MEDLINE. Further 673 abstracts from the American Heart Association and European Society of Cardiology Scientific Meeting Abstracts were found using "atrial fibrillation" and "statins" search terms. We excluded 2,094 studies after title and abstract screening using the predefined inclusion and exclusion criteria; the remaining 54 studies were retrieved in full for detailed evaluation. Two additional studies were identified through manual review of references. Agreement between reviewers for study selection was optimal (K=0.91). Of the 56 retrieved studies, 40 were excluded for the following reasons: 27 did not match inclusion criteria, 10 were editorials or commentaries, two reported duplicate data, and one RCT could not be included since the authors did not provide the absolute number of AF recurrences (28). Sixteen studies (29–44) were therefore included in this systematic review: 15 were published as full text and one as an abstract. The study identification and selection progression is detailed in Appendix 2 (see supplementary material online available at www.thrombosis-online.com).

Study characteristics

Baseline characteristics of patients included in the studies are summarised in ▶Table 1. Five RCTs, nine retrospective cohort studies, and two prospective cohort studies were included in our systematic review. Study size ranged from 44 to 625 patients, for a total of 2,540 patients. AF recurrence was the primary end point of all included studies.

Study quality

Quality assessment items are summarized in Appendix 3 (see supplementary material online available at www.thrombosis-online.com). One of the five RCTs was of high quality. All 11 cohort studies were of low quality.

Catheter ablation

Recurrence of AF after catheter ablation was evaluated in four retrospective cohort studies for a total of 747 patients. Follow up periods varied from 30 days to 18 months. Type and dose of statins used in different studies were not specified. Furthermore, no study indicated when statins were started. AF recurrence occurred in 136 of 297 (45.8%) patients on treatment with statins and in 178 of 450 (39.6%) patients not on treatment with statins. The use of statins was not associated with a reduced risk of AF recurrence (RR 1.04, 95%CI 0.85, 1.28; p= 0.71) (▶Fig. 1). Heterogeneity across the studies was low (I^2= 34%).

Due to the low number of studies, funnel-plot analysis could not be done. Therefore, the presence of publication bias could not be excluded.

Electrical cardioversion

Recurrence of AF after electrical cardioversion was evaluated in 12 studies (5 RCTs, 5 retrospective cohort studies, and 2 prospective cohort studies) for a total of 1,790 patients. Statin regimen was not specified in five of the eight observational studies and the other three used seven different types of statins. Furthermore, none of the observational studies indicated when statins were started. Atorvastatin (at a dose varying from 10 to 80 mg) was used in three RCTs, pravastatin (dose of 40 mg) in one, and rosuvastatin (dose of 10 mg) in one. In these studies, statin initiation varied from three weeks to 48 hours before the electrical cardioversion. Follow up intervals varied from 30 days to more than 3.5 years. AF recurrence occurred in 179 of 475 (38.5%) patients on treatment with statins and in 606 of 1,325 (45.7%) patients not on treatment with statins. The use of statins resulted in a statistically significant reduction in the risk of AF recurrence (RR 0.78, 95%CI 0.67, 0.90; p< 0.001) (▶Fig. 1). Heterogeneity across the studies was low (I^2= 17%). The absolute risk reduction was 7.2% with a NNT of 14.

Funnel plot of RR versus standard error appeared slightly asymmetric with an absence of studies in the bottom right hand corner (see Appendix 4; supplementary material online available at www.thrombosis-online.com).

Sensitivity analysis included five RCTs for a total of 458 patients. AF recurrence occurred in 86 of 229 (37.6%) patients on treatment with statins and in 108 of 229 (47.2%) patients not on treatment with statins. The use of statins was associated with a statistically non significant reduction in the risk of AF recurrence in this subgroup of studies (RR 0.76, 95%CI 0.48, 1.20).

Table 1: Baseline characteristics of included studies.

Author	Population	Number of patients	Type of statin and dosage	Follow-up	Exclusion criteria
Almroth, 2009	Persistent AF undergoing EC	234 (65 ± 10 years)	Atorvastatin 80 mg die (14 days before EC and 30 days after)	30 days	• Age < 18 and > 80 years • Paroxysmal AF or atrial flutter • Contraindication against atorvastatin • Ongoing treatment with lipid-lowering drugs • Ongoing treatment with class I or class III antiarrhythmic • Oral amiodarone < 6 months • Known liver disease or a myopathy • Previous EC = 1 year
Xia, 2009	Persisten AF (> 48 hours) undergoing EC	64	Rosuvastatin 10 mg die (48 hours before and 3 months after)	3 months	• Age < 18 and > 75 years • Paroxysmal AF • Left atrium size > 55 mm • Left atrium trombi • Contraindication to statin treatment • Already in statin treatment • Hypertension • Diabetes mellitus • RF • CAD • History of smoking • Thyroid disfunction • Known rheumatic disease or cancer • Infection < 2 months
Can, 2007	Persistent AF undergoing EC	44	Atorvastatin 40 mg (started 3 weeks before EC)	2 m	–
Ozaydin, 2006	Persisten AF undergoing EC	48 (62 ± 11 years)	Atorvastitin 10 mg (48 hours before and 3 months after)	3 months	• Paroxysmal AF • Left atrium size > 6.5 cm • Moderate to severe heart valve disease • CAD • Unsuccessful EC • NYHA class III or IV heart failure • Cardiac surgery history • Acute reversible condition • Pregnancy or lactation • Contraindication to statin treatment • Already in statin treatment • Hyperthyroidism • Age < 18 years • EF < 30% • Significant RF • Low ejection fraction
Tveit, 2004	AF > 48 hours undergoing EC	114	Pravastatin 40 mg (3 weeks before and 6 weeks after)	6 weeks	• Significant heart valve disease • Cardiothoracic surgery in previous 30 days • Hyperthyroidism • Liver disease • Pregnancy or lactation • Already in statin treatment
Naji, 2009	Persistent AF undergoing EC	198	NS	2 years	• Duration of AF less than one months • Age >85 years • Heart surgery or electrophysiologic procedure prior EC or during follow-up • Implanted pacing device • Discontinuation of amiodaron or statin treatment during the follow-up period

Table 1: continued

Author	Population	Number of patients	Type of statin and dosage	Follow-up	Exclusion criteria
Kim, 2009	Permanent AF undergoing EC	81 (59.1 ± 10.5 years)	NS	13.1 ± 10.6 months	• Any previous EC • Significant mitral valve disease • Left atrium size > 55 mm • Recent infection • Surgery or acute coronary disease within 2 months of blood sample collection
Dogan, 2009	Persistent AF (< than 1 year) undergoing EC	221 (62.5 ± 8.9 years)	NS	ND	• Acute coronary syndrome • Severe valvular disease • Heart failure (NYHA > 2 class) • Left atrium size > 55 mm • Hepatic disfunction • Severe pulmonary disease • Hyperthyroidism • LV dysfunction (EF < 30 %) • RF
Baman, 2009	Persistent AF or atrial flutter undergoing EC	93	NS	15 months (10)	• Patients who have had > 1 ablation to eliminate to AF
Humphries, 2007	New onset AF undergoing EC	625 (mean age 63 years)	Atorvastatin, cerivastatin, sinvastatin, lovastatin, pravastatin	1 year	• Cardiothoracic surgery in previous 30 days • Missing information regarding hypertension history or medication use • Missed one year follow-up visit • Patients died • Patients withdrew from study before 1 year • Patients identified with chronic or permanent AF in the first visit after diagnosis
Watanabe, 2005	Symptomatic AF undergoing EC	106 (63 ± 14 years)	NS	140 ± 140 days	• Acute myocardial infarction • Unstable angina • Major surgical procedure within the previous month • Chronic obstructive pulmonary disease • Connective tissue disease • Acute infectious disease
Siu, 2003	Lone persistent AF (lasting > 3 months) undergoing EC	62 (61 ± 2 years)	4 sinvastatin (mean dose 20 ± 13 mg) 6 atorvastatin (mean dose 10 ± 3 mg) 32 ± 6 weeks before and 44 ± 1 months after	44 ± 1 m	• Structural heart disease • Hypertension • FA lasting > 3 months • Sepsis • Hyperthyroidism • Electrolyte inbalance
Koyama, 2009	Drug-refractory paroxysmal AF undergoing CA	186 59.7 (9.8)	NS	30 days	• Age >75 years, • Previous ablation • Persistent AF lasting >1 week • Hepatic or renal disease • Hyperthyroidism • Uncontrolled hypertension • LV dysfunction (ejection fraction < 45%) • Malignancy • Acute or chronic inflammatory disease
Park, 2009	Drug-refractory paroxysmal or persistent AF undergoing CA	152 NS	NS	18 months (14)	–
Richter, 2007	Patients with drug-resistant paroxysmal or persistent AF undergoing CA	234 56.7 (10.5)	Atorvastatin, sinvastatin, pravastatin, fluvastatin, rosuvastatin	12.7 months median (95%CI 11–14.4 m)	–
Al Chekakie, 2007	Patients with paroxysmal or persistent AF undergoing CA	177 NS	NS	13.8 months (8.6)	• Patients who underwent segmental ostial isolation or additional left atrial linear lesions

• AF, atrial fibrillation; CA, catheter ablation; CAD, coronary artery disease; EC, electrical cardioversion; EF, ejection fraction; LV, left ventricular; NS, not specified; ND, not declared.

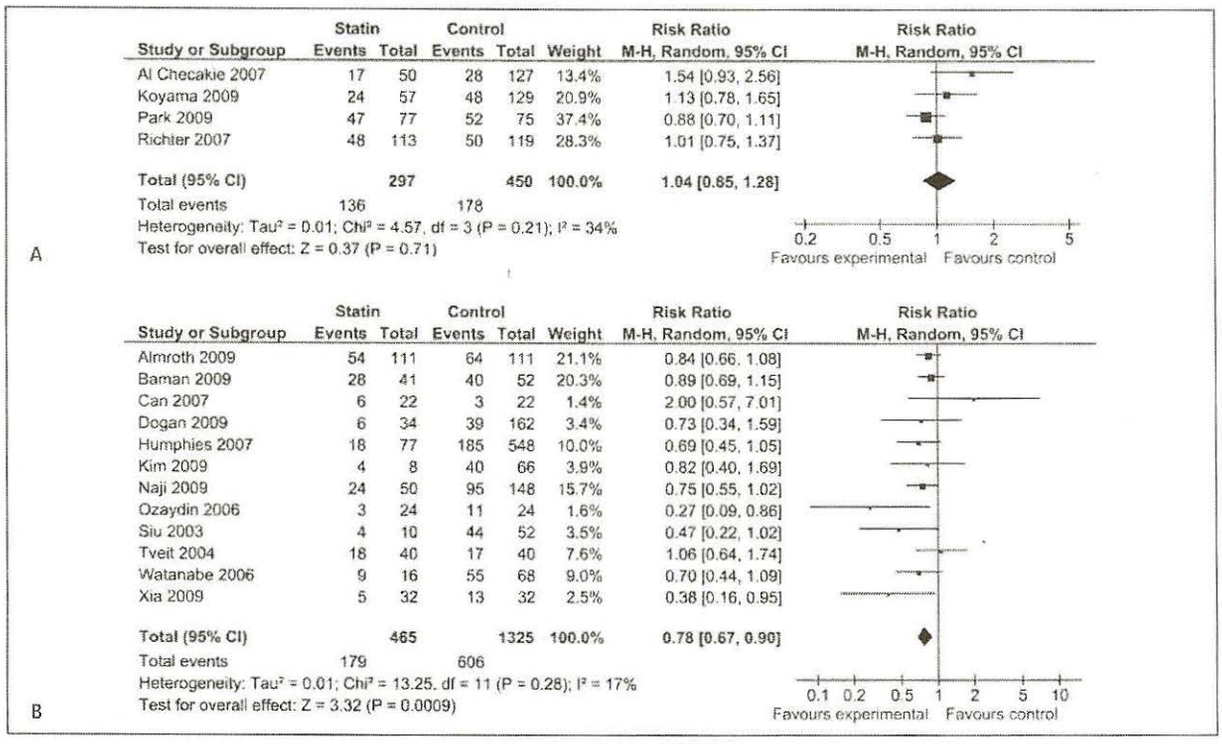

Figure 1: Pooled relative risk (RR) and 95% confidence intervals (CIs) of atrial fibrillation (AF) recurrence after catheter ablation (A) and electrical cardioversion (B).

Discussion

In our systematic review and meta-analysis of the literature we assessed the effect of statin therapy on the risk of AF recurrence after catheter ablation or electrical cardioversion. We found a statistically significant reduction in the incidence of recurrent AF after electrical cardioversion and no effect of statins on AF recurrence after catheter ablation. The 7.2% absolute risk reduction obtained with the use of statins after electrical cardioversion resulted in a number needed to treat of 14 patients. When the analysis was restricted to the five RCTs only, the magnitude of the effect was similar, but statistical significance was not reached. Although possibly due to the small number of patients included in these trials, lack of efficacy cannot definitively be excluded. In addition, the type and dose of statin drug also varied across studies, which raises additional questions of statin equipotency (45).

The results of our meta-analysis of studies conducted in patients undergoing electrical cardioversion are in keeping with the results of previous RCTs and meta-analyses which have shown that statins are effective in reducing the incidence of AF in patients undergoing cardiac surgery (19), after acute coronary syndromes (46), and in patients in sinus rhythm with a history of previous AF (46). There is a strong biological plausibility to support these findings. Rapidly growing evidence supports a relationship between AF and both cellular and plasma markers of inflammation including high-sensitivity CRP, interleukin-6, and interleukin-8. Inflammation may interfere with the structural and electrical properties of the atrial myocardium, creating a susceptible substrate for AF (12, 47). Furthermore, increased atrial oxidative stress may play an important role in inducing and maintaining AF (48, 49). Finally, recent data show that a decrease in endocardial NOS expression and atrial NO bioavailability directly contribute to the pathogenesis of AF (49), and that an imbalanced expression of iNOS/eNOS with nitric oxide overproduction could contribute to protein nitration and cardiomyocyte apoptosis in human AF (50). Statins have been shown to exhibit several vascular protective effects, including anti-inflammatory and antithrombotic properties, that are not related to changes in lipid profile (17, 51). Because statins can improve endothelial NO production, have anti-inflammatory effects and reduce oxidative stress, these drugs may act by preventing the establishment of a substrate for AF (51). Moreover, both Rac1 and RhoA, which are upregulated and mediate signal transduction integral to the pathogenesis of AF (52), are inhibited by statins.

We failed to observe a positive effect of statins in patients undergoing catheter ablation. The long duration of AF prior to ablation might account for the lack of efficacy of these medications since the patients are more likely to have established fibrosis and scarring, and thus less likely to respond to medications that inhibit inflammation. Furthermore, most of the clinical recurrences associated with this procedure are due to recovery of the lesion, mech-

What is known about this topic?

- Statins have important pleiotropic effects and have been shown to reduce vascular inflammation.
- Some evidence suggests that statins may have a role in the primary prevention of atrial fibrillation (AF), whereas little is know on the role of statins in patients with existing AF.

What does this paper add?

- The results of this study indicate that statins may lower the risk of AF recurrence after electrical cardioversion, but not after catheter ablation.
- Our study provides additional information to support the design of future randomised controlled trials to rigorously evaluate this question. Optimal dose selection and periods of follow-up appropriate to answer this question will be paramount.

anism that is independent by the action of these medications (53). On the other hand, this finding may be explained by the small number and by the relatively low quality of studies included, differences in study populations, and the retrospective study design in which temporal relationships between statin exposure and AF recurrence are difficult to discern. In addition, statin type and dose were not specified significantly limiting any informed conclusions. The effect of statins on AF recurrence following catheter ablation awaits results of well-designed RCTs.

Our meta-analysis has several limitations. First, our systematic review includes RCTs and observational studies. Application of formal meta-analytic methods to observational studies is controversial, since bias implicit in the study design may misrepresent the strength of associations within the data (22). To minimise this potential bias, we selected only studies in which the diagnosis of AF recurrence was objectively confirmed. Furthermore, we strictly followed the guidelines for quality of reporting of meta-analysis of RCTs and observational studies (PRISMA, MOOSE) to better clarify our results (21, 22). Second, the studies included in our meta-analysis had different inclusion and exclusion criteria. However, the heterogeneity among the studies, calculated using the I^2 statistic, was generally low. Third, since there were only a few studies assessing the role of statins in patients undergoing catheter ablation, the presence of publication bias in this setting could not be excluded. In patients undergoing electrical cardioversion, the funnel plot of RR versus standard error appeared slightly asymmetric with an absence of studies in the bottom right hand corner, suggesting that smaller, unpublished studies that demonstrate an increased RR of AF recurrence in patients taking statins may be not included in our meta-analysis. Our findings pertain to the effects of statins as a drug class. As stated previously, the type and dose of statin varied significantly across studies, e.g. atorvastatin dose ranged from 10 mg to 80 mg, raising questions of differential potency. Furthermore, due to the limitation of meta-analytic approach we were not able to explore possible additive effects of statins to other drugs with more established efficacy on secondary prevention of AF.

The prevalence of AF is projected to greatly increase over the next few decades particularly among older adults (54). The 30-day mortality related to AF stroke is 24% and haemorrhagic complications limit widespread use of anticoagulant therapy in the oldest and highest risk patients (55). Electrical cardioversion remains the most commonly used method to restore sinus rhythm, and despite a number of pharmacologic strategies to maintain sinus rhythm, a considerable proportion of patients continue to relapse to AF (1). The results of our meta-analysis suggest that statins may be effective in reducing AF recurrence after electrical cardioversion. Our study provides additional information to support the design of future RCTs to rigorously evaluate this question. Optimal dose selection and periods of follow-up appropriate to answer this question will be paramount.

Abstract

Purpose: We sought to describe how patient characteristics influence the frequency of red blood cell (RBC) transfusions among critically ill patients after taking into account hemoglobin (Hgb) level.

Methods: This was a retrospective cohort study using secondary analysis of administrative data of Veterans Affairs intensive care unit (ICU) admissions. The outcome of interest was RBC transfusion during the first 30 days of ICU admission. Besides Hgb level, explanatory variables included demographics, admission-related information, comorbid conditions, ICU admission diagnosis, and selected laboratory test results. Logistic regression modeling quantified associations between explanatory variables and transfusion.

Results: For 259 281 ICU admissions from 2001 to 2005, the overall incidence of RBC transfusion was 12.5%. Increased age, male gender, admission for acute myocardial infarction (AMI), and comorbid heart disease were independently associated with transfusion. Compared with admission for reference diagnoses, transfusions were more likely for admissions for AMI, unstable angina, and congestive heart failure only at Hgb levels below 11, 9, and 6 g/dL, respectively.

Conclusions: Intensive care unit patients admitted for AMI, unstable angina, and congestive heart-failure had higher likelihood of receiving RBC transfusions below specific Hgb levels varying from 6 to 11 g/dL. Further research is needed to determine how these transfusion practices influence outcomes.

1. Introduction

Anemia is exceptionally common among patients admitted to an intensive care unit (ICU). Consequently, red blood cell (RBC) transfusions are extremely common, with some studies suggesting that this occurs among 20% to 53% of critically ill patients [1]. In a prospective, observational study involving 1136 patients from 145 western Europe ICUs, Vincent et al [2] found that 37% received RBC transfusions during the first 28 days of ICU admission. Older patients and those who stayed longer were more commonly transfused. In another prospective, observational cohort study of 4892 patients admitted to 284 ICUs in the United States, Corwin et al [3] found that 44% of patients had RBC transfusions during the first 30 days of ICU admission, with the number of transfusions received by a patient being independently associated with longer ICU stays. These studies had relatively small samples and examined practices in 2001 and earlier. Moreover, only a limited number of potential predictors of transfusion were studied. Although hemoglobin (Hgb) level is clearly an important determinant for transfusion, the decision to transfuse blood in ICU patients is often more complex. There is a need to better understand factors contributing to this decision beyond the Hgb level.

Although RBC transfusion has long been considered a relatively safe procedure, a growing body of literature suggests that it is associated with an increased incidence of nosocomial infections, acute lung injury, multiorgan failure, and mortality [4-8]. The benefits of Transfusions have also been questioned because of the Transfusion Requirements in Critical Care (TRICC) Trial, a landmark, randomized, controlled trial that demonstrated that critically ill patients managed with a liberal transfusion policy had similar outcomes with those managed with a restricted policy that advocated transfusions only at Hgb levels below 7 g/dL [9]. More than ever before, it is critical to identify factors beyond Hgb level that are associated with likelihood of transfusions to gain valuable insights on how physicians make their clinical decisions to transfuse in the ICU setting.

We therefore conducted an observational study to examine transfusion practices among ICU patients of Veterans Affairs (VA) medical centers. The large sample of patients available from the extensive electronic databases of the VA, which is the largest health delivery system in the United States, conferred a significant advantage in achieving our study objective, which was to identify patient characteristics associated with an increased likelihood of RBC transfusion after adjusting for Hgb level. We sought to test our hypothesis that specific comorbid conditions and admitting diagnoses are independently associated with higher likelihood of transfusion among ICU patients. Our results will identify important factors that influence the decision of physicians to transfuse and can then provide the basis for further research and quality improvement efforts.

2. Materials and methods

2.1. Study design and data sources

We conducted a retrospective cohort study using secondary analysis of VA electronic databases at the Center for Health Quality, Outcomes and Economic Research at VA Bedford in Massachusetts. Ethical approval was obtained from the VA Bedford Institutional Review Board, which also approved the study procedures. We obtained detailed clinical information at the national level through several VA databases. Information on each medical encounter was obtained from the National Patient Care Database. Selected laboratory results were extracted from the Decision Support System. The date of death was determined by combining information from the Beneficiary Identification Record Locator Subsystem, National Patient Care Database, and Social Security files.

2.2. Sample

We downloaded relevant data from the Veterans Health Administration Office of Information at the Austin Automation Center. The study database included information on all medical ICU admissions in the VA for the years 2001 through 2005. For hospitals that may have had separate surgical and neurologic ICUs, we only considered the medical ICU. We also excluded operative cases defined as having surgical admitting diagnoses. The purpose was to avoid accounting for postsurgical transfusion practice that probably has different determining factors. We only included the first ICU admission of each year for any given patient.

2.3. Dependent variable

The outcome (dependent) variable for this study was administration of blood transfusion during the first 30 days of ICU admission. A transfusion was considered as having been received if there was the *International Classification of*

Diseases, 9th Revision, Clinical Modification (*ICD-9-CM*) procedure code of 99.04 (transfusion of packed cells) or 99.03 (transfusion of whole blood) on a date in which the patient is known to be in the ICU and from the specific ICU file of the inpatient records. For patients with multiple dates on which transfusions were listed, each date was recorded. Intensive care unit admissions during which at least 1 transfusion had been documented during the first 30 days of stay were collectively assigned as the "transfusion" group. All other ICU admissions were assigned as the "no transfusion" group. To identify hospitals that may be systematically underreporting transfusions, we examined rates at each VA medical center. To exclude hospitals that were possible outliers with respect to transfusion practices, we arbitrarily removed data from 8 out of 120 hospitals where the transfusion rates were beyond 2 standard deviations from the mean rate.

2.4. Independent variables

Besides Hgb level, explanatory (independent) variables examined included (1) demographics: age, sex, race, or ethnicity; (2) admission-related information: year, hospital, source of admission to ICU (direct or transfer); (3) comorbid conditions: based on the set of Elixhauser et al [10] of 30 comorbidity measures, Acute Physiology and Chronic Health Evaluation (APACHE) III chronic health [11], and others [12,13]; (4) ICU admission diagnosis: based on medical diagnoses used by Health Cost and Utilization Project [14]; and (5) laboratory values of blood tests: serum creatinine and others based on APACHE III acute physiologic abnormalities [11].

Demographic variables such as sex and race were included based on clinical opinion. Admission-related variables such as year and medical center were added to take into account the potential clustering effects of time and hospital. Source of ICU admission was either "direct" (from sources outside the hospital) or "transfer" (from another unit in the hospital). This information may reflect the rapidity of illness onset, which in turn may influence likelihood of receiving transfusion.

Hemoglobin level has been shown to be strongly associated with performance of transfusion [2,3] and therefore would need to be adjusted for in the endeavor to isolate the effects of other patient factors. We developed an algorithm to select 1 Hgb value (designated as Hgb level) from among others for that ICU admission. First, we selected the lowest value during the period from ICU admission to blood transfusion within the first 30 days of ICU stay. If they were not transfused in that period, then we selected the lowest value from ICU admission to 30 days after ICU admission or to ICU discharge, whichever occurred earlier. If no value during the first 30 days of ICU admission was available, then we selected the lowest value during the period from day of hospital admission to day of ICU admission. The Hgb test closest to the transfusion was not selected because there was no corresponding test for admissions without transfusion. To account for any acute decrease in Hgb usually caused by hemorrhage, we created an additional variable called Hgb change, defined as the difference between the latest Hgb test before hospitalization and Hgb level.

Chronic comorbid diseases and ICU admission diagnoses may influence the likelihood of receiving transfusion and would also need to be adjusted for. The *ICD-9-CM* codes for comorbid conditions and ICU admission diagnoses were those used in the original study by Elixhauser et al [10] and adapted from those used by Health Cost and Utilization Project [14], respectively. Comorbid conditions were considered present if the *ICD-9-CM* code of the diagnosis was stated at least once in administrative records during the 2 years before the hospital admission. Where there was an overlapping admission diagnosis, the chronic comorbid disease was not assigned to avoid double counting of diagnostic information (Appendix A). To identify patients with chronic kidney disease, we used the following operational definition:

1. estimated glomerular filtration rate (eGFR) less than 60 mL/min per 1.73 m^2 on first day of ICU admission; and
2. eGFR less than 60 mL/min per 1.73 m^2 done at least 90 days before ICU admission.

These criteria were consistent with the Kidney Disease Outcomes Quality Initiative definition of chronic kidney disease that required patients to have glomerular filtration rate less than 60 mL/min per 1.73 m^2 for at least 3 months [15]. The eGFR values were calculated from the serum creatinine values using the predictive equation derived from the Modification of Diet in Renal Disease study [16]. The ICU admission diagnosis was obtained by selecting the first *ICD-9-CM* code from the ICU files.

Besides Hgb level, candidate blood tests based on APACHE III acute physiologic abnormalities [11] were white blood cell count, serum creatinine, blood urea nitrogen, serum sodium, serum albumin, serum bilirubin, and serum glucose. However, arterial blood gases were not included because they were not available from our data sources.

Other candidate independent variables that may be associated with administration of blood transfusion but were not available in the national VA data sets were functional status, cognitive scores, and clinical parameters.

Several studies have evaluated the quality of data included in VA national databases. In 3 studies, diagnoses listed in the database have compared favorably with medical records [17-19]. Data on race have also compared favorably to patient self-report [20].

2.5. Analyses

We excluded variables where there were missing values for more than 20% of the sample. For the remaining

variables, we deleted the entire record if there was a missing value. Although this was likely to result in decrease in the sample size available for the analysis and consequent loss of power, it was the simplest approach. Other commonly used methods, such as simple imputation, were not used because we could not assume that the data were missing completely at random. We compared baseline characteristics for included and excluded ICU admissions to alert us to any major differences between these 2 groups.

We performed principal components analyses to group together comorbidity variables that were highly correlated with each other (Appendix B). The purpose was to reduce the original 30 comorbid conditions to a smaller number of comorbidity groupings to facilitate parsimony in regression modeling. We performed logistic regression to build explanatory models for receipt of transfusion. In addition, we used hierarchical modeling to account for clustering within multiple years hospitals, and ICU admissions for unique patients. The purpose was to determine if treatment estimates and their confidence intervals differed significantly when patient clustering was taken into account. For comorbid heart disease and cardiac ICU admission diagnoses, we included interaction variables of these diagnoses with Hgb level in the model. This is to explore the possibility that Hgb level may be an effect modifier in the relationship between these conditions and transfusion receipt.

We used Statistical Analyses System (SAS Institute, Cary, NC) to perform the data analyses. Statistical significance was taken at $P < .05$.

3. Results

The total number of ICU admissions during the period of fiscal years from 2001 to 2005 was 302 059. After selecting only the first ICU admission for each fiscal year for any patient, the number of ICU admissions per unique patient was 1 (86.2%), 2 (11.4%), 3 (2.0%), 4 (0.4%), and 5 (0.1%). The mean age (SD) of patients was 66.0 years (12.5). Only 2.8% of ICU admissions were for female patients, as was expected for the VA. Ethnic distribution of patients was white (62.7%), black (17.1%), Hispanic (4.5%), and others (15.7%). Rather than transfer from another inpatient hospital unit, direct admission to the ICU from sources outside the hospital occurred in 76.8%. The mean baseline Hgb level (SD) was 11.4 g/dL (2.6).

Due to missing values, 42,778 (14.2%) ICU admissions were excluded, leaving 259,281 available for multivariable analyses. Hgb level and almost all other variables were similar for both included and excluded admissions (Appendix C). The incidence of RBC transfusion during the first 30 days of ICU admission was 12.5%. The mean time (SD) from ICU admission to first blood transfusion received was 1.8 days (3.4).

Patient characteristics of transfused and nontransfused patients are compared in Table 1. Principal components

Table 1 Comparison of the characteristics of transfused with nontransfused patients (N = 259 281)

Explanatory variables	Transfused (n = 32 386)	Nontransfused (n = 226 895)
Hgb level (g/dL)	8.1	11.9
Demographic and admission features:		
Age (y)	68.1	65.8
Male (%)	97.7	97.1
White race (%)	60.6	62.8
Black race (%)	18.0	16.6
Other races (%)	7.0	5.4
Unknown race (%)	14.4	15.2
Direct admission (%)	69.5	76.9

* Interaction between the 2 variables.

analyses permitted us to reduce the original 30 comorbid condition variables to the 13 grouping variables listed. Laboratory test variables, besides serum creatinine and Hgb level, were dropped on account of missing values for more than 20% of the sample population. Statistically significant differences were found for most of these variables. The unadjusted odds ratios (ORs) are presented in the second column of Table 2. Similarly, the unadjusted OR for ICU admission diagnoses where the reference group was admission diagnoses other than the 21 categories specified are also provided in that column.

After adjustment for Hgb level using logistic regression, there were several patient characteristics identified to be independently associated with the administration of RBC transfusion (Table 2). Intensive care unit admission for acute myocardial infarction (AMI) and comorbid heart disease increased the likelihood of transfusion. Other characteristics independently associated with transfusion were increasing age, races other than white or black, direct transfer to the ICU, increasing length of ICU stay, and ICU admission diagnoses of gastrointestinal (GI) bleeding, GI neoplasm, other GI disorders, and orthopedic problems. Additional comorbid conditions independently associated with transfusion included heart disease, liver disease, coagulopathy, anemia, peptic ulcer disease, and chronic kidney disease.

When Hgb level was substituted with Hgb change in the multivariable model, the c-statistic decreased from 0.92 to 0.87. When Hgb change was included as an additional variable, it was not independently associated with transfusion. In view of these findings, Hgb change was not selected for our final model.

The interactions of ICU admission diagnosis of AMI, unstable angina, and congestive heart failure (CHF) with Hgb level were all statistically significant, as shown in Table 3. The negative sign in the coefficient estimate for the interaction variable indicates that when any of these 3 conditions was the reason for ICU admission, the relative increase in likelihood of transfusion was more pronounced

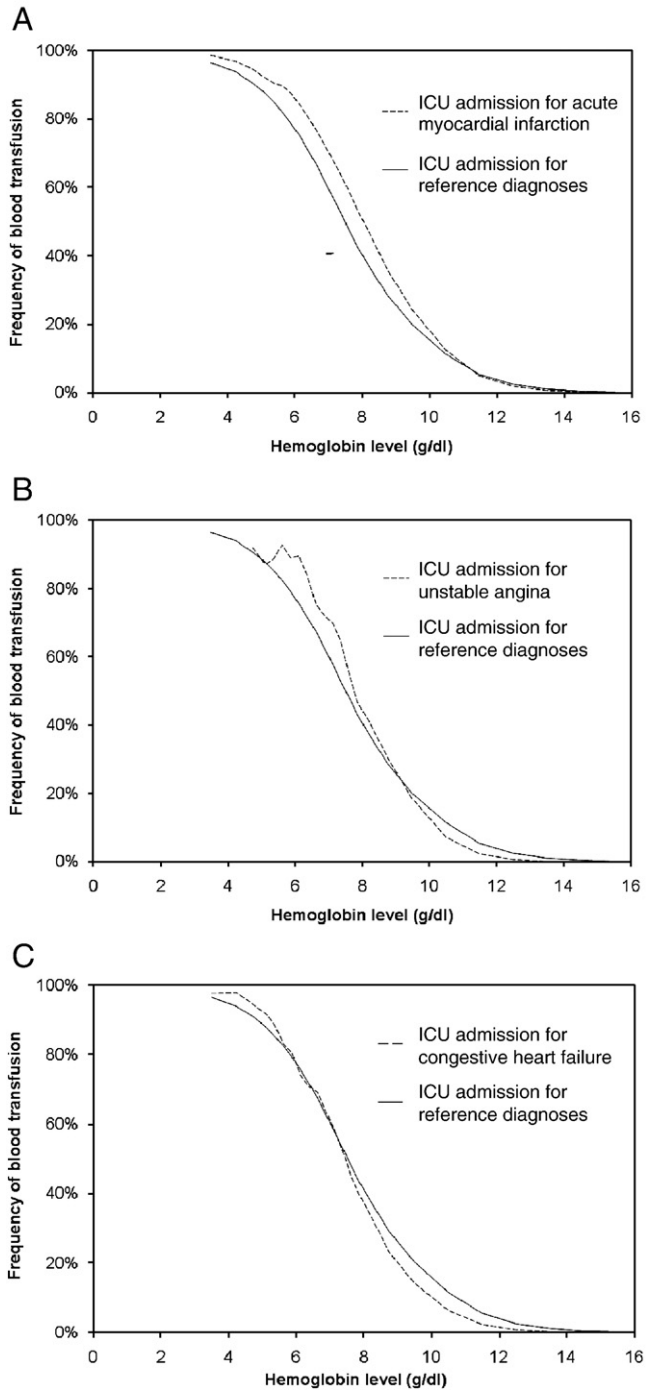

Fig. 1 Relationship between RBC transfusion and Hgb level using model predicted values for ICU admission diagnosis of AMI (A), unstable angina (B), and CHF (C) compared with ICU admission for reference diagnoses.

with decreasing Hgb levels. The interaction of comorbid heart disease and Hgb level was not statistically significant. The graph showing the model-predicted probability of receiving transfusions in Fig. 1A illustrates that ICU admissions for AMI had an increase in likelihood of transfusion when Hgb level was below about 11 g/dL, relative to those for reference medical diagnoses. Similarly,

information for ICU admissions for unstable angina is shown in Fig. 1B, indicating that relative increase in transfusions occurred when Hgb level was below about 9 g/dL. Finally, in the case of ICU admissions for CHF, relative increase in transfusions occurred only when Hgb level was below 6 g/dL. Additional details of this last subgroup are found in Appendix D.

Hierarchical modeling that accounted for clustering of ICU admissions within multiple years of data, multiple hospitals, and more than one ICU admission for individual patients did not result in significant changes in coefficient estimates (results not shown). The intra-class correlation coefficient for the random effects model accounting for clustering around hospitals was 0.25. This indicates that the proportion of transfusion variability explained by hospitals was 25%.

4. Discussion

To a large extent, Hgb level thresholds drive transfusion practices in critically ill patients [21]. In addition, a variable degree of influence is also exerted by other patient factors. In a scenario-based national survey of Canadian critical care practitioners, Hebert et al [22] and the TRICC investigators found that 75% of respondents selected an overall transfusion threshold of Hgb level 9 or 10 g/dL. Where there was GI hemorrhage or AMI, Hgb level 10 g/dL was the most frequently chosen threshold. Increased age, APACHE II score, hypoxemia, shock, coronary ischemia, and chronic anemia also raised transfusion thresholds, whereas CHF did not. Moving on from survey responses to actual clinical practice, the same investigators examined transfusion practice in a multicenter cohort study of 5298 tertiary-level ICU patients. They found that independent predictors of transfusion thresholds were age, APACHE II score, and institution [23]. Subsequently, in a prospective observational study of 3534 patients from 146 western European ICUs, Vincent observed that transfused patients were older and had higher admitting APACHE II scores and lower admitting Hgb levels. The overall mean pretransfusion Hgb level was 8.4 g/dL, with presence of coronary artery disease raising this level marginally to 8.7 g/dL [2]. In the CRIT (Anemia and blood transfusion in the critically ill – Current clinical practice in the United States) cohort study of 4892 patients from 284 American ICUs who were followed prospectively, Corwin et al [3] found that the mean pretransfusion Hgb level was 8.7 g/dL. There was little association of age with transfusion, and the incidence of transfusion was relatively consistent across comorbidities with the exception of anemia and hematologic disease being associated with more frequent transfusions. There were also more transfusions with the admitting diagnosis of GI hemorrhage and with higher APACHE II scores [3]. A recent study of 238 patients admitted to 5 general Israeli ICUs found that those with AMI had significantly higher Hgb level transfusion trigger (8.8 g/dL) than that for the whole group (7.9 g/dL). This trend was also seen for those with history of heart disease [24]. Although these studies were informative on the influence of specific patient characteristics, there is a need to examine how these factors operate while taking into account Hgb level and other patient factors. We argue that adopting this approach will provide insights on the way physicians think about transfusions in clinical practice. To this end, multivariable regression is needed to adjust for Hgb level and other patient factors so as to isolate the effect of any individual factor. Given the wide range of candidate patient factors to work on in regression analyses, a large sample size is required.

To the best of our knowledge, this is by far the largest observational study examining transfusion practices in ICUs. Using a large sample built on data from numerous ICUs across the United States albeit exclusively from the VA health care system, we found that age, male gender, admission for AMI, comorbid cardiac disease, and chronic kidney disease were independently associated with transfusion after adjustment for Hgb level and other measured patient factors. Not surprisingly, this was also the case for comorbid liver disease, coagulopathy, peptic ulcer disease, and anemia, as well as ICU admission for GI and orthopedic diagnoses. It is noteworthy that with the exception of admission for GI bleeding (OR, 5.44), these factors had relatively modest strengths of association (OR between 1.05 and 1.57). This reflects the complex relationships between multiple factors and their association with transfusion. However, demonstration that Hgb level was a significant effect modifier in the relationships between 3 cardiac ICU admission diagnoses and transfusion receipt is perhaps the most important contribution that our study brings to the expanding literature on transfusion practices in the critical care setting.

Relative to reference diagnoses, ICU admission for AMI was associated with higher likelihood of receiving transfusions at Hgb levels below about 11 g/dL. It is conventional clinical wisdom that transfusions will benefit patients with acute heart disease more as Hgb level decreases through facilitation of optimal oxygen delivery. It is quite plausible that this expectation is reflected in clinical practice. This strategy is supported by evidence from a large observational study on 78 974 older adults with AMI in which Wu et al [25] found that transfusions were significantly associated with lower mortality for hematocrit levels up to 33% (or Hgb level of 11 g/dL). With respect to 30-day mortality, the adjusted OR for transfusion was 0.22 for those with hematocrit below 24% (or Hgb level of 8 g/dL or lower) and 0.69 for those with hematocrit of 30.1% to 33.0% (Hgb level of 10.1 to 11.0 g/dL) [25]. Interestingly, a subsequent subgroup analysis of the TRICC trial focusing on 257 patients with ischemic heart disease found that those assigned to the "liberal" strategy of transfusing when Hgb level was below 10 g/dL had a nonstatistically significant reduction in 30-day mortality (21% vs 26%) compared with those who were assigned the "restrictive" strategy of transfusing only when

the Hgb level was below 7 g/dL [26]. Aronson et al [27] demonstrated that transfusion conferred a statistically significant reduction in mortality in another observational study on adults with Hgb levels of 8 g/dL or lower with adjusted hazard ratio of 0.13. Similarly, Alexander et al [28] found that for patients with non–ST elevation acute coronary syndromes including AMI experienced an almost significant trend toward inhospital mortality reduction (OR, 0.67) with transfusion when hematocrit was 24% or lower (or Hgb level of ≤8 g/dL). In contrast, analysis of data from 3 large international trials on acute coronary syndromes by Rao et al [29] showed that transfusion was significantly associated with increased mortality across all categories of hematocrit levels with adjusted hazard ratio of 3.54. Given the somewhat conflicting evidence on the effect of transfusion on mortality in the setting of AMI, further clinical trials are needed to determine the Hgb level below which transfusion will benefit patients rather than harm them. It is telling that although the restrictive transfusion strategy was not recommended for patients with AMI and unstable angina in a recently published clinical practice guideline on RBC transfusions in critical care, no specific guidance on an appropriate Hgb level threshold was offered [30]. Ideally, a randomized, controlled trial like the TRICC focusing specifically on patients with AMI in ICU will be needed. In the absence of such trials, a large and robust observational trial may shed more light on this issue. Given the knowledge of transfusion practices gained from our study, it is important and arguably urgent to obtain the answer to this question.

In contrast, ICU admission for unstable angina was associated with lower likelihood of transfusion compared with admission for reference admission diagnoses. However, transfusions became more likely at Hgb levels below about 9 g/dL. This level is slightly higher than the level (equivalent to Hgb level ≤8 g/dL) below which transfusions had a beneficial impact on mortality among those with non–ST elevation acute coronary syndromes including unstable angina in the study by Alexander [28]. Given the paucity of evidence on the Hgb level threshold for transfusions in the setting of unstable angina, additional clinical trials are needed to provide the answer.

Similarly, ICU admission for CHF was associated with lower likelihood of transfusion compared with reference admission diagnoses. This is not surprising, given that physicians are usually conservative on transfusions in this setting because of concern that transfusions may exacerbate the fluid overload state, preferring to transfuse only when Hgb levels are much lower. Indeed, our study showed that there was higher likelihood of transfusion relative to reference admission diagnoses only at Hgb levels of about 6 g/dL or lower. We are not aware of any published clinical trials that specifically address transfusion thresholds in the setting of CHF.

Compared with the studies by Vincent et al [2] and Corwin et al [3] where 37% and 44% of patients were transfused during the first month of ICU admission, only 12% of our study population received transfusions. It is likely that selection issues have, in part, accounted for these differences. Transfusions tend to be more common among surgical patients. Although the 2 earlier studies included surgical ICUs, we attempted to focus on medical ICUs. We excluded admissions to surgical and neurologic ICUs where these facilities were separate from the medical ICU at that hospital. We also excluded those admissions for diagnoses that were surgical in nature. It seems unlikely that transfusion threshold differences may have contributed to lower transfusion rates in our study, given that the mean pretransfusion Hgb level across all 3 studies were similar and within the 8 to 9 g/dL range.

The ICUs in our study were heterogeneous with respect to whether they were staffed only by attending physicians or had additional residents and fellows, teaching hospitals or not, and located in urban or rural areas. There are no national VA policies on transfusion decisions. Difference in hospitals probably had small to moderate influence on transfusion practice. This is reflected by the proportion of transfusion variability explained by hospitals being 25%. A recent study exploring hospital variation in transfusion among patients after cardiac surgery obtained similar findings [31].

There are 3 important limitations to our study. Firstly, no VA data exist on the accuracy of *ICD-9-CM* codes indicating transfusion receipt. However, among patients with lower Hgb levels, we found that up to about 70% received transfusions (results not shown). This suggests that most transfusions would probably have been identified using these codes. We also relied on external evidence from a previous study on validity of the billing for blood transfusion at one non-VA tertiary care hospital in the United States. Using the relevant ICD-9-CM procedure code, Segal found that sensitivity and specificity for identification of transfusions from blood bank records were 83 percent and 100 percent respectively [32]. Errors in transfusion timing are minimized because we examined the date and time of transfusion from procedure codes, and only identified transfusion codes found in the ICU files. While we acknowledge the possibility of under-coding of transfusions, we argue that its extent was likely to be relatively small. Transfusion codes were also used in a study of VA patients with chronic kidney disease [33]. Secondly, only about 3% of patients were female. However, given that the number of ICU admissions of female patients is in excess of 7000 and that we adjusted for sex in our multivariable regression analyses, we argue that our model is likely to be valid for both sexes. Finally, we did not have information on all dimensions of acute illness severity nor on functional status. We are uncertain on the extent to which the absence of this information may have introduced hidden bias. Given the high level of model discrimination (c-statistic >0.9) achieved, we believe that any unmeasured factors are unlikely to have significant impact on transfusion practice.

5. Conclusions

Independent of Hgb level and other patient factors, ICU admission diagnoses of AMI and comorbid heart disease increased likelihood of RBC transfusion. Compared with patients admitted for reference admitting diagnoses, those admitted for AMI, unstable angina, and CHF were more likely to be transfused only at Hgb levels below about 11, 9, and 6 g/dL, respectively. Given our findings, further research is needed to determine how these transfusion practices influence outcomes of patients admitted to the ICU.

Atrial fibrillation (AF) poses a major global public health challenge because it is increasing in prevalence and is associated with an increased risk of stroke, dementia, heart failure, and death.[1–3] In response to the many challenges posed by AF, the American Heart Association (AHA) convened a conference in Washington, DC, on June 12–13, 2010, that included patients, nurses, physicians, and healthcare policy makers and regulators. In addition, basic, translational, population, outcomes, and clinical scientists participated (Appendix). The 22 presentations and 6 panel discussions were organized into 4 sessions: (1) Mechanisms of AF: Basic and Translational Science and Genetics; (2) Epidemiology, Outcomes, Cost, AF, and Stroke Prevention; (3) Meeting the Clinical Challenges in AF; and (4) Redefining the Therapeutic Goals of AF (Appendix). The focus of the present report is to provide an overview of the key concepts presented and the core recommendations made by the summit participants.

Mechanisms of AF: Basic and Translational Science and Genetics

Attempts to develop safe and effective pharmacological therapy for AF have focused on atrium-selective drugs that take advantage of electrophysiological differences between the atrium and ventricle.[4–7] Heterogeneous abbreviation of the effective refractory period within the atrium provides the electric substrate for development of AF. The reduced effective refractory period results from abbreviation of the atrial action potential duration, which is caused by a decrease in the calcium channel current (I_{Ca}) and an increase in the potassium channel current (I_{K1}) and the constitutively active acetylcholine-sensitive current (CA I_{KACh}).[4–7] Maintenance of AF is facilitated by structural remodeling and additional abbreviation of the effective refractory period. The principal goal of pharmacological therapy is therefore to augment the effective refractory period.

Distinctions in the ion channel currents between the atrium and ventricle open the possibility for development of atrium-specific and -selective drugs for rhythm control of AF, which might avoid ventricular proarrhythmic effects. Atrium-specific targets include I_{Kur}, I_{KACh}, and the constitutively active I_{KACh}, the most investigated of which is inhibition of I_{Kur}.[7] Recent experimental studies have identified atrium-selective I_{Na} blockers that can effectively suppress AF while exerting little or no effect in the ventricles.[5,6] Combinations of

antiarrhythmic medications, such as amiodarone and ranolazine or dronedarone and ranolazine, are a promising avenue of investigation.[8,9] In animal models, such combinations produce potent synergistic effects that result in atrium-selective depression of sodium channel–dependent parameters and effective suppression of AF. Although synergism between atrium-selective drug combinations holds great promise, future work will be required to determine the safety and efficacy of such drug combinations in patients.

Multiple lines of evidence from basic, translational, and human studies suggest that atrial fibrosis plays an important role in the maintenance of AF.[10–13] Understanding of the mechanisms of atrial fibrogenesis will provide better targets for antifibrotic treatment of AF. There is a lack of detailed information about the biological and electrophysiological properties of fibroblasts and myofibroblasts under normal and AF conditions. Insights into signaling pathways suggest that atrial fibroblasts can be effective therapeutic targets for prevention of fibrosis.[14–16] Multiple agents with antifibrotic properties have demonstrated effects on reducing atrial fibrosis in animal models, but clinical evidence supporting their efficacy in AF prevention is currently lacking. Identification of fibroblast-specific genes will help to develop a fibroblast-specific knockout or transgenic mouse model.

Endothelin 1, a potent vasoconstrictor and mitogen involved in blood pressure regulation, may merit further investigation in AF because it modulates calcium cycling in cardiac myocytes and promotes fibroblast proliferation.[17] Because of the differential distribution of downstream signaling elements, endothelin 1 has a greater impact on atrial than on ventricular calcium cycling and contractility.[17] Interestingly, atrial endothelin 1 levels are elevated in the left atrium of patients with structural heart disease and persistent AF.[17]

Late gadolinium enhancement by cardiac magnetic resonance imaging is a highly specific and sensitive method for detecting scar in the ventricular myocardium.[18,19] Furthermore, it has been demonstrated recently that the same gadolinium-based extracellular contrast agents can be used for the quantification of extracellular remodeling and the detection of diffuse interstitial fibrosis.[20,21] Development of methods for direct assessment of myocardial collagen burden using extracellular collagen-binding contrast agents might allow imaging to characterize the presence and severity of atrial fibrosis noninvasively.

Over the past 5 years, family history has been established as a risk factor for AF.[22] Familial forms of AF have been described, and mutations have been identified in ion channel proteins and signaling molecules; however, these genes are rare causes of AF.[23–26] Genome-wide association studies have revealed genetic risk factors for AF unanticipated by prior knowledge. In one case, the genetic variants are adjacent to a transcription factor that specifies left atrial and pulmonary vein development. How variants at this and other loci lead to AF remains unclear. Future efforts should be focused on the identification of new genetic loci, determination of the mechanism by which polymorphisms are associated with the initiation or promotion of AF, and exploration of the relation between genetic data and clinical outcomes for AF. Systems biology approaches can provide important insights by addressing the complex interactions between risk factors and disease and thus may facilitate our understanding of novel AF mechanisms. The major recommendations related to basic and translational science and AF are summarized in Table 1.

Table 1. Recommendations From the AHA Atrial Fibrillation Research Summit: Mechanisms of AF: Basic and Translational Science and Genetics

Conduct research on the mechanisms and pathogenesis of AF.
Explore the relation between genetic data and clinical outcomes for AF.
Determine the properties of sodium channel blockers (kinetics and modes of binding and unbinding, lipid solubility, molecular size, and chemical structure) that influence atrial selectivity.
Define how electrical and structural remodeling and genetics modify atrial selectivity and the utility and safety of I_{Na} blockers for treatment of AF.
Define the short-term and long-term effects of atrium-selective I_{Na} blockers.
Determine methods for direct assessment of atrial myocardial collagen burden, including extracellular collagen-binding MRI contrast agents.
Evaluate the biological, electrophysiological, and signaling properties of fibroblasts and myofibroblasts under normal and AF conditions to identify novel targets for antifibrotic therapy.
Identify biological markers that will allow antifibrotic treatment at early stages of fibrogenesis.
Identify fibroblast-specific genes to allow development of a fibroblast-specific knockout transgenic mouse model.
Determine the role of endothelin 1 in AF.

AHA indicates American Heart Association; AF, atrial fibrillation; and MRI, magnetic resonance imaging.

Epidemiology, Outcomes, Cost, AF, and Stroke Prevention

The AHA strategic plan now sets a goal of improving the cardiovascular health of all Americans by 20% in 10 years.[27] The AHA plan emphasizes primordial prevention: preventing development of risk factors for cardiovascular disease and stroke.[27] Lifestyle and health factors, including blood pressure, weight, glucose, cholesterol, smoking, diet, and physical activity, collectively known as "Life's Simple Seven," are the focus of the strategic plan.[27] The prevalence of hypertension, obesity, and diabetes mellitus, 3 major risk factors for AF,[27–31] will be favorably influenced by successful lifestyle modifications. Because AF represents one of the most potent risk factors for stroke, prevention of hypertension, obesity, and diabetes mellitus should decrease the incidence of ischemic neurological events substantially.

Several factors are associated with electric and structural atrial remodeling of the left atrium and thus are potential targets for primary prevention of AF. These risk factors can be grouped into demographic, anthropometric, behavioral, and classic cardiovascular risk factors; cardiovascular disease; pulmonary disease; and hyperthyroidism. Additionally, multiple biomarkers are associated with AF, including inflammatory (C-reactive protein, interleukin 6), oxidative stress (nicotinamide adenine dinucleotide phosphate [NADPH] oxidase, natriuretic peptides), and vasoactive peptide (endothelin 1) markers.[32] The extent to which biomarkers are causally related to AF onset, as opposed to representing an epiphenomenon of cardiovascular remodeling, remains unknown.

Systems biology approaches may provide important insights for the prediction and prevention of AF because they address the complex interactions between risk factors and disease.[33] Already, genome-wide association studies have revealed genetic risk factors for AF that were unanticipated by prior knowledge.[23–26] Because of the modest effect sizes, replicating and validating such signals will necessitate the collaboration of multiple cohorts and studies.

Although risk-prediction models to identify individuals at increased risk of AF exist, several areas of uncertainty remain.[2] AF is more common in whites than in other racial groups,[26] but the mechanisms underlying these racial differences are unknown. Potential explanations include variation in diagnosis by race, presence of competing risks in minorities, different susceptibility to AF risk factors, and genetic determinants.[2,24–26] It is uncertain whether AF risk-prediction instruments developed in whites are generalizable to blacks or other ethnic groups. In addition, the proper translation of imaging tests, biomarkers, and genomic markers into clinical practice for improved risk prediction is uncertain. The development of genomic and clinical phenotypes that can distinguish different AF subtypes by functional burden, prognosis, and response to treatment would represent a fundamental advance. Classification into mechanistic and pathogenetic subtypes might allow targeted prevention and treatment in the future.

The outcomes of patients with AF can be improved by prompt diagnosis, appropriate treatment, adherence to practice guidelines, quality research that includes comparative effectiveness research, proper utilization of registries, and translation of research findings into better decision making. Evidence-based guidelines from the AHA/American Stroke Association emphasize the need for antithrombotic therapy, in particular warfarin, in eligible patients.[3,30] The efficacy of warfarin at reducing stroke in patients with AF has been well established by randomized clinical trials.[3] Indeed, the AHA Get With The Guidelines (GWTG) program has identified use of antithrombotic therapy among patients with AF as the key performance metric. Although more patients are being treated with antithrombotic therapy over time, community statistics continue to show large numbers of AF subjects who are not treated with antithrombotic therapy. Despite its demonstrated efficacy, warfarin use is associated with many challenges. Thus, novel vitamin K antagonists are in development. Dabigatran, a direct thrombin inhibitor studied in the RE-LY trial (Randomized Evaluation of Long-Term Anticoagulation Therapy), proved superior to warfarin without an increased incidence of major bleeding.[34] Several factor Xa inhibitors are being examined in phase 3 trials.[34–36] The comparative efficacy of these agents versus warfarin and their impact on utilization require further evaluation.

Data from large healthcare systems and electronic medical records may provide key data on practice patterns in AF management and contribute to improving the outcomes of patients with AF.[37] Such "real-world data" will facilitate comparative effectiveness research and may allow comparisons of the effectiveness of treatments as used in routine clinical practice. Given the important health policy implications of conclusions about the comparative effectiveness of various diagnostic and treatment approaches, caution should be exercised in drawing either positive or negative conclusions from observational analyses alone, although such findings may be instrumental in directing definitive prospective randomized trials that are sufficiently powered for noninferiority conclusions. The large numbers of patients in these databases also may allow examination of understudied subgroups. Several AF registries are being developed, including SAFARI (Safety of Atrial Fibrillation Ablation Registry Initiative), a national registry of AF catheter ablation procedures, and ORBIT-AF (Outcomes Registry for Better Informed Treatment of Atrial Fibrillation), whose primary objective is to assess real-world patterns of care and outcomes of patients with AF.[38] The major recommendations related to AF prevention and stroke prevention, epidemiology, outcomes, and cost are summarized in Table 2.

Table 2. Recommendations From the AHA Atrial Fibrillation Research Summit: Epidemiology, Outcomes, Cost, AF, and Stroke Prevention

Encourage international, multiinstitutional, multidisciplinary teams to collaborate in research and integrate approaches to AF prevention.
Determine the cause of variation in AF epidemiology, presentation, risk factors, and prognosis by age, sex, and race/ethnicity.
Develop strategies to detect and monitor AF more effectively in individuals and large populations.
Develop more accurate clinical, imaging, biomarker, and genomic phenotyping to more rigorously classify AF.
Evaluate AF risk-prediction instruments and the added clinical utility of novel markers.
Systematically ascertain the burden and impact of AF in all regions of the world.
Conduct randomized clinical trials of primordial, primary, and secondary AF prevention.
Refine stratification for risk of systemic thromboembolism, intracranial hemorrhage, and other major bleeding.
Improve implementation of proven stroke prevention guidelines, particularly in underserved populations.
Characterize the clinical outcomes, cost, and impact on quality of life and utilization of antithrombotic therapy of new anticoagulants.
Design, fund, and conduct rigorous comparative effectiveness and safety studies of AF therapeutic approaches.
Create and realign meaningful provider, institutional, and payer incentives to encourage participation in databases and registries.
Develop better models of cost in AF management that include quality of life, patient/provider adherence, clinical outcomes, and healthcare utilization.
Develop methods to facilitate the use of cost-effectiveness models by clinicians.

AHA indicates American Heart Association; AF, atrial fibrillation.

Meeting the Clinical Challenges and Redefining the Therapeutic Goals of AF

Antiarrhythmic drugs are likely to remain essential components of any comprehensive therapeutic strategy of maintaining sinus rhythm in patients with AF.[39] Recently, drug development for AF has emphasized multichannel blockers with less potential toxicity than amiodarone, including novel ion channel targets (eg, I_{Kur} blockers, late I_{Na} blockers, calcium current modulators), and non–ion-channel therapeutic targets (eg, fibrosis, gap junctions, and inflammation).[40,41]

Novel approaches being evaluated to prevent AF are the use of statins, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and omega-3 fatty acids.[42] In addition to improving clinical outcomes in patients with heart failure and prior myocardial infarction, angiotensin-converting enzyme inhibitors and angiotensin receptor blocker agents appear to prevent the atrial electric and structural remodeling associated with AF through hemodynamic, antiproliferative, antiinflammatory, antioxidant, and antiapoptotic effects.[42] These agents have been shown to be antisympathetic and to prevent the development of left atrial stretch and interstitial fibrosis, as well as adverse atrial electric remodeling. However, these effects have not yet been clearly translated into clinical benefit, because there have been mixed results for the efficacy of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers in prevention of AF. The evidence-based medicine that supports the use of these agents to prevent AF is insufficient to merit incorporating their use into clinical practice guidelines. Similarly, statins have been shown to possess antiinflammatory, antiischemic, antioxidant, and antiarrhythmic effects while having a beneficial effect on modulation of autonomic tone; however, there have been mixed results related to the efficacy of statins in the prevention of AF. Other potential targets for prevention of AF are aldosterone and endothelin 1 antagonists, but no meaningful clinical data are available.[42]

An important issue related to AF clinical trial design is the selection of optimal monitoring approaches and end point definitions.[39] Traditional end points for AF drug trials have been time to first symptomatic recurrence and total recurrences over time. The total burden of AF, however, may be a better measure of the effectiveness of therapy. Use of this end point will require better understanding of the advantages and disadvantages of intermittent monitoring, 30-day full-disclosure monitors, and implantable loop recorders to quantify the burden of AF and the correlation of AF burden with clinically important end points such as mortality, stroke, and quality of life. The prognostic significance of asymptomatic episodes of AF and the clinical implications of the burden of AF remain unknown.[39]

Although intermediate end points are more easily measured, adequate rate control and the number and timing of AF recurrences do not necessarily correspond to the clinical value of a drug and the patient's prognosis.[39,43,44] Recurrent AF as an outcome may be satisfactory in young patients with highly symptomatic AF; however, AF recurrence fails to tell us about the effects of a given therapy on the most important outcomes, including stroke incidence, cardiovascular morbidity, cardiovascular mortality, total mortality, healthcare costs, New York Heart Association functional class, quality of life, and exercise tolerance.

The ATHENA trial (A Placebo-Controlled, Double-Blind, Parallel Arm Trial to Assess the Efficacy of Dronedarone 400 mg BID for the Prevention of Cardiovascular Hospitalization or Death From Any Cause in Patients With Atrial Fibrillation/Atrial Flutter) showed that antiarrhythmic drug therapy decreases cardiovascular hospitalizations.[45] The major mechanism of dronedarone benefit is probably linked to a combination of decreasing the recurrence of AF and decreasing heart rate, particularly the ventricular response in the presence of AF.[45] However, other effects that antiarrhythmic drugs may have on cardiovascular and noncardiovascular mortality or morbidity, as well as extracardiac effects, remain uncertain.[46] Assessment of rhythm control should be focused not only on recurrence of symptomatic arrhythmias but also on objective measurements of cardiovascular morbidity, mortality, hospitalizations, functional status, quality of life, and cost.[39]

There remain many limitations to the randomized controlled trials evaluating catheter ablation of AF compared with antiarrhythmic agents.[47,48] Further trials are needed to evaluate catheter ablation of AF versus the strategy of rate control or rhythm control. Mortality, freedom from recurrent AF, costs, resource utilization, cost-effectiveness, and impact on quality of life should be included as end points. The Catheter Ablation versus Antiarrhythmic Drug Therapy for Atrial Fibrillation Trial (CABANA) is an ongoing multicenter study of catheter ablation versus pharmacological therapy as treatment of symptomatic AF.[49] This multicenter randomized study is intended to address many of the limitations of previous studies. Nonetheless, like other clinical trials, CABANA will provide only limited insight into important aspects of this procedure such as the techniques, safety, and long-term effectiveness of AF ablation in routine clinical practice. There is a need to address the limitations of available data and other key concerns about the safety of AF ablation with robust registry data.[38] As noted for catheter ablation of AF, complications, mortality, freedom from recurrent AF, costs, resource utilization, cost-effectiveness, and impact on quality of life should be included as end points for the maze procedure and other surgical approaches to AF.[48,50,51] Additionally, prospective multicenter clinical trials are needed to better define the relative safety and efficacy of various surgical tools and techniques for surgical ablation of AF.[48,50,51]

The investigation of advanced approaches to AF management requires an understanding of the complex interplay between AF and heart failure. The prevalences of both conditions are increasing in concert, particularly with an aging population.[52] Heart failure and AF frequently coexist, with heart failure representing an important risk factor for developing AF and AF contributing importantly to the morbidity of patients with heart failure, particularly those without left ventricular dilation and with preserved left ventricular ejection fractions.[1,2] Both the hemodynamic and neurohormonal perturbations of heart failure likely contribute to the pathogenesis of AF via both mechanical and structural changes within the atria. A number of studies have suggested that inhibition of the renin-angiotensin-aldosterone axis reduces the incidence of AF, an effect that may be mediated via reduced atrial stretch, prevention of adverse atrial remodeling, or both.[42] Research into prevention and management of AF should consider the interaction of these 2 conditions, exploration of mechanistic interactions, examination of relationships between treatment effects on both arrhythmic and heart failure–related end points, and addressing the expanding population in which these 2 conditions coexist.

A substantial body of clinical and experimental data indicates that sleep apnea and AF commonly coaggregate.[53–56] Estimates from population-based research suggest that individuals with moderate to severe sleep apnea are

Table 3. Recommendations From the AHA Atrial Fibrillation Research Summit Meeting: Meeting the Clinical Challenges and Redefining the Therapeutic Goals in AF

Evaluate the efficacy and safety of agents with antifibrotic properties.
Evaluate alternative upstream therapies (statins, ACE inhibitors/ARBs, fish oil) to prevent onset and recurrences of AF.
Evaluate efficacy and safety of atrium-selective I_{Na} blocker combinations shown to exert potent synergistic actions in experimental models of AF (ie, ranolazine and dronedarone combination).
Identify appropriate end points for observational studies, comparative effectiveness studies, and clinical trials of AF.
Evaluate whether the burden of AF and benefits of therapies are related to symptoms, QOL, functional status, and cardiovascular outcomes.
Develop a QOL metric that is specific to patients with AF and one that can measure the effect of AF on symptoms as well as outcomes.
Develop methods to efficiently measure AF burden, outcomes, and cost rather than process metrics.
Explore the interactions between AF and heart failure, including mechanistic interactions and relationships between treatment effects on both arrhythmic and heart failure–related end points; develop management strategies that address the expanding population in which these 2 conditions coexist.
Identify the heart rates and duration of AF that result in tachycardia-induced cardiomyopathy.
Compare rhythm control by use of antiarrhythmic drug therapy with catheter ablation of AF.
Conduct clinical and mechanistic studies defining the interactions among sleep apnea–mediated changes in cardiac structure, autonomic function, and inflammation and their impact on AF.
Define strategies for prevention of postoperative AF.
Systematically evaluate strategies for a surgical cure of AF.
Provide both provider and health system incentives to design and embed quality and performance improvement in EMRs, track application of evidence-based therapies and improve patient outcomes.
Design and research decision support tools to enhance clinicians' abilities to implement evidence-based treatment and guidelines.

AHA indicates American Heart Association; AF, atrial fibrillation; ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; QOL, quality of life; and EMRs, electronic medical records.

approximately 4-fold more likely to have AF than those without apnea and that the occurrence of apneas during sleep may serve as a trigger of paroxysms of AF.[57–59] These observations suggest that sleep apnea contributes to AF incidence and recurrence or that there are common mechanisms, such as altered autonomic tone, linked to the pathogenesis of both conditions. Because sleep apnea prevalence appears to be increasing in conjunction with the obesity epidemic, it is possible that unrecognized and untreated sleep apnea may be a significant contributor to the rising population burden of AF. Sleep apnea may provide a new intervention target for the prevention and management of AF. Reversal of sleep apnea–associated hypoxemia, intrathoracic swings, and autonomic imbalance may attenuate triggers for AF.

Multifaceted strategies to facilitate the process of improving clinical care have emerged, with an emphasis on evidence-based medicine, clinical practice guidelines, quality metrics and performance measures, and patient outcomes.[60] By facilitating measurements of cardiovascular healthcare quality, performance measurement sets may serve as vehicles to accelerate appropriate translation of scientific evidence into clinical practice. Application of performance measures related to AF should provide a mechanism through which the quality of medical care can be measured to improve patient outcomes. The major clinical recommendations related to AF are summarized in Table 3.

Conclusions

Although considerable progress has been made in understanding the mechanisms of AF and preventive and treatment strategies, it is evident that much remains unknown. Prevention and treatment of AF will ultimately depend on understanding the pathophysiology in the individual patient. Understanding of several key aspects of AF, including the patterns of its occurrence in different populations, risk factors, and underlying pathophysiology, will result in identification and testing of prevention and treatment strategies. A concerted effort is thus needed on several fronts, as outlined by the recommendations in Tables 1, 2, and 3, to optimally predict, prevent, and treat AF and thereby improve patient outcomes.

Sources of Funding

American Heart Association's Atrial Fibrillation Research Summit was sponsored by Sanofi US.

Appendix

Session I: Epidemiology, Outcomes, Cost, AF, and Stroke Prevention

Section Editor: Sana M. Al-Khatib, MD, Duke University, Durham, NC. *Moderators:* Mark A. Hlatky, MD, Stanford School of Medicine, Stanford, CA; Elaine Hylek, MD, MPH, Massachusetts General Hospital, Boston, MA.

Translating Evidence Into Practice: Reducing Death and Disability Due to Stroke—In Perspective of Ideal Health and Prevention: Ralph L. Sacco, MS, MD, FAHA, FAAN, University of Miami, Miami, FL.

Prediction and Prevention of AF: The Decade Ahead: Emelia J. Benjamin, MD, ScM, FAHA, Boston University Schools of Medicine and Public Health, Boston, MA.

The Global Burden of AF: Sumeet S. Chugh, MD, Cedars-Sinai Medical Center, Los Angeles, CA.

AF in Ethnic Minorities: What Are the Unanswered Questions? Alvaro Alonso, MD, MPH, PhD, University of Minnesota, Minneapolis, MN.

Utilizing Health Maintenance Organizations and Electronic Medical Records to Advance Knowledge in AF: Alan S. Go, MD, Kaiser Permanente of Northern California, Oakland, CA.

Improving Patient Outcomes in AF: Registries, Comparative Effectiveness: Sana M. Al-Khatib, MD, Duke University, Durham, NC.

Developing Better Models of Cost in AF Management: Brian F. Gage, MD, Washington University, St Louis, MO.

New Developments in Anticoagulation for AF: Michael D. Ezekowitz, MBChB, DPhil, FRCP, FAHA, MD, Lankenau Institute for Medical Research, Wynnewood, PA.

Session II: Mechanisms of AF: Basic and Translational Science and Genetics

Section Editor: Patrick Ellinor, MD, PhD. *Moderators:* Sunny S. Po, MD, PhD, University of Oklahoma Health Sciences Center, Oklahoma City, OK; Patrick T. Ellinor, MD, PhD, Massachusetts General Hospital, Boston, MA.

Atrioventricular Distinctions in Ion Channels as the Basis for Development of Atrial-Selective Drugs in the Management of AF: Charles Antzelevitch, PhD, FACC, FAHA, FHRS, Masonic Medical Research Laboratory, Utica, NY.

Sleep Apnea, Experimental Hypertension, and AF: Autonomic and Structural Considerations: Susan Redline, MD, MPH, Brigham and Women's Hospital, Boston, MA.

Novel MRI Markers of Cardiac Fibrosis: Michael Jerosch-Herold, PhD, Brigham and Women's Hospital, Boston, MA.

Fibrosis and AF: Lixia Yue, PhD, University of Connecticut Health Center, Farmington, CT.

Mechanisms of AF in Hypertrophy, Endothelin, Angiotensin Signaling: David R. Van Wagoner, PhD, FAHA, Cleveland Clinic, Cleveland, OH.

Novel Pathways for Pharmacological Treatment and Prevention of AF: Peng-Sheng Chen, MD, Indiana University School of Medicine, Indianapolis, IN.

Session III: Meeting the Clinical Challenges in AF

Section Editor: N.A. Mark Estes III, MD. *Moderators:* Kathryn Wood, PhD, RN, Duke University, Durham, NC; A.E. Epstein, MD, FAHA, FACC, FHRS, VA Medical Center, Philadelphia, PA; Marv Konstam, MD, Tufts University, Boston, MA.

Therapies to Prevent AF: Statins, ACE-I/ARB, Omega-3 Fatty Acids: Anne B. Curtis, MD, FHRS, FACC, FAHA, The State University of New York, University at Buffalo.

Strategies for AF Management: Reevaluating Rate and Rhythm Control: Ken A. Ellenbogen, MD, FAHA, Virginia Commonwealth University, Richmond, VA.

New Pharmacological Agents for AF: John P. DiMarco, MD, PhD, University of Virginia Health System, Charlottesville, VA.

Ablation of AF: Addressing the Gaps in Knowledge: Douglas L. Packer, MD, Mayo Clinic, Rochester, MN.

Session IV: Redefining the Therapeutic Goals of AF

New Initiatives From the NHLBI: Yves D. Rosenberg, MD, MPH, National Heart, Lung, and Blood Institute, Bethesda, MD.

Prevention of Postoperative AF and Advancing the Surgical Frontier for Cure of AF: Richard Lee, MD, Northwestern Medical Center, Chicago, IL.

Developing and Validating Standardized and Quantitative Approaches to Understanding the Burden of Asymptomatic and Symptomatic AF on Quality of Life: Eric N. Prystowsky, MD, FAHA, St Vincent Hospital, Indianapolis, IN.

AF Clinical Guidelines, Performance Measures, and Quality Metrics: Improving Clinical Outcomes in AF Patients: N.A. Mark Estes III, MD, FAHA, Tufts University, Boston, MA.

This table represents the relationships of advisory group members that may be perceived as actual or reasonably perceived conflicts of interest as reported on the Disclosure Questionnaire, which all members of the writing group are required to complete and submit. A relationship is considered to be "significant" if (1) the person receives $10 000 or more during any 12-month period, or 5% or more of the person's gross income; or (2) the person owns 5% or more of the voting stock or share of the entity, or owns $10 000 or more of the fair market value of the entity. A relationship is considered to be "modest" if it is less than "significant" under the preceding definition.

*Modest.

†Significant.

Workplace Telecommunications Technology to Identify Mental Health Disorders and Facilitate Self-Help or Professional Referrals

Ramesh Farzanfar, PhD; Steven E. Locke, MD; Timothy C. Heeren, PhD; Allison Stevens, MA; Louis Vachon, MD; Mai Khoa Thi Nguyen, BA; Robert H. Friedman, MD

Abstract

Purpose. *Test the feasibility and impact of an automated workplace mental health assessment and intervention.*

Design. *Efficacy was evaluated in a randomized control trial comparing employees who received screening and intervention with those who received only screening.*

Setting. *Workplace.*

Subjects. *463 volunteers from Boston Medical Center, Boston University, and EMC and other employed adults, among whom 164 were randomized to the intervention ($N = 87$) and control ($N = 77$) groups.*

Intervention. *The system administers a panel of telephonic assessment instruments followed by tailored information, education, and referrals.*

Measures. *The Work Limitation Questionnaire, the Medical Outcomes Questionnaire Short Form-12, the Patient Health Questionnaire-9, question 10 from the Patient Health Questionnaire to measure functional impairment, and the Perceived Stress Scale-4 and questions written by study psychiatrists to measure emotional distress and social support respectively. The WHO-Five Well-being Index was administered to measure overall well-being.*

Analysis. *Independent sample t-tests and χ^2 tests as well as mean change were used to compare the data.*

Results. *No significant differences on 16 of the 20 comparisons at 3- and 6-month time points. The intervention group showed a significant improvement in depression ($p \leq .05$) at 3 months and on two Work Limitation Questionnaire subscales, the Mental-Interpersonal Scale ($p \leq .05$) and the Time and Scheduling Scale ($p \leq .05$), at 3 and 6 months respectively with a suggestive improvement in mental health at 6 months ($p \leq .10$).*

Conclusions. *This is a potentially fruitful area for research with important implications for workplace behavioral interventions. (Am J Health Promot 2011;25[3]:207–216.)*

INTRODUCTION

Research shows that approximately 30% of American adults suffer annually from mental health disorders[1] and that these disorders are usually chronic or recurring.[2] Furthermore, almost half of the affected individuals have two or more such disorders.[1] More importantly, it has been estimated that only 50% of those afflicted with a serious mental health disorder seek help.[3] The collateral negative impact of undiagnosed, untreated, or poorly treated mental health disorders includes marital and family instability[2,4,5] as well as adverse impacts on the social and economic fabric of the local community and the society at large.[6] The staggering cost is economically important because most working individuals spend a significant amount of time in the workplace. In most circumstances, however, mental health issues are neglected in the workplace until they cause problems such as reduced productivity and/or absenteeism.[2,4,5] It is not known to what extent employers' initiatives such as establishment of Employee Assistance Programs or other venues such as annual depression screening days have addressed the substantially high barriers to the detection and treatment of mental health disorders in the workplace. There has also been a dearth of empirical evidence to demonstrate the feasibility of programs initiated by employers to help employees address mental and emotional health issues, with some exceptions. For example, the study carried out by Wang et al.[7] indicates that organized and integrated

interventions to screen and manage employees with depression show positive results. Wang et al.[7] evaluated the effects of a depression outreach treatment program on workplace outcomes. The intervention consisted of a telephonic outreach and care management program that motivated workers to enter outpatient treatment and at the same time monitored treatment while providing recommendations to the providers. The results demonstrated that workers in the intervention group had significantly lower depression symptoms ($p = .009$) and higher job retention ($p = .02$) as well as more hours worked ($p = .02$). The Wang et al.[7] study demonstrates that an organized approach to addressing mental and emotional health issues in the workplace is possible and recommended. People with symptoms of a mental health disorder are often reluctant to seek treatment because of the stigma attached to mental disorders and fear of the negative personal and social consequences of being ''branded'' with a mental health illness.[8] In the workplace, these barriers are compounded but might be mitigated if there were a confidential, easily accessible, and low-cost method to screen affected individuals and to provide an effective and efficient intervention. There is evidence that computers are considered by many users to be more trustworthy and less judgmental than humans, especially when their use involves inquiring about personal, sensitive, and/or uncomfortable topics.[9,10]

This paper describes the results of a clinical trial conducted with a computer telephony (interactive voice response [IVR]) system for detecting undiagnosed and/or untreated mental health disorders in the workplace and for helping those who screen positive for a given disorder to obtain effective treatment. Our objective was to reach such individuals directly in a convenient setting such as the workplace or at home rather than in the offices of a mental health provider. The system we developed, Telephone-Linked Communications for Detection of Mental Health Disorders (TLC-Detect), was initially deployed for use in workplace settings.

METHODS

Design

The entire study, including eligibility screening and outcome data collection, was carried out over the telephone at baseline and 3- and 6-month follow-ups. After eligibility screening, baseline data were collected from study participants, who were subsequently randomized and connected to the automated program to receive assessment for mental health disorders (all subjects) and intervention (only experimental subjects). The data derived from the control group subjects were used in a comparison to determine the efficacy of the TLC-Detect intervention. From a social perspective, the goal of the system was to improve workplace productivity by reducing the impact of mental health disorders on absenteeism and presenteeism (being at work but not being fully productive). As a result, the study's outcomes of interest were both work-related (absenteeism and presenteeism) and individual-based (physical and mental well-being).

Sample

The study protocol, including the sampling procedures described below, was approved by the Boston University Medical Campus' Institutional Review Board. Once system development was completed, the study was advertised and potential participants called our research headquarters to volunteer for participation. The study was advertised at Boston Medical Center and Boston University in addition to Florida Power & Light, EMC Corporation, and later, because of recruitment difficulties, to employed adults at large. We received the highest number of volunteers from Boston Medical Center and Boston University (253), followed by other companies (193), EMC Corporation (15), and Florida Power & Light (2).

To be eligible for entry into the trial, potential participants had to satisfy the following inclusion criteria: (1) ability to speak and understand conversational English, (2) 18 years of age or older, (3) access to a touch-tone telephone, (4) not undergoing mental health treatment or currently taking a medication prescribed for mental health treatment, and (5) experiencing some type of emotional distress as indicated by scoring positive on the WHO-5 Well-being Index[11–13] and the Functional Impairment question (item 10) from the Patient Health Questionnaire (PHQ) (''If you said *yes* to any of the five questions, how difficult have those problems made it for you to do your work, take care of things at home, or get along with other people''?). One hundred sixty-four participants were randomized in the clinical trial and received full assessment by TLC-Detect, with 87 and 77 randomized into the intervention and control groups respectively. Of these, 152 study participants (intervention = 77, control = 75) completed the study and 12 were lost to follow-up or dropped out of the study (8 before the 3-month and 4 before the 6-month outcome data collection). Of these 10 were in the intervention group and 2 were in the control group.

Measures

The WHO-5 Well-being Index was used to assess eligibility. WHO-5 was derived from a larger rating scale developed for a World Health Organization project on quality of life in patients suffering from diabetes.[16] The instrument has been successfully utilized in psychiatric care with good internal consistency (Cronbach $\alpha = .91$).[17] It has also shown a sensitivity and specificity of .93 and .64 respectively. WHO-5 covers mood (good spirits, relaxation), vitality (being active and waking up fresh and rested), and general interests (being interested in things) on a six-point scale from ''All of the time'' to ''At no time.''[14,15] The total WHO-5 score ranges from 0 to 25, with 25 being the most desired score.

We used several instruments to measure the impact of the intervention on study participants' work productivity (e.g., absenteeism and presenteeism) and physical and mental well-being as well as change in symptom severity (positive or negative) during the study. Outcomes were measured using the Work Limitation Questionnaire, a 29-item instrument with five different scales that address the user's productivity at work;[16] a four-item scale measures absenteeism, and the additional four scales (Mental Demands

scale, Output Demands scale, Physical Demands scale, and Time and Scheduling scale) focus on presenteeism, i.e., the user's actual self-reported impairment of productivity when at work. This instrument has good internal consistency, with four of the five scales (Time Demands, Physical Demands, Mental-Interpersonal Demands and Output Demands) having a Cronbach α of $\geq .90$.[19] The possible range for the total Work Limitation Questionnaire score is from 0 to 100, with a lower score being more desirable.

In addition, we used the Medical Outcomes Questionnaire Short Form-12 (SF-12) to measure physical and mental well-being. The SF-12 is a self-report measure of patient health status and covers a number of physical and health domains. The SF-12 includes all eight SF-36 scales (physical function, role-physical, bodily pain, general health, vitality, social functioning, role-emotional, and mental health). Two items are used to measure four of the constructs and one item is used to measure the other four constructs. Research has shown that the SF-12 replicates 90% of the variance in both the physical component summary (PCS) and mental component summary (MCS) scores of the SF-36. The test-retest reliability of SF-12 is estimated at .89 for the PCS and .76 for the MCS.[20] Both the MCS and the PCS range from 0 to 100, with higher scores being more desirable. Both the Work Limitations Questionnaire and the SF-12 have been validated among groups with chronic conditions and mental health disorders.

Furthermore, we collected data on symptom severity, including administration of the PHQ-9[21] to measure each participant's depression level. The PHQ Total Depression score ranges from 0 to 27, where a higher score is worse. During 3- and 6-month outcome data collection, we also asked study participants whether the symptoms for each specific disorder had improved, remained the same, or worsened. We assessed functional impairment by asking question 10 from the PHQ combined with questions from the Perceived Stress Scale-4[22] to determine the degree to which employees felt their emotional distress interfered with their daily life. In addition, we inquired about social support, using three questions written by our study psychiatrists, to account for possible variations in the support study participants may have received from friends and family during the study. Also, we repeated the administration of the WHO-5 Well-being Index during the 3- and 6-month follow-up outcome data collection (as mentioned above the instrument was used to determine eligibility for study entry).

Finally, upon the completion of the study, we administered the Health Technology Questionnaire (HTQ) to explore the usability of the system. The HTQ has been developed by the first author and is designed to measure users' experience of automated, multi-contact health behavior interventions.[23] This instrument was developed based on two consecutive qualitative evaluations of two different computer telephony (Telephone-Linked Communications [TLC]) systems. The HTQ measures user satisfaction and perceptions of the system's impact on personal health behavior on a 5-point scale from ''Not at All'' to ''Very'' or from ''Strongly Agree'' to ''Strongly Disagree,'' with higher scores being desirable. For example, one of the subscales addresses satisfaction and includes questions such as ''How satisfied were you''? or ''Was the information useful''?[23] Another subscale addresses behavioral constructs, e.g., self-efficacy, motivation, and awareness. The instrument's subscales have displayed good to high reliability, with Cronbach α higher than .7 on 11 of the 12 different subscales.[23] In this paper, we report HTQ's percentages with favorable responses.

Intervention

The TLC-Detect system is based on an IVR technology called TLC.[11,12] TLC communicates with patients/users to promote health and prevent disease. TLC-Detect was designed as a mental health application of TLC to screen for undiagnosed and/or untreated mental health problems and help determine feasible self-management or professional care options.

We designed the system to be an automated mental health screening and counseling program that employees could access from any phone—home, work, etc. The participants used the telephone keypad to record their responses, which eliminated any confidentiality concerns that come from speaking into a telephone receiver. Either the user or the system could initiate the telephone call. At the beginning of each interaction, the user is asked to enter a unique password, which allows the system to easily recognize individual users. TLC-Detect used a prerecorded, digitized voice of a female voice actor. We coached the voice actor's tone and pitch to ensure that her delivery was appropriate for each specific disorder or condition.

The system was designed to include three modules: the screening module, the intervention module, and the intervention follow-up module. Both control and intervention group participants used the screening module; however, only participants in the intervention group were provided with the intervention module and the intervention follow-up module. These contained specific information, education, and referrals for self-help or professional assistance relevant to a specific disorder. In addition, the intervention group participants received monthly follow-up calls to monitor their progress and adherence to the system's advice. Because of ethical considerations, participants in the control arm of the study who reported symptoms during assessment were briefly advised by the system to confer with their clinicians about their symptoms. However, no information, education, or referrals were provided to the control group participants. Upon completion of the study, the study staff reminded subjects in the control arm of the study to visit their physicians and discuss their emotional distress.

The Screening Module

The screening module assesses users for mental health disorders that are known to reduce employee productivity, including major and minor depression (as well as postpartum depression and depression due to acute bereavement), dysthymia (a milder but chronic form of depression), bipolar disorder, generalized anxiety disorder, somatization, posttraumatic stress disorder, social phobia, panic disorder,

acute stress disorder, suicidal ideation, violence, alcohol and drug problems (including abuse and dependence), and general stress such as that related to family, marital, work, or school as well as financial problems.[24]

This module uses instruments that have been used in valid and reliable ways in other studies. The most important of these instruments is the PHQ, which is the self-administered version of the Primary Care Evaluation of Mental Disorders.[21] Additional instruments used by the system include the Impact of Events Scale,[25] the Acute Stress Disorder Scale,[26] the Social Phobia Inventory,[27] and the Mood Disorder Questionnaire.[28]

Although the assessment module screens users for mental health symptoms, it is not intended to be a diagnostic program and should not be considered a substitute for a clinician diagnosis. The ultimate goal of the program is to motivate the user to seek help. The system compares patterns of users' self-reported symptoms with those symptom patterns observed in reference populations of individuals known to be affected by a specific disorder, i.e., diagnosed by a mental health clinician. The system detects symptoms characteristic to a specific disorder, and identifies the severity level of the disorder based on the scaled symptom severity assessment. This includes detecting subsyndromal levels for each identified disorder, i.e., when a person's symptoms do not meet criteria for a disorder but the score is severe enough to cause problems. Symptom severity cutoffs that define a syndrome level are based on the recommendations made by the developers of each screening instrument. In addition, the system measures an employee's level of social support, the employee's daily life stressors, and his/her functional impairment due to mental health problems,[24] particularly because these factors have been shown to have a considerable impact on the severity of a mental health disorder.[29] These factors also play a role in determining the severity level of an employee's distress and therefore affect the content of the intervention.

Subsequently, the system provides appropriate information and advice for any positive screenings of a disorder and its corresponding severity level. First, the user is advised that his/her symptoms are similar to those seen in patients with that disorder. Next, the recommendations are tailored to the symptom severity level. For example, to a person with a symptom pattern consistent with those of severe PTSD, the system will say, ''It is *critical* that you adhere to the following recommendations,'' and will then enumerate what the person needs to do.[24] In contrast, to a person with symptoms implying subsyndromal depression, the system might say, ''I *suggest* that you follow my advice with regards to the following …''

The screening module was designed to function in a hierarchical manner. The first level of screening includes questions for all users. The instruments that are used at this level are mainly derived from the PHQ, minus a few questions that were deemed inappropriate for the study population. Employees with positive responses to this level of screening proceed to the second level of more disorder-specific and in-depth screening by additional screening instruments. For example, an employee who screens positive for depression at the first level will be asked questions that distinguish different types of depression and help identify whether suicidality is present. If suicidality is present, a third tier of screening assesses whether the employee is experiencing suicidal ideation, i.e., whether the employee is only thinking about suicide or has engaged in suicide planning, i.e., has thought about a plan.[24] If a person has been planning a suicide, appropriate action is taken both by the system, which encourages the person to immediately go to the nearest emergency room, and the study staff, who will notify the house psychiatrist.

Because the system is designed to take into account severity, i.e., intensity and/or frequency of symptoms, most of the disorders are characterized as mild, moderate, or severe. However, when alcohol and/or drug problems are identified, the system assigns severity levels unique to substance abuse: risky alcohol/drug use, alcohol/drug abuse, and alcohol/drug dependence. These classifications enable the system to provide appropriate intervention for each disorder category.[24] The system also screens employees to determine whether they have been victims of violence. Because of the sensitivity of this question, reluctant users are allowed to skip answering this question. The system keeps track of those who skip this question in order to take this into consideration for future modifications of the TLC-Detect system.[24]

Another important function of the assessment module is the identification of up to eight different, coexisting disorders, i.e., occurrence of more than one disorder per employee/user. In addition, to address the challenge of prioritizing intervention delivery, the system ranks coexisting disorders based on their relative severity or seriousness.[24] For example, in our model, bipolar disorder is deemed to be a more severe or serious disorder than dysthymia. Similarly, if an employee reports being the victim of violence as well as having symptoms consistent with major depression and social phobia, the system will rank the disorders based on relative severity and adjusts the intervention materials accordingly. As a result, because violence is defined as an immediate concern, it takes clinical precedence and the system will first provide information and advice about violence. Once the employee has listened to the intervention for violence and is ready to hear more, he or she will then hear about major depression, because major depression carries more risk compared to social phobia, and lastly, the system will give intervention information about social phobia.

The screening module also contains a submodule for ''Unspecified Emotional Distress''[24] to address situations in which a person has a high level of life stressors or significant functional impairment, but does not have a positive score for any of the listed mental health disorders. This submodule contains an intervention for general distress. It was particularly important to offer some type of intervention to users who were not positive for any specific disorder but during eligibility screening reported having a specific threshold level of emotional distress. Depending on the number of comorbid disorders, a screening session with

the system takes between 30 and 90 minutes and can be divided into two different sessions.

The Intervention Module

This module provides information, education, and referral information to experimental subjects. The intervention is offered to subjects immediately after they complete the assessment module. Specifically, the two important components of the intervention module are the education and referral submodules. If the user has a criterion-level symptom severity pattern for any disorder, the system provides extensive information about that disorder, including its symptoms, natural history, and available treatments. The referral submodule contains disorder-specific information on both self-management and professional help appropriate to the level of its severity as determined by the system's assessment. Employee/users listen to information about the treatment options, treatment advantages and limitations, and advice on how to access self-help resources. Self-management resources include self-help workbooks, learning and using stress management techniques, participating in support groups, beginning an exercise regimen and/or adopting a healthier diet, etc. Further information on each subtopic is provided. For example, the section on stress management techniques includes instructions on mediation, progressive muscle relaxation, autogenic training, and breathing exercises. When the screening assessment warrants it, users are also given information on how to find appropriate professional treatment. The referral module provides information about available professional help (clinical psychologists, psychiatrists, or social workers) and targets specific geographic areas, employers, and health plans to guide users to find a mental health professional. However, the system does not provide specific clinicians' names and telephone numbers. The referral module also includes individual and group therapy options, based on the screening assessment of disorder severity. For example, to an employee deemed likely to have moderate major depression, the system recommends self-management options such as exercise, healthy diet, meditation, an appropriate workbook, and a support group as well as professional assistance such as group therapy and/or Employee Assistance Program for evaluation.

To ensure that referrals are properly assigned and target each disorder appropriately, the system designers created the Treatment Intensity Adjuster (TIA),[29] which measures the impact of each disorder on a person's personal and social life by assessing his/her functional impairment, daily stressors, and social support level.[24] A high TIA score increases the assigned severity level of each disorder by one level.[29] This enables the system's intervention module to recommend appropriate treatment strategies to each person based on the severity (seriousness) level of his/her disorder. Ideally, the assessment and intervention are provided to users in one 30- to 90-minute session. The average amount of time that a potential user spends on the screening and intervention modules is about 60 minutes, but it varies depending on the number and severity of the identified disorders. If a person has several disorders and thus needs to listen to more information, the session may be divided to two in order to reduce the time burden on the user.

The Intervention Follow-up Module

This module may track employee users on a monthly basis for any given period of time. The principal objective of the intervention follow-up calls is to ensure that users have adhered to the system's advice and sought professional assistance or engaged in self-help. For users who did not seek professional treatment or engage in self-help, the intervention follow-up module provides tailored educational material, which might include description of the disorder and its treatment options. In addition to checking whether a user is following the system's recommendations, the follow-up module is also used to provide additional information to a user about his/her condition(s). Similar to the intervention module, the users again have the choice to spread out the information in the intervention follow-up module into multiple sessions to reduce the time burden. If the users have already listened to *all* of the information offered by the system, they have the option to listen to any information again. The system offers a variety of optional modules, so users are unlikely to complete all the modules in the system. For example, there is an optional book recommendation module that lists descriptions and titles of informative books about any disorder that is of concern to the user. In addition to the above functions, the intervention follow-up module also reviews recommendations and barriers to adherence with nonadherent individuals. Once a barrier is discussed, the system offers appropriate advice to enable these employees to overcome problems or difficulties that prevented their adherence to the system's recommendations. The intention is to empower and motivate users to become actively involved in the management of their mental health. A final function of the intervention follow-up module is to determine the accuracy of the system's assessment by asking whether users have discussed the identified disorders with their health care providers. If so, the system then asks whether the clinicians agreed or disagreed with the assessment.

Analysis

We compared changes in productivity (defined by Work Limitation Questionnaire scores) and changes in mental health symptomatology (SF-12, PHQ, and Stress Level Questionnaire) from baseline to 3 months (initial effects) and baseline to 6 months (longer-term effects), using separate independent sample *t*-tests.

RESULTS

In order to be eligible for the study, all subjects had to have some level of mental/emotional distress at the time of their enrollment. This was determined by the administration of the WHO-5 Well-being Index. Subsequently, all participants were screened by the system and then randomized. This means that the majority of the study participants were identified with a specific disorder or comorbid disorders with the exception of 6% (intervention) and 5% (control) who were identified with unspecified emotional distress. However, after screening by the system only participants random-

ized to the experimental arm received the intervention.

Complete data were collected at baseline, 3 months, and 6 months for 91% of the randomized subjects (total: 152 out of 164; control group: 75 out of 77; intervention group: 77 out of 87). Baseline characteristics of the study sample are presented in Table 1. There were no significant demographic differences between the two study groups at baseline. In both groups, subjects tended to be in their 30s and 40s, with about 75% female and 60% college educated, and with minority representation.

The study lost 12 participants to follow-up. These participants did not substantially differ from those followed on demographic or mental health characteristics. Of these, one participant in the control group did not complete both outcome data collections, compared with seven intervention group participants. In addition, one participant in the control group did not complete the 6-month outcome data collection, compared to three in the intervention group. The higher number of dropouts among the intervention group participants may be an indication of the greater time commitment that was expected from subjects in the intervention arm of the study.

All participants in the intervention group received a brief follow-up call once a month for a total of 6 months to verify that they followed at least one of the program's recommendations and determine whether they have sought help suggested by the system. Of the 87 participants in the intervention group, 68 (78%) responded to at least one follow-up call, with 44 (51%) responding to five or six of the six scheduled calls.

Comparison of the two study groups' baseline mental health and work-related characteristics is presented in Table 2. There were no significant differences between the study groups at baseline. Given the comparability of study groups on demographic, mental health, and work-related characteristics at baseline, these factors should not confound our outcome comparison of the study groups; thus, our primary analyses focused on comparison of the two study groups without adjusting for differences in baseline characteristics.

Changes in outcome measures at 3 and 6 months are presented in Table 3. We examined changes in five work-related outcomes and five health/mental health–related outcomes at two time points (20 comparisons in all). There were no significant differences between the intervention and control groups on 16 of these comparisons, and there was a significant advantage in the intervention group on three of these comparisons with a suggestive result on a fourth comparison.

Those in the intervention group showed a significantly greater reduction in depression ($p \leq .05$) at 3 months, a suggestive improvement in general mental health at 6 months ($p \leq .10$), as well as a significantly greater improvement on two Work Limitation Questionnaire subscales, the Mental-Interpersonal Scale ($p \leq .05$) at 3 months and the Time and Scheduling Scale ($p \leq .05$) at 6 months.

We also examined system usability by administering a structured questionnaire (the HTQ)[21] to all study participants upon the completion of the study. The HTQ measures overall opinion of users in addition to using a number of behavioral constructs. Based on our analysis, intervention group subjects found the system easy to use (84% reporting very easy or somewhat easy to use), friendly (80% very or somewhat friendly), appropriately paced (67% reporting the pace was just right), and informative (76% reporting very or somewhat informative). Furthermore, 65% reported that the system was very or somewhat useful and 47% agreed that the system reduced their visit time with their doctor.[21]

DISCUSSION

The results of this randomized clinical trial indicate that an automated telephony system might be helpful in bringing about small improvements in clinical and work-related outcomes for individuals with common mental health disorders. Our intervention showed a significant improvement at either 3 or 6 months on at least three (and a suggestive fourth) of 10 outcome measures examined including both work-related (Work Limitation Questionnaire Time and Scheduling Scale score) and mental health–related (SF-12 Mental Health Scale, PHQ Total Depression scale) outcomes. Finally, based on the results of our HTQ, the system was usable and acceptable to most study participants, who did not

hesitate to provide it with sensitive and sometimes potentially stigmatizing information. Our findings, taken together with other work in this field,[30] indicate that this is a potentially fruitful area for research with important implications for behavioral interventions targeting work performance impaired by behavioral health disorders.

A myriad of IVR systems have been developed that are used in the provision of mental health services, such as automated interviews to assess depression[31] and anxiety,[32] prediction of suicide risk,[33] personality testing,[34] and others. Most of this research has focused in the area of automating standardized mental health questionnaires and testing them for reliability/validity.[31–34] In addition to mental health assessment, the technology has also been used to provide behavior therapy to patients with various affective disorders.[35,36] Many of these IVR studies, however, are not randomly controlled clinical trials. In fact, the few clinical trials that have used mental health self-assessment by computers (not IVR) have shown some benefits to users. For example, a randomized controlled evaluation of computerized assessment of common mental health disorders in primary care showed small improvements in clinical outcomes for patients with these disorders.[37] The similar results produced by this study shows that computers are of certain value in the applications for assessment and treatment of mental health disorders. Furthermore, a review monograph by Isaac Marks et al.[38] about computer-aided psychotherapy explored advantages and disadvantages of more than 175 different programs developed by researchers and clinicians around the world. They found out that some of these programs are more effective than others for a variety of reasons, including individual preferences (for a therapist or a computer), system design, method of use, and reason for use, among others.[38] This review is indicative of a trend but one that needs close evaluation to make these systems appropriate for widespread utilization by the public.

An important limitation of our study was recruitment problems, which led to the study's being underpowered to detect behavior change in a randomized intervention trial. With our sample size, moderately large effects, corresponding to Cohen's effect size[39] (difference in means divided by the common standard deviation) of d = .46, would be needed for 80% power capable of showing an intervention effect. Our study may have failed to detect a more modest intervention effect. Despite being underpowered and failing to detect more significant intervention effects, the interest given to the potential low cost and widespread access made possible by this type of easily scalable system is noteworthy. Another limitation with the potential to affect the outcome was the

fact that after the assessment was completed by the program, those in the control arm of the study were told by the automated system, ''The interview indicated that you may be suffering from some type of emotional distress. I recommend that you seek mental health care.'' This advice, requested by our Institutional Review Board, had to be provided to control group participants and was ethically required. Thus, those in the control group may have undertaken self-care efforts (e.g., behavioral activation or exercise or seeking care elsewhere) because of the effect of this potentially confounding yet ethical intervention.

SO WHAT? Implications for Health Promotion Practitioners and Researchers

What is already known on this topic?

Research has shown that automated behavioral interventions can yield clinical benefits. Studies targeting depression in primary care indicate that the principal beneficiaries of depression management programs are the employers. However, studies in the workplace that measure the impact of mental health disorders on productivity that use comprehensive automated behavioral health interventions are lacking.

What does this article add?

Our research showed that an automated behavioral health intervention can produce modest improvements in clinical and work-related outcomes. The article invites future work on exploration of human-computer interaction in mental health care with implications for augmenting traditional outpatient mental health care delivery. This innovative study calls for automated, scalable approaches that can reach a larger population of those in need of mental health services.

What are the implications for health promotion practice or research?

A practical contribution of our program is demonstrating the importance of targeting comorbid disorders and exploring whether improvement in one disorder increases the likelihood of achieving improvement in others.

We believe that our future research efforts should focus on a controlled trial of the system in which subjects will be randomized into two groups of automated system and human clinician. We hope to use a larger sample size in order to better detect differences between the intervention and control groups of each disorder. This will not only provide data on feasibility and impact but also measure the fidelity of the automated standardized instruments. Furthermore, because the program was uniquely designed to screen for a variety of common mental health disorders and to provide information and advice, future research should consider evaluation of the system with the general public and not just an employee population.

Acknowledgment

The development of the screening and intervention system was supported by a grant (Automated Assessment of Mental Health Disorders in the Workplace—R01 DP000116) from the Centers for Disease Control and Prevention.

CLINICAL TRIALS *DESIGN* *Clinical Trials* 2011; **8:** 183–195

A point-of-care clinical trial comparing insulin administered using a sliding scale *versus* a weight-based regimen

Louis D Fiore[a,b,c], Mary Brophy[a,c], Ryan E Ferguson[a,b], Leonard D'Avolio[a,d], John A Hermos[a,c,e], Robert A Lew[a,f], Gheorghe Doros[a,f], Chester H Conrad[a,c], Joseph A (''Gus'') O'Neil Jr[a], Thomas P Sabin[a], James Kaufman[a,c], Stephen L Swartz[a], Elizabeth Lawler[a,g,h], Matthew H Liang[a,i], J Michael Gaziano[a,g,h] and Philip W Lavori[j,k]

Background Clinical trials are widely considered the gold standard in comparative effectiveness research (CER) but the high cost and complexity of traditional trials and concerns about generalizability to broad patient populations and general clinical practice limit their appeal. Unsuccessful implementation of CER results limits the value of even the highest quality trials. Planning for a trial comparing two standard strategies of insulin administration for hospitalized patients led us to develop a new method for a clinical trial designed to be embedded directly into the clinical care setting thereby lowering the cost, increasing the pragmatic nature of the overall trial, strengthening implementation, and creating an integrated environment of research-based care.

Purpose We describe a novel randomized clinical trial that uses the informatics and statistics infrastructure of the Veterans Affairs Healthcare System (VA) to illustrate one key component (called the point-of-care clinical trial – POC-CT) of a 'learning healthcare system,' and settles a clinical question of interest to the VA.

Methods This study is an open-label, randomized trial comparing sliding scale regular insulin to a weight-based regimen for control of hyperglycemia, using the primary outcome length of stay, in non-ICU inpatients within the northeast region of the VA. All non-ICU patients who require in-hospital insulin therapy are eligible for the trial, and the VA's automated systems will be used to assess eligibility and present the possibility of randomization to the clinician at the point of care. Clinicians will indicate their approval for informed consent to be obtained by study staff. Adaptive randomization will assign up to 3000 patients, preferentially to the currently 'winning' strategy, and all care will proceed according to usual practices. Based on a Bayesian stopping rule, the study has acceptable frequentist operating characteristics (Type I error 6%, power 86%) against a 12% reduction of median length of stay from 5 to 4.4 days. The adaptive stopping rule promotes implementation of a successful treatment strategy.

Limitations Despite clinical equipoise, individual healthcare providers may have strong treatment preferences that jeopardize the success and implementation of the trial design, leading to low rates of randomization. Unblinded treatment assignment may bias results. In addition, generalization of clinical results to other healthcare systems may be limited by differences in patient population. Generalizability of the POC-CT method depends on the level of informatics and statistics infrastructure available to a healthcare system.

Conclusions The methods proposed will demonstrate outcome-based evaluation of control of hyperglycemia in hospitalized veterans. By institutionalizing a process of statistically sound and efficient learning, and by integrating that learning with automatic implementation of best practice, the participating VA Healthcare Systems will accelerate improvements in the effectiveness of care. *Clinical Trials* 2011; **8**: 183–195. http://ctj.sagepub.com

Introduction

Medical decision making is informed by clinical trials and observational studies. Randomization in clinical trials reduces or eliminates biases of observational studies, such as selection by indication and confounding from unmeasured prognostic factors that affect treatment decisions and outcomes. By their purpose, randomized clinical trials (RCTs) can be designed on a spectrum ranging from *pragmatic* (comparing effectiveness of interventions in the most realistic of situations and with diverse subjects) to *explanatory* (comparing efficacy in precisely described clinical situations and selected patients) [1,2]. The goal of explanatory trials is to better understand how and why an intervention works while pragmatic clinical trials are designed to provide information needed to assist healthcare providers make informed clinical decisions [3].

The *Pragmatic–Explanatory Continuum Indicator Summary (PRECIS)* is a measure of where on this continuum an individual trial is situated [4]. It takes under consideration the attributes of an RCT such as flexibility of the interventions, practitioner expertise required, eligibility criteria, intensity of follow-up and adherence monitoring, and the nature and scope of the primary outcome. RCTs are considered on the pragmatic end of the spectrum when these attributes are chosen to allow the trial to more closely mimic conditions encountered in the clinical care arena. Examples include eligibility criteria that reflect the patient population likely to receive the intervention, study investigators with expertise and experiences similar to the healthcare providers who will ultimately administer the treatments, treatment protocols that allow the flexibility required in routine clinical care, and outcome measures, and follow-up procedures that would be part of routine clinical care. Despite their reflection of routine clinical care, pragmatic trials are currently still complicated and expensive to implement, because of the use of dedicated study personnel to recruit participants, administer the intervention and monitor the participants for study outcomes and adverse events.

We are testing a real implementation of a new methodology for clinical trials, that we have called point-of-care clinical trials (POC-CTs), with features designed to maximize the pragmatic nature of studies. Aspects of the approach we describe here have been proposed or implemented by others [5–8] and discussed in detail under the name of the 'clinically integrated randomized trial' by Vickers and Scardino [9]. The defining characteristic here is that to the maximum extent possible the clinical trial apparatus is embedded in routine clinical care. Optimally, this would include recruitment and randomization of study subjects at their POC by their usual healthcare provider. Once randomized to a treatment arm subjects would continue to be treated by their healthcare provider with minimal or no deviation from usual care. Follow-up of participants would thus reflect current clinical practice. Assessment of subject compliance and practitioner adherence to protocol, and ascertainment of clinically relevant endpoints would be performed through medical record review, with minimal contamination of the clinical care 'ecosystem' by intrusive study dependencies. The intrusiveness of study operations, from randomization through endpoint ascertainment, would be greatly reduced if performed using tools familiar to healthcare providers and data already present in an electronic medical record (EMR).

A POC-CT shifts away from the asynchronous, distinct, and separate environments of research and clinical care, toward a real-time integrated system of research-based care. The goal of POC-CTs is to deliver the best care to patients while

learning from each experience and redefining that care. Under this new paradigm, ongoing results would be more rapidly and more likely adopted by providers who participated in the studies. By synthesizing research with practice and tools to learn from that process, participating facilities can move to the goal of becoming 'learning healthcare systems.'

In this article, we describe a specific POC-CT designed to test the feasibility and usefulness of the method, in answering a question of relevance to the Veterans Affairs (VA) Healthcare System. The clinical context and issues are described and ethical issues discussed. The use of outcome adaptive randomization to enhance implementation also addresses the frequentist operating characteristics of the design. The kinds of comparativeness questions best suited to POC-CT are argued.

Illustrative example: sliding scale insulin regimen *versus* weight-based insulin protocol

We describe a POC-CT which compares two common regimens of administering insulin therapy to hospitalized patients requiring insulin; the sliding scale and weight-based approach. The VA has an EMR that includes electronic ordering of medications and protocols for both of these insulin regimens. Review of EMR data at the VA Boston Healthcare System demonstrated that each of these two approaches is used with approximately equal frequency and discussions with treating clinicians indicated that choice of method administration is based on personal preference and not on patient specific determinants.

There are no published data comparing the effectiveness or the adverse effects of the sliding scale or a weight-based insulin protocol in treating inpatients with hyperglycemia. For the sliding scale, short acting insulin is administered three to four times daily according to the degree of hyperglycemia, and no basal insulin is administered. This regimen, therefore, responds to hyperglycemia after it occurs, and does not prevent it. The weight-based insulin protocol is a twice daily regimen of basal intermediate-acting insulin (NPH) plus a pre-meal twice a day regimen of short acting regular insulin, plus a correction dose of regular insulin depending on the degree of hyperglycemia. In addition, depending on the amount of the correction dose, the basal doses are adjusted upward for the next day's NPH insulin dose to manage the hyperglycemia.

Study design

Overall, the study is an open-label, randomized trial comparing sliding scale to a weight-based regimen in non-intensive care units (ICU) inpatients in a single large VA healthcare facility. There will be no modification to the treatment protocols already in use which will be accessed through the existing order entry menu. Consented patients will be randomized to treatment arms using an adaptive randomization method. Subjects are otherwise treated as usual. That is to say, there is no treatment protocol imposed other than insulin regimen beyond randomization. *There are no required diagnostic procedures and no study-specific follow-up events required*. Outcomes and covariates data will be collected directly from the computerized patient record system (CPRS). The primary endpoint is hospital length of stay (LOS); secondary endpoints include glycemic control and readmissions for glycemic control within 30 days of hospital discharge. Analysis will be based on intention to treat.

We considered using a cluster-randomized design, but the number of natural clusters (treatment units) within a hospital is small and having enough clusters to achieve adequate power would require opening the study at many hospitals, posing too many complex issues for a first use of POC-CT. Furthermore, we are interested in testing the feasibility of individual patient-level randomization, and the use of adaptive randomization to 'close the implementation gap.' While it is possible to imagine an adaptive cluster-randomized design, we have little information on the parameters necessary for design of such a study.

Eligibility

All non-ICU patients who require sliding scale or weight-based insulin therapy are eligible. The decision to obtain consent from a given individual will be made by the ordering clinician at the time of an insulin order (see section 'Methods'). There are no exclusions.

Treatment regimens

The treatment regimens are sliding scale and weight-based insulin as currently operationalized at the VA Boston Healthcare System. The ordering clinician finds these protocols under the electronic endocrine order menu and is led through order entry screens that insure standardization of the treatment protocol. The sliding scale and weight-based insulin regimens order menus in place at the

medical center were not modified other than to add a third choice allowing for randomization through the POC-CT mechanism.

Follow-up

Consenting subjects will be followed until 30 days of post-randomization. Following informed consent subjects will not be contacted by the study team either during their hospitalization or after discharge. All follow-up data will be collected *via* the EMR.

Data collection

Variables collected include demographics (age and gender); admission date, discharge date, and bed location (acute *vs*. non-acute); bed service (medical, surgical, and other); admission and other medical diagnoses (ICD-9 classification); glucose, blood counts, creatinine, and estimated glomerular filtration rate (GFR) values; and body temperature, medications, administered blood transfusion products, readmission date, and readmission diagnosis (ICD-9) if within 30 days of discharge. Non-VA hospitalization data for all subjects enrolled in Medicare will be available through a data-sharing agreement between VA and the Centers for Medicare & Medicaid Services.

Outcomes

The clinical outcomes of potential relevance that were considered included episodes of suspected hypoglycemia and measures previously used in studies examining potential benefit of improved glycemic control such as: (1) shortened length of hospital stay; (2) fewer infections; (3) fewer episodes of acute kidney injury; (4) less need for renal dialysis; (5) lower blood transfusion requirements; and (6) less neuropathy.

LOS is selected as the primary outcome, because LOS has important cost implications, lowers the risk of hospital-acquired complications including falls and infections, and might be expected to be shortened if diabetic control can be made more efficient. It is also readily ascertainable from the EMR. Secondary outcome measures include degree of glycemic control and readmission within 30 days of discharge with the primary readmission diagnosis of control of glycemia. Tertiary outcomes include infections, acute kidney injury, and anemia, all of which have been previously used as outcome measures in studies of insulin regimens. Infection will be defined as new antibiotic administration associated with either fever or leukocytosis. Acute kidney injury is defined as a decrease in estimated GFR of greater than 50% and anemia as a drop in the hemoglobin level of at least 2 g/dL.

Recruitment and enrollment

The POC-CT process is implemented using software tools available in CPRS. CPRS is the clinical care component of the Veterans Health Information Systems and Technology Architecture (VISTA), which supports clinical as well as administrative applications. Software tools available in CPRS include order sets (predefined customizable sets of orders), templates for clinical notes, decision logic (reminder dialog templates), and defined data objects that extract data from the medical record for display purposes (patient data objects). CPRS also has the ability to store flags (indicators in the data base) known as 'health factors' related to clinical parameters and flags derived from the ordering process. These tools make it possible to identify certain data elements in real time (e.g., an insulin order) and to incorporate programmatic logic into the medical record's workflow based on the value of data elements. The order sets and templates utilized for this project were designed to be consistent in format and process with the existing system.

The following describes the workflow of the study and demonstrates how CPRS processes already familiar to clinicians were adopted for POC-CT (Figures 1 and 2):

1) The VISTA order entry screen for insulin has been modified to include a third option in addition to the current options to order sliding scale or the weight-based regimen. The third option is labeled 'No preference for insulin regimen, consider enrollment in an inpatient study of Weight Based vs. Sliding Scale protocols' (Figure 3).
2) Clinicians who choose this third option will be presented with a brief description of the study and given the option to either proceed or not with consideration of their patient for study enrollment.
3) Clinicians who choose not to continue will click on the button labeled 'No. The patient may not be approached. Proceed with usual care.' and will be returned to the previous order entry screen to continue without further consideration of this trial.

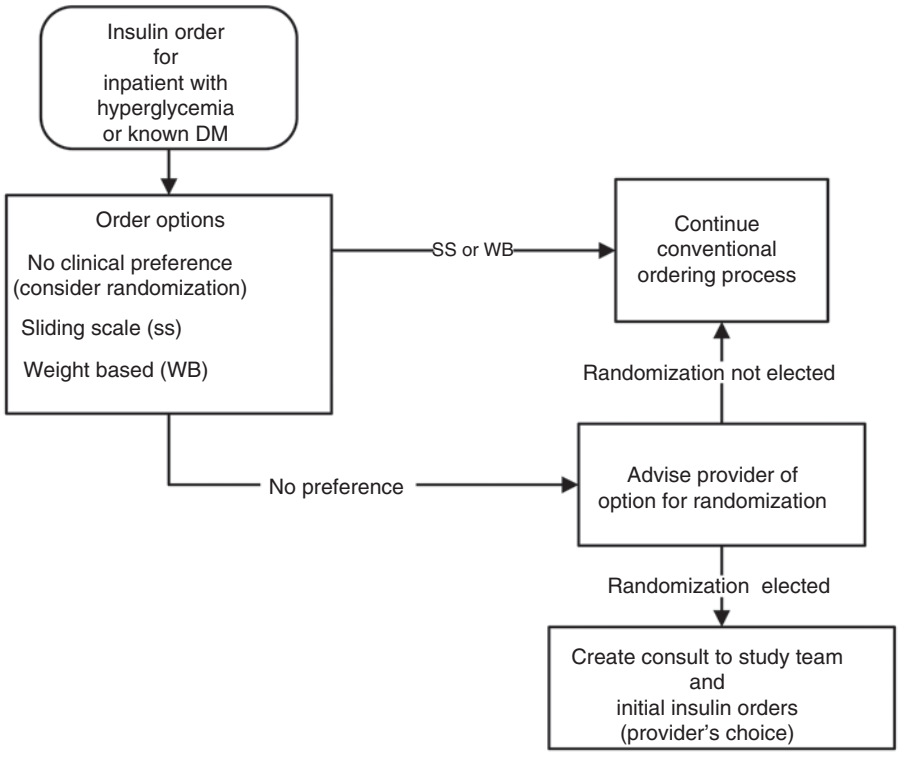

Figure 1 Initial order process performed by clinician

4) Clinicians who choose to proceed will click on the button labeled 'Yes. The research team may approach this patient for consideration of enrollment.' and will be brought to a consult entry screen. The consult entry screen will be pre-populated requesting a 'Research insulin dosing consent request.' After submitting this consult, the clinician will then be directed to the order entry menu and will order either sliding scale or weight-based insulin as per their choice. This order will serve as a holding order to provide insulin treatment until the patient can be consented and randomized.
5) Upon receiving the 'Research insulin dosing consent request,' the study nurse will discuss the study with the patient and obtain informed consent. If the patient declines enrollment, a template progress note completing the consult will be automatically entered. Patients who refuse randomization will be asked for consent to allow access to their VISTA data for comparison to the subset of patients who accepted randomization.
6) Patients who provide consent will be randomized through the VISTA system to one of the two insulin regimens. A template progress note activated by the study nurse will document randomization. This template progress note will generate 'health factors' that will serve to identify patients as subjects in the trial for tracking purposes in VISTA. It will also generate the order for whichever insulin regimen the subject was randomized to receive.
7) Progress notes (for both patients accepting and declining participation) and orders (for those accepting randomization) will be automatically forwarded to the original ordering clinician.
8) By signing these documents, the clinician completes the study enrollment process.

The protocol was approved by the VA Boston Institutional Review Board (IRB) who waived Health Insurance Portability and Accountability Act (HIPAA) authorization to allow the study team, once contacted and prior to seeing the patient, to have access to protected health information in the medical record. Importantly, clinicians, in simply referring patients to the study coordinator for recruitment and signing the insulin orders generated by the randomization procedures were not considered by the IRB to be 'engaged in clinical research' and thus were not required to be research credentialed.

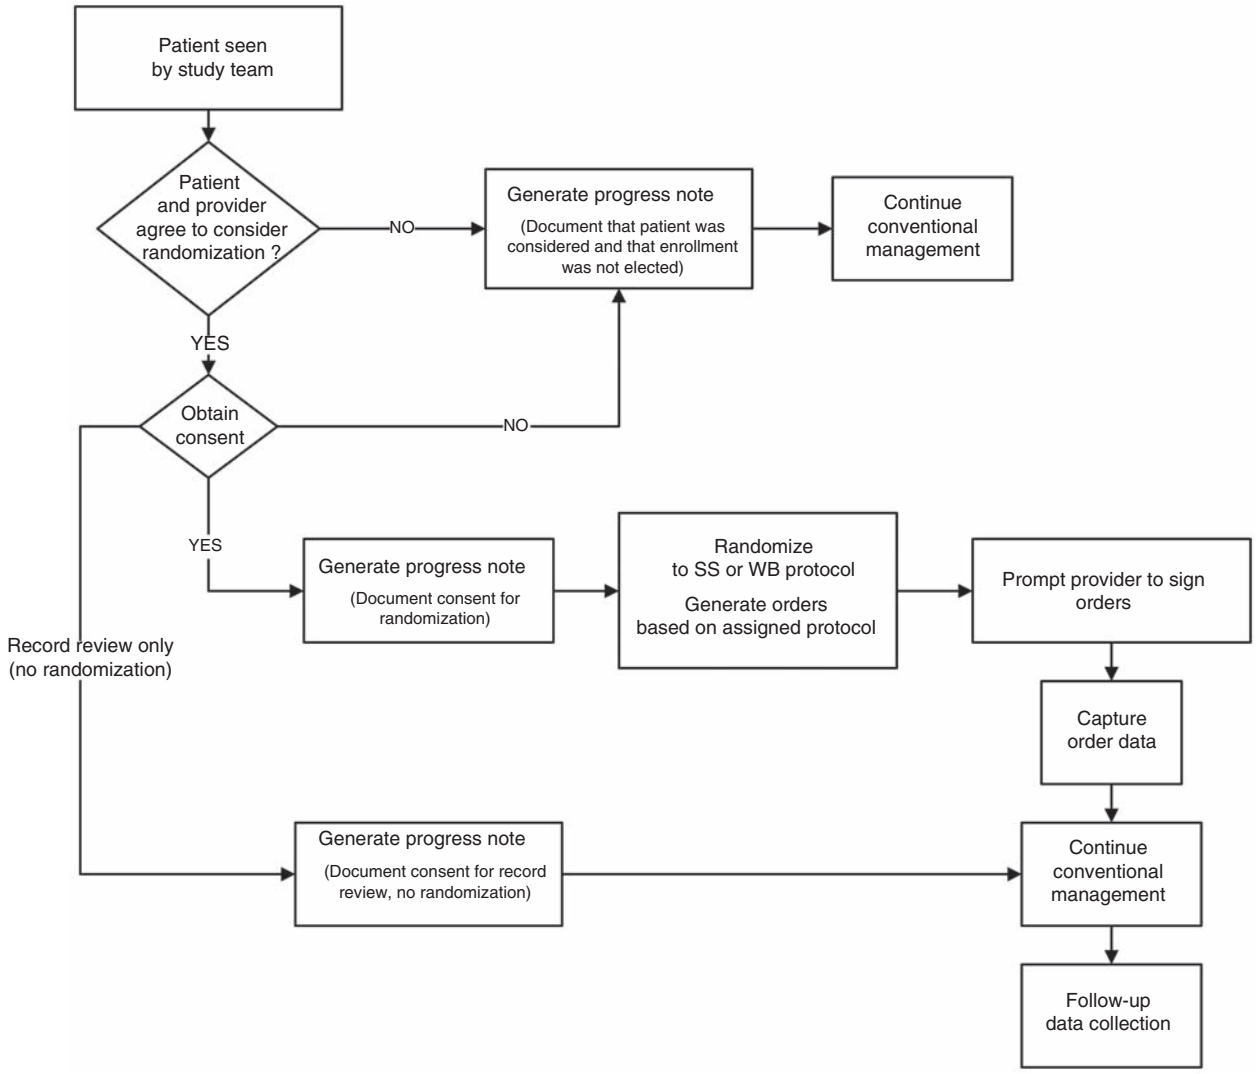

Figure 2 Workflow beginning when clinician has agreed to consider randomizing patient into one of two interventions

Statistical issues

We define three main aims: (1) to determine the physician and patient acceptance of POC randomization, (2) to test the null hypothesis of no difference against reasonable alternatives (two-sided), and (3) to demonstrate successful implementation of the superior strategy. The first aim requires descriptive statistical approaches, including estimating proportions and defining patient- and physician-level predictors of acceptance. The second aim requires tuning the design parameters to achieve acceptable operating characteristics. The third aim motivates an adaptive randomization, adjusting the assignment probabilities to increase the chances that patients are assigned to the better treatment.

Adaptive design

In the proposed study, the response or outcome is hospital LOS and the parameters of interest are the median LOS with each of the two protocols: (1) weight-based (Protocol A) and (2) sliding scale (Protocol B). We predict that the patients using the weight-based protocol will have a smaller median LOS than patients using the sliding scale protocol. To test this hypothesis, we propose using a Bayesian adaptive design.

The rules of adaptation considered herein modify the assignment probability each time the study accrues a new fixed number or 'batch' of patients, with practical batch sizes of at least 100 patients to allow more time for review and cleaning of data as is implicit in group sequential designs.

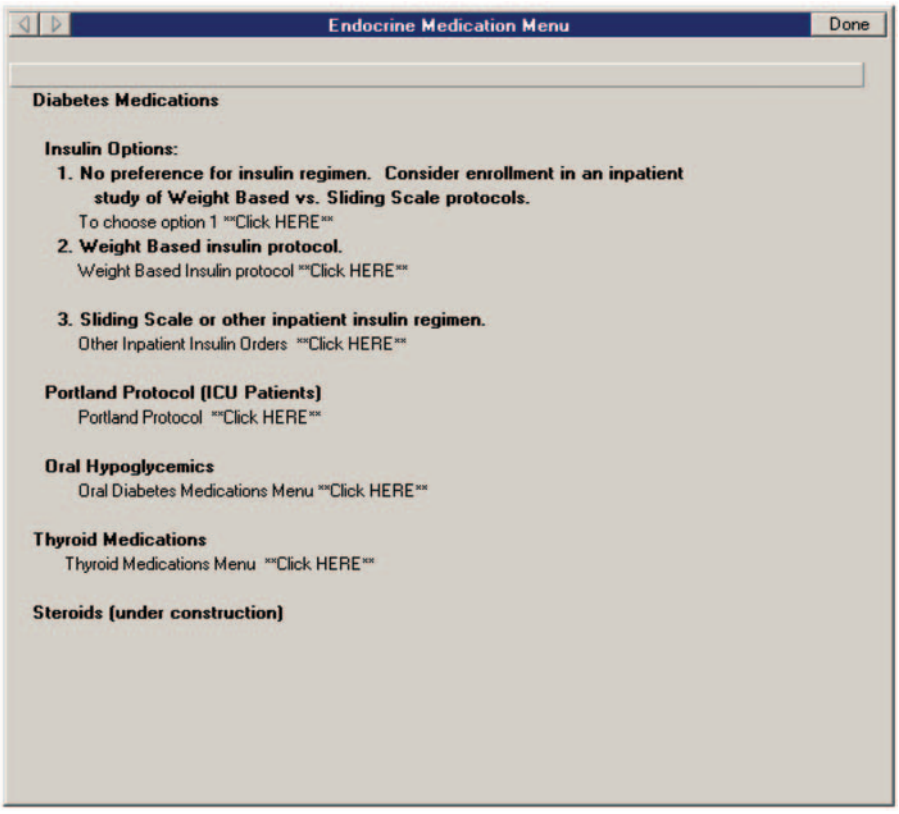

Figure 3 Screen shot of CPRS showing introduction of POC-CT option into the insulin options menu

According to this scheme (Figure 4)

1) First, subjects will be assigned to either weight-based protocol (Group A) with probability $\pi = 0.5$ or to sliding scale protocol (Group B) with probability $1 - \pi = 0.5$. This assignment probability is utilized for the first batch of patients.
2) Then, the data collected on the first group of subjects are used to calculate the probability that Protocol A is superior to Protocol B given the accumulated data, that is

$$\begin{aligned} p_A &= P(\text{Protocol A is superior to Protocol B}) \\ &= P(\theta_A < \theta_B | DATA) \end{aligned}$$

The '*DATA*' here refers to the data collected on the first batch of patients, with allowance for a period (UPDATE strip in Figure 4) in which the investigators clean the data and do the update and θ_A and θ_B are the median LOS in Groups A and B, respectively. The 'posterior' probability p_A ('*probability of Protocol A being superior to Protocol B given the data*') is calculated using Bayesian methods. Bayesian methods use prior information or beliefs, along with the current data, to guide the search for parameter estimates. Prior information/beliefs are input as a distribution, and the data then help refine that distribution and construct the posterior distribution. Our statistical model is based on an exponential data model for the LOS with conjugate Inverse Gamma prior for the median LOS [10]. Prior distributions in each group were chosen to be centered on the null median value and have a shape parameter α.

1) The posterior probability p_A is then used to evaluate whether the accumulated information overwhelmingly supports one protocol over the other so that the termination of the trial is warranted. In particular, we would stop the trial if

$$p_A > \kappa \text{ or } p_A < 1 - \kappa$$

where κ is the *cutpoint* reflecting the level of evidence demanded by the investigators to terminate the trial. If $p_A > \kappa$, then the study is terminated and Protocol A is chosen as being superior while if $p_A < 1 - \kappa$, the study is terminated and Protocol B is chosen to be superior. The value for κ is at the

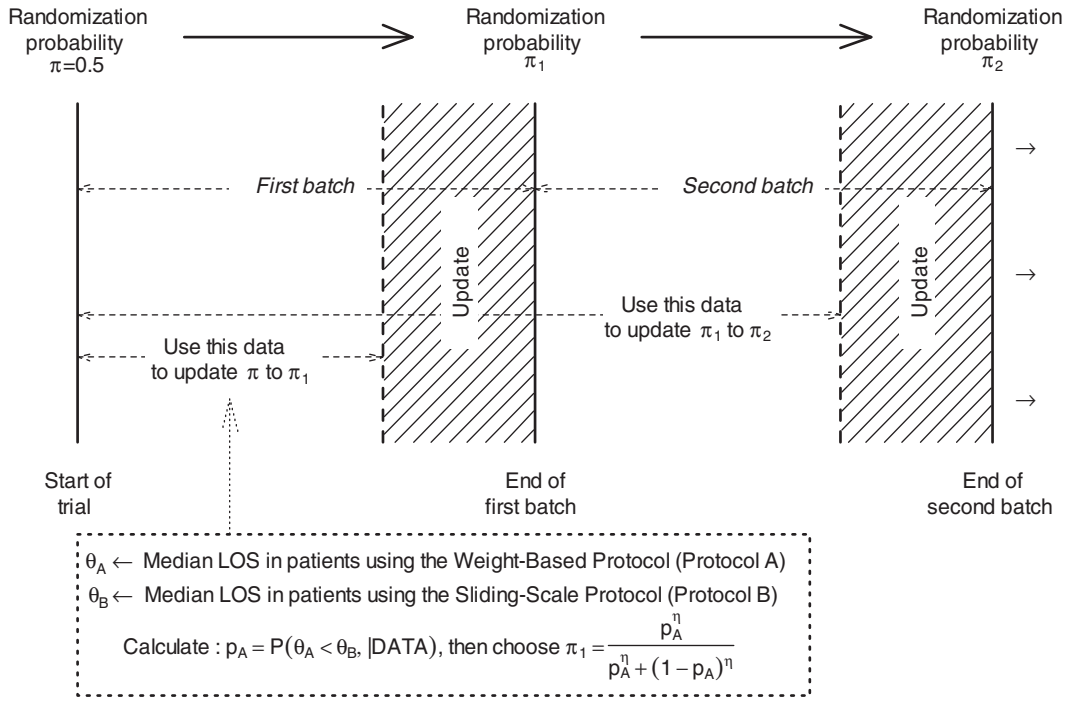

Figure 4 Diagram representing the flow of the design In the figure above, π represents the probability of assigning the weight-based protocol to a patient

investigators' disposal and it is usually a value that is close to 1 (for example 0.9, 0.95, or 0.99).

1) If the decision to terminate is not made, the posterior probability p_A is used to update the assignment probability to π_1 using the transformation [11]

$$\pi_1 = \frac{(p_A)^\eta}{(p_A)^\eta + (1-p_A)^\eta}$$

where $\eta > 0$ is a *calibration parameter*. If η is set to 1, the updated assignment probability is $\pi_1 = p_A$, while a value of $\eta = 0$ leads to a balanced randomization design. Values greater than 1 (less than 1) lead to more aggressive (less aggressive) adaptation.

1) The second batch of patients will then be assigned to Protocol A with probability π_1 and to Protocol B with probability $1 - \pi_1$. After the data on the second batch of patients are collected, the assignment probability π_1 is updated to π_2 using the above algorithm and the termination criterion is checked. If the termination criterion is met, the study is terminated. If not, the assignment probability π_1 is updated to π_2 using the above algorithm and the third batch is then enrolled.
2) This process is continued until either the termination criterion is met or the number of subjects enrolled reaches a pre-specified maximum number of subjects $N_{\max}$.

Proposed design

Extensive computer simulations were done to select a design for the study based on their operating characteristics. The following operating characteristics were considered in selecting the final design:

1) *Overall Type I error* – the chance of declaring one of the two protocols better at any time during the trial when in fact there is no difference between the two protocols.
2) *Overall power* – the chance of declaring a protocol better at any time during the trial when in fact that protocol is better.
3) *The number of patients assigned to each protocol.* The number of patients enrolled will depend on the data collected and hence is a random variable.
4) *Time until a decision is made.* The duration of the study will depend on the data collected and hence is a random variable.

We chose a design with the following parameters: prior shape parameter $\alpha = 100$, batch size = 200, cutpoint $\kappa = 0.99$, calibration parameter $\eta = 0.5$, and maximum number of patients to be randomized $N_{max} = 3000$. In addition, the updation occurs after 150 patients of each batch have entered the study, we do not update or allow stopping after the first batch, and we censor the LOS at 30 days.

We studied the above design under various scenarios. Our null hypothesis is that the median LOS with both protocols is 5 days. As alternative, we posit a minimal clinically important reduction of at least 12% in median LOS.

The operating characteristics of the design are represented in Table 1.

Type I error: Under the assumption of no difference (first row in Table 1 – median LOS is 5 days with both protocols) the probability of (incorrectly) selecting either protocol as superior was 0.06.

Power: Under the alternatives (median LOS with Protocol A < median LOS under Protocol B) presented in the remaining rows of the table, the probability of correctly selecting Protocol A represents the power. For a difference of 12% in median LOS, across the interim looks, the design will correctly select Protocol A as superior with 86% probability (power), while the probability of wrongly selecting Protocol B as superior decreases fast to levels close to 0%. The decision to stop increases with time (Figure 5); thus, the probability or terminating the trial by the 6th interim look (after 1400 subjects have been enrolled) is 50% and it increases to 86% by the 14th look (after all 3000 subjects have been enrolled).

From among the many alternatives designs we evaluated, we briefly discuss here the *balanced* design that has the same parameters as the design presented above. Additional information on the simulation study including the R [12] script used in running the simulations can be obtained from the authors.

With a balanced design, the Type I error is the same, the power is slightly higher (for example, 77% *vs*. 71% to detect a difference with Protocol A of 10% in median LOS), the median number of patients enrolled is about the same (~2000),

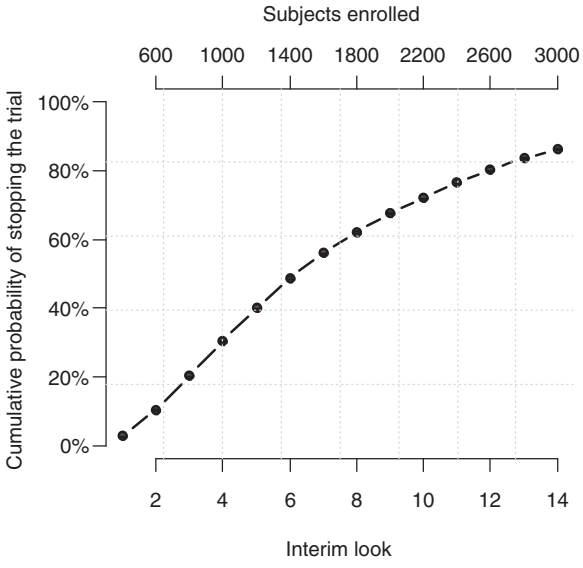

Figure 5 Cumulative probability of stopping the trial across interim looks; assumed median LOS with Protocols B and A are 5 and 4.4 days, respectively

Table 1 Operating characteristics of the proposed design

Difference in median LOS (B–A) in days [median under Protocol B = 5 days]	Probability of selecting Protocol A as superior (%)	Probability of selecting Protocol B as superior (%)	Median number of patients on Protocol A	Median number of patients on Protocol B	Median duration (days)[a]
0	3	3	1495	1461	599

[a]In calculating the duration of the study, we assumed an accrual rate of 5 patients per day.

however, while with the balanced design the enrollment is balanced, with our proposed design the number of patients assigned to the superior treatment is higher.

The operating characteristic simulation is dependent on the accuracy of the data model used to generate the LOS. In Table 1, we use the exponential model to generate the data, as well as to do the updating. Thus, it makes the assumption that the Bayesian model is correctly specified, as is done in most published work, when estimating (frequentist) operating characteristics. But the LOS data from a historical sample of patients approximating the proposed study intake criteria indicates a heavier tail, such as log-normal. Therefore, we assessed the sensitivity of the assumptions by using the log-normal model to generate the data (but still using the exponential model for the updates; Table 2).

The difference between these two simulations illustrates the modest sensitivity of the operating characteristics to misspecification of the data model. For example, the Type I error estimate rises from 6% to 7%, and the power at a difference of 0.5 days drops from 71% to 62%. However, we consider the Type I error less relevant in this context, comparing the effectiveness of two widely used procedures for setting dose. In a different context, the Type I error might be more important. The probability of making the right choice when it matters (a full day difference) is high (100%) in the log-normal scenario, too. These results illustrate the value of a hybrid approach, where the Bayes method is confined to updating the randomization probability (thus closing the implementation gap and maximizing the number of patients receiving the right treatment) and inference is based on operating characteristics from a range of more realistic models.

Discussion

POC-CT methodology is well suited for studies with the following features:

- Interventions already approved by the FDA.
- A clinical question where there is equipoise regarding clinically relevant alternative interventions.
- Interventions that are part of routine practice, well tolerated, and have well-recognized toxicities which mitigates the need for adverse event monitoring beyond that in routine clinical care.
- Subject identification, inclusion and exclusion criteria, and endpoints that are accurately obtained from the EMR.
- Outcomes are objective and require little or no adjudication.
- Study protocol requiring minimal deviations from usual care.
- No systematic laboratory or clinical follow-up required for either safety or comparative effectiveness.

This trial is designed to be on the pragmatic extreme of the clinical trial spectrum with the subject consent process being the sole perturbation of the clinical care 'ecosystem.' The absence of study specific interventions, procedures, and monitoring together with passive data capture attempts to maximize the relevance of the findings to

current practice at the VA Boston Healthcare System. Adaptive randomization is designed to assign subjects preferentially to the treatment arm that, in real time, appears superior, with an 'efficacy' stopping rule that has acceptable Type I error. If the study terminates without reaching its 'efficacy' boundary, it will reliably rule out a substantial difference, in which case cost, convenience, and other factors will dictate which treatment arms continue to be supported. Such direct translation of study results into clinical practice defines a 'learning healthcare system.'

The clinical question posed in this protocol, comparison of insulin administration methods, was chosen because it is amenable to a maximally pragmatic study as defined by the PRECIS criteria and because:

- Broad participation by healthcare providers is expected. The clinical question is compelling and in practice there is apparent equipoise between the two regimens in that roughly half of patients are currently treated by each technique.
- The inclusion/exclusion criteria will allow enrollment of nearly all the VA Boston patients who require the intervention.
- The study interventions are currently utilized at VA Boston, have known toxicities that are monitored as part of usual care, and thus require no specific study related monitoring.
- All study data elements are objective, resident in the EMR and do not require study specific interactions or visits for capture.
- Adaptive randomization methodology leads to real-time incorporation of study results into practice, if one treatment proves superior.

The ability to implement this study is made possible by the VA's EMR environment. CPRS is in use at all the VA's 1500-plus points of care and was designed to incorporate clinical data as part of efforts to improve clinical care. As a result, it features several packages that allow end users to automatically generate reports, 'listen' for certain values associated with patient data objects, consider these values with programmatic logic, and introduce information and workflows directly into the EMR. To capitalize on this level of flexibility, most VA healthcare systems employ Clinical Application Coordinators, who use these tools to create and report measures of the quality of care, to implement guidelines, and to create clinical reminders based on the priorities of each hospital. This infrastructure will allow for the relatively easy roll-out of this and other POC-CT studies system-wide as well as systematic implementation of findings.

The ability to use existing functionalities, as opposed to developing custom software is important for a number of reasons. First, development of new software functionality is constrained by time for development, testing, and approval, and development resources. Second, by capitalizing on existing system functionality, we increase the likelihood of a successful deployment to other VA hospitals or clinics, each one of which employs CPRS. Finally, although this particular use of CPRS may be novel, the POC-CT processes are presented through familiar interfaces and into a culture of robust CPRS use, which we hope will facilitate adoption of this approach.

The ability of institutions to implement POC-CTs is dependent on the ability to use the EMR to: (1) identify events as they present in real time; (2) intervene in the clinical care workflow; and (3) track longitudinal data. It is worth noting that these functionalities are critical to the creation and implementation of many novel approaches to learn from and improve healthcare based on real data and that few systems offer such capabilities to end users. The need for such functionalities is of particular relevance in light of the US Federal Government's upcoming investment of $19 billion to support the adoption of EMRs [13]. Much of this funding is contingent on the adoption of 'certified' EMR systems and the 'meaningful use' of such systems. Definitions that require flexible integration with EMR data and workflows are essential to meeting the goals of such enormous investments [14].

The ethical and practical considerations of informed consent have been extensively discussed and debated [15–19] as have methods such as cluster randomization which might obviate or preclude individual informed consent [20,21]. Detailed analyses of these considerations are outside the scope of this article. However, as POC-CTs or similarly designed trials become an important component of clinical research, it will be incumbent on investigators, ethicists, and IRBs to fully consider the potential benefits and apparently minimal incremental risks of a POC-CT, and to take responsibility for helping their healthcare systems to lower the barriers to successful study design and implementation of improvements in care.

A study coordinator will obtain written informed consent for all subjects entered into this trial. This requirement accounts for a significant proportion of the study cost and introduces the single most tangible perturbation to the usual care workflow. We recognize that replacement of such full written informed consent by an alternative (such as simple 'notification' by the healthcare provider and verbal consent by the subject with subsequent

randomization through a fully automated computerized process) would result in an even more efficient design, with a closer match to clinical care. The IRB could consider such a variation on the usual research informed consent, on a study-by-study basis, especially when the POC-CT results in care materially identical to usual clinical practice. Parallel requirements would be a waiver of HIPAA authorization to obtain study data from the EMR and acknowledgement that treating clinicians who authorize automated randomization are not 'engaged' in research.

A POC-CT will likely require significantly less study-specific infrastructure and cost than traditional RCTs (after the up-front investment in coordinating center and informatics, already made by the VA). These advantages together with an economy of scale once an investment in the methodology has been made could lead to low incremental cost per study as well as allowing study designs of sufficient duration to capture clinically relevant (as opposed to surrogate) endpoints.

Limitations

Several issues may impede adoption of POC-CTs. Some patients may find it surprising and troubling that healthcare providers do not know what is the best treatment for them. This disclosure could make the consent process lengthy and difficult. Although the medical community might be at equipoise regarding treatment options, individual healthcare providers may have strong treatment preferences, either in general or for particular individual patients. Both of these issues could have ramifications for recruitment rates and the success of a POC-CT. We note that 'reluctance to randomize' is an issue for all RCT designs, not just POC-CT.

Most (if not all) uses of POC-CT we envision would have an open (unblinded) design, which raises the possibility of cross-contamination of treatments, or differential clinical interventions due to physicians' perceptions of patients' needs, or other failures of the exclusion principle, such as observational bias in the outcome. Therefore, the use of POC-CT may be restricted to clinical situations where the effects are likely to be minimal. We think that the EMR-based protocols we compare here, as well as the outcome of LOS, sharply reduce physician unblinding as a threat. We emphasize that POC-CT is not a universal alternative to the classical double-blind RCT with its many controls for bias; rather, it can be seen as a competitor to observational studies, by removing the particular bias from selection by indication that plagues such non-experimental studies.

Our pragmatic intent requires us to rely on individual clinician judgment of eligibility, which is another mark of distinction between POC-CT and conventional trials, which often have elaborate procedures for defining 'inclusion and exclusion.' This certainly restricts the use of POC-CT to contexts where such precision is unnecessary. However, it also contributes to the 'ecological validity' of treatment effects.

Highly pragmatic POC-CTs such as this study may yield results that are locally convincing but are not easily generalized to other healthcare systems. A healthcare system such as the VA, motivated to conduct POC-CTs and with the organization and infrastructure capable of supporting it, could generate 'locally selfish' evidence-based medicine to gain evidence of comparative effectiveness most relevant to its population and systems. In general, comparative effectiveness findings are most applicable to the systems and individuals who participated in its creation rather than to the 'free riders' – those who may desire evidence-based medicine but who are unwilling to be a part of that evidence.

The above may suggest that the POC-CT approach is limited to a narrow range of clinical questions and contexts. We are just now beginning to expand our list of possible use cases, and we do not want to speculate in advance of the facts. We agree with Vickers and Scardino [9] that features of POC-CT might be implemented in practice in four distinct areas: surgery, 'me too' drugs, rare diseases, and lifestyle interventions. In addition to questions of optimizing care (such as the insulin example described here) use cases currently under consideration include technology introduction (imaging, robotics, and biomarker-guided therapy), pre-hydration with bicarbonate *versus* saline with or without n-acetylcysteine in contrast-induced nephropathy, and comparing prolonged exposure and cognitive processing therapies as alternative treatment strategies for post-traumatic stress disorder.

Finally, the proposed study design using outcome adaptive randomization leads to real-time implementation into practice, and stimulates reconsideration of the role of the traditional peer review process that subjects study results to expert outside review before planning their implementation in practice.

Funding

This study was supported by the Department of Veterans Affairs Cooperative Studies Program. Dr Lavori's efforts have been supported by grants UL1

RR025744 and R01 MH051481 to Stanford University.

Steven R. Simon is chief of the Section of General Internal Medicine, Veterans Affairs Boston Healthcare System.

ABSTRACT The ability to generate and use registries—lists of patients with specific conditions, medications, or test results—is considered a measure of physicians' engagement with electronic health record systems and a proxy for high-quality health care. We conducted a pre-post survey of registry capability among physicians participating in the Massachusetts eHealth Collaborative, a four-year, $50 million health information technology program. Physicians who participated in the program increased their ability to generate some types of registries—specifically, for laboratory results and medication use. Our analysis also suggested that physicians who used their electronic health records more intensively were more likely to use registries, particularly in caring for patients with diabetes, compared to physicians reporting less avid use of electronic health records. This statewide project may be a viable model for regional efforts to expand health information technology and improve the quality of care.

The American Recovery and Reinvestment Act of 2009, which included the Health Information Technology for Economic and Clinical Health (HITECH) provisions, allocated more than $48 billion to promote the spread of health information technology (IT) throughout the United States.[1,2] Widespread use of electronic health records is seen as a foundation for health reform.[3] However, considerable doubt remains as to how deeply health IT will penetrate US health care and whether it will actually produce the anticipated quality improvements.

To foster the adoption of health IT among ambulatory practices, HITECH authorizes the Office of the National Coordinator for Health Information Technology to establish regional extension centers to assist providers in selecting and implementing certified interoperable electronic health records for their practices. These centers aim to disseminate "lessons learned" and "best practices" throughout their communities and to promote participation in health information exchange.[4]

Policy makers and leaders of regional extension centers will naturally look to existing models of communitywide efforts to promote the adoption of health IT. One of the most visible examples of such programs is the Massachusetts eHealth Collaborative, a statewide consortium of health care stakeholders founded in 2004 to improve the quality and safety of health care through community-based adoption of health IT.[5–10]

During 2006–08, the Massachusetts eHealth Collaborative sponsored a program to implement electronic health records within ambulatory medical practices and establish health information exchange. With a $50 million grant from Blue Cross and Blue Shield of Massachusetts, the collaborative used a competitive

process to select three communities to participate in the program. Additional details about the program are presented elsewhere.[5,7]

Our study evaluates one aspect of the potential impact of this program on the quality of health care. Because effects on patient outcomes and costs of care are likely to require several years to become measurable, we identified the ability to generate patient registries as an early proxy measure for the Massachusetts eHealth Collaborative's potential impact on the quality of care.

Registry capability, defined as the ability to generate lists of patients based on defined clinical characteristics requiring specific action, is frequently viewed as an essential tool for improving the health care of individuals and populations.[11,12] It is included in the "meaningful use" criteria of the Centers for Medicare and Medicaid Services.[13] Although registries can be paper based, practices with electronic health records are considerably more likely than practices that use paper records to have registry capability.[11]

Therefore, we hypothesized that the Massachusetts eHealth Collaborative would increase registry capability among participating practices. As a secondary hypothesis, we examined whether primary care practices with more extensive use of their electronic health records were more likely to use their registries in the care of patients with chronic conditions, as compared with practices with less avid use of electronic health records.

Study Data And Methods

STUDY DESIGN We evaluated the implementation of electronic health records using pre- and post-intervention surveys to measure physicians' perceived ability to generate registries. The Partners HealthCare Human Research Committee approved the study protocol.

INTERVENTION The Massachusetts eHealth Collaborative installed robust electronic health records and provided work-flow redesign and technical support at no cost to the offices of participating physicians during 2006–08. The electronic health records were certified by the Certification Commission for Health Information Technology. "Practice consultants" with expertise in implementing ambulatory electronic health records and redesigning office practices met with office staff and physicians in preparation for the record systems' deployment, during the deployment, and after the systems were fully deployed.

The intervention was evaluated according to several measures, including the use of technology, assessment of barriers and facilitators, implementation tactics, safety, impact on quality of care, and fiscal parameters.[6,7,10]

SETTING AND PARTICIPANTS The Massachusetts communities of Brockton, Newburyport, and North Adams were selected for the pilot program. The characteristics of these communities and the physicians and practices within them reflected the demographics and practice characteristics of physicians and practices across Massachusetts.[8,14]

A total of 167 physician practices participated, representing 86 percent of all eligible primary care and specialty practices in these communities. All were invited to respond to pre-intervention (2005) and post-intervention (2009) surveys (see the online Appendix).[15]

For the pre-intervention survey we identified 464 physicians from 167 practices; 355 completed the survey (response rate: 77 percent).[14] In 2009, 468 physicians were eligible to participate; of these, 319 completed the survey (response rate: 68 percent).

Between 2005 and 2009, some practices dissolved, and some physicians departed, while new physicians entered the communities. A total of 163 physicians from 134 practices completed both the 2005 and 2009 survey questionnaires. This set of physicians constituted the main analytic sample.

SURVEY DESIGN The pre- and post-intervention surveys were based on similar statewide surveys of physicians, described elsewhere.[11,14,16–18] Briefly, the 2005 survey measured physicians' attitudes toward the use of computers in health care and specifically assessed the ability of each practice to generate registries. The post-intervention (2009) survey retained the original survey items and added new questions related to health information exchange and the electronic health record implementation process.

MAIN OUTCOME MEASURES The main outcome measure was the ability to generate registries, as reflected by the responses to the following questions asked identically in 2005 and 2009: "With your current medical record system (paper and/or electronic), how easy would it be for you or your staff to generate the following information about your patients? A) List of patients by diagnosis or health risk (e.g., diabetes); B) List of patients by laboratory results (e.g., patients with abnormal hematocrit levels); C) List of patients by medications they currently take (e.g., patients on warfarin)." These questions referred to the three different types of registries we referenced in the study: for diagnoses, laboratory results, and medications.

Responses were elicited along a five-point Likert-type scale and were dichotomized to classify physicians as able (very easy, somewhat easy, somewhat difficult, very difficult) versus

not able (cannot generate) to generate each registry type. Because "very difficult" and "cannot generate" may reflect a similar set of physicians who need health IT implementation support, we dichotomized the outcome in post hoc analyses to classify physicians as capable (very easy, somewhat easy, somewhat difficult) versus needing support (very difficult, cannot generate).

OTHER OUTCOME MEASURES The 2009 survey asked physicians about their actual use of registry functions in office practice. Specifically, it asked whether their office, by either paper or electronic means, did the following tasks annually for patients with diabetes and patients with coronary artery disease: prompted the practice to notify patients who are overdue for office visits; generated a list of patients who are overdue for tests; and generated a list of patients with clinical data suggesting that they needed an intervention (for example, their blood tests indicated elevated hemoglobin A1c greater than 7, or their systolic blood pressure measured greater than 140).

OTHER VARIABLES The surveys also recorded physician characteristics, such as age, sex, race, years in practice, and number of outpatients seen per week, and practice characteristics, such as number of physicians in the practice, specialty, ownership, and financial resources available for expansion.

DATA ANALYSIS To assess for nonresponse bias, we compared demographics and practice characteristics of physicians who completed both the 2005 and 2009 surveys with those of physicians who completed only the 2005 (baseline) survey.

For our initial pre-post analysis, we compared the proportion of physicians who were able to generate each type of registry in 2009 versus 2005. We first examined these proportions among all survey respondents in 2009 ($N = 319$) compared with all survey respondents in 2005 ($N = 355$) to provide a "snapshot" of registry capability in each time period. In all subsequent analyses, we restricted the sample to physicians who had completed both the 2005 and 2009 surveys ($n = 163$).

We compared pre- and post-intervention rates separately for each of the main outcome measures of ability to create registries—based on diagnoses; laboratory results; and medications—using McNemar's test for all three outcomes. We also used logistic regression with generalized estimating equations to generate confidence intervals and odds ratios and to account for repeated measures (that is, the same physician's completing the survey in 2005 and 2009). In all analyses, results were qualitatively similar between generalized estimating equations and McNemar's test.

The ability to generate registries is an integral component of the patient-centered medical home.

In a secondary cross-sectional analysis, we examined the relationship between the use of electronic health record functions and registry functions among internal medicine and family medicine physicians ($n = 87$) in 2009, for whom the measure was most relevant. We classified physicians as "high" and "low" electronic health record users based on a previously developed measure of usage.[18] This aggregate measure reflects each physician's reported use of ten key functions in the electronic health record, with each physician's calculated score ranging from 0 (no usage of available functions) to 1 (consistent usage of all available functions).

We dichotomized the sample as high users (above the median value of 0.8) or low users (below the median). This score did not include any measure of registry usage. We compared rates of use of each of the three registry types (diagnosis, laboratory test, medication) among high and low electronic health record users, using Fisher's exact test. Analyses were performed using the statistical analysis software package SAS, version 9.2.

STUDY LIMITATIONS Our study had several limitations. Most important, our study lacked a control group, which prevented us from excluding longer-term trends as an explanation for our observed findings. It is possible that a trend toward increased attention to quality measurement and improvement during the study period, including interest in pay-for-performance initiatives, might have included registry capabilities. Our unpublished statewide data, mentioned in the Discussion section, do in fact suggest a noncyclical trend toward increased registry capability. However, the magnitude of the pre-post intervention effect observed in this study seems too great to be accounted for by this secular trend alone.

Another important limitation is that we re-

stricted our main analyses to physicians who completed both pre- and post-intervention surveys. Although this approach minimizes potential confounding, it may limit generalizability. Future studies and similar intervention programs must consider the inevitable flux of physicians into and out of communities.

We also note that the study evaluated the effect of the Massachusetts eHealth Collaborative on registry capabilities through physician self-report rather than actual use. All physicians within the collaborative actually had the ability to generate registries as part of their electronic health records, whether or not they were aware of it, because the installed electronic health records all featured registry capability. Future studies should measure actual registry usage from data extracted directly from electronic health records, as will ultimately be required to determine "meaningful use."[19] Furthermore, we did not assess whether traditional quality measures or patient health outcomes improved during the study period.

Study Results

BASELINE CHARACTERISTICS Baseline characteristics of the 163 physicians completing both the 2005 and 2009 surveys are shown in Exhibit 1. These physicians were similar to those who responded to only the 2005 survey ($n = 192$) with respect to age ($p = 0.32$), sex ($p = 0.74$), years in practice ($p = 0.10$), specialty ($p = 0.34$), average number of patients seen per week ($p = 0.66$), and resources available for practice expansion ($p = 0.06$). However, they were more likely to practice in groups of more than five physicians (58 percent versus 46 percent; $p = 0.01$) and more likely to be full or partial owners of their practices (66 percent versus 58 percent; $p = 0.02$).

MAIN OUTCOME MEASURES Compared with all survey respondents in 2005, all survey respondents in 2009 were more likely to be able to generate each registry type (Exhibit 2).

Among the 163 physicians who completed both surveys, the ability to generate a diagnosis registry was similar over the study period (88 percent in 2009; 89 percent in 2005). In contrast, 78 percent of these physicians in 2009 were able to generate a laboratory results registry, compared with 44 percent in 2005, and 83 percent in 2009 could generate a medication registry, compared with 33 percent in 2005.

In analyses that adjusted for all available covariates, physicians in 2009 were more likely to be able to generate a laboratory and a medication registry than they were in 2005. In contrast,

EXHIBIT 1

Baseline Characteristics Of The Massachusetts eHealth Collaborative Physicians And Practices

Characteristic	Participants (*N* = 163)
Age, mean, in years (SD)	49 (9.9)
Male	123 (75%)
Race

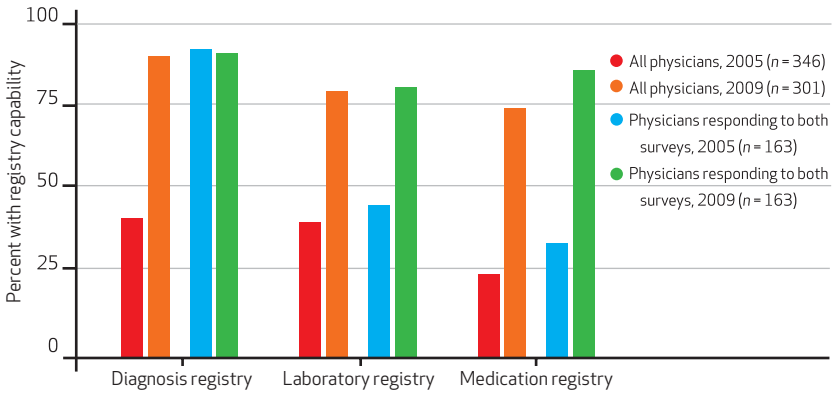
Adequate resources for practice expansion, number[d]	30 (18%)

SOURCE Authors' data. **NOTES** All measures are based on 2005 survey data, with the exception of race, which was ascertained only in 2009. SD is standard deviation. IQR is interquartile range. [a]Practice owner indicates physicians who described themselves as full or part owners of the practice. [b]Primary care includes general internal medicine ($n = 26$), pediatrics ($n = 16$), family practice ($n = 25$), and primary care (not otherwise specified; $n = 11$). [c]Non–primary care includes general surgery and surgical subspecialties ($n = 39$), subspecialties of internal medicine ($n = 21$), obstetrics/gynecology ($n = 12$), and other specialties ($n = 13$). [d]Participants indicated whether their practice had adequate resources for improvement or expansion.

EXHIBIT 2

Ability Of Physicians In The Massachusetts eHealth Collaborative To Generate Diagnosis, Laboratory Test, And Medication Registries



SOURCE Authors' data. **NOTE** The exhibit shows, from left to right for each registry type, the proportion with registry capability among all physicians in 2005, all physicians in 2009, physicians in 2005 who completed both surveys, and those in 2009 who completed both surveys.

there was no change in ability to generate a diagnosis registry (odds ratio: 1.0; 95 percent confidence interval: 0.4–2.4) (Exhibit 3). The online Appendix shows complete results of the multivariate analysis.[15]

Practice size was significantly associated with the ability to generate all registry types: Smaller practices were consistently less likely than larger practices to be able to generate registries. Specialty type was significantly associated with the ability to generate both medication and laboratory registries, but not diagnosis registries. Older physicians were less likely to be able to generate diagnosis registries compared to younger physicians; however, a significant age effect was not observed with medication or laboratory registries (Exhibit 3).

In a post hoc analysis, with the registry capability outcome dichotomized as those who are capable of generating registries and those who need support, we found that the Massachusetts eHealth Collaborative intervention increased capability for all three registry types: diagnosis (odds ratio: 1.9; 95% confidence interval: 1.0–3.9); laboratory results (odds ratio: 7.6; 95% confidence interval: 4.2–13.7); and medication (odds ratio: 10.2; 95% confidence interval: 5.2–9.9).

ELECTRONIC HEALTH RECORD AND REGISTRY USE We were interested in primary care physicians' actual use of registries. Eighty-seven internal medicine and family medicine physicians completed the 2009 questionnaire. We dichotomized these physicians as "high users" ($n = 44$) and "low users" ($n = 43$) of the electronic health record.

Exhibit 4 shows the proportion of these physicians who indicated that they performed registry-based tasks for patients with diabetes mellitus and coronary artery disease. For diabetes, there was a trend toward greater use of registry functions among high users. The result reached statistical significance for the use of registry functions to remind patients about overdue testing (odds ratio: 2.8; 95% confidence interval: 1.1–7.1). There was no consistent relationship observed between electronic health record usage and the use of registry functions for patients with coronary artery disease.

Discussion

During 2006–08 the Massachusetts eHealth Collaborative implemented electronic health records and provided work-flow redesign and technical support to more than 160 physician prac-

Performance Of Registry Tasks Among High And Low Users Of The Electronic Health Record (EHR) In The Massachusetts eHealth Collaborative

	For diabetes mellitus			For coronary artery disease		
Generate list of patients with	**High EHR users (*n* = 43)**	**Low EHR users (*n* = 43)**	***p* value**	**High EHR users (*n* = 41)**	**Low EHR users (*n* = 43)**	***p* value**
Overdue visits	60%	51%	0.39	51%	47%	0.67
Overdue tests	55	30	0.02	34	30	0.70
Abnormal labs	51	37	0.20	28	35	0.47

SOURCE Authors' data. **NOTES** *N* = 87. Of the eighty-seven primary care physicians, one did not provide responses to the items related to diabetes mellitus, while three did not provide responses to the items regarding coronary artery disease. We classified physicians as high and low EHR users. We calculated an EHR usage score for each physician that ranged from 0 (no usage of available functions) to 1 (consistent usage of all available functions), and we dichotomized the sample as high users (above the median value of 0.8) or low users (below the median). This usage score did not include any measure of registry usage.

tices in a well-funded community-based outreach intervention. In this pre-post analysis, we found that the intervention was associated with improved ability to generate registries based on laboratory test results and medications, but not based on diagnosis. The failure to observe an increase in diagnosis registry capability is probably due to the fact that nearly 90 percent of practices reported being able to generate diagnosis registries prior to the intervention. Practices may have been able to generate diagnosis registries from computerized practice management systems—used for billing purposes—which may have been implemented well before this study. These practice management systems would not have enabled the practices to generate laboratory results or medication registries.

The results of this study suggest that communitywide implementation of electronic health records through an organized approach of strategic planning, work-flow redesign, and technology deployment may increase capacity to use registries—a proxy measure of the ability to deliver high-quality health care.

POTENTIAL FOR WIDER IT IMPLEMENTATION Much of the current multibillion-dollar federal investment in health information technology is expected to take the form of community-based interventions to increase electronic health record adoption, such as through the Beacon Communities and regional extension centers. The Massachusetts eHealth Collaborative's efforts provide a prototype, as evident in the increased registry capability from 2005 to 2009. They support the notion that these programs can achieve widespread health IT implementation and potentially improve the quality of care delivered.

Further study is needed to determine whether practices in other states have similar levels of registry capability. The health IT regional extension centers should assess the various registry capabilities of their constituent practices to tailor the transformation efforts needed for each practice.

OTHER REASONS FOR IMPROVEMENT Although these results show that implementation of this program led to improvements in registry capability, alternative explanations need to be considered. This study was not designed to measure whether or not the quality of care actually improved as a result of the Massachusetts eHealth Collaborative program. Most notably, it is conceivable that the pre-post increases in registry capability could be due to secular trends, and not a result of the program intervention.

Over a similar time period in a companion study, randomly sampled physicians across Massachusetts reported increased capability for generating registries, but the magnitude of the increases (absolute increases of 4–10 percent) were considerably smaller than those seen in the present study (33 percent increase for laboratory result registry capability and 50 percent increase for medication registry capability) (Adam Wright, Brigham and Women's Hospital; personal communication, August 3, 2010).

PRACTICE SIZE The observation that 89 percent of practices at baseline were able to generate registries deserves further mention. More than 70 percent of large physician organizations can generate diagnosis registries.[20] However, little is known about small and medium-size practices, such as those in our study. Anecdotally, physicians in the study communities validated our study's estimates of nearly universal registry capability; however, physicians also noted wide variability in the extent to which their practices actually use registries.

SPECIALTY Based on our results, the relationship between specialty and registry capability is unclear. Specialists were more likely to be able to generate laboratory registries, while primary care physicians were more likely to be able to generate medication registries. There was no re-

lationship between specialty and diagnosis registry capability. Some specialists, such as nephrologists and oncologists, whose practices rely heavily on the interpretation of laboratory test results, might logically be expected to have developed robust capability to generate laboratory registries to support their practice needs. Whether this type of practice specialization accounts for the differences observed between specialists and primary care doctors remains unknown. Moreover, it is difficult to explain why primary care physicians should be more likely to be able to generate medication registries than specialists, many of whom prescribe medications with the same frequency as generalists. Clearly, further study is needed to characterize how different specialists and primary care physicians use registries.

Specialists increasingly appreciate the value of regional and national registries that report complications and other measures of the quality of their care.[21,22] Moreover, physicians in all specialties are recognizing the need to track and manage their own patient populations over time.[23] However, little is known about how specialists and primary care physicians use registries, so further research is warranted.

CORRELATION WITH ELECTRONIC HEALTH RECORD USE Our secondary analyses suggested a trend toward greater reported registry use among physicians with greater electronic health record usage, although this finding was seen for diabetes care but not for coronary artery disease. Diabetes mellitus is more prevalent than coronary artery disease and may be more widely recognized as a target for population health management and quality improvement than is the case for coronary artery disease.

It is possible that in the Massachusetts effort we studied, practice consultants may have emphasized the potential value of using registries for diabetes care as an example of how the electronic health record could be used to improve quality of care. Moreover, because diabetes is more prevalent than coronary artery disease, it is plausible that practices aggressively using their electronic health records would embrace registry usage for diabetes more than for coronary artery disease.

These results support the model of planned, organized, community-based health IT implementation.

Although not conclusive, the results of this analysis are consistent with the notion that greater electronic health record usage may be associated with greater registry usage. This study also adds to the literature in its evaluation of a broad community implementation using commercial electronic health record systems.

Studies of registry use and capability to date have been generally descriptive and cross-sectional.[24,25] This analysis provides evidence that the intervention resulted in improved registry capability—an important indicator of health care quality. The ability to generate registries is also an integral component of the patient-centered medical home.[26]

POLICY IMPLICATIONS Although our results must be interpreted with some caution, this study nonetheless has important implications for health care policy. These results support the model of planned, organized, community-based health IT implementation programs. They suggest that Beacon Community programs and regional extension centers may be successful, although both approaches should be evaluated. We found that a community-level intervention was associated with increased ability to generate registries, which should ideally result in commensurate improvement in the quality, safety, and cost of health care. ■

An earlier version of this article was presented in oral abstract form at the Society of General Internal Medicine Regional meeting in Providence, Rhode Island, March 2010, and as a poster at the Society of General Internal Medicine national meeting in Minneapolis, Minnesota, April 2010. This study was funded by the Agency for Healthcare Research and Quality, Cooperative Agreement No. 1UC1HS015397, and by the Massachusetts eHealth Collaborative. ABOUT THE AUTHORS: MARSHALL FLEURANT, RACHEL KELL, JENNIFER LOVE, CHELSEA JENTER, LYNN A. VOLK, FANG ZHANG, DAVID W. BATES & STEVEN R. SIMON

Marshall Fleurant is a general internal medicine research fellow at the Harvard Pilgrim Health Care Institute and Harvard Medical School.

Marshall Fleurant and coauthors report in this month's *Health Affairs* on results from their survey of physicians who participated in the Massachusetts e-Health Collaborative. The study reports that participating physicians increased their ability to generate registries of laboratory results and medications—essential tools for improving health care of individuals and populations.

Fleurant is a general internal medicine research fellow in the Department of Population Medicine at the Harvard Pilgrim Health Care Institute and Harvard Medical School. His current interests are in health information technology and its effect on

primary care and ambulatory practice. He received a medical degree from the Albert Einstein College of Medicine and a master of public health degree from the Harvard School of Public Health.

Rachel Kell is the evaluation coordinator at the Massachusetts eHealth Collaborative.

Rachel Kell works for the Massachusetts eHealth Collaborative, where she has been involved in the evaluation of its electronic health record implementation pilot program. She earned a master of public health degree in health policy and management from Boston University.

Jennifer Love is a former research assistant at Partners HealthCare System.

Jennifer Love is a former research assistant with the Clinical and Quality Analysis IT group at Partners HealthCare System. She is now a medical student at the Perelman School of Medicine, University of Pennsylvania.

Chelsea Jenter is a research project manager at Brigham and Women's Hospital.

Chelsea Jenter is a senior research project manager in the Division of General Medicine at Brigham and Women's Hospital. She earned a master of public health degree in health policy and management from Boston University.

Lynn A. Volk is an associate director at Partners HealthCare System.

Lynn A. Volk is associate director of the Clinical and Quality Analysis Department within Partners HealthCare System's Information Services. She earned a master's degree in health science from the Johns Hopkins Bloomberg School of Public Health.

Fang Zhang is an instructor in population medicine at the Harvard Pilgrim Health Care Institute.

Fang Zhang is director of programming in the Drug Policy Research Group at the Harvard Pilgrim Health Care Institute and an instructor in population medicine at Harvard Medical School and Harvard Pilgrim. He has a master's degree in statistics from Worcester Polytechnic Institute and a doctorate in biostatistics from Boston University.

David W. Bates is division chief, general internal medicine, at Brigham and Women's Hospital.

David Bates is chief of the Division of General Internal Medicine at Brigham and Women's Hospital, a professor of medicine at Harvard Medical School, and a professor of health policy and management at the Harvard School of Public Health, where he codirects the Program in Clinical Effectiveness. His medical degree is from Johns Hopkins.

Steven R. Simon is chief of the Section of General Internal Medicine, Veterans Affairs Boston Healthcare System.

Steven Simon is chief of the Section of General Internal Medicine at the Veterans Affairs Boston Healthcare System and an associate professor at Harvard Medical School and Brigham and Women's Hospital. He is a general internist and health services researcher with a focus on interventions to improve the quality and safety of health care, principally through the use of health information technology and education on the evaluation of innovative medical education and quality improvement programs.

Simon received a medical degree from Yale University and a master of public health degree from the Harvard School of Public Health.

Patient Navigation: The Promise to Reduce Health Disparities

Karen M. Freund, MD, MPH

Women's Health Unit, Section of General Internal Medicine, Evans Department of Medicine, and Women's Health Interdisciplinary Research Center, Boston University School of Medicine, Boston, MA, USA.

J Gen Intern Med 26(2):110–2
DOI: 10.1007/s11606-010-1593-5

There is a great need for effective interventions to address health disparities for vulnerable populations, which may be defined by low education, low literacy, low income, inadequate health insurance, or minority racial / ethnic status. Many efforts have focused on the social determinants of health, resting on the notion that the magnitude of health outcome disparities affecting so many different racial and ethnic groups argues against biologic differences, but is rather due to social and cultural influences on how patients use or receive care. This implies that personalized medicine to address genetic risk alone will not eliminate health disparities, but rather systems interventions to improve access and the process of care delivery are critical to improving the health of the entire nation.

Looking specifically at cancer outcomes, lower screening rates are well described for underserved populations[1]. Even where screening rates are similar between racial and ethnic groups,[2] differences exist in follow up rates after abnormal screening,[3] resulting in differences in stage and size of tumors at diagnosis which in turn contribute to ongoing disparities[4]. Safety net institutions, which are less likely to have sufficient resources to track and support patients, have populations with greater barriers to completing their diagnostic or treatment care. This perfect storm of patients with limited resources to support themselves and their families when cancer is diagnosed, and resource-poor safety net institutions with limited resources to provide extra support is at the heart of many of our nation's health disparities.

This problem has become more acute with the economic downturn, where resources to safety net institutions are increasingly strained, even while the numbers of patients losing employer-based coverage grows. As an example, in Massachusetts, the two largest safety net hospitals, Boston Medical Center, and Cambridge Health Alliance have experienced huge budget gaps. This is due to both marked state reductions in their Medicaid reimbursement rates, and payment rates for insured patients from health insurance companies being sometimes two to three times lower than those provided to nearby teaching hospitals [5–7]. As a result, our reimbursement systems perpetuate the continued presence of fewer resources to institutions whose patient populations have few resources.

Published online December 15, 2010

Added to this disparity the advent of pay for performance,[8] where institutions will receive payments based upon performance to quality benchmarks for their entire populations. While most would agree that paying for improved outcomes provides the appropriate incentives to our health care systems, it also serves to put at greater risk those institutions caring for those most in need[9]. Those institutions that require additional resources to provide care may lose additional resources to care systems with patient populations better able to adhere to their doctors' recommendations. How to make the playing field level for safety net institutions is not obviously clear. The notion of having a lower achievement standard to receive performance payments for safety net institutions on its face seems to codify rather than improve health disparities, and it also is based on the notion that disparities are an intractable problem.

Patient navigation is an emerging model of improving healthcare delivered to vulnerable populations, which has primarily focused on improved cancer outcomes. Patient navigation has been defined as the logistic and emotional support offered to persons through the cancer care continuum from screening, through diagnostic evaluation and cancer treatment. The goal of patient navigation is to support patients in overcoming logistical barriers to care and facilitate timely access to quality cancer care that meets cultural needs for all patients. Navigators work to address financial and insurance issues, coordinate appointments and care among multiple cancer providers, address language and health literacy needs and train patients to advocate for themselves in the health care system[10]. The term "patient navigation" was coined by Dr. Harold Freeman, as a care management system to address cancer disparities. His initial demonstration project[11] has been followed by studies demonstrating that additional staffing resources to providers in safety net institutions can improve intermediate outcomes of completion and timeliness of screening and diagnostic care, as a mechanism to ultimately improving health outcomes[12–14].

Patient navigation shares many attributes with other care management models. Most patient navigation programs have been housed directly with the providers of health care and facilitate care through providing a liaison between patients and the health care team. A recent Centers for Medicare and Medicaid (CMS) program investigating the clinical and financial benefit of care management programs funded multiple models of care, ranging from off-site telephone-based interventions, to clinically-based programs linked with the providers of care. Of the 15 funded programs, only two showed a benefit; both were programs with face to face as opposed to telephone-only contact, and were programs housed and organized with the providers of care[15].

The two studies published in this issue of JGIM provide further support of the patient navigation model. Both programs are funded through the Avon Foundation, which has

provided consistent support for breast cancer care to safety net programs over the past decade. The study by Phillips and colleagues[16] addressed low HEDIS-measured screening mammography, and studied the impact of patient navigation through a pre-post difference in difference analysis. The 10% improvement in HEDIS rates achieved by the intervention is noteworthy in that it would allow such a safety net system to benefit from most pay for performance programs. The findings illustrate that unstable housing and incorrect contact information in their patient populations remain limitations to this patient navigation model.

Donelan and colleagues[17] studied patient satisfaction with the patient navigator model of care. They compared patients from their community health center affiliates, predominantly low income, minority women, with a primarily white, educated population whose primary care was not through a safety net institution. Both populations reported similar satisfaction with care after abnormal breast cancer screening. The lack of demographic overlap between the two groups prevents multivariable or propensity adjustment to fully understand what impact the navigation model played in the results. The authors conclude that the navigated and non-navigated groups report similar perceptions of the quality of their care. It is not clear whether this indicates that the navigated group would have been equally satisfied with their care without navigation or whether prior to navigation, the minority population would have reported a poorer experience with care that was ameliorated with navigation. Further research needs to study this issue with appropriate control populations, to understand if patient navigation is serving to benefit the quality of care in low income and minority communities.[18,19]

The initial reports suggest that patient navigation holds promise to address care needs to vulnerable populations, and bridge the disparities gap. Currently, however, patient navigation systems are more likely to be found and marketed in systems caring and targeting patients who are insured, employed and educated. Paradoxically, if patient navigation is an effective modality for improving care, there is a risk of it increasing rather than eliminating health disparities. Few safety net institutions have the ongoing resources to support this augmentation to care, and insurers do not reimburse this care. This is in contrast to hospitals and health care systems providing care to predominantly insured populations, where resources are present to support patient navigation services. The websites of most private cancer care centers tout the benefits of their patient navigation, and these are now seen as standards of care by some cancer care accreditation organizations including the National Accreditation Program for Breast Centers[20], and the National Comprehensive Cancer Networks[21]. Even as patient navigation is studied to ensure appropriate care to the underserved, its major implementation has been in insured populations who already have better health outcomes. Health care reform has at its goal a transition into a care management approach, as a necessary step to improving quality and reducing cost. We will need to carefully watch that resources including patient navigation and case management are provided to safety net institutions to address the challenges that their populations face, if we hope to reduce and not increase disparities in care.

Abstract

Coinfection with hepatitis C (HCV) significantly increases the risk of acute and chronic renal disease in HIV-infected individuals. However, the burden of acute kidney injury (AKI) directly attributable to HIV among HCV-infected individuals and associated risk factors are not well understood. Within a prospective cohort, AKI episodes were identified by a rise in creatinine of 0.5 mg/dL. Incidence of first AKI events was calculated for HIV/HCV coinfected versus HCV monoinfected subjects, and multivariable analyses using Cox proportional hazards were performed to identify predictors of AKI. Throughout the study period, 35% HIV/HCV coinfected and 17% HCV monoinfected subjects developed AKI, with incidence of 8.74/100 person-years and 3.53/100 person-years, respectively (hazard ratio (HR) 2.48; [95% confidence interval (CI) 1.50, 3.74]). In multivariable analysis, HIV coinfection (HR 2.19 [1.33, 3.62]), decompensated cirrhosis (HR 6.64 [3.81, 11.6]), and cocaine use (HR 2.06 [1.15, 3.71]) were independently associated with AKI. HCV genotype, HCV viral load, hazardous drinking, and heroin use were not associated with AKI. Study limitations included potential misclassification bias of HCV-infected individuals as serial HIV antibody testing was not routinely performed after study entry, and inability to adjust for tenofovir use in multivariable analysis. In conclusion, among subjects with HCV infection, decompensated cirrhosis, HIV coinfection, and cocaine use are associated with increased risk of AKI. These findings highlight the importance of preventing and treating cirrhosis, controlling HIV coinfection, and reducing cocaine use in HIV/HCV coinfected persons.

Introduction

Renal disease is an increasingly important cause of morbidity and mortality among HIV-infected individuals.[1,2] It is estimated that 30% of HIV-infected patients in the United States have abnormal renal function.[1] Recent epidemiologic studies have revealed that coinfection with hepatitis C virus (HCV) confers an even greater risk of both acute kidney injury (AKI) and chronic kidney (CKD) disease among individuals infected with HIV.[3–7]

AKI is a common complication among both ambulatory and hospitalized HIV-infected patients in the highly active antiretroviral therapy (HAART) era.[3,4] In one study involving hospitalized HIV patients by Wyatt and colleagues,[3] AKI was associated with a 5.83 increased odds of in-hospital mortality. Franceschini and colleagues[5] examined predictors of AKI among HIV-infected patients and found that coinfection with HCV was significantly associated with AKI, along with male gender, CD4 count less than 200 cells/mm^3, HIV viral load (VL) greater than 10,000 copies per milliliter, and HAART exposure. A recent meta-analysis of studies involving HIV/HCV coinfection and renal disease found a pooled relative risk of 1.64 [95% confidence interval (CI) 1.21, 2.23] for AKI in HIV/HCV-coinfected versus HIV-monoinfected patients. However, the authors commented that few of the studies provided a clear definition of HCV coinfection, and only one

required HCV RNA testing for diagnosis.[8] Thus, additional investigation is needed to understand the mechanisms underlying the association between HIV/HCV coinfection and renal disease.

Individuals with HIV/HCV coinfection demonstrate an accelerated course of liver disease progression to cirrhosis,[9] and experience a high degree of liver-related morbidity and mortality.[10] AKI is a frequent complication of decompensated cirrhosis in the general population, and in Franceschini's study,[4] liver failure accounted for 18% of AKI events among HIV/HCV-coinfected subjects. A subsequent study in the United Kingdom demonstrated that among 20 HIV/HCV-coinfected patients with AKI, 7 had advanced cirrhosis while 5 experienced infectious complications of injection drug use (IDU).[7]

Although decompensated liver cirrhosis and infectious complications of IDU underlie some of the etiologies by which HIV/HCV coinfected patients develop AKI, additional mechanisms remain unexplored. HCV has independently been associated with immune complex-mediated renal injury, but epidemiologic studies of the association between HCV monoinfection and renal disease have been inconclusive. Several studies have found increased associations between HCV infection and albuminuria, CKD, and end-stage renal disease (ESRD),[11–13] while others have found no association.[14] Since most studies of HIV/HCV infection and renal disease have relied solely on HCV antibody data, the impact of various HCV-specific factors such as viral load and genotype have not been well studied. In addition, despite the high prevalence of substance use among coinfected patients, the associations between various substances of abuse and AKI have not been elucidated.

In this study, we sought to determine the incidence of AKI in HIV/HCV-coinfected versus HCV-monoinfected subjects, and to examine the association between HCV-specific factors and exposure to various substances of abuse, and the subsequent development of AKI.

Methods

Study design/subject assembly

Subjects with HIV/HCV coinfection and HCV monoinfection were enrolled in a prospective cohort study of the natural history of liver disease progression. The present analysis covers the time period August 15, 2000 to December 31, 2007. Subjects were included if they had at least two creatinine (Cr) measures obtained a minimum of 3 months apart, and were excluded if they had less than 6 months of follow-up. Subjects were categorized as HCV monoinfected or HIV/HCV coinfected based on their status at study entry.

Data collection

The study database contains information collected prospectively through semiannual patient surveys and annual electronic medical chart review. Data are available on self-reported illicit drug and alcohol use, clinical laboratory data, hospitalizations, liver events, and deaths.

Main exposures of interest Subjects reporting any quantity of heroin or cocaine use (through any route) within 6 months of interview were defined as having a positive exposure. Hazardous alcohol use was defined as 5 or more drinks at least once per month. Nonhazardous alcohol use was defined as 5 or more drinks less than once per month or 1–4 drinks at any time. Nondrinkers were defined as having no alcohol use within 6 months of interview. Liver events, signifying the presence of decompensated cirrhosis, included: hepatic encephalopathy, ascites, spontaneous bacterial peritonitis, gastrointestinal variceal bleed, and hepatocellular carcinoma. HCV genotypes were grouped into categories 1 versus non-1 as the majority of subjects were infected with genotype 1. Subjects were defined as having a high versus low HCV VL, dichotomized at 750,000 copies per milliliter, which was the mean VL of the cohort. Among HIV/HCV-coinfected subjects, HIV VL levels were defined as undetectable (<50 copies per milliliter), intermediate (50–4000 copies per milliliter), and high (>4000 copies per milliliter) based upon previous findings of an association between renal failure and HIV VL greater than 4000 copies per milliliter.[15]

Case ascertainment Electronic chart reviews were performed to identify episodes of incident AKI. For subjects with baseline Cr 1 mg/dL or less, AKI was defined as an absolute rise in Cr to more than 1.5 mg/dL or a relative rise of 0.5 mg/dL. For subjects with baseline Cr 1–2 mg/dL, AKI was defined as a rise in Cr of 0.5 mg/dL or more. For those with baseline Cr 2–4.9 mg/ dL, AKI was defined as a rise in Cr of 1.0 mg/dL or more. For those with baseline Cr greater than 5 mg/dL, AKI was defined as a rise in Cr of 1.5 mg/dL or more, as described previously.[1,4] When a rise in serum Cr occurred, available clinical data were reviewed to determine the probable cause. Events were categorized as prerenal, intrinsic renal, obstructive, or unknown. An event was attributed to prerenal azotemia when there was a clinical history of volume depletion and/or hypotension and renal function improved with hydration. Events were attributed to instrinsic renal disease from ischemic or toxic injury, based on available clinical data. Events were attributed to obstructive renal disease if clinical or radiographic evidence of nephrolithiasis or other forms of obstructive disease were identified. If data were insufficient, cause was characterized as unknown. Cases were reviewed by a nephrologist (M.H.) to ensure that criteria were met and events consistently characterized.

Statistical analysis

Data were analyzed using SAS version 9.1 (SAS Institute, Cary, NC). AKI incidence rates (IR) were calculated by dividing number of events by person time at risk. IRs were calculated for first AKI events, but not for subsequent events. $\chi 2$ and Fisher exact tests were utilized to compare baseline characteristics between HIV/HCV-coinfected and HCV-monoinfected subjects. Kaplan-Meier estimates of time to AKI were produced and stratified by infection status. For subjects who died or were lost to follow-up, data was censored at the time of study drop out. Data was censored on December 31, 2007 for all subjects who reached this date without developing AKI. Cox proportional hazards were utilized to determine risk factors for AKI. Variables significant in univariate analysis, as well as potential confounders, were included in multivariable analysis. Due to concern for collinearity between heroin, cocaine, and alcohol use, adjusted models were run separately for each of these variables prior to their inclusion

into a final model. Certain variables including liver event history and heroin, cocaine, or hazardous alcohol use within the past 6 months, were also evaluated as time-varying covariates at 6-month intervals. All tests were two tailed with a significance level of 0.05.

Results

Two hundred sixteen HIV/HCV-coinfected and 151 HCV-monoinfected subjects were included in the analysis. Other than higher rates of cocaine use among coinfected subjects, no significant differences in baseline characteristics were found. Table 1 summarizes baseline characteristics. A substantial percentage of HIV/HCV coinfected and HCV monoinfected subjects demonstrated use of cocaine, heroin, or hazardous alcohol within 6 months of study entry.

AKI incidence

Among HIV/HCV-coinfected subjects, 75 first AKI events occurred over 858 person-years, with an IR of 8.74 per 100 person-years. Among HCV-monoinfected subjects, 25 first AKI events occurred over 708 person-years, with an IR of 3.53 per 100 person-years. Kaplan Meier estimates of time to AKI by infection status are displayed in Fig. 1.

Etiology of AKI

Of the 100 AKI events, 45% were due to prerenal causes, 31% were due to intrinsic renal causes, and one case was due to obstructive nephrolithiasis from indinavir use. In 23% of cases, the mechanisms of AKI could not be determined. Of the 31 cases of AKI due to intrinsic renal etiologies, three cases each were due to acute interstitial nephritis, acute tubular necrosis, and rhabdomyolysis. Two cases each were attributed to renal crystaluria secondary to high-dose acyclovir, amphotericin B treatment for cryptococcal meningitis, and staphylococcal sepsis. One case each was attributed to complications of chemotherapy and pentamidine treatment for PCP pneumonia. Only one case was attributed to HIV-associated nephropathy. The etiology of intrinsic AKI could not be determined for 13 cases.

Table 1. Baseline Characteristics by Infection Status

Characteristic	*HIV/HCV* n = *216 (%)*	*HCV* n = *151 (%)*	p *Value*

HCV, hepatitis C virus.

Univariate analysis

Table 2 summarizes results of univariate analysis of baseline risk factors for AKI. Significant predictors of AKI included black race, hypertension, HIV/HCV coinfection, liver event, cocaine use, and hazardous drinking within 6 months of study entry.

Multivariable analysis

Successive multivariable Cox proportional hazards regression models showed the following variables to be significant independent risk factors for AKI: cocaine use within 6 months of study entry (HR 2.06 [95% CI 1.15, 3.71]), history of liver event ever (HR 6.64 [95% CI 3.81, 11.6]), and HIV/HCV coinfection (HR 2.19 [95% CI 1.33, 3.62]). HCV-specific factors, including genotype and HCV VL, did not show significant associations in univariate or adjusted analyses. Results of multivariable analyses are summarized in Table 3. While hazardous alcohol use is associated with AKI in univariate analysis, the association loses statistical significance in the adjusted analysis. Heroin use appears to be significantly associated with AKI in an adjusted model, but loses statistical significance when cocaine use is subsequently added into the model.

Certain variables, including liver event, cocaine, heroin, and hazardous alcohol use, were also evaluated as time-varying covariates over 6-month intervals throughout the study period. In an adjusted model, liver event (HR 4.70 [95% CI 2.85, 7.75]) and cocaine use (HR 1.92 [1.10, 3.36]) within the past 6 months remained significantly associated with AKI over time.

Subgroup analysis in HIV/HCV-coinfected subjects

Among subjects with HIV/HCV coinfection, additional analysis of risk factors for AKI was performed with adjustment for CD4 cell count and HIV VL. In univariate analysis, baseline CD4 cell count less than 200/mm^3 was significantly associated with AKI (HR 1.90 [95% CI 1.17, 3.31]) compared to CD4 cell count greater than 350/ mm^3. HIV VL greater than 4000 copies per milliliter was also associated with AKI (HR 1.53 [95% CI 0.90, 2.60]) compared to HIV VL less than 50 copies per milliliter, although not statistically significant. Results of multivariable analyses among coinfected subjects, adjusting first for CD4 cell count and then for HIV viral load, are summarized in Tables 4 and 5. Cocaine use within 6 months of study entry and history of a liver event remained significantly associated with AKI, even after adjustment for CD4 cell count and HIV VL.

HAART and AKI

Antiretroviral regimens (ARVs) at the time of AKI were examined for the 75 HIV/HCV-coinfected subjects. Forty percent of subjects were not on ARVs at the time of AKI. Of the 45 subjects on ARVs, 38% were on tenofovir-containing regimens, 7% were on indinavir-containing regimens, and

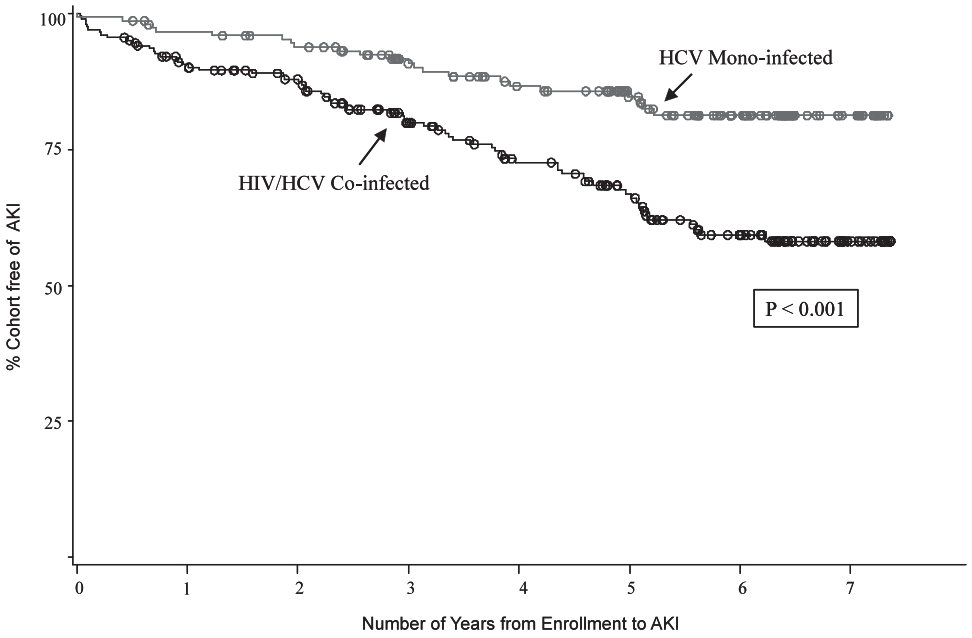

FIG. 1. Kaplan Meier curves of time to incident acute kidney injury (AKI) stratified by infection status. Mean follow up time was 5.15 years.

55% were on other ARV regimens. Collection of tenofovir data for the cohort did not begin until 2005 and was inconsistent. Upon query of medication logs, we determined that 74 (34%) of HIV/HCV-coinfected subjects reported ever taking tenofovir. In univariate analysis, the RR of AKI for HIV/HCV coinfected subjects reporting tenofovir use versus no use was 0.70 (95% CI [0.44–1.13]); *p* value 0.137.

AKI associated morbidity and mortality

The majority of AKI events were associated with either an emergency department visit or hospitalization, including 68% of episodes among HCV-monoinfected subjects and 89% of episodes among HIV/HCV coinfected subjects. While no AKI events among HCV-monoinfected subjects resulted in need for hemodialysis, six (8%) events among HIV/HCV-coinfected subjects led to a transient need for hemodialysis. AKI resulted in death in one (0.4%) HCV-monoinfected subject and six (8%) HIV/HCV coinfected subjects. Results are displayed in Fig. 2.

Table 2. Univariate Analysis of Risk Factors for Acute Kidney Injury

Variable	*HR (95% CI)*	p *Value*
Male gender	1.03 (0.69, 1.53)	0.89
Age $\leq$ 45	0.72 (0.49, 1.07)	0.11
Black race[a]	1.60 (1.07, 2.39)	0.02
Hypertension	1.80 (1.22, 2.67)	<0.001

[b]HCV monoinfection.
[c]HCV genotype 1.
[d]Moderate alcohol use or no alcohol use.
HR, hazard ratio; CI, confidence interval; HCV, hepatitis C virus; VL, viral load.

Discussion

In this analysis, AKI incidence was 2.2 times higher in subjects with HIV/HCV coinfection than in HCV monoinfection. In comparison to Franceschini's study,[5] in which subjects with HIV/HCV coinfection and HIV monoinfection had a combined incidence of first AKI event of 4.3 per 100 person-years, AKI incidence was twofold higher (8.74 per 100 person-years) among HIV/HCV-coinfected subjects in our

Table 3. Multivariable Analysis of Risk Factors for Acute Kidney Injury

Model	*Variable*	*HR (95% CI)*	p *Value*

current analysis. After adjusting for the elevated risk of AKI attributed to HIV coinfection, additional significant risk factors for AKI included decompensated liver cirrhosis and cocaine use. These risk factors remained significant among HIV/HCV-coinfected subjects, even after adjustment for CD4 cell count and HIV VL.

In contrast to findings that higher HIV VL is associated with increased risk of AKI, we did not find an association between HCV VL and AKI incidence in our analysis. While several studies have demonstrated that HIV infection may be linked to renal disease through direct viral infection of renal parenchyma,[16] a similar mechanism has not been demonstrated for HCV infection. HCV has been linked to several types of glomerular lesions including membranoproliferative glomerulonephritis (MPGN) and membranous glomerulopathy. These pathologic lesions appear to result from deposition of circulating immune complexes that contain HCV and anti-HCV antibody. Although a few reports of immunohistochemical localization of HCV antigen in renal tissue have been published, results have not been consistently demonstrated.[16,17] Although in our study, higher HCV VL and genotype were not associated with AKI, these findings add important information to currently available data as other epidemiologic studies examining the relationship between HCV and renal disease have not included HCV VL or genotype data.[11–14]

In addition to HIV/HCV coinfection and decompensated liver cirrhosis, cocaine but not heroin use was strongly associated with AKI. Indeed, the entity previously known as heroin nephropathy has greatly decreased in recent years and likely represented primary focal and segmental glomerulosclerosis (FSGS) rather than a consequence of heroin use.[18] FSGS is now the most common cause of nephrosis in African American individuals in the United States. In contrast, cocaine clearly causes deleterious effects on the kidney and can lead to AKI both from rhabdomyolysis and malignant hypertension.[19,20] This study further supports the existence of an association between cocaine use and AKI among persons with HIV/HCV coinfection.

Table 5. Multivariable Analysis of Risk Factors for Acute Kidney Injury, Adjusted for HIV Viral Load

Variable	*HR (95% CI)*	p *Value*
HIV viral load		
<50 copies/mL (reference group)	—	—
51–4000 copies/mL	0.97 (0.53, 1.79)	0.9321
>4000 copies/mL	1.72 (0.98, 3.03)	0.0583
Liver event	5.85 (3.23, 10.61)	<0.0001
Cocaine use	2.19 (1.31, 3.67)	0.0028

Cox proportional hazards regression model is adjusted for age, race/ethnicity, diabetes, and hypertension.
HR, hazard ratio; CI, confidence interval.

Among the HIV/HCV-coinfected subjects, there was only a single case of HIV-associated nephropathy identified. No cases of other diagnoses attributable to HIV infection, such as HIV immune complex kidney disease, IgA nephropathy or thrombotic thrombocytopenic purpura (TTP), were found. The bulk of cases were related to prerenal azotemia or drug toxicity. In multivariable analyses, lower CD4 cell count and higher HIV VL were both associated with AKI, although only CD4 cell count less than 200 was statistically significant. Lower CD4 count may have been associated with AKI through higher rates of nephrotoxic drug use for opportunistic infections and ARV toxicity. Indinavir-associated renal dysfunction is well documented and there is also growing evidence of an association between tenofovir use and loss of renal function.[22–27] In a recent meta-analysis that included 17 studies to assess the renal safety of tenofovir in HIV-infected patients, a statistically significant greater loss in creatinine clearance was observed among tenofovir recipients compared to control subjects, as well as a significantly greater risk of acute renal failure among tenofovir recipients.[22] Of subjects on ARVs at the time of AKI, 45% were receiving indinavir or tenofovir-containing regimens, reflecting evolving drug availability and prescribing practices during the study period. However, sufficient data were not available to examine the independent association between tenofovir use and AKI. The interrelationships between CD4 cell count, HIV VL, exposure to ARVs, and the subsequent development of AKI warrant further investigation among HIV/HCV-coinfected subjects.

There were several limitations to this analysis. Serial HIV antibody testing was not performed as part of the research protocol after study entry, and could have resulted in misclassification of some dually infected subjects as having HCV monoinfection. Such a misclassification may have dampened the true impact of HIV coinfection on the incidence of AKI among subjects with HCV infection. HCV VL and genotype data was missing for 12% of the cohort and may have diminished the power to detect a true association between HCV VL and AKI. Furthermore, kidney biopsies were not performed in this study to look for direct HCV viral effects on renal tissue. Data on tenofovir use were not consistently collected for the cohort and the data presented likely underestimates the true proportion, of individuals that were taking tenofovir. Due to concerns with the quality of the tenofovir data and associated biases, we did not adjust for tenofovir use in the final multivariable analyses. Thus, tenofovir use may have been a potential confounder of the association between variables of interest and AKI among coinfected subjects. As no standard definition for AKI exists, a traditional definition of AKI, which has been shown to affect mortality in hospitalized patients without HIV or HCV, was utilized.[4] Recently, smaller changes in serum Cr have been found to be of clinical import, such that a rise in Cr of 0.5 mg/dL is utilized in the RIFLE criteria (Risk Injury Failure Loss End Stage) and a rise of only 0.3 mg/dL is utilized in the AKIN criteria (Acute Kidney

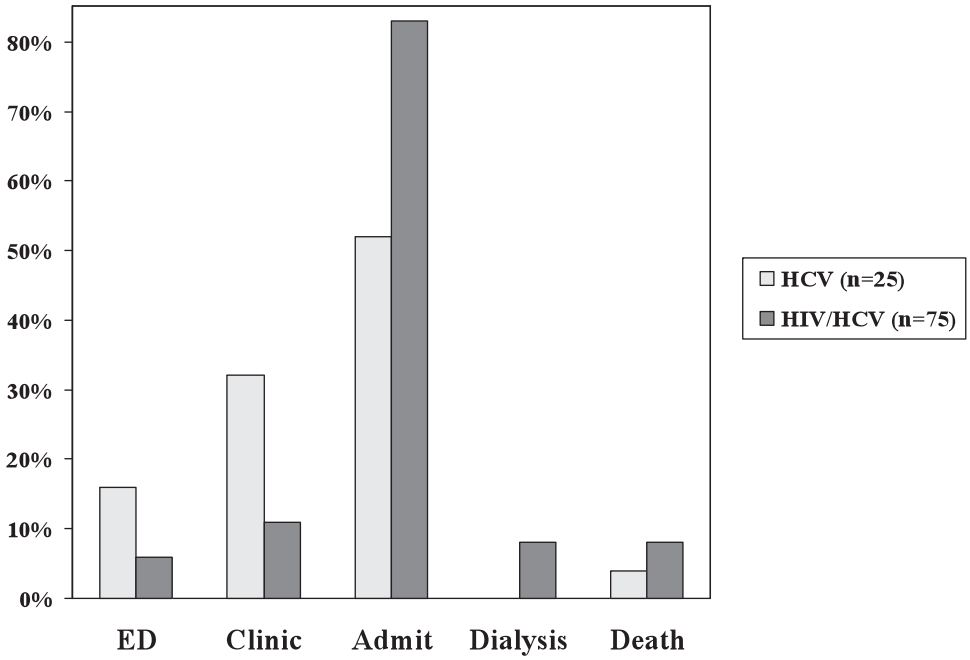

FIG. 2. Percentage of acute kidney injury (AKI) episodes associated with emergency department visit, clinic visit, hospital admission, need for transient or permanent dialysis, and death. Results are broken down by infection status.

Injury Network).[28] In our study, we chose to utilize the more conservative definition of AKI to capture the most serious events.

The findings of the association between AKI and decompensated liver cirrhosis, HIV coinfection, and cocaine use in this study, highlight the importance of controlling HIV infection in coinfected individuals and preventing liver disease progression and cocaine use in persons with both HIV/HCV coinfection and HCV monoinfection. While the relationship between AKI and other substances of abuse, including heroin and hazardous alcohol, was not statistically significant after adjusting for cocaine use, intermediate multivariable models did demonstrate a positive association between these agents and AKI. Thus, targeted interventions to reduce heroin and alcohol use may further reduce the burden of renal disease among these individuals. Further studies are required to determine the association between HCV VL and AKI, and whether lowering HCV VL may impact AKI incidence. By addressing the identified modifiable risk factors, a reduction in AKI-associated morbidity and mortality, including rates of hospitalization, transient hemodialysis and death, may potentially be achieved in this population.

INTRODUCTION

Generalist clinicians routinely care for patients who misuse or are dependent on alcohol, nicotine, and other drugs of abuse.[1,2] These problems contribute to significant morbidity, health care utilization, cost, and preventable death.[3,4] The aim of this update is to identify and examine recent advances in addiction medicine that have practice implications for generalist physicians and their patients. To accomplish this, we independently selected articles in the field of addiction medicine, summarized and critically appraised, and examined the articles in the context of their implications for generalist practice using methodology we used in prior updates.[5,6] During an initial review, we identified articles through an electronic MedLine search (limited to human studies and in English) using search terms for alcohol, nicotine, and other drugs of abuse from January 2008 through January 2010. From the citations, the authors selected articles for more intensive review. After this initial review, we searched for other literature in web-based or journal resources (e.g., www.aodhealth.org, ACP Journal Club, table of contents of relevant journals). All authors then agreed collectively on the important articles regarding addiction medicine that have implications for practice for generalist clinicians.

PRESCRIPTION DRUG ABUSE

In treating chronic pain, physicians must balance the pain-relieving benefits of opioids with the risks of overdose and triggering addiction. Efforts to improve pain treatment since the 1990s have led to increases in opioid prescriptions. At the same time, there have been substantial increases in misuse and diversion of prescription opioids, opioid-related emergency department visits, and fatal opioid overdoses.

What Factors Increase the Overdose Risk of Prescribed Opioids?

Dunn KM and colleagues. Opioid prescriptions for chronic pain and overdose: a cohort study. Annals of Internal Medicine.2010;152(2):85–92.[7]

Dunn and colleagues sought to estimate rates of fatal and non-fatal opioid overdose and determine whether these rates vary by prescribed opioid dose among patients receiving medically prescribed, long-term opioid therapy.[7] By linking pharmacy, electronic medical and state mortality records, investigators evaluated outcomes among 9,940 persons in a health maintenance organization who received three or more opioid prescriptions within 90 days for chronic non-cancer pain between 1997 and 2005. They estimated non-fatal and fatal overdose risk as a function of average daily opioid dose (morphine equivalents) received at the time of overdose. Over a mean follow-up time of 42 months, they identified 51 patients with opioid-related overdoses, 6 of whom died (mean follow-up time of 42 months). The rate of any opioid overdose was 0.15 per 100 person-years, and the rate of overdose mortality was 0.02 per 100 person-years. Overdose rates were found to be dose-related; compared with patients receiving 1 to 20 mg/day of opioids, patients receiving 100 mg/day or more had an 8.9 fold (95% CI: 4.0–19.7) increase in overdose risk. Overdose rates were also increased by two to three fold in patients who had a history of a substance abuse diagnosis, depression, or were receiving a concomitant sedative-hypnotic prescription.

Are Increases in Overdose Deaths Related to the Diversion of Prescription Drugs?

Hall AJ and colleagues. Patterns of abuse among unintentional pharmaceutical overdose fatalities. Journal of the American Medical Association.2008;300(22):2613–20.[8]

Hall and colleagues sought to evaluate the risk characteristics of persons dying of unintentional prescription drug overdose in West Virginia in 2006.[8] They linked data from the state's medical examiner database, prescription drug monitor-

ing program, and opiate treatment programs to describe the type of substance use and concomitant behaviors. Among 295 people who died from an unintentional prescription drug poisoning, 78% had a history of substance abuse, 63% had taken a prescription drug not prescribed, 21% had 5 or more different prescribers over 12 months, 17% had a previous overdose, 16% had cocaine, heroin or methamphetamine also present, and 4% were enrolled in a methadone maintenance program. Prevalence of prescription drugs not prescribed was greatest among decedents aged 18 through 24 years and decreased across each successive age group. More than one substance was detected in 79% of deaths. The most common substance was opioids (93% of deaths); of these, only 44% had ever been prescribed these drugs. Methadone was the most common opioid (40%), followed by hydrocodone (23%) and oxycodone (21%). However, only 32% of decedents with methadone present at death had a prescription for it, whereas 85% with hydrocodone and 61% with oxycodone had prescriptions for hydrocodone and oxycodone, respectively. The authors concluded that the majority of prescription drug overdose deaths in West Virginia in 2006 were associated with nonmedical use and diversion of prescription drugs, primarily opioid analgesics.

What is the Arrhythmia Risk from Methadone?

Anchersen K and colleagues. Prevalence and clinical relevance of corrected QT interval prolongation during methadone and buprenorphine treatment: a mortality assessment study. Addiction.2009;104:993–999.[9]

Studies conducted by Hall and others have documented an increasing and disproportionate prevalence of methadone-related deaths, which has led to increasing focus on QT prolongation in methadone patients and the risk of torsades de pointes.[8,10] In this setting, recent expert panel recommendations for universal electrocardiography (ECG) screening and regular monitoring for corrected QT (QTc) prolongation for patients prescribed methadone[11] have been challenged as reaching beyond the evidence.[12] Anchersen determined the maximum mortality rate potentially attributable to QTc prolongation by linking the Norwegian Opioid Maintenance Treatment (OMT) registry and the national death certificate register.[9] They found 90 deaths occurring among 2,382 patients between 1997 and 2003, a rate of 1.3/100 patient-years. After review of each of these case records, four deaths were identified in which QTc prolongation could not be excluded as the cause of death. Thus, at most, 4% of methadone deaths could be potentially attributable to arrhythmias, resulting in a maximum mortality rate of 0.06 per 100 patient-years.

IMPLICATIONS FOR PRACTICE

Among patients treated with prescription opioids for chronic pain, having a substance use disorder, concomitant prescriptions for sedative-hypnotics, and higher doses of opioids increase the risk of overdose. However, most overdose deaths from prescription drugs involve diverted medications, particularly those involving methadone. Overdose victims commonly have a substance abuse history, mix multiple substances, and seek prescriptions from multiple prescribers. Methadone is disproportionately involved in overdoses, yet this is not explained by overdoses among patients receiving methadone maintenance for opioid dependence. Although methadone prolongs the QTc interval, other factors, such as prolonged and variable metabolism and mixing methadone with other sedating substances, likely explain the disproportionate number of deaths with methadone present compared to other opioids. Prescribers and patients should be educated about these overdose risk factors. Opioid prescribers should have a goal-directed approach, continuing or increasing opioid therapy only when there is demonstrated improvement in function or quality of life.[13] They should consider strategies to assess adherence and limit diversion, such as prescription monitoring programs, toxicology testing, and pill counts.

ADDICTION SCREENING AND BRIEF INTERVENTIONS

Cost Effectiveness of Screening for Addictions

Solberg LI and colleagues. Primary care intervention to reduce alcohol misuse: ranking its health impact and cost-effectiveness. American Journal of Preventive Medicine.2008;34(2):143–152.[14]

The US Preventive Services Tasks Force (USPSTF) recommends screening and behavioral counseling interventions in primary care to reduce alcohol misuse. Screening, Brief Intervention, and Referrals and/to Treatment (SBIRT) is a strategy that has been tested in emergency room and primary care settings with proven efficacy, yet is incorporated into practice less than 9% of the time.[15] To measure the clinically preventable burden (CPB) and cost-effectiveness of screening and brief interventions (SBI) compared with other recommended preventive services, Solberg and colleagues conducted a systematic review of randomized controlled trials and cost-effectiveness studies.[14] CPB was calculated as the product of effectiveness and the alcohol-attributable fraction of mortality and morbidity (measured in quality-adjusted life years [QALYs]). Cost effectiveness was estimated from both the societal perspective and the health system perspective. Calculated CPB was 176,000 QALYs saved over the lifetime of a birth cohort of 4,000,000 individuals. Screening and brief counseling were cost-saving from the societal perspective and had a cost-effectiveness ratio of $1,755/QALY saved. SBI is one of the top five ranking preventive services, comparable to screening for colorectal cancer, hypertension, visual problems, and for influenza and pneumococcal vaccination.

Screening for Addictions in Primary Care

Smith PC and colleagues. Primary care validation of a single-question alcohol screening test. Journal General Internal Medicine.2009;24(7):783–8.[16]

Unhealthy alcohol use is under-diagnosed in primary care settings.[17] High performing screening instruments, such as the Alcohol Use Disorders Identification Test (AUDIT) and the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST), are lengthy and can be difficult to administer in primary care environments.[18–20] Several prior studies have

examined the performance characteristics of abbreviated and single-item alcohol screening questionnaires, but none have examined the single-item screening test recommended by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) in primary care settings.[21–24] Smith and colleagues validated, in an urban safety net primary care clinic, the performance of the single screening question, "How many times in the past year have you had X or more drinks in a day?" where X is 5 for men and 4 for women, and a response of ≥1 is considered positive.[16] They defined unhealthy alcohol use as the presence of an alcohol use disorder (either Alcohol Abuse or Dependence[25]) or risky consumption, as determined using a validated 30-day calendar method.[26,27] Among 286 patients, the single-question screen was 82% sensitive (95%, CI=73%–89%) and 79% specific (CI=73%–84%) for the detection of unhealthy alcohol use. It was more sensitive (88%, CI=73%–95 %) but less specific (67%, CI=61%–72%) for the detection of a current alcohol use disorder. Test characteristics were similar to that of a commonly used three-item screen (first three items of the AUDIT) and were affected very little by subject demographic characteristics. They concluded that the single screening question recommended by the NIAAA accurately identified unhealthy alcohol use in this sample of primary care patients. One potential limitation of this study was that the high prevalence of alcohol problems in this urban safety-net population (44%) may have been a marker for greater disease severity and/or selection bias, thus leading to greater sensitivity than would be observed in a lower risk population.

Application of SBIRT for Drug Use

Madras BK and colleagues. Screening, brief interventions, referral to treatment (SBIRT) for illicit drug and alcohol use at multiple healthcare sites: comparison at intake and 6 months later. Drug and Alcohol Dependence.2009;99:280–295.[28]

Components of SBIRT have been studied extensively for unhealthy alcohol use with evidence of efficacy, effectiveness, and cost-effectiveness.[29–33] However, research regarding the efficacy and effectiveness of SBIRT components for alcohol dependence and illicit drug use have been limited. In the last decade, an alcohol-focused SBIRT service program was initiated by the Substance Abuse and Mental Health Services Administration (SAMHSA) in a wide variety of medical settings (and diverse patient populations) in six states (http://www.sbirt.samhsa.gov). As part of this initiative, patients were screened and offered score-based progressive levels of intervention (brief intervention, brief treatment, referral to specialty treatment). Through a secondary analysis, Madras and colleagues examined illicit drug use at baseline and 6-month follow-up in a randomly selected sample of the nearly 60,000 patients who screened positive for drug use at baseline and received an SBIRT intervention.[28] Among those reporting baseline illicit drug use, rates of drug use at 6-month follow-up (4 of 6 sites) were 68% lower ($p<0.001$) and heavy alcohol use was 39% lower ($p<0.001$) than at baseline, with comparable findings across sites, gender, race/ethnic, and age subgroups. However, improvements in alcohol and illicit drug use from baseline were self-reported, assessed only in a sample of patients screening positive at baseline, and included subjects who all received an intervention, either brief intervention or more intensive treatment. Therefore, the true efficacy of brief intervention for illicit drug use needs further investigation.

IMPLICATIONS FOR PRACTICE

Generalist physicians must select among numerous recommended preventive medicine measures for their patients during brief visits. Solberg's study should encourage primary care physicians to prioritize SBIRT over other, less effective preventive interventions. Smith's study provides evidence that clinicians can screen for alcohol use disorders using the single-item alcohol screening question recommended by NIAAA. Moreover, the question detects alcohol use disorders, binge drinking, and risky drinking. Binge drinking is episodic, but deleterious to health, and risky drinking is a prevalent problem in primary care settings. Madras' evaluation of a large-scale SBIRT program implementation concluded that combined screening and intervention for alcohol and illicit drug use is feasible across a range of health care sites and diverse patient populations, though the true efficacy needs further investigation.

Applications of SBIRT-type interventions to populations other than at-risk drinkers have yielded mixed results, but remain an important area for ongoing investigation. A recent study of a counseling intervention among inpatients with prescription drug misuse showed a reduction in drug misuse at 3 months, but these improvements were no longer evident at 12 months.[34,35] A meta-analysis of 11 trials investigating brief intervention for hospitalized heavy drinkers had inconclusive results.[36] Finally, a study of brief intervention for dependent drinkers versus non-dependent drinkers enrolled in a clinical trial suggested that dependent drinkers decreased drinks per day similar to non-dependent drinkers 6 months following intervention.[37] Although promising, these studies do not provide definitive conclusions on the use of SBIRT for illicit drug use, prescription drug misuse, inpatient populations, or dependent drinkers. Further studies with controlled designs and standardized interventions are needed to assess the efficacy of SBIRT to these populations and settings.

Evidence for Interventions Associated with Co-Morbid Improvements in Health

Stewart SH and colleagues. Blood pressure reduction during treatment for alcohol dependence: results from the Combining Medications and Behavioral Interventions for Alcoholism (COMBINE) study. Addiction.2008;103:1622–28.[38]

Heavy alcohol consumption and alcohol use disorders are associated with a variety of health conditions, including hypertension. Stewart and colleagues evaluated blood pressure changes occurring during treatment for alcohol dependence among 1,383 subjects participating in the Combining Medications and Behavioral Interventions for Alcoholism (COMBINE) study, a large multi-center treatment study for alcohol dependence.[38,39] Over the 16-week treatment period, the authors assessed the relationship between percentage of drinking days (PDD) and systolic and diastolic blood pressure. Systolic blood pressure decreased by an average of 12 mmHg

and diastolic blood pressure decreased by an average of 8 mmHg; however, these reductions were only evident in people who were above the median blood pressure at baseline and occurred during the first month of treatment.

Nordback I and colleagues. The recurrence of acute alcohol-associated pancreatitis can be reduced: a randomized controlled trial. Gastroenterology. 2009;136(3):848–55.[40]

Alcohol-associated pancreatitis often recurs in patients who continue to consume alcohol. In this randomized clinical trial, Nordback and colleagues evaluated whether the recurrence of alcohol-associated acute pancreatitis can be reduced through a counseling intervention.[40] They examined 120 patients admitted to a university hospital for an initial episode of alcohol-associated acute pancreatitis and randomized them either to a 30-min, nurse-led pre-discharge intervention with repeated (6-month intervals) outpatient interventions or an initial, pre-discharge intervention only. They found that repeated interventions, each consisting of 30 min of counseling, appear to be better than a single intervention at hospital discharge in reducing the development of recurrent acute pancreatitis during a 2-year period.

IMPLICATIONS FOR PRACTICE

While alcohol can be deleterious to health, there has been scant but emerging literature indicating that interventions for alcohol may improve the effects of alcohol-related co-morbidities. Both the Stewart and Nordback studies suggest that a counseling intervention for alcohol use can have a positive impact on co-morbid health conditions. However, future research should focus on determining the appropriate intervention intensity (i.e., length and frequency of counseling) to produce improvements in outcomes of alcohol-related diseases commonly encountered in the clinical setting and whether alcohol counseling can improve other health outcomes.

ADDICTION PHARMACOTHERAPY

Pharmacotherapy for Smoking Cessation Treatment

Gunnell D and colleagues. Varenicline and suicidal behaviour: a cohort study based on data from the General Practice Research Database. British Medical Journal.2009;339:b3805.[41]

Pharmacotherapy is an important tool in helping smokers quit, and varenicline is an effective option.[42,43] However, reports of depression and suicidal thoughts have raised concerns about its safety.[44,45] Gunnell and colleagues investigated whether varenicline is associated with an increased risk of suicide and suicidal behavior when compared with other smoking pharmacotherapy. They evaluated fatal and non-fatal self-harm, suicidal thoughts, and depression among 80,660 patients in the UK who were prescribed a new course of a smoking cessation product; hazard ratios were adjusted for a number of factors, including current or previous psychiatric history. Those who received varenicline, when compared with nicotine replacement, had an adjusted hazard ratio (HR) for fatal or non-fatal self-harm of 1.17 with a 95% confidence interval of 0.59–2.32; the HR for suicidal thoughts was 1.43 (CI=0.53–3.85), and for start of antidepressant therapy, it was 0.88 (CI=0.77–1.00). There likewise was no significant difference in the adjusted hazard ratios associated with bupropion for any of these outcomes.

IMPLICATIONS FOR PRACTICE

While it is reasonable to warn patients of the potential for psychiatric side effects when prescribing varenicline, patients and providers can be reassured that the risk appears to be fairly low. Based on these data, approximately one out every 750 smokers who take varenicline for 3 months may experience an episode of self-harm. There is a possibility that all smoking pharmacotherapy, and perhaps smoking cessation itself, are associated with a modestly increased risk of self-harm and other psychiatric problems.

Office-Based Opioid Agonist Therapy

Walley AY and colleagues. Office-based management of opioid dependence with buprenorphine: clinical practices and barriers. J Gen Intern Med. 2008;23(9):1393–8.[46]

Office-based opioid-agonist therapy (OBOT) was made possible by the Drug Addiction Treatment Act of 2000, allowing physicians to prescribe approved medications (buprenorphine and buprenorphine/naloxone).[47] However, adoption by primary care physicians has been slow. Walley and colleagues assessed buprenorphine clinical practices and barriers in a survey mailed to all 225 office-based physicians in Massachusetts who were waivered to prescribe buprenorphine.[47] Prescribing physicians reported treating a median of ten patients; most non-prescribers (54%) reported they would prescribe if barriers were reduced. Factors associated with prescribing included being a primary care physician compared to a psychiatrist (AOR: 3.02; CI=1.48–6.18) and solo compared to group practice (AOR: 3.01; CI=1.23–7.35). On the other hand, reporting low patient demand (AOR: 0.043, CI=0.009–0.21) and insufficient institutional support (AOR: 0.37; CI=0.15–0.89) were associated with not prescribing.

Barry DT and colleagues. Integrating buprenorphine treatment into office-based practice: a qualitative study. Journal General Internal Medicine.2008;24(2):218–25.[48]

In a qualitative study, Barry and colleagues used semi-structured interviews of 23 office-based physicians in New England to identify physician, patient, and logistical factors that would either facilitate or serve as a barrier to OBOT.[48] Facilitators included promoting continuity of care, positive perceptions of buprenorphine, and viewing buprenorphine as a positive alternative to methadone. Physician barriers included competing activities, lack of interest, and lack of expertise in addiction treatment. Physicians' perceptions of patient-related barriers included concerns about confidentiality and cost, and low motivation for treatment. Perceived logistical barriers in-

cluded lack of remuneration for OBOT, limited ancillary support, time limitations, and a perceived low prevalence of opioid dependence.

Soeffing JM and colleagues. Buprenorphine maintenance treatment in a primary care setting: outcomes at 1 year. Journal Substance Abuse Treatment.2009;37(4):426–30.[49]

In clinical trials, buprenorphine has been shown to be efficacious at reducing illicit opioid use and improving other clinical outcomes.[50] The effectiveness has been supported by a number of recent observational studies in a variety of settings.[51,52] However, subjects in these studies were not treated in a manner typical of other chronic conditions in primary care practice, where the effectiveness of buprenorphine is less clear, particularly when onsite psychosocial services are not available. Soeffing and colleagues sought to investigate this question by assessing the 12-month outcomes of 255 patients given at least one prescription for buprenorphine in a primary care practice in Baltimore.[49] Patients were classified as "opioid-positive" or "opioid-negative" each month based on patient report, urine toxicology, and provider assessment. After 12 months, 145 (56.9%) patients remained in treatment, and the percentage who were opioid negative increased from 49% in the first month to 76% by month 12. These results are comparable to those reported in the landmark clinical trial of office-based buprenorphine, in which the percentage of opiate negative urine rose from 35% to 64% over a year.[53]

IMPLICATIONS FOR PRACTICE

The adoption of OBOT has the potential to expand treatment availability for opioid-dependent patients, particularly where methadone maintenance therapy is unavailable.[54] There are concerns and barriers that have limited the use of buprenorphine by physicians, even those who have undergone the required training and obtained a waiver.[55] Although not expressed in these studies, there is also a stigma associated with addiction and addiction treatment at a physician and institutional level that needs to be overcome.[56] Physicians who are interested in providing this treatment should be given institutional support and encouragement.

Observational studies support the effectiveness of office-based buprenorphine treatment for opioid dependence. There are a variety of approaches and treatment protocols, but providing this treatment in a setting where opioid dependence is incorporated into primary care and treated like other chronic illnesses appears to be effective. However, there are still unanswered questions about the optimal treatment approach, including intervals for visits, toxicology testing, and “dose” of counseling. It is likely that treatment needs to be individualized, and some patients will require a more intensive approach with closer monitoring and additional psychosocial support.

ABSTRACT

BACKGROUND

Vitamin K antagonists are highly effective in preventing stroke in patients with atrial fibrillation but have several limitations. Apixaban is a novel oral direct factor Xa inhibitor that has been shown to reduce the risk of stroke in a similar population in comparison with aspirin.

METHODS

In this randomized, double-blind trial, we compared apixaban (at a dose of 5 mg twice daily) with warfarin (target international normalized ratio, 2.0 to 3.0) in 18,201 patients with atrial fibrillation and at least one additional risk factor for stroke. The primary outcome was ischemic or hemorrhagic stroke or systemic embolism. The trial was designed to test for noninferiority, with key secondary objectives of testing for superiority with respect to the primary outcome and to the rates of major bleeding and death from any cause.

RESULTS

The median duration of follow-up was 1.8 years. The rate of the primary outcome was 1.27% per year in the apixaban group, as compared with 1.60% per year in the warfarin group (hazard ratio with apixaban, 0.79; 95% confidence interval [CI], 0.66 to 0.95; P<0.001 for noninferiority; P=0.01 for superiority). The rate of major bleeding was 2.13% per year in the apixaban group, as compared with 3.09% per year in the warfarin group (hazard ratio, 0.69; 95% CI, 0.60 to 0.80; P<0.001), and the rates of death from any cause were 3.52% and 3.94%, respectively (hazard ratio, 0.89; 95% CI, 0.80 to 0.99; P=0.047). The rate of hemorrhagic stroke was 0.24% per year in the apixaban group, as compared with 0.47% per year in the warfarin group (hazard ratio, 0.51; 95% CI, 0.35 to 0.75; P<0.001), and the rate of ischemic or uncertain type of stroke was 0.97% per year in the apixaban group and 1.05% per year in the warfarin group (hazard ratio, 0.92; 95% CI, 0.74 to 1.13; P=0.42).

CONCLUSIONS

In patients with atrial fibrillation, apixaban was superior to warfarin in preventing stroke or systemic embolism, caused less bleeding, and resulted in lower mortality. (Funded by Bristol-Myers Squibb and Pfizer; ARISTOTLE ClinicalTrials.gov number, NCT00412984.)

This article (10.1056/NEJMoa1107039) was published on August 28, 2011, and updated on August 30, 2011, at NEJM.org.

N Engl J Med 2011;365:981-92.

Patients with atrial fibrillation are at increased risk for stroke. Warfarin and other vitamin K antagonists are highly effective treatments, reducing the risk of stroke by about two thirds, but their use is limited by a narrow therapeutic range, drug and food interactions, required monitoring, and risk of bleeding.[1] A randomized trial has confirmed the effectiveness of warfarin in the current era.[2] Two new oral anticoagulants have recently been shown to be equivalent or superior to warfarin in preventing stroke or systemic embolism.[3,4] Apixaban is a direct oral factor Xa inhibitor with rapid absorption, a 12-hour half-life, and 25% renal excretion.[5] In patients with atrial fibrillation who were not candidates for vitamin K antagonists, apixaban, as compared with aspirin, reduced the rate of stroke or systemic embolism by 55% without increasing the risk of major bleeding.[6] In the Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation (ARISTOTLE) trial,[7] we compared apixaban with warfarin for the prevention of stroke or systemic embolism in patients with atrial fibrillation and at least one additional risk factor for stroke.

Methods

Study Oversight

The trial was designed and led by a steering committee that included academic investigators and representatives of the sponsors (Bristol-Myers Squibb and Pfizer). Approval by the appropriate ethics committees was obtained at all sites. All patients provided written informed consent. The primary analyses were performed both at Bristol-Myers Squibb and at the Duke Clinical Research Institute. All the authors participated in the design of the trial and the planning of the analyses. The first author wrote the first draft of the manuscript, and all the authors participated in subsequent revisions (with no writing assistance other than copy editing) and approved the final version of the manuscript. The trial protocol and statistical analysis plan are available with the full text of this article at NEJM.org. All the authors assume responsibility for the accuracy and completeness of the data and the analyses and for the fidelity of the study to the protocol.

Trial Design

The trial design has been reported previously.[7] With the use of a double-blind, double-dummy design, we randomly assigned patients to treatment with apixaban or dose-adjusted warfarin. The primary objective was to determine whether apixaban was noninferior to warfarin in reducing the rate of stroke (ischemic or hemorrhagic) or systemic embolism among patients with atrial fibrillation and at least one other risk factor for stroke. The primary safety outcome was major bleeding, according to the criteria of the International Society on Thrombosis and Haemostasis (ISTH). Key secondary objectives were to determine whether apixaban was superior to warfarin with respect to the primary outcome and to the rates of major bleeding and death from any cause. To control the overall type I error, prespecified hierarchical sequential testing was performed first on the primary outcome for noninferiority, then on the primary outcome for superiority, then on major bleeding, and finally on death from any cause.

Study Population

Eligible patients had atrial fibrillation or flutter at enrollment or two or more episodes of atrial fibrillation or flutter, as documented by electrocardiography, at least 2 weeks apart in the 12 months before enrollment. In addition, at least one of the following risk factors for stroke was required: an age of at least 75 years; previous stroke, transient ischemic attack, or systemic embolism; symptomatic heart failure within the previous 3 months or left ventricular ejection fraction of no more than 40%; diabetes mellitus; or hypertension requiring pharmacologic treatment. Key exclusion criteria were atrial fibrillation due to a reversible cause, moderate or severe mitral stenosis, conditions other than atrial fibrillation that required anticoagulation (e.g., a prosthetic heart valve), stroke within the previous 7 days, a need for aspirin at a dose of >165 mg a day or for both aspirin and clopidogrel, and severe renal insufficiency (serum creatinine level of >2.5 mg per deciliter [221 μmol per liter] or calculated creatinine clearance of <25 ml per minute).[7] Patients were classified as not having received warfarin previously if they had used warfarin or another vitamin K antagonist for no more than 30 consecutive days. Investigators at

all study centers were encouraged to enroll a sizable proportion of patients (≥40%) who had not previously received warfarin.

RANDOMIZATION AND STUDY DRUGS

Randomization was stratified according to whether patients had received warfarin previously and according to clinical site. Apixaban or matching placebo was administered twice daily, with apixaban given in 5-mg doses; 2.5-mg doses were used in a subset of patients with two or more of the following criteria: an age of at least 80 years, a body weight of no more than 60 kg, or a serum creatinine level of 1.5 mg per deciliter (133 μmol per liter) or more. Warfarin (or matching placebo) was provided as 2-mg tablets and was adjusted to achieve a target international normalized ratio (INR) of 2.0 to 3.0. Patients who were receiving a vitamin K antagonist before randomization were instructed to discontinue the drug 3 days before randomization, and the study drug was initiated when the INR was less than 2.0. INRs were monitored with the use of a blinded, encrypted, point-of-care INR device. An algorithm was provided to guide the adjustment of the warfarin dose. The time that patients' INRs were within the therapeutic range was calculated by the Rosendaal method.[8] A program was implemented to improve the quality of INR control through education and feedback at the site and country levels.

An algorithm was provided to manage temporary discontinuations of the study drug around the time of interventional procedures while maintaining concealment of the group assignments. At the end of the trial, when patients discontinued the study drug, guidance was provided in making the transition to open-label warfarin while maintaining concealment of the treatment assignments and ensuring appropriate anticoagulation. In addition to monthly study visits focusing on control of the INR, visits every 3 months included an assessment of clinical outcomes and adverse events. For each patient who was lost to follow-up or who withdrew consent, attempts were made to determine vital status at the end of the trial.

STUDY OUTCOMES

The primary efficacy outcome was stroke or systemic embolism. Stroke was defined as a focal neurologic deficit, from a nontraumatic cause, lasting at least 24 hours and was categorized as ischemic (with or without hemorrhagic transformation), hemorrhagic, or of uncertain type (in the case of patients who did not undergo brain imaging or in whom an autopsy was not performed). The key secondary efficacy outcome was death from any cause. The rate of myocardial infarction was also assessed as a secondary efficacy outcome.

The primary safety outcome was major bleeding, which was defined, according to the ISTH criteria,[9] as clinically overt bleeding accompanied by a decrease in the hemoglobin level of at least 2 g per deciliter or transfusion of at least 2 units of packed red cells, occurring at a critical site, or resulting in death. The secondary safety outcome was a composite of major bleeding and clinically relevant nonmajor bleeding, which was defined as clinically overt bleeding that did not satisfy the criteria for major bleeding and that led to hospital admission, physician-guided medical or surgical treatment, or a change in antithrombotic therapy. Other safety outcomes included any bleeding, other adverse events, and liver-function abnormalities.

The primary and secondary efficacy and safety outcomes were adjudicated on the basis of prespecified criteria by a clinical-events committee whose members were not aware of study-group assignments. For details, see the Supplementary Appendix, available at NEJM.org.

STATISTICAL ANALYSIS

The primary noninferiority hypothesis required that apixaban preserve at least 50% of the relative reduction in the risk of stroke or systemic embolism associated with warfarin (62%) in six previous, major randomized, controlled trials.[10] This hypothesis provided a lower 95% confidence interval of 1.88 for the relative risk with placebo as compared with warfarin, and one half of this value was 1.44 (or 1.38 on a log scale). We estimated that with the occurrence of the primary outcome in 448 patients, the study would have 90% power to ensure that the upper boundary of the 99% confidence interval for the relative risk would be less than 1.44 and that the upper boundary of the 95% confidence interval for the relative risk would be less than 1.38, on the assumption that apixaban and warfarin had identical effects. On the basis of the overall event rate during the trial, we planned to recruit 18,000 pa-

tients in order to reach this number of events with approximately 2 years of follow-up. An independent data and safety monitoring committee reviewed the accumulating trial data, with one prespecified interim analysis for efficacy.

The primary and key secondary analyses were performed with the use of the Cox proportional-hazards model, with previous warfarin status and geographic region (North America, South America, Europe, or Asian Pacific) used as strata in the model. The primary and secondary efficacy analyses included all patients who underwent randomization (intention-to-treat population) and included all events from the time of randomization until the cutoff date for efficacy outcomes (predefined as January 30, 2011). The analyses of bleeding events included all patients who received at least one dose of a study drug and included all events from the time the first dose of a study drug was received until 2 days after the last dose was received. In a modified intention-to-treat sensitivity analysis, we analyzed bleeding events that occurred in patients who received at least one dose of a study drug and included all

* Analyses were performed on data from the intention-to-treat population and included all events through the cutoff date for efficacy outcomes of January 30, 2011; comparisons of the primary outcome and of death from any cause were analyzed as part of hierarchical sequence testing (starting with testing the primary outcome for noninferiority, then the primary outcome for superiority, then major bleeding, and finally death from any cause), to control the type I error.

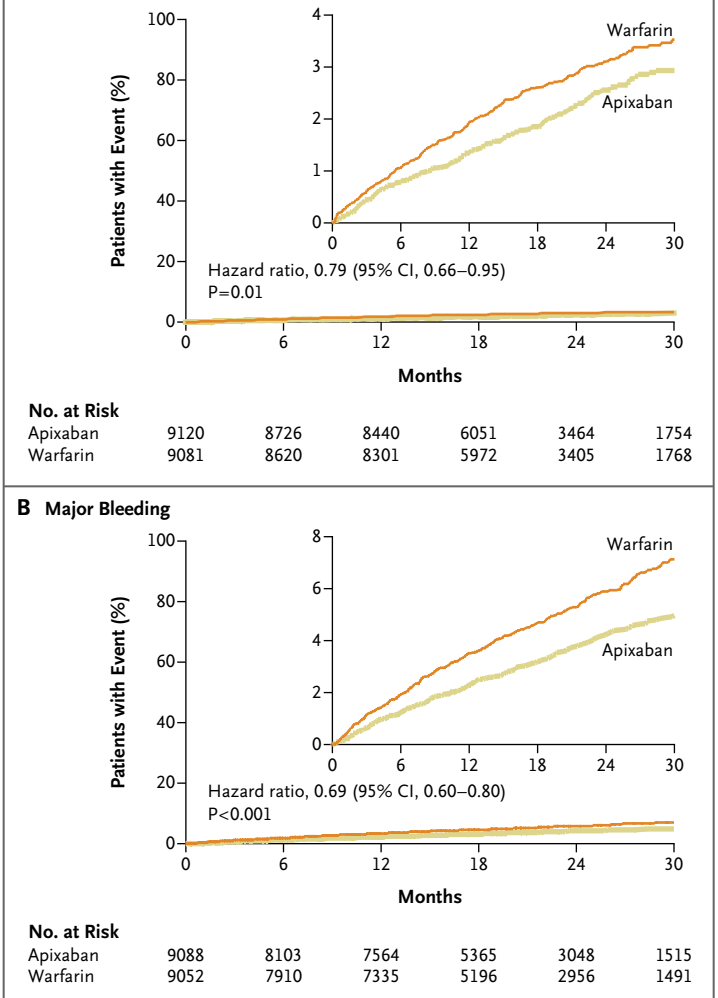

Figure 1. Kaplan–Meier Curves for the Primary Efficacy and Safety Outcomes.
The primary efficacy outcome (Panel A) was stroke or systemic embolism. The primary safety outcome (Panel B) was major bleeding, as defined according to the criteria of the International Society on Thrombosis and Haemostasis. The inset in each panel shows the same data on an enlarged segment of the y axis.

events from the time of randomization until January 30, 2011. All reported P values for noninferiority are one-sided, and all reported P values for superiority are two-sided. All statistical analyses were performed with the use of SAS software, version 9.0 (SAS Institute).

RESULTS

PATIENTS AND FOLLOW-UP

From December 19, 2006, through April 2, 2010, we recruited 18,201 patients at 1034 clinical sites in 39 countries. A total of 9120 were assigned to the apixaban group and 9081 to the warfarin group. The two groups were well balanced with respect to baseline characteristics (Table 1). The median age was 70 years; 35.3% of the patients were women, and the mean $CHADS_2$ score was 2.1. (The $CHADS_2$ score, an index of the risk of stroke in patients with atrial fibrillation, ranges from 1 to 6, with higher scores indicating a greater risk of stroke.) Approximately 57% of the patients had previously received a vitamin K antagonist, and 19% had had a previous stroke, transient ischemic attack, or systemic embolism.

Data on vital status at the end of the trial were missing for 380 patients (2.1%). The absence of data on vital status was due to withdrawal of consent in the case of 92 patients in the apixaban group (1.0%) and 107 patients in the warfarin group (1.2%) and was due to loss to follow-up in the case of 35 patients in the apixaban group (0.4%) and 34 in the warfarin group (0.4%).

STUDY DRUGS

A reduced dose of apixaban (2.5 mg twice daily) or placebo was administered in 428 patients in the apixaban group (4.7%) and 403 in the warfarin group (4.4%). Fewer patients in the apixaban group than in the warfarin group discontinued a study drug before the end of the study: 25.3% of the patients in the apixaban group, with 3.6% of the discontinuations due to death, versus 27.5% of patients in the warfarin group, with 3.8% due to death (P=0.001). Patients in the warfarin group had an INR in the therapeutic range (2.0 to 3.0) for a median of 66.0% of the time and a mean of 62.2% of the time, after the exclusion of INR values during the first 7 days after randomization and during study-drug interruptions.

PRIMARY OUTCOME

The primary outcome of stroke or systemic embolism occurred in 212 patients in the apixaban group (1.27% per year) as compared with 265 patients in the warfarin group (1.60% per year) (hazard ratio in the apixaban group, 0.79; 95% confidence interval [CI], 0.66 to 0.95; P<0.001 for noninferiority and P=0.01 for superiority) (Table 2 and Fig. 1A). The rate of hemorrhagic stroke was 49% lower in the apixaban group than in the warfarin group, and the rate of ischemic or uncertain type of stroke was 8% lower in the apixaban group than in the warfarin group (Table 2). Fatal or disabling stroke occurred in 84 patients in the apixaban group (0.50% per year) as com-

* The bleeding outcomes were assessed in patients who received at least one dose of a study drug and events that occurred from the time the patients received the first dose of the study drug through 2 days after they received the last dose. The net clinical outcome includes all efficacy outcomes through the cutoff date for the efficacy analysis and bleeding outcomes that occurred from the time the patients received the first dose of the study drug through 2 days after they received the last dose. GUSTO denotes Global Use of Strategies to Open Occluded Coronary Arteries, and TIMI Thrombolysis in Myocardial Infarction.

† The comparison of the primary safety outcome of bleeding according to the International Society on Thrombosis and Haemostasis (ISTH) criteria is in the hierarchical sequence preserving a type I error.

pared with 117 patients in the warfarin group (0.71% per year) (hazard ratio, 0.71; 95% CI, 0.54 to 0.94). Ischemic stroke occurred in 149 patients in the apixaban group and in 155 patients in the warfarin group, and an unknown type of stroke occurred in 14 patients in the apixaban group and 21 patients in the warfarin group. Among the patients with ischemic strokes, hemorrhagic transformation occurred in 12 patients in the apixaban group and 20 patients in the warfarin group. Fatal stroke occurred in 42 patients in the apixaban group and 67 patients in the warfarin group.

KEY SECONDARY AND OTHER EFFICACY OUTCOMES

The rate of death from any cause was lower in the apixaban group than in the warfarin group (3.52% per year vs. 3.94% per year; hazard ratio, 0.89; 95% CI, 0.80 to 0.99; P=0.047). The rate of death from cardiovascular causes (including death from hemorrhagic stroke) was 1.80% per year in the apixaban group and 2.02% per year in the warfarin group (hazard ratio, 0.89; 95% CI, 0.76 to 1.04), and the rate of death from noncardiovascular causes (including fatal bleeding other than that from hemorrhagic stroke) was 1.14% per year in the apixaban group and 1.22% per year in the warfarin group (hazard ratio, 0.93; 95% CI, 0.77 to 1.13). The rate of myocardial infarction was lower in the apixaban group than in the warfarin group, but the difference was not significant (Table 2).

BLEEDING

Major bleeding, as defined according to ISTH criteria, occurred in 327 patients in the apixaban group (2.13% per year), as compared with 462 patients in the warfarin group (3.09% per year) (hazard ratio, 0.69; 95% CI, 0.60 to 0.80; P<0.001) (Table 3 and Fig. 1B). There appeared to be an even greater reduction in the rate of serious bleeding as defined according to the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) criteria for severe bleeding and according to the Thrombolysis in Myocardial Infarction (TIMI) criteria for major bleeding (Table 3). Figure 2. Relative Risks of the Primary Efficacy and Safety Outcomes, According to Major Prespecified Subgroups.

Prespecified subgroups not included in the figure were subgroups according to race, ethnic group, body-mass index, number of risk factors, age of 75 years or more, and use or nonuse of clopidogrel at the time of randomization, as well as subgroups of women according to age group. Heart failure was defined as symptomatic heart failure or a left ventricular ejection fraction of 40% or less. The $CHADS_2$ score, an index of the risk of stroke in patients with atrial fibrillation, ranges from 1 to 6, with higher scores indicating a greater risk of stroke. TIA denotes transient ischemic attack.

rate of intracranial hemorrhage was 0.33% per year in the apixaban group and 0.80% per year in the warfarin group (hazard ratio, 0.42; 95% CI, 0.30 to 0.58; P<0.001), and the rate of any bleeding was 25.8% per year in the warfarin group and 18.1% per year in the apixaban group, an absolute reduction of 7.7 percentage points (P<0.001). In a modified intention-to-treat sensitivity analysis that included the entire treatment period, there was a consistent 27% relative reduction in

the rate of major bleeding in the apixaban group, as compared with the warfarin group (P<0.001). Fatal bleeding (including fatal hemorrhagic stroke), as evaluated in the intention-to-treat analysis, occurred in 34 patients in the apixaban group and 55 patients in the warfarin group.

SUBGROUPS

The reduction in the primary outcome with apixaban was consistent across all major subgroups (Fig. 2), and statistical tests for interaction were not significant (P>0.10) for all of the 21 predefined subgroups. With respect to the outcome of major bleeding, the only baseline characteristics for which the interaction was significant were diabetes status and renal function, with a greater reduction in bleeding among patients who did not have diabetes (P=0.003 for interaction) and among patients with moderate or severe renal impairment (P=0.03 for interaction).

OVERALL SAFETY OUTCOMES

Adverse events occurred in almost equal proportions of patients in the apixaban group and in the warfarin group (81.5% of the patients in the apixaban group and 83.1% of patients in the warfarin group), as did serious adverse events (35.0% and 36.5% in the two groups, respectively) (for details, see the Supplementary Appendix). The rates of abnormalities on liver-function testing and liver-related serious adverse events were similar in the two groups.

DISCUSSION

In patients with atrial fibrillation and at least one additional risk factor for stroke, the use of apixaban, as compared with warfarin, significantly reduced the risk of stroke or systemic embolism by 21%, major bleeding by 31%, and death by 11%. For every 1000 patients treated for 1.8 years, apixaban, as compared with warfarin, prevented a stroke in 6 patients, major bleeding in 15 patients, and death in 8 patients. The predominant effect on stroke prevention was on hemorrhagic stroke, with prevention of a hemorrhagic stroke in 4 patients per 1000 and prevention of an ischemic or unknown type of stroke in 2 patients per 1000.

The results were consistent in subgroups according to geographic region, status with respect to previous warfarin exposure, age, sex, level of renal impairment, and risk factors for stroke, as well as in other predefined subgroups. Apixaban had an acceptable side-effect profile, with no unexpected side effects, and the rate of discontinuation of the study drug was lower in the apixaban group than in the warfarin group.

Warfarin is highly effective in preventing stroke in patients with atrial fibrillation but is associated with a variable response, has drug and food interactions, requires regular monitoring for dose adjustment, and carries a risk of bleeding (including intracranial hemorrhage). In part because of these limitations, only about half of patients who would benefit from warfarin therapy actually receive the drug.[11] The alternative treatment regimen with apixaban (at a dose of 5 mg twice daily), which does not require anticoagulation monitoring, not only is more effective than warfarin for stroke prevention but also accomplishes this goal at a substantially lower risk of bleeding and with lower rates of discontinuation. These findings are supported by the results of the Apixaban Versus Acetylsalicylic Acid [ASA] to Prevent Stroke in Atrial Fibrillation Patients Who Have Failed or Are Unsuitable for Vitamin K Antagonist Treatment trial (AVERROES; ClinicalTrials.gov number, NCT00496769),[6] in which the same apixaban regimen, as compared with low-dose aspirin, was shown to substantially reduce the risk of stroke without any difference in the rates of major bleeding and with lower rates of discontinuation. Although major bleeding was less common with apixaban, at a dose of 5 mg twice daily, than with warfarin in patients with atrial fibrillation, the use of the same dose of apixaban, as compared with placebo, resulted in more bleeding in patients with acute coronary syndromes who were receiving both aspirin and clopidogrel.[12] The significant reduction in mortality observed in our study was consistent with trends toward lower rates of death among patients receiving apixaban than among those receiving aspirin in the AVERROES trial.

Two alternative oral anticoagulants, the direct thrombin inhibitor dabigatran[3] and the factor Xa inhibitor rivaroxaban,[4] have recently been shown in randomized clinical trials to be at least as effective as warfarin in preventing stroke. Each of these agents, like apixaban, has the major advantage of convenience, since there is no need for anticoagulation monitoring. In the Randomized Evaluation of Long-Term Anticoagulation Therapy trial (RE-LY, NCT00262600) the oral di-

rect thrombin inhibitor dabigatran administered in two doses per day was compared with open-label warfarin. The 150-mg dose of dabigatran administered twice daily, as compared with warfarin, was shown to reduce the rate of stroke, including ischemic or unspecified stroke, with a similar overall rate of bleeding, although the rate of gastrointestinal bleeding was increased. The 110-mg dose administered twice daily was associated with a rate of stroke that was similar to that with warfarin but with a lower rate of major bleeding. Both doses resulted in lower rates of intracranial hemorrhage. In our study, apixaban at a dose of 5 mg twice daily (with the recommendation to use a reduced dose in patients with a predicted higher drug exposure) appears to combine the advantages of each of the two doses of dabigatran, with both a greater overall reduction in the rate of stroke and a lower rate of bleeding than the rates with warfarin. As compared with warfarin, apixaban is also associated with a reduction in the rate of gastrointestinal bleeding and with consistently lower bleeding rates across age groups[13] and all other major subgroups. Fewer patients receiving apixaban had a myocardial infarction than those receiving either warfarin (in our study) or aspirin (in the AVERROES trial).

Rivaroxaban, the second new alternative, was shown to be noninferior to warfarin for the prevention of stroke and systemic embolism in the intention-to-treat analysis in the Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET AF, NCT00403767).[4] The rates of intracranial hemorrhage and fatal bleeding were lower with rivaroxaban than with warfarin, but there was no advantage with respect to other major bleeding. The differences between our findings and those of other trials comparing novel anticoagulants with warfarin may be related to differences in the doses of drugs, the pharmacokinetic and pharmacodynamic properties of the drugs,[14] patient populations, or other features of the clinical-trial design. The lower risk of hemorrhagic stroke associated with all three novel anticoagulants suggests that there is a specific risk associated with warfarin, possibly related to its inhibition of multiple coagulation factors or interaction between warfarin and tissue factor VIIa complexes in the brain.[15]

In conclusion, in patients with atrial fibrillation, apixaban was superior to warfarin in preventing stroke or systemic embolism, caused less bleeding, and resulted in lower mortality.

Hepatitis C

ABSTRACT

Objective: Chronic hepatitis C infection (HCV) is a major health problem that disproportionately affects people with limited resources. Many people with HCV are ineligible or refuse antiviral treatment, but less curative treatment options exist. These options include adhering to follow-up health visits, lifestyle changes, and avoiding hepatotoxins like alcohol. Herein, we describe a recently developed self-management program designed to assist HCV-infected patients with adherence and improve their health-related quality of life (HRQOL).

Methods: The development of the Hepatitis C Self-Management Program (HCV-SMP) was informed by scientific literature, qualitative interviews with HCV-infected patients, self-management training, and feedback from HCV clinical experts.

Results: The Hepatitis C Self-Management Program (HCV-SMP) is a multi-faceted program that employs cognitive-behavioral principles and is designed to provide HCV-infected people with knowledge and skills for improving their HRQOL. The program consists of six 2-h workshop sessions which are held weekly. The sessions consist of a variety of group activities, including disease-specific information dissemination, action planning, and problem-solving.

Conclusion: The intervention teaches skills for adhering to challenging treatment recommendations using a validated theoretical model. A randomized trial will test the efficacy of this novel HCV self-management program for improving HRQOL in a difficult to reach population.

Published by Elsevier Ireland Ltd.

1. Introduction

Hepatitis C virus (HCV) infects millions of people in the US and in Europe [1], and often co-occurs with substance abuse, homelessness, and impoverishment [2–5]. Long-term medical consequences of HCV include cirrhosis, hepatocellular carcinoma [6], and liver transplant [7]. HCV-infected individuals also experience physical and psychological symptoms and functional limitations [8,9]. Antiviral treatment can eliminate the virus in some patients [10,11], but the majority of patients are either ineligible for treatment, refuse treatment, or fail treatment [12].

Treatment recommendations for HCV-infected patients often include attending follow-up appointments, obtaining laboratory tests, undergoing psychiatric evaluation [13], abstention from alcohol [14,15], avoiding transmission of the virus to others, avoiding certain foods or medications, and losing weight [16–19]. Yet this population lacks resources in general, and many may not have the information or skills required to adhere to these recommendations successfully [8].

Like other chronic illnesses, patients can use social, behavioral, and cognitive skills to participate more effectively in caring for their HCV. These strategies may help patients self-manage symptoms, increase functionality, make more informed decisions about treatment, and increase their chances of completing treatment successfully. Chronic disease self-management programs are primarily grounded in social cognitive learning theory [20,21] and augment traditional patient education with behavioral change and problem-solving skills. Patients learn to identify and prioritize their problems, take appropriate action, and to solve problems in collaboration with health care professionals and supportive others.

Self-management programs for other chronic diseases have been studied extensively and have produced good results for

people with asthma, diabetes, heart failure, and arthritis among others [33–42]. Despite the clear need, these principles have not been applied to HCV previously. Our purpose is to describe the development of a self-management program adapted specifically for people with HCV.

2. Methods

2.1. Program development

The program was adapted for HCV-infected individuals from the Chronic Disease Self-Management Program (CDSMP) which is based primarily on cognitive-behavioral principles [22]. The adaptation/development of the HCV-SMP was informed by CDSMP training sessions, scientific literature review, qualitative interviews with HCV-infected patients [8], and by feedback from expert HCV clinicians and researchers. First, the developer of the HCV-SMP and staff members attended a week-long training session at the Stanford Patient Education Research Center [23] to fully understand the content and processes of the CDSMP. Going forward, Stanford Patient Education staff made themselves available for ongoing consultation.

Because chronic disease self-management approaches are often multi-faceted and allow participants to choose what they would like to change in their lives, generic health-related quality of life was chosen as the target outcome for the program. Accordingly, the main theoretical model used to inform the development of the program was the General Health Policy Model [24] which identifies symptoms (physical and psychological) and functioning as the primary determinants of well-being. Behaviors and cognitions shown to directly or indirectly impact HRQOL were considered for the program.

Scientific literature on the impact of HCV on HRQOL was also reviewed to further inform the development of the HCV-SMP and the main results of this review have been published [9]. The results identified fatigue [25], sexual dissatisfaction [26], depression, and anxiety [4] as some of the symptoms experienced by HCV-infected persons that could be addressed in a cognitive-behaviorally based program. Lifestyle factors associated with reduced HRQOL among persons with HCV included cigarette smoking [27] and current IV drug use. Other lifestyle factors known to impact the liver and/or HRQOL are alcohol use [14] and excess bodyweight [17,19]. Finally, there is evidence that HCV-infected patients report communication problems with physicians [28].

Qualitative interviews were conducted with 23 HCV-infected VA patients to learn more about the challenges of, and beneficial strategies for, living with HCV. The interviews were designed for the purpose of informing the development of an HCV-specific self-management program. Interview data were analyzed for themes by two independent raters using an HRQOL conceptual framework. More detail on the methods and results is available [8]. We found that: many participants had misconceptions about HCV, being diagnosed with HCV caused ongoing health concerns, HCV status affects interpersonal relationships, and the connection between substance use and HCV affects patient motivation for HCV treatment and substance abuse recovery.

After proposed changes to the existing CDSMP manual were developed, expert HCV clinicians reviewed these changes and provided feedback. Feedback included keeping the program to no more than six sessions, not intentionally emphasizing the common experience of veterans so that the program would generalize to others with HCV, limiting the time spent addressing severe active alcoholism or IV drug use primarily to referral, and devoting extra time to HCV treatment decision-making.

3. Results

The generic CDSMP adequately addressed many of the topics identified. Excess bodyweight was addressed in two modules on exercise and one module on healthy eating. Depression and anxiety were addressed in modules on cognitive symptom management, dealing with difficult emotions, depression management, self-talk, and multiple relaxation/stress reduction modules, so the only change was to spend more time on these areas. Interpersonal relationships were primarily discussed in the communication skills module, but also emerge during action planning and problem-solving. Garnering support from others is a tool for succeeding at behavioral change. We decided not to devote a module specifically to sexual satisfaction, but expected it to arise during the communication skills module where talking to others about HCV is discussed. Finally, patient-provider communication is addressed in modules on physician recommendations/medication usage, and informing the health care team.

To address a lack of accurate information about hepatitis C, we added HCV-specific education modules developed by the VA National Hepatitis C Office in sessions 1 and 2 [29]. Alcohol and drug usage in relation to HCV are addressed in the education modules, and an additional 20–25 min module was added that referred those with severe substance use to appropriate services, while providing tools for abstinence or harm reduction for those with minimal to moderate substance usage. We added material to the existing CDSMP module on fatigue, expanding it in length slightly. Another major addition to the existing program was adding a 40-min discussion panel about antiviral treatment in which 2–3 peers and an HCV health care provider described their experiences with antiviral treatment. This was followed by a module on shared treatment decisions which replaced a module on "making informed treatment decisions", with the former focusing on patient participation while the latter had focused on critically evaluating evidence as a consumer.

To keep the program to six sessions overall as recommended by the expert clinicians and researchers, we needed to eliminate a few modules. Namely, we eliminated modules on distraction from pain and advance directives for health care. Both topics seemed potentially useful to people with HCV, but not a priority based on our development process.

Two pilot programs were conducted to test the feasibility and participant reactions to the program. Although 12 patients attended the first assessment, 3 left before the program began, 9 attended the second session, 1 brought a friend who also attended, and eight attended regularly and completed baseline and post-intervention assessments. Overall patients showed improvement as shown in Table 1. From the pilot programs, we learned that participants usually attend the program regularly once they experienced the first session, and that conducting a larger study was feasible among VA patients.

The Hepatitis C Self-Management Program (HCV-SMP) is designed to provide HCV-infected people with the knowledge and skills they need to improve their current and future HRQOL. The HCV-SMP consists of six 2-h workshop sessions which are held weekly. The sessions consist of a variety of group activities, including disease-specific information dissemination, action planning, and problem-solving (see Table 2). Sessions are designed to promote participant interaction and the development of social support throughout. Program activities are modeled for patients by the co-leaders. Participants are provided with materials including an HCV information packet and resource guide, a copy of the book "Living a Healthy Life with Chronic Conditions" [30] and an audio recording of two relaxation exercises. The HCV-SMP is co-led by a health professional and a peer-leader. Both co-leaders are trained by studying the intervention manual and attending 40 h of training

Table 1
Pilot program outcome results.

Measures ($n = 8$)	Baseline mean (SD)	Follow-up mean (SD)	Effect size (d)	p-value (2-tail)
HRQOL—QWB score	.459 (.134)	.480 (.131)	.16	.318

HCV knowledge score	8.6 (2.7)	11.1 (1.6)	1.16	.038
Health distress	2.00 (1.22)	1.71 (1.41)	.22	.547
Exercise—self-report	4.4 (2.3)	5.0 (1.2)	.35	.553

at the Stanford Patient Education Research Center. A few of the most important modules from the CDSMP and new additions are described below.

Action plans are weekly goal setting activities in which goals are broken down into specific, manageable behaviors. The program leaders model this activity for participants by choosing an action plan and operationalizing it. Participants take turns stating their action plan and describing *What* they will do (something desirable and reasonable), *How Much* (i.e. time, effort), *How Often* (# of times week) and *When* (i.e. mornings, weekdays). Participants report their confidence level for each action plan on a scale from 0 to 100%. When participants are less than 70% sure they can complete their action plan, they modify their plan to make it more achievable.

Feedback/problem-solving sessions. Participants state their action plan and report their success completing the plan. If they were not successful, three problem-solving steps (identify the problem, list ideas to solve the problem, select one idea to try) are discussed with the group. The discussion follows a "brainstorm" format in which other group members suggest many ideas for solving the problem. The participant with the problem then chooses ideas to implement.

Substance use and HCV. Participants are directed to the VA web site for hepatitis and alcohol (www.hepatitis.va.gov/vahep). Participants are told about resources within the VA such as the Alcohol Drug Treatment Program (ADTP), and encouraged to seek help if they are surpassing VA guidelines for moderate drinking or actively using drugs. Many participants have been through substance use treatment or are involved with substance abuse recovery. The fit between abstinence/sobriety and self-management of HCV, barriers to sobriety, the pros/cons of abstinence, and strategies for reducing and abstaining from substance use are discussed.

Treatment discussion panel. The panel typically consists of 2–3 peers who have undergone antiviral treatment for HCV and one HCV health care provider. The peers describe their experience with HCV antiviral treatment and the health care provider offers additional insights based on clinical experience. Participants then ask questions about antiviral treatment. After the panel concludes, participants discuss active participation on treatment decision-making in light of the panel experience.

Table 2
Hepatitis C Self-Management Program modules.

	Modules
Session 1	Introductions—identifying common problems (20 min) Workshop overview and responsibilities (8–10 min) Hepatitis C—specific information with questions (25–30 min) Differences between acute and chronic conditions (12–15 min) Introduction to cognitive symptom management (10–12 min) Introduction to action plans (30 min) Brief review of topics and closing (10 min)
Session 2	Feedback/problem-solving session (20 min) Dealing with anger, fear and frustration (20 min) Introduction to exercise (30 min) Hepatitis C—specific information with questions (35 min) Making an action plan (20 min) Brief review of topics and closing (5 min)
Session 3	Feedback/problem-solving session (15–20 min) Fatigue management (15–20 min) Alcohol/drug use and hepatitis C (20–25 min) Better breathing (15 min) Endurance exercise (20 min) Making an action plan (15 min) Brief review of topics and closing (5 min)
Session 4	Feedback/problem-solving/making an action plan (20–25 min) Panel of veterans discussing interferon treatment (40 min) Making shared treatment decisions (10–15 min) Communication skills (15 min) Problem-solving (20 min) Muscle relaxation (10 min) Brief review of topics and closing (5 min)
Session 5	Feedback/problem-solving/making an action plan (20 min) Physician recommendations/medication usage (15–20) Healthy eating (25 min) Depression management (15 min) Self-talk (25 min) Guided imagery (20 min) Brief review of topics and closing (5 min)
Session 6	Feedback/problem-solving (20 min) Informing the health care team (10 min) Working with your health care professional (20 min) Looking back and planning for the future (35 min) Brief review of topics and closing (10 min)

4. Discussion and conclusion

Chronic hepatitis C infection is a major health problem both globally and in the US, that affects people who often lack resources [31,32]. Many of those infected may not be eligible or ready for antiviral treatment, and they receive treatment recommendations that are mostly behavioral in nature [12]. However, these recommendations are difficult to follow without additional support. Self-management programs are a novel option for helping HCV-infected patients adhere to treatment recommendations and improve their HRQOL. Similar programs for other chronic diseases have produced well-established results [33–42].

The HCV-SMP intervention was adapted specifically for people with HCV from an established chronic disease self-management program. The program teaches broad self-management skills that can be utilized to improve multiple aspects of health. The program's development was guided by the General Health Policy Model, and informed by scientific literature, qualitative interviews with HCV-infected patients, self-management training, and feedback from HCV clinical experts.

A possible limitation of the intervention is that it is not designed for people who are currently receiving antiviral treatment, but it does educate participants about antiviral treatment, assist them with treatment decision-making, and prepare them to succeed at treatment in the future. Although individuals on antiviral treatment may benefit from a self-management approach, such a program would likely focus more on side effects of treatment and adherence to antiviral medications. However, the current program can be adapted to help patients on antiviral treatment in the future.

The program is currently being evaluated among HCV-infected VA patients in a randomized controlled trial fund by VA HSR&D.

The study compares the HCV-SMP to an information-only comparison group. The study assesses self-reported outcomes such as HRQOL, energy, mental health, self-efficacy, HCV knowledge, and health behaviors in addition to clinical outcomes such as appointment attendance, antiviral treatment rates, and rates of sustained viral response. If efficacy is established in the RCT, the program will be implemented on a larger scale.

Conflict of interest

The authors do not have any conflicts of interest relating to this study or manuscript.

Received February 2010; accepted for publication March 2010

SUMMARY. Chronic hepatitis C (HCV) infection afflicts millions of people worldwide. While antiviral treatments are effective for some patients, many either cannot or choose not to receive antiviral treatment. Education about behavioural changes like alcohol avoidance and symptom management, in contrast, is universally recommended, particularly in HCV-infected persons from disadvantaged groups where liver risk factors are most prevalent. Self-management interventions are one option for fostering improved HCV knowledge and health-related quality of life (HRQOL). One hundred and thirty-two patients with VA with HCV (mean age of 54.6, 95% men, 41% ethnic minority, 83% unmarried, 72% unemployed/disabled, 48% homeless in last 5 years) were randomized to either a 6-week self-management workshop or an information-only intervention. The weekly 2-h self-management sessions were based on cognitive-behavioural principles and were adapted from an existing self-management programme that has been efficacious with other chronic diseases. HCV-specific modules were added. Outcomes including HRQOL, HCV knowledge, self-efficacy, depression, energy and health distress were measured at baseline and 6 weeks later. Data were analysed using ANOVA. When compared to the information-only group, participants attending the self-management workshop improved more on HCV knowledge ($P < 0.001$), HCV self-efficacy ($P = 0.011$), and SF-36 energy/vitality ($P = 0.040$). Similar trends were found for SF-36 physical functioning ($P = 0.055$) and health distress ($P = 0.055$). Attending the self-management programme improved disease knowledge and HRQOL 6 weeks later in this disadvantaged population. The intervention can improve the health of people with hepatitis C, independent of antiviral therapy. Future research will study longer-term outcomes, effects on antiviral treatment and costs.

Keywords: behavioural interventions, health-related quality of life, hepatitis C, self-management, US veterans.

Hepatitis C virus (HCV) infects about 1.8% of the US population [1] and often co-occurs with substance abuse problems, homelessness and impoverishment [2–5]. Long-term medical consequences of HCV include cirrhosis, hepatocellular carcinoma [6] and/or the need for liver transplant [7]. In addition, most HCV-infected individuals experience a variety of physical and psychological symptoms, functional limitations and impaired quality of life as a result of having HCV and co-existing chronic health problems [8,9].

Treatment with antiviral medications eliminates the virus in many patients [10,11], but lower success rates have been found outside of clinical trials [12]. Nevertheless, the vast majority of patients are either ineligible for treatment, refuse treatment, fail treatment, or treated with watchful waiting [13]. In fact, it is estimated that only about 20% of patients with VA with HCV have ever initiated antiviral treatment [12]. Common reasons for not receiving treatment are ongoing substance abuse, psychiatric disorders [12] and poor attendance of clinic appointments. Thus, despite ongoing improvements in antiviral treatments, there are few treatment alternatives for people with HCV.

Treatment recommendations for HCV-infected patients often include attending regular follow-up visits, obtaining additional laboratory tests, undergoing psychiatric

evaluation [14], abstention from alcohol [15,16], avoiding transmission of the virus, avoiding certain foods or medications, exercise/losing weight [17–20] and making decisions concerning antiviral treatment [21]. Yet, many patients may not have the information or skills required to adhere to these recommendations successfully [8].

As with other chronic illnesses, there are social, behavioural, and cognitive skills that patients can use to participate more effectively in the management of their HCV. These self-management strategies can help patients manage their symptoms, increase their functionality, make more informed decisions about treatment and potentially help prevent them from spreading the virus to others. Despite the need for such approaches, little or no research on self-management for hepatitis C has been undertaken.

Self-management interventions go beyond traditional patient education in that they are more comprehensive, focus more on facilitating change, teach problem-solving skills instead of primarily disseminating information [22] and engage the patient in the day-to-day management of his/her illness. Self-management programmes are primarily grounded in social cognitive learning theory [23,24]. Social learning theory emphasizes several dimensions along which change can occur, such as increasing self-efficacy and motivation, learning-specific illness management information and skills, enlisting support from a social network and monitoring symptoms and emotions [25]. Good self-management programmes typically address (i) disease management, medications, general health; (ii) role management and (iii) emotional management [26]. Patients learn to identify and prioritize their own problems, take appropriate action and enlist the support needed to solve these problems in collaboration with healthcare professionals and family.

The purpose of this study was to examine the effects of a hepatitis C self-management intervention on the quality of life of HCV-infected individuals who are not currently on or scheduled to start antiviral treatment.

METHODS

Study design

The study was a randomized controlled trial comparing the effects of the hepatitis C self-management programme to an HCV information-only intervention among VA patients with chronic hepatitis C. A total of 137 patients were recruited and randomized to one of the two intervention groups. After obtaining informed consent and a release of medical information, patients were randomized to one of two interventions and completed a baseline assessment. Self-management or comparison interventions were delivered over a 6-week period. Follow-up assessments occurred 6 weeks after the baseline assessment. The study was conducted at the VA San Diego Healthcare System, San Diego, CA, USA. Inclusion criteria were: (i) a confirmed diagnosis of chronic hepatitis C; (ii) US military veterans age 18 or older; (iii) eligible to receive care at the VA San Diego Healthcare System; (d) willing and able to attend six weekly programme sessions lasting about 2.5 h each. Exclusion criteria were: (i) ongoing antiviral treatment for hepatitis C or scheduled to start antiviral treatment within 6 months; (ii) residence in a geographical area outside of San Diego County (intervention attendance is too difficult); (iii) ongoing treatment for another life-threatening co-morbid illness; (iv) fatal co-morbidity (life expectancy <6 months indicated by treating physician).

Recruitment and retention

A multi-faceted recruitment approach was used. The approach was designed to reach a full spectrum of HCV-infected individuals, especially those who were impoverished and/or homeless, and often have been underrepresented in research. Patients were also told about the study by healthcare providers in the Hepatitis C Clinic and in primary care units at the VA San Diego Healthcare System. Flyers were posted in the Hepatitis C clinic, primary care clinics, the alcohol and drug treatment programme (ADTP) clinic, psychiatry and psychology clinics, common areas of the main VA hospital in San Diego, and at VA satellite clinics. Study recruiters also visited and established contacts at local recovery homes, homeless shelters, VA Stand Down San Diego and nonprofit organizations that serve veterans, such as St. Vincent De Paul and Veterans Village of San Diego (VVSD).

To minimize attrition and attendance problems, frequent contact with participants was maintained via phone and mail. The recruitment timeline for each cohort was approximately 1–2 months, so it was imperative to keep current phone numbers and addresses for interested persons. Prospective participants without working phone numbers were asked to contact study staff biweekly for study updates. After the initial baseline assessment, participants were given a printed schedule with the dates of their remaining assessments and/or self-management sessions.

Assignment and masking

As directed by referrals and flyers, potential participants called research project staff for more information on the study and eligibility screening. Participants who met study inclusion/exclusion criteria were added to a list of those interested in the study. Once a cohort of 20–25 participants had expressed interest, patients were randomized to one of the two interventions. Patients were recruited in nine cohorts over the course of 14 months. Research staff completed randomization for each participant using a computer-generated random number generator [27]. Blinding of participants and interventionists was not possible but both conditions could reasonably expect some improvement

in outcomes. Intervention staff were not blinded, but all assessments were self-report questionnaires.

Interventions

In an effort to standardize the amount of HCV-specific information available to participants and create a meaningful intervention for participants in the comparison group, both interventions were provided with an HCV-specific information packet upon completion of their baseline assessment. The packet contained information that is available to all patients with VA nationally through their healthcare providers and/or via the Internet and the Hepatitis C Resource Centers. In addition, all participants received a patient resource guide, containing an indexed list of health-related organizations and telephone numbers. Clinical care for chronic HCV infection continued as usual for participants in both interventions.

HCV information only

The HCV-specific information booklet consisted of printed materials that are currently available in the Hepatitis C Clinic and in other usual care clinics for patients with Hepatitis C. The materials included brochures and handouts titled 'Overview of Hepatitis C', 'Understanding the Side Effects of Interferon Therapy', Coping with Hepatitis C: Diet and Nutrition' and 'Talking with Others About Hepatitis C' to name a few. In general, the materials described hepatitis C and cover the topics of preventing the transmission of hepatitis C, avoiding certain foods and medications, discussing one's diagnosis with others, antiviral treatment and general behavioural recommendations. Also, included were printouts of the same presentation used for the self-management workshop intervention. The presentation was prepared and disseminated by the VA National Hepatitis C Resource Centers. Patients in the information-only intervention were able to ask their healthcare providers about the information they received at any time. Questions specific to the research study were directed to the project coordinator.

Hepatitis C self-management programme

Programme development

The programme was adapted for veterans with chronic HCV infection from the chronic disease self-management programme (CDSMP) developed by Lorig *et al.* [28]. The adaptation and development of the HCV-SMP were informed by a qualitative pilot study with HCV-infected veterans [8], scientific literature, CDSMP training sessions at Stanford University and input from collaborators at the VA Hepatitis C Resource Centers and the VA HIV/Hepatitis QUERI Coordinating Center. Our main modifications to the CDSMP include the addition of three HCV-specific education modules developed by the VA National Hepatitis C Resource Centers, each about 20 min in length, a panel discussion with patients who had already completed antiviral treatment, treatment decision-making, discussion of substance use disorders and treatment, and increased time devoted to psychological issues, evaluating alternative treatments and communication with healthcare providers. To keep the intervention to a maximum of six sessions similar to the CDSMP, modules on advanced directives and cognitive distraction were removed and other modules were shortened.

The hepatitis C self-management programme (HCV-SMP) is designed to provide HCV-infected people with the knowledge and skills they need to improve their current and future health and health-related quality of life (HRQOL). The programme is based primarily on cognitive-behavioural principles and is multi-faceted, focusing not only on hepatitis C, but also on general health improvement. The programme incorporates a client-centred, empowerment-based approach that allows the participants to prioritize which elements of the programme that they would like to focus on most.

The HCV-SMP consists of six weekly workshop sessions that are 2–2.5 h in length. The sessions consist of a variety of group activities, including disease-specific information dissemination, problem solving, development of action plans, and re-evaluation and revision of action plans. Action plans consist of small behavioural changes that each participant aims to accomplish during the week between sessions. Participants report back on their success and are assisted with problem solving when they are not successful. In addition to the interaction and the exchange of social support that takes place between participants before and after the sessions, a 20-min break occurs at the middle of each session, and often encourages additional interactions among participants. Patients are encouraged, but not required, to discuss their experiences and problems with other group members and with the group as a whole. All programme activities are modeled for patients by the group leaders, and participants can opt out of activities at any time. In addition to the HCV information packet and the patients' resources guide, each patient attending the HCV-SMP receives a copy of the book Living a Healthy Life with Chronic Conditions [29] and a cassette tape or CD containing two relaxation exercises. Light refreshments were served at each session because the sessions are up to 2.5 h long, and fatigue can be a problem for patients with hepatitis C.

The HCV-SMP was co-led by a health professional and a peer-leader. Research has shown that peer-leaders can teach self-management as well as health professionals when properly trained and that patients may obtain additional benefit from being able to identify with someone who has the same illness [30–32]. To maintain consistency and fidelity of the multiple intervention cohorts, all workshops were delivered by the same leader and peer leader.

Between each workshop session, participants were contacted by the group leader via phone. The phone call is

aimed to check on the progress of the participant's action plan and remind them of the upcoming group. After the first workshop session, participants are given the option to call each other once during the week instead of being called by the leader. Based on data from preliminary studies, participants look forward to the phone call, but many prefer to be called by the group leader.

Measures

The primary outcomes for the study were generic and disease-specific HRQOL. It was hypothesized that self-management participants would have greater improvements in HRQOL than information-only participants. Secondary outcomes were examined with the same hypothesis as the primary outcomes. These measures included HCV-related knowledge, self-efficacy, depression, energy/fatigue, alcohol use and health distress. A sociodemographic questionnaire was used to assess variables such as age, gender, race/ethnicity, education level, marital status, employment status, transportation and living situation.

Generic health-related quality of life

The SF-36 and the quality of well-being scale–self-administered (QWB-SA) were used to assess generic HRQOL. The SF-36 is a generic, descriptive measure of HRQOL that includes eight domains: physical functioning, role limitations – physical, bodily pain, general health perceptions, vitality, social functioning, role limitations – emotional, and overall mental health [33]. The measure has well-established norms, and the reliability and validity of the SF-36 are well documented [34–36]. The QWB-SA is a preference-based measure that produces a single total summary score that is appropriate for cost-effectiveness analysis [37–42]. The QWB-SA also asks respondents to rate their global health over the past 12 months using a visual analogue type rating scale (VAS), anchored at 0 and 100.

Hepatitis C-specific quality of life

The hepatitis quality of life questionnaire (HQLQ) is a hepatitis-specific quality of life measure administered in conjunction with the SF-36. Domains assessed include physical and social functional limitations, health distress, sleep and vitality/energy. It was validated in HCV-infected individuals [43] and has been used in a number of HCV clinical trials [44–46].

Hepatitis C knowledge

HCV knowledge was assessed using a measure developed by the study investigators to assess topics covered in the VA National Hepatitis C Resource Center presentation that is available to all veterans via the Internet or through their healthcare providers. The measure consists of 15 questions with Yes/No/Not Sure response options.

Self-efficacy

Confidence in the ability to perform HCV-related self-management activities was measured using HCV-specific self-efficacy questions adapted from other studies [47].

Energy/Fatigue

Energy/Fatigue was measured using a five-item scale adapted from the medical outcomes study [47]. The five items ask about how often symptoms of fatigue are present on average during the past month.

Depression

Depression was assessed using the Center for Epidemiologic Studies Short Depression Scale (CES-D 10) [48]. A score of 10 or greater is considered depressed. Normative data from assorted chronic illnesses are available [32].

Health distress

Health distress health-related anxiety is a common symptom in people with a chronic, potentially life-threatening illness. Health distress was measured with a four-item scale [47].

Alcohol usage

The Alcohol Usage Disorders Identification Test (AUDIT) was used to measure alcohol usage [49]. The measure is 10 questions and can be completed in 1–2 min. It is well validated and has been used extensively for many years [49–52].

Statistical analyses

Means and proportions of demographic and clinical characteristics for each group were compared with independent sample t-tests and chi-square analyses. Continuous variables were checked for violations of normality prior to t-test analysis. Equal variances were not assumed for the t-tests. Intention-to-treat analyses included repeated measures ANOVA and ANCOVA, which were used to compare differences between the two groups from baseline to the 6-week follow-up. Age and self-reported history of homelessness in the past 5 years were tested as covariates in the repeated measures ANOVA analyses. The covariates were retained in the model when significant at $P < 0.05$ level.

Based on previous studies of self-management programmes [53,54], the study was powered to have an 80% chance, with alpha of 0.05, of detecting a medium effect size of 0.25, and required 64 subjects per group or 128 total subjects after attrition.

RESULTS

Figure 1 shows the identification, enrolment and randomization of patients in the study. Of the 372 individuals who expressed interest in the study, 81 were ineligible because they were currently on, had successfully completed, or were scheduled to start antiviral treatment in the next 6 months

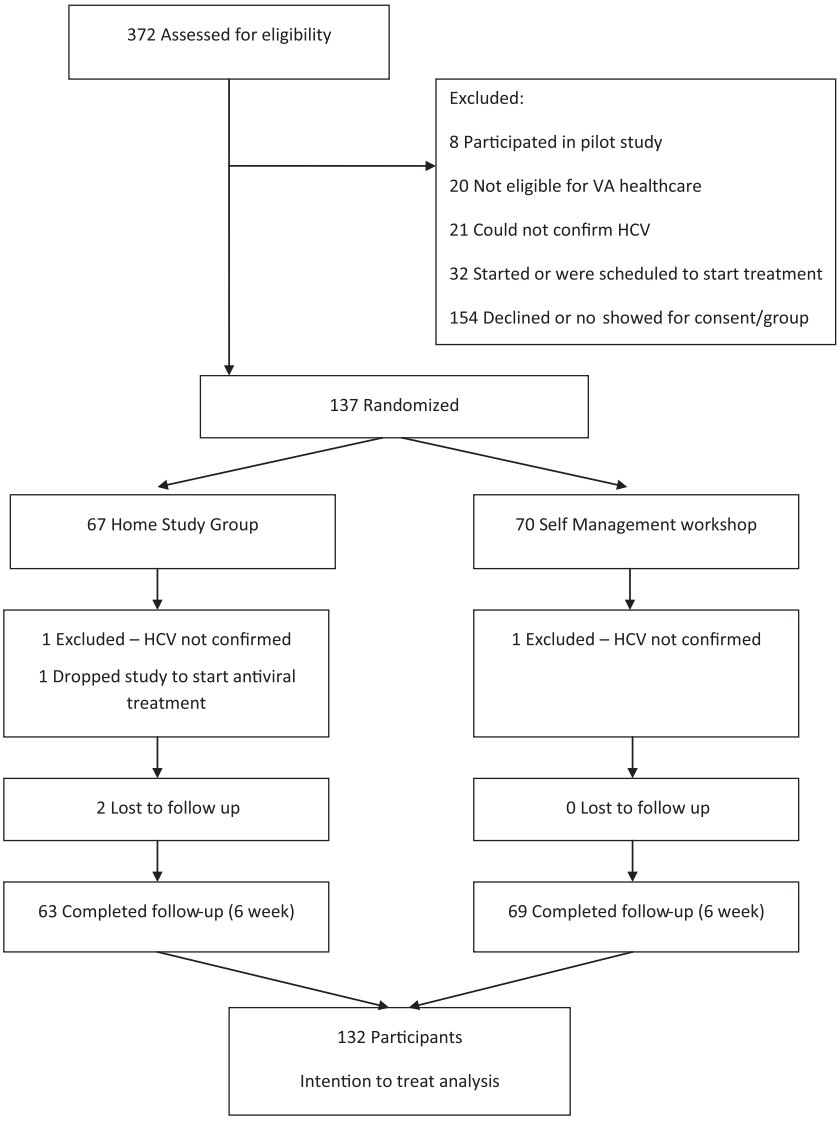

Fig. 1 Recruitment, randomization and retention flowchart.

(n = 32), were not eligible for VA healthcare (n = 20), their HCV could not be confirmed (n = 21), or had previously participated in the self-management pilot intervention (n = 8). An additional 154 individuals were initially eligible but declined enrolment when it became available. All 137 participants were recruited and consented between May 2007 and November 2008. Confirmation of HCV infection could not be produced from any source for two people, who were subsequently unenrolled. One other patient withdrew from the study and analysis. Of the remaining 134 participants, two information-only participants did not complete the 6-week follow-up assessment, leaving data on 132 participants for analysis.

Overall, the 132 participants had a mean age of 54.6, and 95% were men. Non-Hispanic white race/ethnicity was self-reported by 59% of the sample, with African Americans (24%) and Hispanics (10%) representing the next largest groups. The overall participant sample was 79% divorced, separated, or never married, 72% were disabled or unemployed, 35% never attended college, 68% relied on public transport or other people for transportation, 14% were homeless while another 36% lived in group living situations or with relatives, and 48% of the sample reported being homeless at some point in the last 5 years. The mean self-report year of contracting HCV was 1983, while mean self-report year of being diagnosed with HCV was 1997.

The two experimental groups were compared on three continuous and eight categorical variables. On average, participants in the information-only group were significantly older (t (1,130) = 3.07, P = 0.003) and more likely to be homeless in the past 5 years when compared with those randomized to the self-management programme. However, there was no difference between the two groups in the proportion that were currently homeless (See Table 1). Thus, age and self-reported history of homelessness were tested as covariates in the repeated measures ANOVA

**$P < 0.01$, *$P < 0.05$.

analyses. The covariates were retained in the model when significant at $P < 0.05$ level.

Participants randomized to HCV-SMP attended an average of 5.2 of six sessions (87%). As shown in Table 2, participants in the self-management group had better outcomes that were statistically significant at $P < 0.05$ on a number of important variables. SF-36 energy/vitality scores increased almost 5 points in the self-management workshop while the mean scores in the information-only group decreased 2.6 points ($P = 0.040$). Statistically significant differences over time were also found for HCV knowledge ($F(1,129) = 20.35$, $P < 0.001$) and HCV-related self-efficacy ($F(1,130) = 6.57$, $P = 0.011$). Trends towards greater improvements for HCV-SMP participants were found for SF-36 physical functioning, SF-36 bodily pain, health distress, depression and VAS global health. Overall, self-management workshop participants had greater improvements on 18 of the 22 variables.

DISCUSSION

Antiviral medication can eliminate HCV for some infected patients, but depending on patient and viral characteristics and treatment compliance, viral clearance for some patient subgroups is very low [12]. Furthermore, patients are very often either ineligible for treatment, refuse treatment, or are offered watchful waiting [13]. Substantial improvements in treatment success rates are expected over the next couple of years [55], but there is a need for programmes that can help patients improve HRQOL while preparing them to become treatment candidates, and increasing their chances for achieving an SVR if they are eventually treated. Despite the need for such approaches, there has been little or no research conducted with self-management programmes for patients with hepatitis C. The randomized, controlled trial described here assesses the efficacy of the hepatitis C self-management programme for improving the HRQOL and other outcomes for patients with VA living with chronic hepatitis C.

The HCV self-management programme was well attended and produced significant improvements along a number of dimensions of HRQOL and other outcomes. Improving health-related knowledge is a main goal of most self-management programmes. While increased knowledge may improve healthcare satisfaction in consumers, it is not always considered sufficient for producing changes in other health outcomes. Improved self-efficacy (confidence in one's own ability to manage one's health condition) has been conceptually linked to changes in health outcomes in the social cognitive model on which the HCV self-management programme is based [23,24,56]. Self-efficacy is thought to interact with outcome expectations and sociostructural factors in the setting of goals and performance of behaviours. Behaviours in turn affect health outcomes, but it is also hypothesized that improved self-efficacy alone can improve quality of life, by reducing anxiety or distress associated with having a chronic disease and reducing powerlessness [57].

HQLQ, hepatitis quality of life questionnaire; VAS, visual analogue type rating scale. $^{**}P < 0.01$, $^{*}P < 0.05$, $^{\dagger}P < 0.10$.

The finding that the HCV self-management intervention improved scores on the energy/vitality subscale of the SF-36 is important. Fatigue is the most commonly reported symptoms of chronic HCV infection [58,59]. Fatigue has also been implicated as one of the symptoms most likely to impact other aspects of HRQOL, such as physical, occupational and/or social functioning.

Six other outcomes showed trends towards benefit from the HCV self-management intervention. Although we ran 22 separate statistical analyses, only one outcome would be expected to be significant by chance at the $P < 0.05$ level and 2 at a $P < 0.10$ level. Thus, there is fairly strong evidence that the intervention produced significant benefit for participants, but the study may have been underpowered to detect other effects not found to be significant. Given our final sample for these analyses, the study was powered to detect medium *F*-test effects (0.25) 81% of the time. Some of the effects were smaller than 0.25, but approached clinical significance. For example, a difference of 0.030 is considered clinically significant for the QWB-SA [60], and our study produced group differences of 0.028 after just 6 weeks. Thus, our study may have benefitted from a larger sample size.

Effect sizes in the range of 0.20–0.25 and adjusted mean differences between groups for the SF-36 fatigue and physical functioning subscales of 6.7 and 6.9 respectively are similar to those found in other studies of chronic disease self-management programmes [32,61,62]. Other self-management studies have found differences on other outcome measures such pain, disability, etc., but found no differences on validated measures of HRQOL [63–65]. In fact, most self-management studies do not formally measure HRQOL at all

[66]. This literature suggests that although the differences we have found are not large, they are meaningful, and it is important to start measuring self-management outcomes with widely used HRQOL measures such as the SF-36.

Chronic disease self-management interventions have also impacted other outcomes such as reduced health care utilization and increased health behaviours [54,67]. Our intervention was not designed to reduce health care costs and encourages HCV-infected patients to be properly evaluated for antiviral treatment which can be costly. However, if participants in the self-management programme are more likely to go on to be treated, there are well-established health benefits for those that achieve an SVR. Rates of antiviral treatment and response to treatment will be forthcoming. In addition, we plan to examine the costs of conducting the self-management intervention and conduct cost-effectiveness analyses. In general, we expect that the per person cost of the intervention will be low, because the intervention is delivered in group format for 6 weeks using existing facilities with few materials required. The cost analysis of a similar 6-week self-management programme found the intervention cost approximately £101 per person [68].

Although not all outcomes improved significantly, the results are notable for a few important reasons. First, the project was successful in recruiting and retaining vulnerable veterans with few resources who have faced many life challenges, such as those with a history of substance use, homelessness and psychological disorders. Overall, participants appear to be representative of HCV-infected individuals in VA care and in the general community [12]. Thus, the intervention may be beneficial to a large majority of HCV-infected individuals, but should be studied for efficacy among nonveterans.

Second, the current results were achieved between baseline and a 6-week follow-up. Although some variables are expected to change the most directly between pre and post intervention, HRQOL outcomes combine many factors and can be hard to change in the short term with behavioural and cognitively oriented interventions. Often, behavioural interventions must be sustained for a longer period of time to achieve significant changes [69,70].

One important unanswered question considers how many HCV-infected individuals will actually attend a 6-week self-management programme. This is difficult to determine because this is the first Hepatitis C self-management programme that has been developed. However, only 34 of 373 individuals who contacted study staff to inquire about the project declined because they did not want to attend. Many others expressed interest but could not attend at the time offered. A study of an asthma self-management programme examined the 'reach' of their programme and found that 474 of the 1303 in the target population with asthma actually enrolled in the programme [71]. This suggests that a sizable portion of the HCV-infected population who have not been successfully treated may be receptive to this type of intervention. However, more translational research is needed to more fully answer this question.

It is important to note that the intervention is not designed for patients who are receiving antiviral treatment. Although they comprise a minority of all HCV-infected patients, patients on medication must cope with a variety of difficult side effects and manage their medications carefully. Thus, they may need even more supportive resources because antiviral treatment poses unique challenges, but patients on antiviral treatment are also usually higher functioning on average than those who are ineligible for treatment. In general, more healthcare resources are devoted to helping patients receiving antiviral treatment, which highlights the need for interventions like the HCV-SMP, which serve those who are not on antiviral treatment. Conceivably, the current programme could be extended to patients on antiviral therapy, but efficacy would need to be tested with patients on antiviral treatment.

Study enrolment was limited to patients with VA with hepatitis C, so our conclusions may not generalize well beyond the VA system. However, similar self-management programmes addressing other diseases have been studied extensively in nonveteran samples and have regularly produced good results. The intervention will be studied in nonveteran samples in the future.

A possible limitation of the study is that eligibility for the study and the intervention itself required participants to attend six self-management sessions at a large medical centre. Classes were typically held on weekday afternoons because that was the time when most individuals were available. This excluded people who could not attend during these times, or those who lived in distant areas. Thus, it may be helpful to explore options for greater time flexibility and delivering this type of intervention to remote sites using medical informatics.

In conclusion, the hepatitis C self-management programme produced a number of important health benefits among patients with VA with chronic hepatitis C infection. There are few, if any, interventions available for HCV-infected individuals who have failed, or are not immediate candidates for antiviral therapy and this group makes up almost three quarters of all HCV-infected persons. The programme is broad and may impact general health and other co-morbid disorders instead of just HCV itself. Planned research will examine longer term outcomes and clinical outcomes and costs. If successful, the intervention is a model for larger scale implementation in the VA and other systems with large numbers of disadvantaged HCV-infected patients.

ACKNOWLEDGEMENTS

This study is funded by a research grant from the VA HSR&D, Project # IAC 05-067. This project is registered at clinical Trails.gov, registration # NCT00328042.

Potential Underuse, Overuse, and Inappropriate Use of Antidepressants in Older Veteran Nursing Home Residents

Joseph T. Hanlon, PharmD, MS,[abcdef] Xiaoqiang Wang, MS,[b] Nicholas G. Castle, PhD,[g] Roslyn A. Stone, PhD,[bh] Steven M. Handler, MD, PhD,[abcd] Todd P. Semla, PharmD, MS,[ijk] Mary Jo Pugh, PhD,[l] Dan R. Berlowitz, MD, MPH,[m] and Maurice W. Dysken, MD[n]

OBJECTIVES: To examine prevalence and resident- and site-level factors associated with potential underuse, overuse, and inappropriate use of antidepressants in older Veterans Affairs (VA) Community Living Center (CLC) residents.

DESIGN: Longitudinal study.

SETTING: One hundred thirty-three VA CLCs.

PARTICIPANTS: Three thousand six hundred ninety-two veterans aged 65 and older admitted between January 1, 2004, and June 3, 2005, with long stays (≥90 days).

MEASUREMENTS: Prevalence of potential underuse, inappropriate use, and overuse of antidepressants in residents with and without depression (as documented according to *International Classification of Diseases, Ninth Revision*, Clinical Modification, codes or Depression Rating Scale).

RESULTS: Selective serotonin reuptake inhibitors were the most commonly prescribed antidepressant. Of the 877 residents with depression, 25.4% did not receive an antidepressant, suggesting potential underuse. Of residents with depression who received antidepressants, 57.5% had potential inappropriate use due primarily to problems seen with drug–drug and drug–disease interactions. Of the 2,815 residents who did not have depression, 1,190 (42.3%) were prescribed one or more antidepressants; only 48 (4.0%) of these had a Food and Drug Administration–approved labeled indication, suggesting potential overuse. Overall, only 17.6% of antidepressant use was appropriate (324/1,844). The only consistent resident factor associated with potential underuse and overuse use was taking an antipsychotic without evidence of schizophrenia (underuse: adjusted relative risk ratio (ARRR) = 0.56, 95% confidence interval (CI) = 0.33–0.94; overuse: adjusted odds ratio = 1.52, 95% CI = 1.21–1.91). Having moderate to severe pain (ARRR = 1.54, 95% CI = 1.08–2.20) and the prescribing of an anxiolytic or hypnotic (ARRR = 1.33, 95% CI = 1.02–1.74) increased the risk of potential inappropriate antidepressant use.

CONCLUSION: Potential problems with the use of antidepressants were frequently observed in older U.S. veteran CLC residents. Future studies are needed to examine the true risks and benefits of antidepressant use in CLC and non-VA nursing homes. **J Am Geriatr Soc 59:1412–1420, 2011.**

Key words: aged; nursing homes; depression; pharmacoepidemiology

Depression is common in older nursing home residents.[1] One seminal study reported a 12% prevalence rate for major depression using the American Psychiatric Association *Diagnostic and Statistical Manual of Psychiatric Disorders, Third Edition, Revised* (DSM-III-R) criteria in older residents in a 1,100-bed nursing home.[2,3] Minor, subsyndromal, or subthreshold depression was seen in an additional 30% of these older nursing home residents.[3] In contrast, a more-recent national study of nursing homes found that only 20% of older residents had a diagnosis of

depression indicated in their quarterly Minimum Data Set (MDS) assessment.[4] Depression is important to treat in older nursing home residents and is commonly associated with morbidity (e.g., hospitalization, functional status decline) and mortality.[1]

Depression in nursing homes can be treated with one or a combination of the following modes of treatment: electroconvulsive therapy, psychological or psychiatric intervention, and antidepressant therapy.[1] Antidepressant therapy is the most common treatment in nursing home residents.[1] Moreover, the prevalence of antidepressant use in U.S. nursing home residents has more than doubled—from 21.9% in 1996 to 47.5% in 2006.[5] This prevalence rate of 47.5% is consistent with the national rate of antidepressant use in Veterans Affairs (VA) Community Living Centers (CLCs).[6] Despite these high rates, data are conflicting regarding possible undertreatment of depression in nursing home residents. Recent national information shows that fewer than 5% of nursing home residents with symptoms of depression determined through the quarterly MDS assessments were not treated with an antidepressant.[7] In contrast, a 2000 study of Ohio nursing home residents found that 23% of those with a depression diagnosis did not receive an antidepressant.[8] Concomitantly, there is limited information that suggests that potential overuse and inappropriate use of antidepressants may be problematic in older nursing home residents.[9,10] Given this background, the objectives of this study were to estimate the prevalence and resident- and site-level factors associated with potential underuse, inappropriate use, and overuse of antidepressants in older VA CLC residents.

METHODS

Study Design, Setting, Data Sources, and Sample

This was a longitudinal study of 3,692 long-stay (≥90 days) residents aged 65 and older admitted to any one of the 133 VA CLCs located in the United States between January 1, 2004, and June 30, 2005. The mission of these CLCs (previously called Nursing Home Care Units) is to provide compassionate care to eligible veterans with sufficient functional impairment to require this level of service. Veterans with chronic stable conditions, including dementia, those requiring rehabilitation or short-term specialized services such as respite or intravenous therapy, and those who need inpatient hospice, can receive this type of care in VA CLCs. These CLCs are located in 21 regions across the United States called Veterans Integrated Services Networks (VISNs). The development of a merged database that included Minimum Data Set (MDS) and medication dispensing information from the Pharmacy Benefits Management Services (PBM) used for this study was recently described.[6] Briefly, CLC staff evaluated all veterans receiving care in a VA CLC using the MDS version 2.0. MDS 2.0 is a reliable standardized tool to identify the functional, psychological, and health status needs of residents and to evaluate the quality of care that these residents are receiving.[11] All MDS data were collected through resident interviews, staff interviews, and reviews of medical records. For all CLC residents, the MDS was completed at admission (within 14 days of admission), quarterly thereafter (within 90 days of previous evaluation), and at the time of any significant change in status (e.g., major change in cognitive function or functional status decline). The VA PBM provided all prescription data for the defined study cohort. These data included the start date, drug name, drug strength, dosage form, directions for use, VA therapeutic class, and amount of each drug dispensed. *International Classification of Diseases, Ninth Revision*, Clinical Modification (ICD-9-CM) codes for inpatient and outpatient diagnoses in the previous year from the VA National Patient Care Database (NPCD) records were also linked to the merged database mentioned previously. This final merged database, which was prepared using encrypted identifiers that were consistent across the three individual databases, was used to conduct the present analyses.

The sample was first stratified according to depression status determined according to ICD-9 codes. Specifically, any hospitalization or outpatient visit to a VA in the previous year during with depression was addressed was identified and noted using ICD-9-CM codes (296.2, 296.3, 298.0x, 300.4x, 309.1x, 311.xx, 301.12, 309.0x).[12,13] This approach was chosen because it was used in two previous VA studies examining the quality of depression care in outpatients and because a previous study using ICD-9 codes to identify depression found acceptable specificity (88%) but lower sensitivity (52%).[12–14] Thus, although this approach may underestimate the "true rate" of depression, it is likely to be more accurate than using just the listing of depression on a resident's problem list or in Section I of the MDS, entitled "Disease Diagnoses."[11] To ensure that those who did not have VA health service utilization in the previous year were not misclassified and to improve sensitivity, those with a high likelihood of depression on admission (MDS Depression Rating Scale (DRS) score >3)[15] were also included. The DRS is a summary of seven symptoms detected by nursing home staff that capture verbal and nonverbal indicators of depressed mood and has been shown to be a reliable (sensitivity, 91% and specificity, 69% with a psychiatrist diagnosis) and valid measure of depression in nursing home residents.[15] Eight hundred seventy-seven residents were included in the depression sample (796 according to ICD-9 codes and 181 according to DRS >3 only); the remaining 2,815 had no documented depression. The Pittsburgh VA institutional review board and research and development committees approved this study.

Main Outcome Measures

Antidepressants on the VA national formulary in 2004/05 (VA Classes CN601, CN609, CN802) included those in the following four discrete groups: tricyclic antidepressants (TCAs; amitriptyline, desipramine, doxepin, nortriptyline), selective serotonin reuptake inhibitors (SSRIs; paroxetine, sertraline, fluoxetine, citalopram), serotonin-norepinephrine reuptake inhibitors (SNRIs; venlafaxine), and other antidepressants (trazodone, mirtazapine, methylphenidate, bupropion). Methylphenidate was included because it is frequently used to treat depression in older adults.

To operationally define potential underuse and inappropriate use of antidepressants in the depression group, two specific authoritative sources were consulted: a guideline from the American Medical Directors Association (AMDA) and quality-of-care indicators from the Centers

for Medicare and Medicaid Services (CMS) for appropriate use of antidepressants for treating depression in nursing homes.[16,17] The Veterans Health Administration and Department of Defense (VHA/DOD) guideline for treating adults with depression and another from England that focused on treating older adults with depression in the primary care setting were also used.[18,19] Using a previously published and validated approach, explicit criteria for potentially inappropriate use were created that an expert panel consisting of a nurse pharmacoepidemiology researcher (MJP), a geriatric clinical pharmacist (TPS), two geriatricians (SMH, DRB), and a geriatric psychiatrist–psychopharmacologist (MWD) reviewed, edited, and agreed upon.[20] Potential inappropriate use in those in the depression group was ascertained by applying these explicit criteria to determine whether there were one or more problems in five specific quality areas: selection (e.g., choosing an antidepressant such as amitriptyline that has anticholinergic or orthostatic effects), maintenance dosage exceeding or below minimum effective dosage (e.g., highest daily dose during the 90-day period to account for the time needed to "start low and go slow" or titrate new antidepressants), clinically important drug–drug interactions; clinically important drug–disease interactions, and therapeutic duplication (use of $\geq$2 TCAs, SSRIs, or SNRIs concomitantly) (Appendix I). The lack of an order for an antidepressant during the 90-day follow-up period indicated potential underuse in the group with depression. The rationale for this operational definition is that many experts recommend antidepressant treatment for a period of time ranging from 1 to 3 years to reduce the likelihood of major depression reoccurrence and relapse in older residents with depression.[17,18] All persons in the group with depression taking an antidepressant that was not considered potentially inappropriate were included in the appropriate use category.

To operationally define potential overuse in those without depression, two specific authoritative sources were consulted: a joint statement of the members of the Long Term Care Professional Leadership Council (LTCPLC) and the Food and Drug Administration (FDA) Web site.[21,22] Potential overuse of antidepressant use in residents without depression was operationally defined as lack of a FDA-approved labeled indication. (See footnote of Table 2 for further details.)[21,22] ICD-9 codes were used to determine these indications using previously established methods.[23] Appropriate use of antidepressants in participants without depression was defined as any use not deemed to be overuse.

Independent Variables

Based on previous literature, the independent variables included demographic characteristics, health status factors, and psychiatric or neurological problems.[10,23,24] Using data from the admission MDS, categorical variables were created for age (65–74, 75–84, $\geq$85), race (black, white, or other), sex (male or female), and educational level ($<$high school, high school, $>$high school).

Regarding health status factors, a continuous variable for activity of daily living (ADL) dependencies was created from the admission MDS that had a range from 0 to 20 points and identified the amount of assistance needed from staff for five activities (bathing, dressing, grooming, toileting, and eating).[25] A continuous variable was created for the Charlson Comorbidity Index based on the methods of Deyo, which creates a score (range 0–34) calculated based on the presence of 18 chronic conditions documented in the electronic medical record using ICD-9 codes.[26,27] The number of prescribed drugs at admission was also quantified (excluding those specified below), and a dichotomous variable for physical restraint use was created as noted on the MDS. In addition, dichotomous variables for individual conditions noted on the admission MDS were examined (cancer, chronic obstructive pulmonary disease, diabetes mellitus, arteriosclerotic heart disease, arthritis, hip fracture history, hypertension, and osteoporosis).

Psychiatric and neurological problem variables were created using ICD-9 codes from VA hospitalizations or outpatient visits in the previous year. Specifically, dichotomous variables were created for cerebrovascular accident (CVA); seizure disorder; Parkinson's disease; any neuropathic pain; bipolar disease; posttraumatic stress disorder (PTSD); other anxiety disorder; and Alzheimer's, vascular, or other dementia.[27] Data from the admission MDS evaluation were also used to create a dichotomous variable for behavioral problems and moderate to severe pain and a categorical variable for cognitive function (Cognitive Performance Score (CPS): intact, mild to moderate, severe).[28,29] Finally, from PBM data, a dichotomous variable was created denoting use of individual medication classes (antipsychotics (CN701 and 709) in residents without schizophrenia, anxiolytics and hypnotics (CN302 and 309), acetylcholinesterase inhibitors (ACHEIs) and memantine (CN900)). Two dichotomous variables (bed size and geographic region) were also included to control for potentially confounding site factors.[5]

Statistical Analyses

Descriptive statistics were used to summarize independent variables and study outcomes. To include the approximately 3% of residents with missing data on education or cognitive performance status in the analyses, dummy variables were created for a "missing" category. The number and percentage of residents who were prescribed individual classes of antidepressants (TCAs, SSRIs, SNRIs, other) was described. In those with depression, the number and percentage of residents with specific types of potentially inappropriate antidepressant use were also described. A multinomial regression analysis was conducted to identify resident factors associated with underuse or inappropriate use versus appropriate use (reference group) of antidepressants in residents with depression. A backward selection approach (alpha = 0.10) was used to identify health status factors and psychiatric and neurological conditions to be added to the demographic characteristics and resident site factors in the final models. Estimated adjusted relative risk ratios (RRRs) and 95% confidence intervals (CIs) adjusted for clustering according to CLC are reported. Multiparameter Wald tests quantified the association between each outcome and the categorical variables with more than two levels. A multivariable logistic regression analysis in residents without depression was also conducted by first removing from the sample those with a FDA-approved labeled indication ("appropriate use") and the overuse

group was compared with those with no use of antidepressants.[30] Statistical analyses were performed using SAS, version 9 (SAS Institute, Inc., Cary, NC) and Stata (StataCorp, College Station, TX).

RESULTS

Table 1 compares the characteristics of CLC residents who were depressed (n = 877) with the characteristics of those who were not (n = 2,815). The groups were similar with regard to most characteristics. White residents and those with more comorbidities were more likely to be depressed than not. Those who were not depressed had more ADL dependencies and more-severe cognitive impairment than those who were depressed. The most common medication class that those without schizophrenia in both groups were taking was antipsychotics.

Table 2 summarizes antidepressant use overall and according to specific classes for residents with and without depression. The most common antidepressant class used by both groups was SSRIs. No use of monoamine oxidase inhibitors (MAOIs) was documented. Of the 877 residents with depression, 74.6% (n = 654) took an antidepressant, which suggests potential underuse in 25.4% (n = 223) of these residents. Of residents without depression, 42.3% took an antidepressant, which suggests potential overuse, because only 48 of these 1,190 taking an antidepressant had evidence of a FDA-approved labeled indication. Thus, only 4.0% of antidepressant use in those without depression was appropriate.

Table 3 summarizes potential inappropriate drug use in residents with depression. Nearly six in 10 residents with depression (n = 378) who received an antidepressant had one or more prescribing problems. Thus, appropriate antidepressant use was seen in 276 of 654 (42.5%). Drug–drug and drug–disease interactions were the most common problems, whereas therapeutic duplication and selection were the least frequent prescribing problems. By combining appropriate use regardless of depression group (48+276/1,190+654 = 17.6%), fewer than two in 10 antidepressant prescriptions were not problematic.

Table 4 summarizes the results of the multivariable multinomial logistic regression models for potential underuse and inappropriate use of antidepressant versus appropriate use in those who were depressed. Factors significantly associated with a lower risk of potential underuse in residents with depression included polypharmacy (taking >5 medications), having a history of cancer, and taking an antipsychotic without evidence of schizophrenia; the only factor associated with a greater risk of potential underuse was having ADL dependencies. Regarding potential inappropriate use, black residents and residents with cancer were significantly less likely to have this problem. Residents with moderate to severe pain and those taking an anxiolytic or hypnotic were at significantly greater risk of inappropriate use than appropriate use.

Table 5 summarizes the results of the multivariable logistic regression models for potential overuse versus no antidepressant use in residents who were not depressed. Residents aged 85 and older had a significantly lower risk of overuse, and the risk of overuse decreased with increasing comorbidity index score. Overuse was significantly more

Any problem	378 (43.1)	

* Sums to more than 43.1% because some residents had more than one type of problem.

SSRI = selective serotonin reuptake inhibitor.

DISCUSSION

In this study, nearly 50% of all older long-stay veteran nursing home residents received an antidepressant, which is consistent with the rate of nearly 48% of non-VA nursing home residents taking an antidepressant.[6] That depression was found in nearly 25% of residents is also consistent with previously published studies,[3,10] although it was found that nearly 25% of those with depression did not receive an antidepressant, suggesting potential underuse. This rate is considerably less than the 45% of nursing home residents with MDS-reported depression who were not being given an antidepressant in a multistate U.S. sample,[10] but it is consistent with the rates from more-recent studies that show that between 21% and 34% of nursing home residents with depression do not receive an antidepressant.[8,31] The multivariable analyses of factors associated with underuse of antidepressants suggest that prescribers may be more cautious in residents with greater ADL dependencies. This may reflect appropriate concern that the likelihood of antidepressant adverse effects is greater than the potential benefits in these vulnerable people. It is hoped that better detection and monitoring of depression using the valid, reliable, and frequently used nine-item Patient Health Questionnaire, which is replacing the DRS in MDS version 3.0 and is scheduled to be implemented in non-VA nursing homes in the fall of 2010 and VA CLCs in 2011, will further reduce the rate of antidepressant underuse.[32]

Of persons who were depressed and receiving an antidepressant, nearly 60% had evidence of potentially inappropriate use, with one or more prescribing problems. The least-frequent problems were therapeutic duplication and selection. Medication selection was potentially

problematic primarily because TCAs are notorious for causing orthostatic hypotension and having both of anticholinergic effects, which can increase the risk of falls and cognitive impairment in older adults.[16–18] Under- and overdosing problems were seen in nearly 9% of residents with depression. Underdosing was most common with sertraline, trazodone, and venlafaxine. Trazodone may have been misclassified as underdosed because it may have been prescribed to manage sleep and weight loss, despite little evidence-based data to support these indications.[33] Drug–drug interactions were seen in one in four antidepressant users who were depressed. The most common drug–drug interactions were the use of multiple drugs that increase

serotonin (and thus increase the risk of serotonin syndrome); this would include the use of multiple antidepressants regardless of therapeutic intent.[34] The next most common drug–drug interactions involved the use of paroxetine, fluoxetine, or bupropion, which are potent inhibitors of CY2D6 hepatic enzymes, in combination with important substrate drugs such as metoprolol and other antidepressants (TCAs, venlafaxine), which could result in preventable adverse drug events.[35] Drug–disease interactions were just as common in this resident group and frequently involved the prescribing of antidepressants in residents with a history of a fall. The risk of falls with SSRIs is the same as that with TCAs.[36] The only potentially modifiable risk factors associated with potential inappropriate prescribing of antidepressants in this study were residents with moderate to severe pain and the prescribing of an anxiolytic or hypnotic.

To the best of the knowledge of the authors, this is one of the first studies to examine potential overuse of antidepressants in nursing home residents. In residents without depression, only a small number (48/1,190) had a FDA-approved labeled indication for the antidepressants. One explanation is that a recent study showed that U.S. physicians have limited knowledge of which indications are FDA approved versus being off-label.[37] Of potential concern is the recent report that five antidepressants are among the top 25 drugs used off label with inadequate efficacy evidence.[38] One factor associated with potential overuse was anxiety, for which there is evidence that specific antidepressants classes (and not just individual agents) may be effective; this use is supported by various nursing home organizations.[21] Finally, coprescribing of antipsychotics (in residents without schizophrenia) was associated with greater risk of antidepressant overuse.

So what are the implications of these results? One is that that there are prescribing quality problems involving antidepressants that clinicians should be aware of in VA CLCs. It is likely that similar prescribing problems are also occurring at similar levels in non-VA nursing homes given their equally high rates of antidepressant use.[5] What is not clear is the effect that this antidepressant prescribing quality has on nursing home resident outcomes. Nonetheless, it is clinically sensible to consider ways to address this quality prescribing problem. Three recently published articles describe successful approaches used in randomized controlled trials (academic detailing, pharmacist interventions, multidisciplinary teamwork, computerized decision support systems) to improve prescribing of psychotropic medications for nursing home residents,[39–41] although none of these studies examined changing the quality of antidepressant prescribing. In part to address this concern, the VA is launching a variety of initiatives, including increasing the availability and integration of psychology and psychiatric services in CLCs and increasing staff education. Similar initiatives in non-VA nursing homes will be also be necessary to address the stigma associated with diagnosing and treating psychiatric problems in nursing homes and historically low reimbursement rates for nonpsychiatrist providers.

This study has a number of potential limitations. There is potential misclassification because an independent research psychiatrist did not diagnose depression. Instead, those with depression were classified according to ICD-9 codes or severe depressive symptoms based on MDS data. Examining alternative classifications of depression, including shortening the lookback period for ICD-9 codes to 6 months and using the listing of depression in the MDS, did not substantially change the depression sample. The application of explicit criteria to evaluate the quality of prescribing is limited because they cannot take into account individual resident characteristics. In addition, the rate of potential underuse may be somewhat inflated because residents may have been receiving effective nonpharmacological treatment that this and other studies did not capture. Some explicit guideline criteria published in 2006 or later were also applied to data from 2004/05, which does not allow for prior dissemination of this information to providers. Finally, it is unclear what the generalizability of the current findings are to non-VA nursing home settings, given that the majority of their residents are older women and that the use of some antidepressant medications may be different in VA because of their use of a national formulary.

Despite these potential limitations, potential problems with the use of antidepressants were observed frequently in older U.S. veteran nursing home residents. Future studies are needed to examine the true risks and benefits of antidepressant use in nursing homes.

ACKNOWLEDGMENTS

Conflict of Interest: This study was supported by National Institute of Aging Grants P30AG024827, T32 AG021885, K07AG033174, R01AG034056, R56AG027017, and 3U01 AG012553; National Institute of Mental Health Grant R34 MH082682; National Institute of Nursing Research Grant R01 NR010135; Agency for Healthcare Research and Quality Grants R01 HS017695, R01 HS018721, and K12 HS019461; and VA Health Services Research Grant IIR-06-062.

Author Contributions: Dr. Hanlon conceived of and designed the study, acquired the data, supervised the analyses and interpretation of the data, and drafted the initial manuscript. Mr. Wang performed the analyses and assisted in the interpretation of data and preparation of the manuscript. Dr. Castle served as an expert on the creation and use of MDS scales as important covariates; contributed to the design, analyses, and interpretation of data for this study; and assisted in preparing the manuscript. Drs. Handler, Semla, Pugh, Berlowitz, and Dysken served on the expert panel that created the explicit criteria for evaluating potentially inappropriate antidepressant use, and all contributed to the design, analyses, and interpretation of data for this study and assisted in preparing the manuscript. Dr. Stone assisted in the development of the study design and analytical plan, oversaw the statistical analyses performed by Mr. Wang, contributed to the interpretation of data for this study, and assisted in preparing the manuscript.

Sponsor's Role: The organizations that funded this study had no role in the design, methods, analysis, or preparation of this paper.

APPENDIX I

Table A1. Explicit Criteria for Antidepressant Use in Older Nursing Home Residents

Class and Agent	Selection	Minimum/Maximum Daily Dosage (mg/d)	Drug–Drug Interaction to Avoid	Drug–Disease Interactions*	Therapeutic Duplication
Miscellaneous antidepressant					
Bupropion	Recommended	150–300	CYP2D6 substrates[†]	Seizure disorder	NA
Mirtazapine	Recommended	15–45 (30 if estimated creatinine clearance <30 mL/min)	Clonidine, other drugs that ↑ serotonin[‡]	None	NA
Trazodone	Recommended	25–150	Other drugs that ↑ serotonin[‡]	None	NA
Methylphenidate	Recommended	5–20	Monoamine oxidase inhibitors	Hypertension, seizure disorder, arrhythmia, long QT interval	Other amphetamines and modafinil
Serotonin-norepinephrine reuptake inhibitor					
Venlafaxine	Recommended	50–225	Other drugs that ↑ serotonin[‡]	Hypertension	NA
SSRI					
Citalopram	Recommended	10–40	Other drugs that ↑ serotonin[‡]	Falls	Concurrent SSRI
Fluoxetine	Recommended	10–40	CYP2D6 substrates,[†] other drugs that ↑ serotonin,[‡] phenytoin	Falls	Concurrent SSRI
Paroxetine	Recommended	10–40	Anticholinergics,[‡] CYP2D6 substrates,[†] other drugs that ↑ serotonin[‡]	Falls	Concurrent SSRI
Sertraline	Recommended	50–200	Other drugs that ↑ serotonin[‡]	Falls	Concurrent SSRI
TCA					
Amitriptyline	Not recommended[1]	10–75	Anticholinergic,[§] bupropion, clonidine, other drugs that ↑ serotonin[‡]	Benign prostatic hypertrophy, constipation, dementia, falls, heart block, orthostatic hypotension	Concurrent TCA
Desipramine	Recommended	10–75	Anticholinergic,[§] bupropion, clonidine, other drugs that ↑ serotonin[‡]	Benign prostatic hypertrophy, constipation, dementia, falls, heart block, orthostatic hypotension	Concurrent TCA
Doxepin	Not recommended	10–75	Anticholinergic,[§] bupropion, clonidine, other drugs that ↑ serotonin[‡]	Benign prostatic hypertrophy, constipation, dementia, falls, heart block, orthostatic hypotension	Concurrent TCA
Nortriptyline	Recommended	10–75	Anticholinergic,[§] bupropion, clonidine, other drugs that ↑ serotonin[‡]	Benign prostatic hypertrophy, constipation, dementia, falls, heart block, orthostatic hypotension	Concurrent TCA

* Diseases were determined from admission Minimum Data Set (version 2.0) assessments and through the use of specific *International Classification of Diseases, Ninth Revision*, codes. Although this approach may not be highly sensitive, it is likely to be highly specific.

† CYP2D6 substrates (metoprolol, tricyclic antidepressants, venlafaxine).

‡ Other nonantidepressant drugs that increase serotonin that in combination with specific antidepressants increase the risk of serotonin syndrome (buspirone, dextromethorphan, meperidine, sumatriptan, tramadol).

§ Nonantidepressant drugs with anticholinergic activities included antiarrhythmic (disopyramide), anti-emetic and anti-vertigo (meclizine, prochlorperazine), antiparkinsonian (trihexyphenidyl), antipsychotic (all conventional antipsychotics, olanzapine, quetiapine), antispasmodic (e.g., belladonna, oxybutynin), cold and allergy drug (e.g., hydroxyzine and other first-generation antihistamines), sleep aid (diphenhydramine), and skeletal muscle relaxant (cyclobenzaprine and methocarbamol).

SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant.

Relation between Sex Hormone Concentrations, Peripheral Arterial Disease, and Change in Ankle-Brachial Index: Findings from the Framingham Heart Study

Robin Haring, Thomas G. Travison, Shalender Bhasin, Ramachandran S. Vasan, Henri Wallaschofski, Maithili N. Davda, Andrea Coviello,* and Joanne M. Murabito*

Preventive Medicine and Epidemiology Section (R.H., R.S.V., A.C.); Sections of Endocrinology, Diabetes, and Nutrition (T.G.T., S.B., M.N.D., A.C.) and General Internal Medicine (J.M.M.); and Department of Biostatistics (T.G.T.), Boston University School of Public Health, Boston University School of Medicine, Boston, Massachusetts 02118; Institute of Clinical Chemistry and Laboratory Medicine (R.H., H.W.), University of Greifswald, 17475 Greifswald, Germany; and National Heart, Lung, and Blood Institute's Framingham Heart Study (R.S.V., J.M.M.), Framingham, Massachusetts 01701

Objective: Our objective was to investigate cross-sectional and longitudinal associations of sex hormone concentrations with ankle-brachial index (ABI) and peripheral arterial disease (PAD).

Methods and Results: We used data from 3034 (1612 women) participants of the Framingham Heart Study. ABI was measured and PAD defined as ABI below 0.90, intermittent claudication, or lower extremity revascularization. Sex hormone concentrations were measured by liquid chromatography-tandem mass spectrometry [total testosterone (T), total estradiol, and estrone], immunofluorometric assay (SHBG), or calculated (free T). Sex-specific multivariable linear and logistic regression models were conducted for each sex hormone separately. Cross-sectional multivariable analyses revealed that men with lower free T and higher estrone (E1) concentrations had a significantly lower ABI [for free T, lowest *vs.* higher quartiles, $\beta = -0.02$, with 95% confidence interval (CI) $= -0.04$ to -0.001; and for E1, highest *vs.* lower quartiles, $\beta = -0.02$, with 95% CI $= -0.04$ to -0.002, respectively). Lower total T and SHBG concentrations were also associated with prevalent PAD in age-adjusted [odds ratio (OR) = 2.24, 95% CI = 1.17–4.32; and OR = 2.06; 95% CI = 1.07–3.96, lowest *vs.* highest quartile, respectively), but not in multivariable logistic regression models. Longitudinal multivariable analyses showed an association of lower SHBG with ABI change (decline ≥ 0.15; n = 69) in men [OR for SHBG quartiles 1, 2, and 3 as compared with quartile 4 were 2.56 (95% CI = 1.01–6.45), 2.28 (95% CI = 0.98–5.32), and 2.93 (95% CI = 1.31–6.52), respectively]. In women, none of the investigated associations yielded statistically significant estimates.

Conclusion: Our investigation of a middle-aged community-based sample suggests that sex hormone concentrations in men but not in women may be associated with PAD and ABI change. **(*J Clin Endocrinol Metab* 96: 3724–3732, 2011)**

Peripheral artery disease (PAD) is one of the most common manifestations of atherosclerosis, affecting about 27 million individuals in Europe and North America (1). PAD is a powerful and independent risk factor of cardiovascular morbidity and mortality (2–4). As an early indicator of PAD, a low ankle-brachial index (ABI) has also been associated with increased risk of subsequent cardiovascular disease (CVD) and mortality (5). Several pro-

* A.C. and J.M.M. contributed equally.

Abbreviations: ABI, Ankle-brachial index; CI, confidence interval; CV, coefficient of variation; CVD, cardiovascular disease; E1, estrone; E2, estradiol; FHS, Framingham Heart Study; IC, intermittent claudication; LC-MS/MS, liquid chromatography-tandem mass spectrometry; OR, odds ratio; PAD, peripheral arterial disease; TT, total testosterone.

spective investigations have shown that low total testosterone (TT) concentrations in men were associated with a less favorable cardiovascular risk profile including obesity (6), incident metabolic syndrome (7), diabetes mellitus (8), dyslipidemia (9), hypertension (10), and mortality (11). In women, previous studies of the relation between T, SHBG, and CVD have yielded conflicting results (12). However, most studies in women suggest that higher T and lower SHBG concentrations are associated with an adverse CVD risk factor profile including visceral fat accumulation (13), insulin resistance, adverse lipid profiles (14), diabetes (15), subclinical atherosclerosis (16–18), and increased risk of incident CVD (19, 20).

Given the suggested associations of sex hormones, ABI, and PAD with cardiovascular risk factors, morbidity, and mortality, it is intriguing that data relating circulating sex hormone concentrations to ABI and PAD are very limited. To date, there is only one cross-sectional study in elderly men reporting a positive correlation between low free T concentrations and prevalent PAD (21). However, cross-sectional studies are limited in their ability to assess causality, and therefore, no directionality for the observed association can be inferred from these studies. Thus, evidence for a prospective association of sex hormones with PAD is lacking to date. Accordingly, we investigated the cross-sectional and longitudinal associations of circulating sex hormone concentrations with ABI and PAD in the community-based Framingham Heart Study (FHS) Offspring cohort.

Subjects and Methods

Study population

The FHS Offspring Study was initiated in 1971 to examine 5124 adult children (and offspring spouses) of the original FHS cohort approximately every 4–8 yr (22). Written informed consent was obtained at each examination, and the Institutional Review Board of the Boston University Medical Center approved the examination content. From the 3334 FHS participants participating in in-person clinical evaluations at the seventh Offspring examination cycle (1998–2001), we excluded individuals missing sex hormone data due to insufficient stored serum (n = 176), missing ABI at examination 7 (n = 83), or with ABI higher than 1.40 at examination 7 (n = 15); men reporting use of medications that could influence sex hormones, such as leuprolide for prostate cancer or T replacement (n = 4); and women taking oral contraceptives (n = 19) or for whom menopause status was indeterminate at examination 7 (n = 3). Due to their large proportion (31.6%), postmenopausal women on hormone therapy were not excluded, and we performed subsidiary analyses that included this subgroup. Our final study population comprised 1422 men and 1612 women; of these individuals, 2473 had ABI measured at examination 8 (2005–2008) and were eligible for longitudinal analyses of ABI change between the two examinations (Fig. 1).

FIG. 1. Study population flow chart indicating the number of subjects and exclusions separately for men and women. FT, Free T; HT, hormone therapy; OC, oral contraceptive.

Sex hormone measurements

Serum samples were drawn from the antecubital vein in the supine position between 0800 and 0900 h, after an overnight fast of about 10 h. The samples were aliquoted and immediately stored at −80 C and remained frozen until the time of assay. TT, total estradiol (E2), and estrone (E1) concentrations were measured by liquid chromatography-tandem mass spectrometry (LC-MS/MS) as previously described (23, 24). As part of the Centers for Disease Control's Testosterone Assay Harmonization Initiative, quality control samples were run for TT after each batch of 200 study samples. In addition, 28 serum samples from men and women with TT concentrations across the entire male

TABLE 1. Baseline characteristics of the study population

Variable	Men (n = 1422)	Premenopausal women (n = 217)	Postmenopausal women (+ HT) (n = 510)	Postmenopausal women (− HT) (n = 885)

Diabetes	191 (13.5%)	7 (3.2%)	29 (5.7%)	99 (11.2%)
CVD	218 (15.3%)	3 (1.4%)	34 (6.7%)	77 (8.7%)

Data are absolute number (percentages) or mean ± SD. To convert the values of TT from nanomoles per liter to nanograms per deciliter, multiply by 28.82. To convert the values for free T to picograms per milliliter, divide by 3.467. To convert estradiol and estrone from picomoles per liter to picograms per milliliter, divide the estradiol value by 3.671 and the estrone value by 3.699. Clinical PAD was defined as a composite outcome including an ABI lower than 0.90, IC, or lower extremity revascularization. HDL, High-density lipoprotein cholesterol; HT, hormone therapy.

and female range were measured in a blinded manner in the Boston University and Mayo Clinics laboratories. Pearson correlation coefficient (>0.99) and Bland-Altman plots revealed no significant differences between values obtained in the two laboratories at any concentration (25). The functional sensitivity of the assay was 2 ng/dl, and interassay coefficients of variation (CV) were 10.6% at 0.82 nmol/liter (23.5 ng/dl), 7.9%, at 1.7 nmol/liter (48.6 ng/dl), 7.7% at 8.4 nmol/liter (241 ng/dl), 4.4%

Results in women are provided in Supplemental Table 1. T and SHBG concentrations are given in nanomoles per liter, and the estrogens are given in picomoles per liter. Sex hormones ranged across quartiles 1–4 for TT are <14.5, 14.5/19.5, 19.5/24.8, and >24.8; for free T are <0.23, 0.23/0.29, 0.29/0.35, and >0.35; for SHBG are <39.7, 39.7/53.3, 53.3/72.6, and >72.6; for E1 are <144.04, 144.04/184.25, 184.25/223.9, and >223.9; and for E2 are <73.97, 73.97/92.88, 92.88/115.9, and >115.9. To convert the values of TT from nanomoles per liter to nanograms per deciliter, multiply by 28.82. To convert the values for free T to picograms per milliliter, divide by 3.467. To convert E2 and E1 from picomoles per liter to picograms per milliliter, divide the E2 value by 3.671 and E1 by 3.699. Clinical PAD was defined as a composite outcome including an ABI below 0.90, IC, or lower extremity revascularization. Number of men exhibiting clinical PAD at baseline was 89 (6.3%). Ref., Reference.

[a] Results are obtained from multiple linear (ABI) and logistic regression (PAD) with statistical control for the confounding influences of age, waist circumference, smoking status, total and high-density lipoprotein cholesterol, diabetes, hypertension, and cardiovascular disease. Estimates are interpreted as differences or relative odds expressed vis-a-vis the reference sex hormone quartile.

[b] $P < 0.05$.

at 18.5 nmol/liter (532 ng/dl), and 3.3% at 35.3 nmol/liter (1016 ng/dl), respectively. E2 and E1 were measured simultaneously by LC-MS/MS with functional sensitivity of 2.5 pg/ml with use of volume dilution for samples with very low levels (24). For E2, the interassay CV were 9.4% at 29.6 pg/ml, 8.9% at 57.6 pg/ml, 7.6% at 109.9 pg/ml, and 7.6% at 329.3 pg/ml. The interassay CV for E1 were 13.5% at 29.8 pg/ml, 13.8% at 58.8 pg/ml, 12.4% for 114.2 pg/ml, and 11.4% for 341.0 pg/ml. SHBG concentrations were measured using an immunofluorometric assay (DELFIA-Wallac, Inc., Turku, Finland). The interassay CV were 8.3, 7.9, and 10.9% in the low, medium, and high pools (26, 27). Free T was calculated by using a modified law of mass action equation (28).

Peripheral arterial disease

Ankle-brachial index

Ankle-brachial systolic blood pressure measurements were obtained in the seventh and eighth examination cycles of the FHS by trained technicians according to a standard protocol, as previously described (29). Systolic blood pressure was measured twice in both arms and both ankles using an 8-MHz Doppler pen probe and an ultrasonic Doppler flow detector (Parks Medical Electronics, Inc., Aloha, OR). A third measurement was taken when the initial and second blood pressure measurements differed by more than 10 mm Hg at any site. Measurements were obtained from the dorsalis pedis artery only if the posterior tibial pulse could not be located by palpation or with Doppler probe. ABI was calculated as the ratio of the mean systolic blood pressure in the ankle divided by the systolic blood pressure in the arm with the greater mean. The lower of the two ABI ratios was used for analysis (29). A clinically meaningful change in ABI was defined as a decline of at least 0.15 between baseline and follow-up (30, 31) because this level of ABI decline is associated with a significant increase in risk for CVD (31).

Composite clinical PAD

Intermittent claudication (IC) was assessed using a standardized physician-administered questionnaire that inquired about the presence of exertional calf discomfort related to walking uphill or walking rapidly and was relieved with rest. Two physicians independently interviewed all participants with responses indicative of IC. An endpoint panel, comprised of three senior investigators, examined all medical evidence and made the final diagnosis of the presence of IC. Participants were also queried about revascularization procedures including lower extremity bypass surgery and percutaneous transluminal angioplasty. The endpoint panel used hospital records to validate all cardiovascular procedures, and the date and type of procedure was recorded. PAD was defined as a composite outcome including an ABI below 0.90, IC, or lower extremity revascularization.

Covariates

Sociodemographic and behavioral characteristics as well as medical history and medication use were assessed by standardized personal interviews. Current smokers were defined as those who reported having smoked at least one cigarette per day regularly during the year preceding the exam. Waist circumference, height, and weight were measured with the subject standing and body mass index calculated (kilograms per square meter). The examining physician measured resting blood pressure twice, and the average of the two readings was used to determine the presence of hypertension. Hypertension was defined as systolic blood pressure of at least 140 mm Hg or diastolic blood pressure of at least 90 mm Hg or self-reported use of antihypertensive medication. Diabetes was defined as fasting glucose of at least 126 mg/dl or self-reported use of insulin or oral hypoglycemic medications. Fasting plasma total cholesterol and high-density lipoprotein cholesterol concentrations were measured using standard enzymatic methods, as previously described (32). Prevalent

CVD was assessed according to previously reported standardized protocols [including coronary heart disease (recognized or unrecognized myocardial infarction, angina pectoris, coronary insufficiency, or coronary heart disease death), cerebrovascular disease (stroke or transient ischemic attack), or congestive heart failure] and confirmed with the aid of medical histories, physical examinations at the study clinic, and hospitalization records and, finally, validated by the endpoint committee (22).

Statistical analyses

Sex hormone concentrations were categorized into quartiles. Given the known gender dimorphism in sex hormone effects, models were sex specific. In women, models were additionally stratified by menopausal status and postmenopausal use of hormone therapy. Independent analyses were performed for each sex hormone. Exploratory models included graphical and tabular displays to determine patterns of association and magnitude of change in ABI between examinations. Multivariable linear and logistic regression models adjusted for age, waist circumference, smoking status, total and high-density lipoprotein cholesterol, diabetes, hypertension, and prevalent cardiovascular disease were used, with estimates expressed as linear regression coefficient (β) or odds ratio (OR) and their corresponding 95% confidence interval (CI). Longitudinal associations of baseline sex hormone concentrations with meaningful change in ABI (decline of $\geq$0.15 between baseline and follow-up) were analyzed only among individuals without baseline PAD using multivariable logistic regression models. A separate sensitivity analysis assessed the mediating effects of statin use. Two-sided P values <0.05 were considered statistically significant. All statistical analyses were performed using SAS statistical software (SAS Institute Inc., Cary, NC).

Results

Table 1 presents the baseline characteristics of the study population according to sex, menopausal status, and postmenopausal use of hormone therapy. Postmenopausal women, mean age 64.6 yr, constituted the majority of our female study sample (86.5%). Clinical PAD was prevalent among 6.3% (n = 89) of men, 1.4% (n = 3) of premenopausal women, 3.7% (n = 19) of postmenopausal women using hormone therapy, and 6.7% (n = 59) of postmenopausal women not using hormone therapy.

Cross-sectional multivariable linear regression models revealed that men with lower free T and higher E1 concentrations had a significantly lower ABI (for free T, lowest *vs.* higher quartiles, $\beta = -0.02$, with 95% CI = -0.04 to -0.01; and for E1, highest *vs.* lower quartiles, $\beta = -0.03$, with 95% CI = -0.05 to -0.01, respectively). A higher TT/E1 and TT/E2 ratio was associated with higher ABI after adjustment for age and other confounders (Table 2). Furthermore, lower TT and SHBG concentrations in men were associated with prevalent PAD in age-adjusted (OR = 2.24, with 95% CI = 1.17–4.32; and OR = 2.06, with 95% CI = 1.07–3.96, lowest *vs.* highest quartile, respectively, although there was no significant trend noted across TT, $P = 0.08$, and SHBG, $P = 0.17$, quartiles) but not in multivariable logistic regression models (Table 2). Similarly, a higher TT/E1 ratio showed a protective effect on prevalent PAD in age-adjusted (OR = 0.34; 95% CI = 0.17–0.69) but not in multivariable-adjusted logistic regression models (Table 2). In women, we found no cross-sectional associations of any sex hormone with ABI (Supplemental Table 1, published on The Endocrine Society's Journals Online web site at http://jcem.endojournals.org), and the number of prevalent PAD cases (overall n = 81) was too low to yield meaningful estimates when stratifying by menopause and postmenopausal use of hormone therapy (data not shown).

Over the 6.7-yr (median) follow-up period, the distribution of measured ABI values in men showed no statistically significant differences (Student's t test, $P = 0.78$), although a substantial number of men (n = 69) experienced a meaningful change in ABI (decline of $\geq$0.15) between baseline and follow-up (Fig. 2 and Supplemental Fig. 1). Multivariable logistic regression models revealed an association of baseline SHBG concentrations with meaningful change in ABI among men (n = 1076 men free of baseline PAD and data at exam 8). OR for men in SHBG quartiles 1, 2, and 3 compared with quartile 4 were 2.56 (95% CI = 1.01–6.45), 2.28 (95% CI = 0.98–5.32), and 2.93 (95% CI = 1.31–6.52), respectively (P for trend = 0.07). No such association was observed for TT, free T, E1, E2, or TT/E ratios (Table 3). The number of incident PAD cases was too low (women, n = 24; men, n = 21) to perform incidence analyses (Supplemental Fig. 1). Also the number of women with meaningful change in ABI was too low (n = 6 premenopausal women; n = 24 postmenopausal women on HT; n = 43 postmenopausal women not on HT) to perform any regression modeling. Additional adjustment for statin use showed no impact on the overall estimates (data not shown).

Discussion

Principal findings

The present study is the first investigation of cross-sectional and longitudinal associations between sex hormone concentrations with ABI, PAD, and ABI change, analyzing data from a large community-based sample of men and women. In men, cross-sectional analyses revealed a positive association of free T and a negative association of E1 concentrations with ABI, respectively. Longitudinal analyses also showed sex-specific associations of SHBG concentrations with ABI change in men.

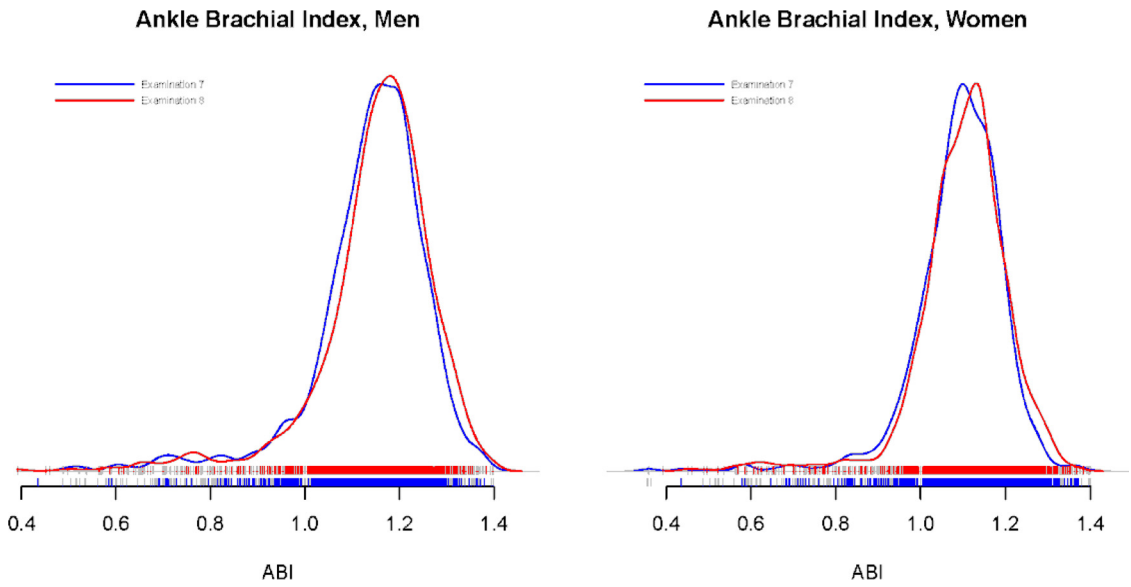

FIG. 2. Kernel density estimates for ABI, by sex and examination. *Hash marks at bottom* depict actual ABI values.

Findings in men

Previous studies examining the association of sex hormones with PAD among men are very sparse. One previous cross-sectional study among 3014 elderly men (mean age 74.5 yr) found that low free T and TT concentrations were associated with ABI and prevalent PAD (defined as an ABI <0.90) (21). But in contrast to our results, this previous study showed a significant association between TT and prevalent PAD after multivariable adjustment, suggesting that differences in the adjustment set could have mitigated or abolished significant effects of TT on PAD in our analyses. The previous study also differed from our study in that no evidence of an association between SHBG and PAD or ABI was observed (21).

Although E1 is at least as abundant in circulation as E2, its biological role remains poorly understood. We found a negative association between E1 concentrations and ABI in cross-sectional models. However, in line with previous findings, E2 was not associated with ABI or prevalent PAD in our study (21). The potential role of sex hormones in vascular disease has been reinforced by a recent cross-sectional study among 3620 community-dwelling men aged 70–88 yr, showing that low free T and high SHBG concentrations are independently associated with abdominal aortic aneurysm, itself a powerful predictor of cardiovascular events and mortality (33). Additionally, previous studies reported associations between low free T and TT concentrations with carotid plaques and carotid in-

For men free of clinical PAD at examination 7 and ABI data at examination 8, n = 1076. For meaningful change in ABI (decline of at least 0.15), n = 69. Ref., Reference.

[a] Estimates are adjusted for age, waist circumference, smoking status, total and high-density lipoprotein cholesterol, diabetes, hypertension, and cardiovascular disease.

[b] $P < 0.05$.

tima media thickness, respectively (34–36). Taken together, present evidence about the potential role of sex hormones in vascular disease is largely based on cross-sectional studies, requiring future prospective studies to dissect the temporal relationship between sex hormones and the atherosclerotic process.

Thus, we conducted longitudinal analyses to investigate the effect of baseline T, estrogen, and SHBG concentrations on ABI change. We found that SHBG concentrations in men were associated with meaningful ABI decline ($\geq$0.15) between baseline and follow-up, but without any evidence for a linear trend across SHBG quartiles. Furthermore, the comparably large CI reflect a lack of precision for the revealed risk estimates due to the low number of men with meaningful change in ABI. Similarly, we were not able to investigate longitudinal associations between sex hormone concentrations and incident PAD because the number of incident cases was too low. However, preliminary results from a small cross-sectional case-control study among PAD patients showed no significant associations between sex hormone concentrations and clinical PAD in either sex (37). Furthermore, associations between sex hormone concentrations and incident clinical CVD are conflicting (38, 39). Therefore, the extent to which SHBG and other sex hormones could be a useful risk marker or exert independent effects on the atherosclerosis process needs to be determined.

Findings in women

In the present study, we did not observe any associations of sex hormone concentrations with ABI or PAD in women. It is also possible that sex hormones play a role in the atherosclerotic process earlier in life, independent of the substantial decrease in estrogen concentrations during the menopause. Therefore, we performed stratified analyses with regard to menopausal status and postmenopausal use of hormone therapy but without revealing any statistically significant differences between these groups. We also considered postmenopausal hormone therapy (*i.e.* exogenous estrogen or estrogen/progestin combinations) as a potential mediator of the investigated associations but were not able to detect different associations of sex hormones with ABI or PAD in postmenopausal women who used hormone therapy *vs.* those who did not. Similarly, previous studies of hormone therapy in postmenopausal women showed no effect of E2 on progression of carotid atherosclerosis (40, 41). However, the lack of associations observed in our study may reflect a lack of statistical power to detect differential effects of sex hormones in women within menopause and hormone therapy subgroups.

Previous studies investigating the relation between sex hormone concentrations and cardiovascular risk factors in women revealed associations of higher T (free T and TT) and lower SHBG concentrations with increased cardiovascular risk factor burden (12) including visceral fat accumulation (13), insulin resistance, adverse lipid profiles (14), diabetes (15), and incident CVD (19, 20). In particular, higher SHBG concentrations were associated with reduced subclinical atherosclerosis progression in healthy postmenopausal women (16–18). In contrast, two studies have shown that lower circulating TT may be associated with incident cardiovascular morbidity (42) and heart disease (43) but were limited by imprecise immunoassay-based TT measurements in the low concentration range of women and missing free or bioavailable T assessment. Given the conflicting reports in the literature, firm conclusions about the association between sex hormones and clinical CVD events in women cannot be drawn (12). However, because our power to detect an association was low, the present lack of statistically significant association of sex hormones with ABI and PAD in women needs to be interpreted with caution until further investigation in other large prospective epidemiological studies with long-term follow-up.

To determine whether exogenous sex hormones are an effective treatment for PAD patients, a review identified only three, small-scale trials in predominately male populations, involving the use of T (no estrogenic hormones) over relatively short time periods with variable methods of measuring PAD (44). Overall, T supplementation had no significant effect on PAD progression, including subjective improvement in symptoms and tests of walking distance (44). Additionally, a recent trial among elderly men reported that T supplementation increased the risk of adverse cardiovascular events (45). However, it is still possible that exogenous T could affect PAD progression, but at present, there are insufficient data to support this hypothesis.

Potential limitations of the present study include the small number of PAD events precluding incidence analyses and constraining analyses of ABI change as well as a study sample of adult white men and women limiting the generalizability of our findings to individuals of other ethnicities. Strengths of the present study include its large community-based sample; TT, E2, and E1 concentrations measured by LC-MS/MS from fasting morning samples; and a comprehensive directly measured covariate assessment.

In conclusion, our investigation of a middle-aged community-based sample suggests that lower free T and higher E1 concentrations may be associated with PAD and ABI change in men, but sex hormones were not associated with

PAD or ABI in women. Additional investigations are warranted to confirm these findings and to elucidate the biological basis for the sex-related differences in associations between sex hormones and PAD.

BRIEF REPORT

A Telerehabilitation Intervention for Persons with Spinal Cord Dysfunction

ABSTRACT

Houlihan BV, Jette A, Paasche-Orlow M, Wierbicky J, Ducharme S, Zazula J, Cuevas P, Friedman RH, Williams S: A telerehabilitation intervention for persons with spinal cord dysfunction. Am J Phys Med Rehabil 2011;90:756–764.

Pressure ulcers and depression are common preventable conditions secondary to a spinal cord dysfunction. However, few successful, low-cost preventive approaches have been identified. We have developed a dynamic automated telephone calling system, termed *Care Call*, to empower and motivate people with spinal cord dysfunction to improve their skin care, seek treatment for depression, and appropriately use the healthcare system. Herein, we describe the design and development of Care Call, its novel features, and promising preliminary results of our pilot testing. Voice quality testing showed that Care Call was able to understand all voice characteristics except very soft-spoken speech. Importantly, pilot study subjects felt Care Call could be particularly useful for people who are depressed, those with acute injury, and those without access to quality care. The results of a randomized controlled trial currently underway to evaluate Care Call will be available in 2011.

Key Words: Spinal Cord Injuries, Telemedicine, Pressure Ulcer, Depression

Pressure ulcers and depression are common preventable secondary conditions for people with spinal cord dysfunction (SCD). Unfortunately, diagnosis and/or treatment of secondary conditions is often delayed.[1–4] This can undermine rehabilitation and have a significant impact on a person's quality-of-life and his/her healthcare costs.[5–8]

A patient's self-care behavior can impact the onset and severity of secondary conditions after an SCD. Pressure ulcers, for example, can be prevented through the use of patient education.[9] Depression can be improved and successfully managed if a patient receives treatment.[10] Nonetheless, persons with SCD do not generally receive the necessary follow-up care[11] that could promote self-management behaviors. Patients report various obstacles to complying with self-care management and annual follow-up evaluations, including cost, transportation, time, and reluctance to seek treatment,[12] such that they are not being successfully encouraged to prevent or seek treatment for pressure ulcers and depression.

Interventions to promote healthy behaviors, which can in turn prevent secondary conditions, are typically resource intensive.[13,14] Telerehabilitation and

related technologies are a promising strategy that, if successful, could improve the quality and reduce the cost of secondary prevention.[15] For persons with spinal cord injury (SCI), particular attention in telerehabilitation interventions has been paid to using telephone contact and video monitoring for the prevention and management of pressure ulcers.[16,17] However, because telerehabilitation interventions have not been evaluated, few successful, low-cost approaches that prevent secondary conditions have been identified[18,19]; such a system could bring not only substantial long-term cost savings but also enhanced quality-of-life of people with SCD.

With this goal in mind, we have developed *Care Call*—an innovative telerehabilitation intervention system designed to empower and motivate people with SCD to improve their skin care and mental health. The system does not replace face-to-face health care, rather, it supplements a clinician's role in long-term management after SCD. Care Call has the potential to help significant numbers of people after an SCD using a low-risk, low-cost approach that could be used for long-term patient monitoring and service provision. If efficacious, this intervention could be offered by clinicians to patients across multiple settings. Herein, we describe the design, development, and initial pilot testing of the Care Call intervention, with the ultimate goal of informing the final intervention protocol for an initial randomized controlled trial (RCT) now underway.

METHODS

Description of the Care Call Technology

The Care Call intervention is delivered from the Telephone-Linked Computer System (TLC),[20] an automated, interactive conversation system that speaks with a digitized human voice.[21] TLC, which functions as an at-home monitor, educator, and counselor for reinforcing or changing health-related behaviors, has been used to screen and monitor numerous diseases[22–27] and has been applied to important health-related behaviors.[28] Clinical trials show TLC to improve medication adherence,[29] increase exercise among the general[13] and elderly populations,[30] decrease the degree of dyspnea for people with chronic obstructive pulmonary disease,[31] and improve eating habits[32] and lower serum cholesterol levels through dietary changes.[31]

TLC uses an interactive voice response system to generate digitized speech over the telephone, a speech recognition software, a conversation control system that directs the content and flow of individual TLC conversations with users, and a database management system for storing user information and call logs. It is a call-in and call-out system; that is, users can call (from any telephone) at any time and the system will also call the user according to an adaptive scheduling protocol that reflects how well a person is doing with his/her self-care. If the system initiates a call and no contact is made, it will leave a message for the person to call TLC and will call again according to a call schedule protocol. TLC automatically produces reports on utilization statistics to assist in system operation, intervention evaluation, and patient monitoring.

Design of the Care Call Intervention

The target population for the Care Call intervention consists of persons with SCD who use a wheelchair at least 6 hrs a day. For the Care Call clinical trial, further exclusion criteria were developed, including having nontraumatic SCI diagnoses with fast progression (amyotrophic lateral sclerosis, postpolio, and metastatic disease of the spine), having severe major depression, and having a stage III or greater pressure ulcer. In practice, the appropriateness of Care Call for subgroups meeting these exclusion criteria would need to be evaluated on an individual basis.

We designed the Care Call intervention to (1) screen for pressure ulcers and depressive symptoms, (2) educate about the prevention of depression and pressure ulcers and the appropriate use of heath care services, and (3) alert a nurse telerehabilitation coordinator (NTC), when appropriate, for direct medical or mental health attention. Furthermore, we hypothesized a secondary goal, that Care Call would improve community integration and quality-of-life. Each of these goals is being evaluated in the RCT. An interdisciplinary team of rehabilitation professionals developed the content, design, and overall functionality of the Care Call system.

The content of the Care Call intervention is based on the Transtheoretical Model[33] and Social Cognitive Theory,[34] as well as on the heuristics of experienced counselors. The Transtheoretical Model posits that people at different stages of readiness to make a desired behavioral change will respond to different counseling messages. A fundamental precept in the Social Cognitive Theory is that individuals use self-referent thought to mediate between knowledge and behavior, which allows them to evaluate their own experiences and thought processes.[35] Through the process of self-evaluation,

individuals may alter their own thinking about their abilities and the outcomes of their actions and subsequently alter their behavior.

Care Call targets pressure ulcers and depression, in particular, because of their prominence for people with SCD and their preventability through self-management. The prevalence of pressure ulcers in a community-based sample of individuals with SCD is estimated at 33%.[36] Patient education is generally considered paramount for proper prevention of pressure ulcers.[36] The percentage of adults with disabilities who reported that feelings of depression kept them from being active was three times that of the general population, 28% compared with 7%, respectively.[15] Research has shown that TLC technology has been able to successfully change health behavior and disease outcomes.[13,20,23,32,37] Although there is little research on using TLC to prevent or treat depression, screening for another sensitive mental health issue, substance use, has proven effective using TLC.[25] In addition, several randomized trials over the last decade have demonstrated that telehealth interventions can decrease depression severity.[38,39]

General Description of Care Call

The Care Call scripts are organized into modules and integrate information relative to three targeted areas: skin care, depression and wellness, and healthcare utilization. Although most content is delivered by computer voice, the system also has recorded vignettes from people with SCD and recorded comments from healthcare professionals. Throughout each module, users are referred to local community and informational resources via the Care Call Resource Book (see below).

The Skin Care Module assesses and monitors old and new skin problems, trains users in skin care, and assesses and monitors risk factors such as incontinence and equipment needs. Care Call reviews barriers to skin care adherence to offer specific encouragement and advice.[34] To provide individualized messages, the system is adapted based on data collected at baseline (e.g., history of pressure ulcers, consistency of sensation, and level of paralysis) and on responses in previous calls.

The Depression and Wellness Module screens, monitors, and educates users on depression and adjustment. For those with existing untreated depression, Care Call provides education and encouragement to improve their understanding and management of depression. The system assesses satisfaction with treatment and promotes adherence. Care Call also has a wellness track for decreasing depression in which participants are assessed; educated about exercise, sleep habits, and alcohol use; and offered a brief relaxation exercise that can be done at any time.

As part of the depression track, a "Self-harm Protocol" was developed for use when a subject endorsed thoughts of hurting himself/herself within the past 2 wks. When used, a follow-up script would be immediately implemented (by Care Call, the NTC, or field staff) to assess a subject's risk of self-harm. If the subject was found to be at immediate risk of self-harm, the system or Care Call staff would page an on-call clinical psychologist with the subject's status. The clinical psychologist would then reply within 1 hr to assess the situation and contract for safety, when appropriate. Otherwise, subjects would be counseled that if they ever began to feel like they could hurt themselves, they should go to the emergency department, and they would be provided with a national hotline number. In all cases, the NTC follows up within 48 hrs to see how a subject is doing.

The Health Care Utilization Module tracks each person's medical and mental health appointments. Because seeking treatment to prevent these problems is paramount, Care Call both reviews with users logistical factors before a healthcare visit and coaches them in communicating with a provider during a visit. If users miss an appointment, Care Call assesses barriers and offers recommendations to overcome them.

Care Call integrates audiotaped vignettes from actual patients with SCD. We recorded interviews with nine key informants with SCD to illustrate tips and personal experiences on all three modular topics. The key informants represented a range of SCDs (including multiple sclerosis and SCI) and ethnic/racial backgrounds (seven white non-Hispanic, two black; five men, four women). Users hear at least one audio clip per call, with relevant audio clips embedded throughout. Additional vignettes provide advice from SCD clinicians.

Lastly, Care Call offers users the opportunity throughout to speak with the NTC and alerts the NTC to contact the user for follow-up on important issues that are identified. The main role of the NTC is to respond to Care Call alerts in a timely manner, providing appropriate referral, resources, and/or action steps for users. Care Call does not act as an emergency responder to medical situations or dispense medical advice; the NTC provides an important triage role to further ascertain the needs of each Care Call user beyond the limitations of automated technology. The NTC uses a Web-based

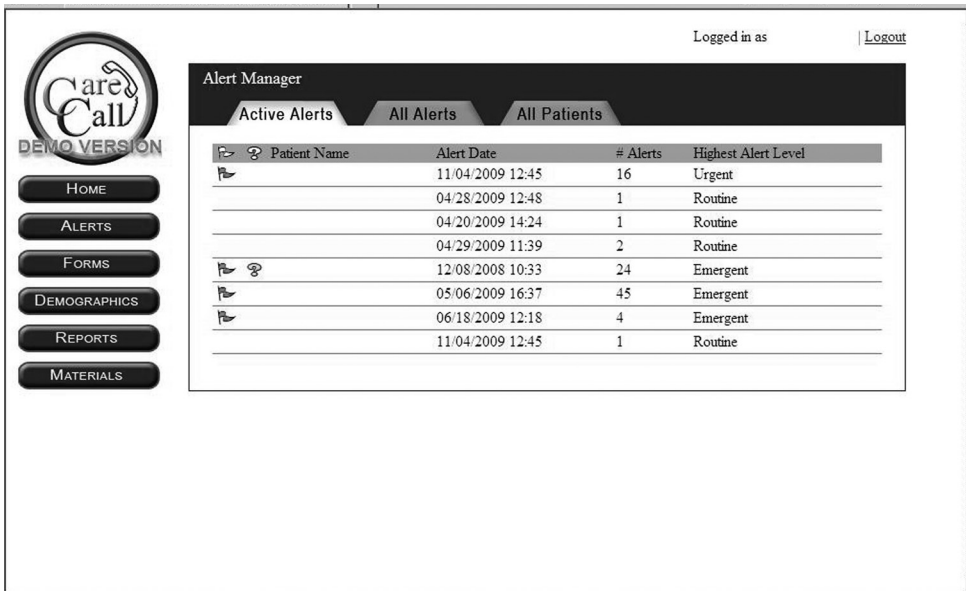

FIGURE 1 *Screenshot of the demo version of the Alert Manager, a Web-based tool for the nurse telerehabilitation coordinator, showing all active alerts (using mock data; mock names have been deleted).*

tracking form to document the length, content, and outcome of each contact with a user. We developed three levels of alerts for problems identified in Care Call: emergent (e.g., new skin problem), urgent (e.g., equipment problem), and routine (e.g., old problem that user wants to discuss with NTC). When an emergent medical problem is identified, Care Call directs users to contact their physician immediately or go to the emergency department or call 911. For urgent matters, Care Call tells users to see their physician as soon as possible and to ask for proper contact information for urgent medical problems at their next office visit (Figs. 1 and 2).

One of the major companions to Care Call is a Resource Book that all users receive at enrollment. Care Call and the NTC use this book in each encounter with participants. The Resource Book includes both local resources and informational resources for topics like medical supplies, mental and physical health providers, and personal care assistants. Included within the Resource Book is a set of user-friendly forms created by the research

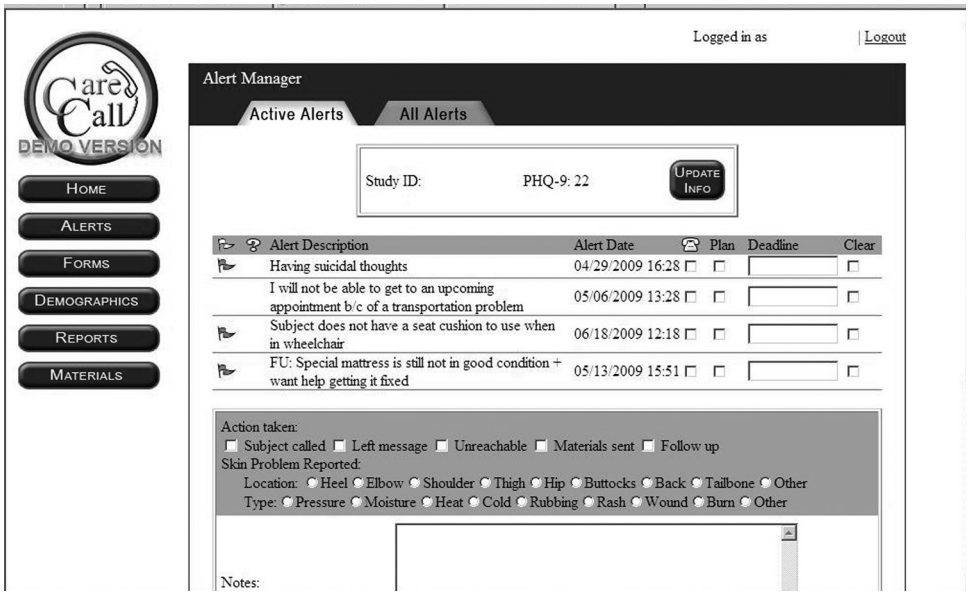

FIGURE 2 *Screenshot of active alerts for an individual mock subject in the demo version of the Alert Manager.*

team which Care Call reviews to help a user prepare for upcoming office visits to a health provider.

A Care Call Encounter

A Care Call user typically engages with Care Call weekly by receiving a call from TLC at an appointed time. Alternatively, a user may call into the system at any time to do their regular weekly call, report a new problem, hear the relaxation exercise, or leave a message for the NTC or technical staff. A typical conversation lasts 5 to 20 mins, depending on the patient's condition. After a unique password is entered, Care Call greets a user and a predetermined sequence of modules is delivered, as illustrated in Figure 3.

After an initial inquiry into any new skin problems, users hear different contents and questions in each call. User responses from previous encounters and the current encounter shape ensuing questions and feedback, such that content varies for each user and within each encounter. Throughout the entire conversation, Care Call alerts the NTC as needed and offers relevant patient audio clips, as well as tips from Care Call.

Pilot Testing

We used three types of testing in Care Call's development, the results of which have shaped both the final intervention and the clinical trial research protocol. The first was voice quality testing, which evaluates Care Call's ability to process various voice characteristics specific to our target population. Participants in the voice quality testing included five people with notable voice characteristics (ventilator use, pseudobulbar affect, dysarthria, soft-spoken speech, and stuffy nose) and one person with no notable voice characteristics. Testing the feasibility of Care Call for differing voice qualities was crucial for informing the criteria for participation in the clinical trial.

The second approach was pilot testing a beta version of the Care Call system with nine people with SCD to garner consumer feedback on content and to uncover any logic errors or technical difficulties. The Care Call team then revised the beta version of the Care Call system to create a final version for the trial. Subjects participated in six calls focusing on different scripts of the Care Call system and provided feedback during an in-depth interview.

All pilot testing procedures followed the approved protocol of the Boston University Medical Campus Institutional Review Board, conducted in accordance with the Declaration of the World Medical Association. Informed consent was obtained from all pilot participants.

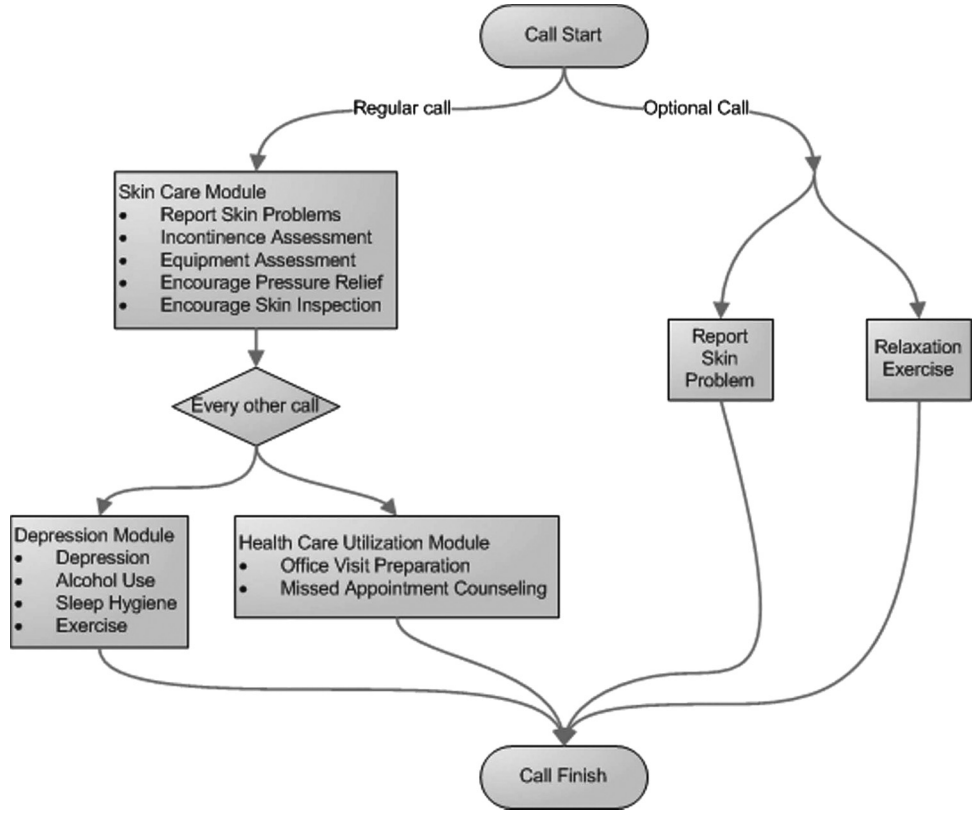

FIGURE 3 *Flow diagram depicting the architecture of Care Call.*

The final stage involved quality control testing to evaluate the final version of the Care Call intervention being deployed for the randomized controlled clinical trial, primarily for wording changes or technical errors. Three members of the development team assumed the identities of mock subjects with differing baseline characteristics. A report of unexplored areas of the system was distributed several times as the testing continued to guide testers in which untested pathways to follow with their responses. Pilot testing allowed the development team to address any possible issues before starting the trial.

RESULTS

The results of the voice quality testing showed that Care Call was able to understand all voice characteristics except very soft-spoken speech. In particular, the TLC system had difficulty hearing and understanding the responses of a soft-spoken user. After inquiring twice without being able to understand one of the response options provided, the system stated that there were technical difficulties and discontinued the call, per protocol. Voice quality results confirmed that the study could enroll subjects with a wide range of voice quality.

In the beta test, pilot study subjects found Care Call to be an acceptable intervention overall. They felt that Care Call could be useful particularly for people who were depressed, those with a new injury (SCI), and those without access to quality care. Several subjects mentioned repetition of information but recognized at the same time how this could be helpful for those with limited education in, for example, the topic of skin breakdown. Because of their feedback, we staggered content from week to week to shorten call times and modified content to acknowledge individual differences in perceived need for various recommendations. For instance, one pilot study subject felt that heel protectors did not apply to him/her and thus did not like that Care Call would continue to suggest use of them and inquire about obtaining them. Care Call was modified to include shoes as heel protectors while in the wheelchair and to have the nurse follow up with a user rather than having Care Call repeatedly promote the use of heel protectors.

Lastly, our quality control testing uncovered some logic problems in the scripts and identified content sequences that needed modification to maintain the utmost sensitivity to the varying circumstances of individuals in the clinical trial. For instance, a member of our research team first reported having two new skin problems and was then asked about the location of each. She imagined one on either side of her buttocks, yet Care Call did not specifically probe for this. When asking more about each skin problem, Care Call referred to each as being on the buttocks without differentiation between the right or the left buttock cheek. This line of questioning was confusing to the user, who did not know which problem to report on first.

Clinical experience suggested that most likely, skin problems on the same area of the body would be similar in cause and nature. Barring a total rewrite of this script and its logic, this issue was resolved most efficiently by adding a question with some instruction to users as follows: "Are you having a skin problem in just one area or in more than one area? If you're having problems on both sides of your body, for example both knees, count that as one area." Care Call was also revised to subsequently ask users if they had more than one skin problem in a particular area (in this case, the buttocks) to report on the worst skin problem, thus relieving any confusion or need for differentiation.

In terms of modifying content for sensitivity to individual differences, there was consensus that language needed to be softened related to feedback and education on adherence to skin care. Test callers felt that the weekly repetition of this content was reinforcement enough, such that the language itself should be less forceful, asking users if they would be willing to try to do more in the week ahead, rather than stating that they should. This change also allowed Care Call to be sensitive to the potential individual circumstances that might prevent a user from proper skin care, such as illness or a death in the family.

DISCUSSION

The Care Call telerehabilitation approach described in this article uses a ubiquitous instrument (the telephone) and, if shown to be efficacious, has the potential for widespread dissemination at low cost. Although automated, TLC programs can successfully emulate the educational and behavioral content, support, and conversational style of a human professional.[20,21,40] Research to date has shown that TLC technology in other disease areas has been able to successfully change health behavior and disease outcomes.[31] The preliminary results of our pilot testing are encouraging. The results of the voice quality testing showed that Care Call was able to understand all voice characteristics except very soft-spoken speech. This problem could, in some

cases, be alleviated with coaching via three-way calling on required voice volume levels. Ventilator use was not a problem, and the TLC system was able to appropriately confirm responses for the user with a stuffy nose and cough. And, importantly, pilot study subjects felt that Care Call could be useful particularly for people who are depressed, those with a new SCI, and those without access to quality care.

The results of an RCT evaluating the Care Call intervention will be available in 2011. The final intervention protocol was shaped in important ways by pilot testing the results. In the trial, intervention subjects receive weekly calls for 6 mos. Because of pilot testing, we were able to decrease the length of calls by removing some marginal content and staggering modules across calls. For instance, we removed most of a script that attempted to assess possible bowel leakage problems in detail because we found that this problem is so individualized that it is better to ask generally about whether the problem exists and then let the NTC follow up to further assess and make appropriate recommendations and referrals. We also ended up staggering modules to decrease call length from 30 mins to 15 mins, on average, with some individual variation based on choosing to hear optional content and/or need for follow-up from previously identified issues.

Different types of follow-up care have been developed to fill the gap in the continuum of rehabilitative care, especially for people with lifelong health needs, such as people with SCD. A systematic review of the literature in 2005 on follow-up care for people with SCI in the community showed that the most important methods have been telemedicine, outpatient consulting hours, home visits, or a combination of methods.[16] Because the quality of these studies was generally low, the authors were not able to draw conclusions as to the effect of these follow-up interventions on secondary conditions or long-term costs of care. Another systematic review of the literature in 2006 on preventing pressure ulcers showed that there were few well-designed RCTs following standardized criteria and providing data on cost-effectiveness,[41] suggesting that more need to be developed. As technology continues to advance, experts and clinicians are looking to the field of telehealth to fill this gap.[14] These technologies offer accessibility to potentially highly effective behavior change interventions at low cost. For instance, the TLC-Hypertension trial was the first telehealth chronic disease application to be evaluated in a randomized clinical trial, involving 267 elderly, poorly controlled hypertensive patients. Mean adjusted diastolic blood pressure decreased significantly; 69% of TLC users rated TLC in the upper quartile of satisfaction on a visual analog scale, whereas the cost per patient user for 6 mos of use was $32.50.[29]

There are limitations to TLC technology and the Care Call intervention that must be noted. First, because TLC is an automated system, technical errors of varying kinds can occur (e.g., the system does not always recognize the user's responses or accept responses that it is not prepared to hear). To address this, technical staff needs to be available to assist users, and all calls should be logged line by line on a server to record any errors in detail for proper follow-up. In addition, the system is limited to the conversational pathways that were designed; it cannot truly take each individual user's situation into account or discuss any topic that the user is interested in pursuing. This means that Care Call may be advocating for a certain behavior that is not appropriate or not perceived to be relevant to a particular user. The system includes statements to explain these limitations, but users may still ultimately be frustrated at times. The extent to which this limits the impact of the system is an empirical question about which we will learn from our clinical trial.

CONCLUSION

Care Call is designed to reduce the incidence and severity of secondary conditions such as pressure ulcers and depression, to be relevant across multiple consumer settings, and to facilitate long-term monitoring. The system is a low-risk, inexpensive intervention that could be widely disseminated. Results of pilot testing of Care Call demonstrated the intervention's feasibility for a wide variety of voice qualities and its general acceptability by consumers, with some minor content and logic changes. Pilot testing also allowed the team to uncover important content and logic changes that improved the system. These findings resulted in a stronger intervention and protocol for the clinical trial of Care Call.

Experience from the RCT will establish if people with SCD will use the Care Call system and if the intervention will successfully promote self-management in a cost-effective manner.

ACKNOWLEDGMENTS

We acknowledge Dr Dave Rosenblum and Mercedes Martinez for their contribution to the design and development of the Care Call intervention; Sippy Olarsch and Kelsey Williams for assisting with the development of the Web-based tools;

and the Medical Systems Information Unit team for technical guidance and support throughout.

(*Received 1 March 2010; final version received 16 February 2011*)

Unhealthy alcohol use (the spectrum of risky use through dependence) is common in HIV-infected persons, yet it can interfere with HIV medication adherence, may lower CD4 cell count, and can cause hepatic injury. Carbohydrate-deficient transferrin (CDT), often measured as %CDT, can detect heavy drinking but whether it does in people with HIV is not well established. We evaluated the operating characteristics of %CDT in HIV-infected adults using cross-sectional data from 300 HIV-infected adults with current or past alcohol problems. Past 30-day alcohol consumption was determined using the Timeline Followback (TLFB), a validated structured recall questionnaire, as the reference standard. Sensitivity and specificity of %CDT (at manufacturer's cut-off point of 2.6%) for detecting both "at-risk" ($\geq$4 drinks in a day or $>$7 drinks per week for women, $\geq$5 drinks in a day or $>$14 per week for men) and "heavy" drinking ($\geq$4 drinks in a day for women, $\geq$5 drinks in a day for men on at least seven days) were calculated. Receiver operating characteristic (ROC) curves were estimated to summarize the diagnostic ability of %CDT for distinguishing "at risk" and "heavy" levels of drinking. Exploratory analyses that stratified by gender and viral hepatitis infection were performed. Of 300 subjects, 103 reported current consumption at "at-risk" amounts, and 47 reported "heavy" amounts. For "at-risk" drinking, sensitivity of %CDT was 28% (95% confidence interval (CI) 19%, 37%), specificity 90% (95% CI 86%, 94%); area under the ROC curve (AUC) was 0.59. For "heavy" drinking, sensitivity was 36% (95% CI 22%, 50%), specificity 88% (95% CI 84%, 92%); AUC was 0.60. Sensitivity appeared lower among women and those with viral hepatitis; specificity was similar across subgroups. Among HIV-infected adults, %CDT testing yielded good specificity, but poor sensitivity for detecting "at-risk" and "heavy" alcohol consumption, limiting its clinical utility for detecting unhealthy alcohol use in this population.

Keywords: carbohydrate-deficient transferrin; CDT; alcohol; HIV

Background

HIV-infected populations in the USA have a high prevalence of unhealthy alcohol use, which can contribute to declines in their health (Cook et al., 2001; Galvan et al., 2002; Saitz, 2005; Samet, Phillips, Horton, Traphagen, & Freedberg, 2004). Alcohol can adversely affect immune function (Greiffenstein & Molina, 2008; Watzl & Watson, 1992), nutritional status (Lieber, 2003; Martin Villares et al., 2004) and adherence to medications (Braithwaite et al., 2005; Heckman, Catz, Heckman, Miller, & Kalichman, 2004). It can interfere with hepatic metabolism and is hepatotoxic. Furthermore, HIV co-infection with viral hepatitis is common (Shire et al., 2007; Tedaldi et al., 2003), and both HIV and viral hepatitis are adversely impacted by alcohol. For these reasons, detection of unhealthy alcohol use is important in the clinical care of HIV-infected individuals.

There is evidence that early intervention for unhealthy alcohol use can be effective (Kaner et al., 2009; Nilssen, 2004), but early clinical signs are often missed (Weisner & Matzger, 2003) and unhealthy alcohol use often goes undiagnosed by HIV health-care providers (Conigliaro et al., 2003). The National Institute on Alcohol Abuse and Alcoholism (NIAAA) advises screening for unhealthy alcohol use (National Institute on Alcohol Abuse and Alcoholism, 2007) by assessing for "at-risk" drinking amounts. These are drinking amounts that put individuals at increased risk of adverse health

effects including alcohol use disorders (abuse and dependence).

Practice guidelines recommend screening by using questionnaires. Biomarkers are not standard for universal alcohol screening because they are more costly and less sensitive for unhealthy use than questionnaires (Coulton et al., 2006). But some have recommended their use. Biomarkers can be useful for detecting unhealthy use among those who deny it, helping to confirm unhealthy use, or to facilitate discussions with patients about alcohol by having a seemingly more objective medical test in hand (Miller & Anton, 2004). Biomarkers are sometimes used for monitoring of heavy alcohol use (Anton, Lieber, Tabakoff, & CDTect Study Group, 2002).

A number of biomarkers are affected by unhealthy alcohol consumption, e.g., lipids and liver enzymes, but none has both sufficient sensitivity and specificity for screening. The most common biomarkers currently used for detection of unhealthy alcohol use include the liver enzyme γ-glutamyltransferase (GGT), which is neither particularly sensitive nor specific for detecting unhealthy alcohol use (Conigrave et al., 2002; Schmidt et al., 1997; Schwan et al., 2004). Other biomarkers are red blood cell mean corpuscular volume (MCV), and a protein produced by the liver, carbohydrate-deficient transferrin (CDT), often measured as %CDT. Of these, only CDT has high specificity for unhealthy alcohol use (Schwan et al., 2004), does not remain elevated as long after an episode of unhealthy drinking as GGT (Schmidt et al., 1997), and retains specificity when liver disease is present (e.g., primary biliary cirrhosis) (Arndt, Meier, Nauck, & Gressner, 2006).

CDT's performance for detecting unhealthy alcohol use in people with HIV has not been well-established. HIV-infected populations have a high prevalence of abnormal liver enzymes. CDT might therefore be more sensitive and less specific for unhealthy alcohol consumption than it is in populations without HIV infection or with undetermined HIV status.

CDT operates in a dose-dependent manner as a biomarker for detecting alcohol consumption (Schellenberg et al., 2005). If CDT were able to detect "at-risk" drinking (the spectrum of "at-risk" use through dependence) in HIV-infected individuals, it could be very useful clinically (Conigliaro et al., 2003). Therefore, our primary objective was to evaluate the diagnostic accuracy of CDT to distinguish between "at-risk" and lesser than "at-risk" drinking in adults with HIV infection.

Methods

Subjects

We studied cross-sectional data collected prospectively for an observational cohort study, the HIV-Longitudinal Interrelationships of Viruses and Ethanol (HIV-LIVE) study (Samet et al., 2007). Subjects ($n = 400$) were recruited from 2001 to 2003 in the Boston area mainly from clinical settings (Samet et al., 2007). Mean age was 43, 75% were male, 33% white, 41% black, 19% Hispanic, approximately two-thirds were "heterosexual," one-third "gay or homosexual," and 56% had a lifetime history of injection drug use.

All subjects met the following eligibility criteria: (1) current or past alcohol problems ($\geq$two affirmative responses to the CAGE alcohol screening questionnaire or diagnosis of alcohol abuse or dependence based on clinical assessment by a physician-investigator); (2) HIV infection documented by an ELISA antibody test confirmed by western blot; (3) ability to speak English or Spanish; and (4) at least one contact person to assist with follow-up. Eligible subjects provided written informed consent before enrollment.

Exclusion criteria for the HIV-LIVE study were score of <21 on the Mini-Mental State Exam or trained-interviewer assessment of individual's inability to comprehend informed consent or answer interview questions. Additional exclusion criteria were lack of baseline hepatitis C RNA (viral load) data, missing responses to the TLFB questions, insufficient blood sample quantity, and inability to match blood sample to same-day questionnaire data.

Assessments

Laboratory tests and interviews by trained research associates were done at baseline and every six months for at least 24 months and up to 42 months ending in 2006. Blood samples were collected for storage annually. The Federal Government provided a certificate of confidentiality for added protection for the research data. The study was approved by the Institutional Review Boards at Boston Medical Center and Beth Israel Deaconess Hospital.

The reference standard used for determining past 30-day alcohol consumption was the TLFB, a lengthy validated structured recall questionnaire for assessing alcohol consumption over time in research studies (Carey, Carey, Maisto, & Henson, 2004; Sacks, Drake, Williams, Banks, & Herrell, 2003; Sobell & Sobell, 1995). We evaluated the ability of %CDT and GGT to detect three levels of unhealthy alcohol consumption: "at-risk," "heavy," and "frequent

heavy'' drinking as determined by the reference standard TLFB.

We used the NIAAA definition of ''at-risk'' drinking (National Institute on Alcohol Abuse and Alcoholism, 2007), but placed it in the context of a 30-day period: ≥ 4 drinks in a day in past 30 days or >7 drinks per week on average for women; ≥ 5 drinks in a day in past 30 days or >14 drinks per week on average for men. We defined ''heavy'' drinking as at least seven days of drinking at ≥ 4 drinks in a day for women and ≥ 5 drinks in a day for men in past 30 days, amounts at which physiologic and/or organ damage become more likely (Conigrave et al., 2002; White, Altmann, & Nanchahal, 2002). We defined ''frequent heavy'' drinking as at least seven consecutive days of ''heavy'' drinking in past 30 days. We used the NIAAA definition of one drink: 12 ounces beer, 5 ounces of wine or 1.5 ounces of 80 proof liquor (containing approximately 14 grams or 0.6 fluid ounces of pure alcohol) (National Institute on Alcohol Abuse and Alcoholism, 2007).

Data collection at study entry included the following: age, gender, current viral hepatitis B and C infection (hepatitis B infection determined by the presence of surface antigen; hepatitis C infection determined by the presence of hepatitis C RNA). Follow-up interviews were conducted every six months and generally replicated the baseline interview content.

Sample selection and testing

This study allowed for the testing of 300 blood specimens for %CDT. To ensure adequate sample sizes for the estimation of sensitivity and specificity of %CDT for distinguishing between ''at-risk'' drinking and lesser than ''at-risk'' drinking, we sought to have the sample consist of approximately equal numbers of ''at-risk'' and lesser than ''at-risk'' drinkers. Sensitivity is the proportion of people who meet criteria for unhealthy alcohol use and who have a positive test result. Specificity is the proportion of people who do not meet the criteria who have a negative test result. Thus, all 103 HIV-LIVE subjects reporting ''at-risk'' drinking were included in the sample of 300, including 47 who reported ''heavy'' drinking amounts, 22 of whom also reported ''frequent heavy'' drinking.

All 67 HIV-LIVE subjects who reported consumption that was lesser than ''at-risk'' but not abstinent (no drinking in past 30 days) were included in the study sample. All of these were included in an attempt to have similar numbers with lower risk drinking as with abstinence. To complete the sample of 300 unique subjects, 130 were randomly selected from the remaining subjects, all of whom who reported abstinence. Subjects with multiple samples had a single sample randomly selected.

Selected blood samples were sent for %CDT and GGT analysis to a single laboratory, the Clinical Neurobiological Laboratory at the Medical University of South Carolina. CDT was measured as %CDT using the most recent iteration of the Axis-Shield turbidimetric immunoassay, %CDT-TIA, using the manufacturer's recommended cut-off point of 2.6% to define a positive test. GGT positive cut-off points were defined as ≥ 30U/L for women and ≥ 40U/L for men.

Analysis

All analyses were performed using SAS version 9.1.3 (Cary, NC, USA). The primary analysis was estimation of the sensitivity and specificity of %CDT (cut-off point of 2.6%) for detecting past 30-day ''at-risk,'' ''heavy,'' and ''frequent heavy'' drinking. Ninety-five percent exact binomial confidence intervals were calculated for sensitivity and specificity. Receiver operating characteristic (ROC) curves, plots of sensitivity versus 1-specificity across the range of possible cut points for %CDT, were estimated to summarize the overall diagnostic accuracy of %CDT as well as to evaluate the optimal cut-off point for distinguishing subjects with ''at-risk,'' ''heavy,'' and ''frequent heavy'' levels of drinking. The point of perfect classification (i.e., 100% sensitivity and specificity) is in the upper left hand corner of the plot. We defined the optimal cut-off point as the single point on the curve that is closest to the top left corner of the graph (i.e., the point that maximizes the combination of sensitivity and specificity). The area under the ROC curve (AUC) is a summary measure of the performance of %CDT and represents the probability of ranking a randomly chosen ''at-risk'' drinker above a randomly chosen lesser than ''at-risk'' drinker. An AUC of 1.0 represents a perfect test and while a value of 0.5 represents a test that does not discriminate better than chance. Positive and negative predictive values (PPV, NPV, the probability of having [PPV] or not having [NPV] the condition given the test result) were estimated to further describe the markers.

Exploratory analyses, which stratified by gender and viral hepatitis (hepatitis B or C or both versus neither), were performed to assess potential differences in the accuracy of %CDT across subgroups. Secondary analyses were also conducted to evaluate the accuracy of %CDT for detecting past 14-day ''at-risk'' drinking and of the marker GGT as a test for detecting past 30-day ''at-risk,'' ''heavy,'' and ''frequent heavy'' drinking in an HIV-infected cohort.

We also evaluated the performance of a test discussed in the literature which combines CDT and GGT: $0.8 \times \ln(\text{GGT}) + 1.3 \times \ln(\%\text{CDT}) = \gamma\%\text{CDT}$ (Sillanaukee & Olsson, 2001).

Results

Of the 400 subjects in the cohort, 394 met our study criteria, yielding 1123 available serum samples, of which we tested 300 from unique subjects. Table 1 provides characteristics of study subjects: 34% and 16% drank "at-risk" and "heavy" amounts, respectively; mean age was 44 years; 77% were men; and median CD4 count was 389. More than half were currently taking antiretroviral medication. More than half had viral hepatitis, mainly hepatitis C. Median GGT levels were above normal.

The estimated sensitivity of %CDT for detecting past 30-day "at-risk," "heavy," and "frequent heavy" drinking amounts was 28%, 36% and 41%, respectively (Table 2). Corresponding estimates for specificity were 90%, 88% and 86%, respectively. In analyses that stratified by gender, estimates of sensitivity of %CDT appeared lower for women compared to men; however, the differences were not statistically significant; estimates of specificity were similar for the two groups (Table 3). Sensitivity of %CDT was lower for the subjects with viral hepatitis compared to those without, although the difference was not statistically significant. Specificity did not appear to differ by viral hepatitis status.

The ROC curves for %CDT in detecting 30-day levels of unhealthy alcohol use in the overall sample appear in Figures 1–3. The ROC curves show that with increasing amounts of drinking, %CDT has greater diagnostic accuracy, i.e., the estimated AUC for %CDT was 0.59, 0.60, and 0.68 for 30-day "at-risk," "heavy," and "frequent heavy" drinking, respectively. The optimal %CDT cut-off points for detecting past 30-day "at-risk," "heavy," and "frequent heavy" drinking were 2.2 (sensitivity = 39%, specificity = 81%), 2.3 (sensitivity = 47%, specificity = 78%), and 2.0 (sensitivity = 73%, specificity = 62%), respectively.

Secondary analyses indicated that the sensitivity of %CDT (at the manufacturer's recommended cut-off point) for detecting past 14-day unhealthy drinking ranged from 21% to 39%, and specificity ranged from 86% to 94%. The sensitivity of GGT for detecting past 30-day unhealthy drinking ranged from 79% to 91% for detecting "at-risk," "heavy," and "frequent heavy" drinking amounts while the specificity ranged from 28% to 32%.

The positive and negative predictive values of %CDT were 60% and 70%, respectively, for detecting 30-day "at-risk" drinking and 58% and 74%, respectively, for detecting 14-day "at-risk" drinking. The positive and negative predictive values for detecting 30-day "heavy" drinking were 35% and 88%, respectively. The area under the ROC curve for the plot of γ%CDT sensitivity versus 1-specificity was 0.62 for detecting "at-risk" drinking, 0.63 for "heavy" drinking, and 0.73 for "frequent heavy" drinking.

Discussion

Among HIV-infected adults with alcohol problems, %CDT had poor overall accuracy for detecting unhealthy drinking. At the manufacturer's recommended cut-off point, %CDT had good specificity; however, the sensitivity was too low for %CDT to be a clinically useful screening test. At the optimal cut-off for %CDT in this sample, the diagnostic accuracy of %CDT did not improve sufficiently to make it a clinically useful screening test.

Although the sensitivity of %CDT for detecting "at-risk" drinking appeared higher for men and those without hepatitis, 31% and 43%, respectively, it remained unacceptably low for these subgroups. However, even in a population such as the HIV-LIVE cohort, with a high prevalence of unhealthy alcohol use, the PPV was only 60%. NPV of 70% was similarly not very high, consistent with the low observed sensitivity.

The sensitivity and specificity for detecting past 14-day "at-risk" drinking was similar to the 30-day data, meaning that %CDT did not perform any better even when drinking was more recent. The high specificity of %CDT could make it useful in sequential testing, i.e., as a follow-up test to a positive finding on a highly sensitive questionnaire that screened for unhealthy alcohol use. Such an approach would require further study of both the precision and cost-effectiveness of sequential testing for determining unhealthy alcohol consumption by patients with HIV.

In spite of its recognized shortcomings, we analyzed the operating characteristics of GGT for detecting unhealthy drinking in an HIV-infected cohort because it is a test whose results are commonly available in clinical practice. The sensitivity of GGT was high in our study, much higher than what has been generally reported in the literature where GGT has been shown to have similar or even lower sensitivity than %CDT in samples of undetermined HIV status. It is common for GGT to be elevated in HIV-infected individuals. The high median GGT in

CD4 cells/mm^3	389 (231–582)	410 (250–608)	321 (187–543)	289 (160–474)	214 (95–387)
% CDT	1.8 (1.5–2.3)	1.8 (1.5–2.1)	2 (1.6–2.7)	2.1 (1.5–2.9)	2.3 (1.7–2.9)
GGT	64 (35–169)	58 (30–146)	105 (43–202)	126 (42–213)	149 (77–341)

[a]"at-risk" drinking uses N.I.A.A.A. definition of ≥ 4 drinks in a day or > 7 drinks per week on average for women; ≥ 5 drinks in a day or > 14 drinks per week on average for men, but placed in past 30 days.
[b]"heavy" drinking: ≥ 4 drinks in a day for women; ≥ 5 drinks in a day for men on at least 7 days in past 30 days.
[c]"frequent" heavy: at least seven consecutive days of drinking "heavy" amounts in past 30 days.
[d]Current hepatitis determined from $n = 299$. Hepatitis B infection determined by the presence of surface antigen; hepatitis C infection determined by the presence of hepatitis C RNA, i.e., positive hepatitis C viral load. Seven subjects had no record of hepatitis B surface antigen and one of those had undetectable hepatitis C viral load.
[e]CD4 median determined from $n = 287$. Thirteen subjects had no record of same-day CD4 count.
[f]Q1 = 25th percentile, Q3 = 75th percentile.

Table 2. Sensitivity and specificity of %CDT and of GGT for detecting 30-days "at-risk," "heavy" and "frequent heavy" drinking.

			Subsets of "at-risk"			
	"at-risk"[a]		"heavy" (subset of "at-risk")[b]		"frequent heavy" (subset of "heavy")[c]	
Categories of unhealthy alcohol consumption	Sensitivity (95% CI)	Specificity (95% CI)	Sensitivity (95% CI)	Specificity (95% CI)	Sensitivity (95% CI)	Specificity (95% CI)
Sample size for estimate (% of total sample)	103 (34%)	197 (66%)	47 (16%)	253 (84%)	22 (7%)	278 (93%)
%CDT[d]	28% (19%, 37%)	90% (86%, 94%)	36% (22%, 50%)	88% (84%, 92%)	41% (20%, 61%)	86% (82%, 90%)
GGT[e]	82% (74%, 9%)	32% (26%, 9%)	79% (67%, 0%)	28% (23%, 4%)	91% (79%, 100%)	29% (24%, 34%)

[a]"at-risk" drinking: $\geq$4 drinks in a day or $>$7 drinks per week on average for women; $\geq$5 drinks in a day or $>$14 drinks per week on average for men.
[b]"heavy" drinking: $\geq$4 drinks in a day for women; $\geq$5 drinks in a day for men on at least 7 days in past 30 days.
[c]"frequent heavy" drinking: at least seven consecutive days of drinking "heavy" amounts.
[d]%CDT positive cut-off point was $\geq$2.6%
[e]GGT positive cut-off points were $\geq$30 U/L for women and $\geq$40 U/L for men

Table 3. Sensitivity and specificity of %CDT stratified by gender and viral hepatitis.

			Subsets of "at-risk"			
	"at-risk"[a]		"heavy"(subset of "at-risk")[b]		"frequent heavy" (subset of "heavy")[c]	
	Sensitivity (95% CI[d])	Specificity (95% CI)	Sensitivity (95% CI)	Specificity (95% CI)	Sensitivity (95% CI)	Specificity (95% CI)
Women $n=68$	0.17 (0.02, 0.33)	0.91 (0.83, 0.99)	0.20 (0.00, 0.40)	0.91 (0.83, 0.98)	0.20 (0.00, 0.55)	0.89 (0.81, 0.97)
Men $n=232$	0.31 (0.21, 0.41)	0.90 (0.85, 0.95)	0.44 (0.27, 0.61)	0.87 (0.82, 0.92)	0.47 (0.23, 0.71)	0.85 (0.80, 0.90)
No hepatitis $n=131$	0.43 (0.27, 0.58)	0.91 (0.85, 0.97)	0.64 (0.39, 0.89)	0.86 (0.80, 0.93)	0.57 (0.21, 0.94)	0.83 (0.76, 0.90)
Hepatitis B or C $n=168$	0.19 (0.09, 0.29)	0.90 (0.84, 0.95)	0.24 (0.10, 0.39)	0.89 (0.84, 0.94)	0.33 (0.09, 0.57)	0.88 (0.83, 0.93)

[a]"at-risk" drinking: $\geq$4 drinks in a day or $>$7 drinks per week on average for women; $\geq$5 drinks in a day or $>$14 drinks per week on average for men.
[b]"heavy" drinking: $\geq$4 drinks in a day for women; $\geq$5 drinks in a day for men on at least 7 days in past 30 days.
[c] "frequent heavy" drinking: at least seven consecutive days of drinking "heavy" amounts.
[d]CI = confidence interval.
Notes: Hepatitis B = hepatitis B surface antigen; positive Hepatitis C = presence of detectable viral load. Hepatitis strata calculated from $n=299$ (Seven subjects had no record of hepatitis B surface antigen and one of those had undetectable hepatitis C viral load.)

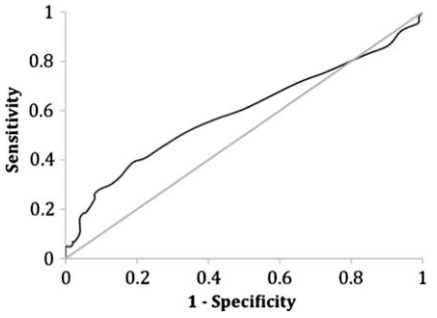

Figure 1. %CDT sensitivity vs. 1-specificity for detecting 30-day "at-risk" drinking.
Notes: Area Under the Curve (AUC): 0.59. The optimal%CDT cut-off point to discriminate 30-day at-risk drinking is 2.2. Sensitivity = 39%, Specificity = 81%.

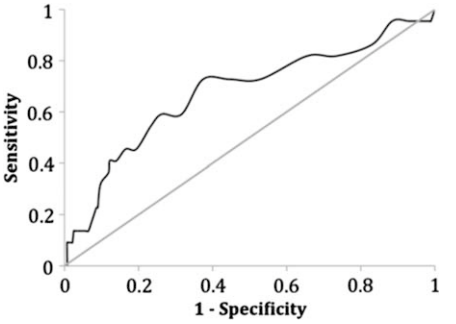

Figure 3. %CDT sensitivity vs. 1-specificity for detecting 30-day "frequent heavy" drinking.
Notes: Area Under the Curve (AUC): 0.68. The optimal%CDT cut-off point to discriminate 30-day frequent heavy drinking is 2.0. Sensitivity = 73%, Specificity = 62%.

our sample, likely of multifactorial etiology, resulted in a very high sensitivity of GGT for detecting unhealthy alcohol use in our sample. This high sensitivity of GGT came at a cost of specificity. Specificity was too low for GGT to be useful as a screening test for unhealthy alcohol use. Also, we found that γ %CDT does not provide a clinically significant advantage over %CDT alone in HIV-infected individuals.

The operating characteristics of %CDT for detecting the spectrum of unhealthy alcohol use by HIV-infected adults has not received adequate attention. Many studies with adults with undetermined HIV status have found %CDT to have greater sensitivity than observed in this study (Bortolotti, De Paoli, & Tagliaro, 2006). These studies included subjects who were drinking more heavily and tested whether %CDT could detect these heavier amounts (Anttila, Jarvi, Latvala, & Niemela, 2004; Chrostek, Cylwik, Szmitkowski, & Korcz, 2006; Zierau et al., 2005). When studies that evaluated %CDT for detecting daily heavy alcohol consumption are excluded, as was done in a systematic review by Koch et al (2004), the range of %CDT sensitivity for detecting lower levels of consumption is similar to our findings.

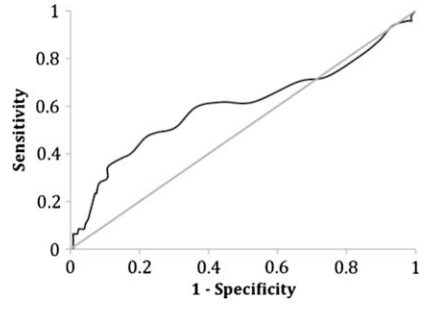

Figure 2. %CDT sensitivity vs. 1-specificity for detecting 30-day "heavy" drinking.
Notes: Area Under the Curve (AUC): 0.60. The optimal%CDT cut-off point to discriminate 30-day heavy drinking is 2.3. Sensitivity = 47%, Specificity = 78%.

This study had its limitations. First, it included a small number of people with "frequent heavy" drinking. On the other hand, this may also be viewed as a strength since we studied an adequate number of people with the condition that is the target of greater importance for screening – the spectrum of unhealthy alcohol use – thereby avoiding the spectrum bias that limited a number of prior studies. Nevertheless the sample size limited the precision of our estimates, particularly in subgroup analyses (e.g., by gender and viral hepatitis). Second, we did not study subjects who had never had alcohol problems. However, we did include subjects with abstinence and those who consumed amounts of alcohol in a range from moderate to heavy use. Third, since we were studying a biomarker, one might question what the reference standard should be. The common biomarkers mentioned, GGT and MCV, lack specificity, and self report may be biased. We chose a widely agreed-upon and validated self-report research tool; our interviews were conducted with assurance of confidentiality and coincide with both an alcohol breath test and blood testing to encourage truth telling.

This study had a number of strengths. We did not exclude people who used ART medications, had liver disease and other co-morbidities. As such, our sample provided a generalizable test of %CDT in HIV-infected adults. In addition, our sample was relatively young, CD4 counts were relatively high, HIV RNA viral loads were relatively low, and so the performances of %CDT and GGT in our study are not likely attributable to very advanced HIV disease.

These findings suggest that %CDT is not sufficiently sensitive for use in screening for unhealthy

alcohol use by people with HIV infection. Next steps for research might include testing other biomarkers for this purpose. Numerous self-report questionnaires have been validated for detecting unhealthy alcohol use. These will likely remain the least expensive, most accurate and most easily implementable tools for screening patients with HIV for unhealthy alcohol use.

Acknowledgements

This study was funded by the following grants: T32HP10028-06, R01AA013216, K24AA015674, and General Clinical Research Centers at Boston University School of Medicine (M01 RR00533) and Beth Israel Deaconess Medical Center (M01 RR01032). Structural and Reliability Analysis of a Patient Satisfaction With Cancer-Related Care Measure

A Multisite Patient Navigation Research Program Study

Pascal Jean-Pierre, PhD, MPH[1,2]; Kevin Fiscella, MD, MPH[3]; Karen M. Freund, MD, MPH[4]; Jack Clark, PhD[5]; Julie Darnell, PhD, MHSA[6]; Alan Holden, PhD[7]; Douglas Post, PhD[8]; Steven R. Patierno, PhD[9]; Paul C. Winters, MS[3]; and the Patient Navigation Research Program Group

BACKGROUND: Patient satisfaction is an important outcome measure of quality of cancer care and 1 of the 4 core study outcomes of the National Cancer Institute (NCI)-sponsored Patient Navigation Research Program to reduce race/ethnicity-based disparities in cancer care. There is no existing patient satisfaction measure that spans the spectrum of cancer-related care. The objective of this study was to develop a Patient Satisfaction With Cancer Care measure that is relevant to patients receiving diagnostic/therapeutic cancer-related care. **METHODS:** The authors developed a conceptual framework, an operational definition of Patient Satisfaction With Cancer Care, and an item pool based on literature review, expert feedback, group discussion, and consensus. The 35-item Patient Satisfaction With Cancer Care measure was administered to 891 participants from the multisite NCI-sponsored Patient Navigation Research Program. Principal components analysis (PCA) was conducted for latent structure analysis. Internal consistency was assessed using Cronbach coefficient alpha (α). Divergent analysis was performed using correlation analyses between the Patient Satisfaction With Cancer Care, the Communication and Attitudinal Self-Efficacy–Cancer, and demographic variables. **RESULTS:** The PCA revealed a 1-dimensional measure with items forming a coherent set explaining 62% of the variance in patient satisfaction. Reliability assessment revealed high internal consistency (α ranging from 0.95 to 0.96). The Patient Satisfaction With Cancer Care demonstrated good face validity, convergent validity, and divergent validity, as indicated by moderate correlations with subscales of the Communication and Attitudinal Self-Efficacy–Cancer (all $P < .01$) and nonsignificant correlations with age, primary language, marital status, and scores on the Rapid Estimate of Adult Literacy in Medicine Long Form (all $P > .05$). **CONCLUSIONS:** The Patient Satisfaction With Cancer Care is a valid tool for assessing satisfaction with cancer-related care for this sample. ***Cancer* 2011;117:854–61.** *© 2010 American Cancer Society.*

KEYWORDS: cancer, disparities, satisfaction, psychometrics, measurement, patient navigation, race-ethnicity.

Patient satisfaction reflects a core dimension of healthcare quality and patient-centered care.[1-3] Patient satisfaction indicates the extent to which patients' healthcare experiences match their expectations.[4,5] The construct of patient satisfaction has been linked to health status, quality of life, adherence to recommended treatment and medical advice including cancer treatment, initiation of complaints, and patient-healthcare provider communication in the clinical dyad.[6-16] Patient satisfaction with care represents an important outcome measure for healthcare in general and cancer care in particular.[17]

Patient satisfaction is 1 of the primary study outcomes of the National Cancer Institute (NCI)-supported Patient Navigation Research Program to reduce disparities in cancer care for individuals from racial/ethnic minorities and lower socioeconomic groups. The Patient Navigation Research Program involves 9 independent research programs operating under cooperative agreements with the NCI Center to Reduce Cancer Health Disparities to evaluate the impact of patient navigation on outcomes among patients with cancer screening abnormalities or diagnosed cancer.[18]

Although there are numerous patient satisfaction measures, including several measures related to cancer treatment, none of these measures spans the spectrum of cancer-related care from screening to treatment of diagnosed cancer.[19-25] For example, the widely used EORTC-IN-PATSAT32 is designed to assess satisfaction with the inpatient cancer care, and FAMCARE assesses satisfaction among those with advanced cancer.[20,24]

In the present study, we aimed to develop a Patient Satisfaction With Cancer Care measure that had: 1) sufficient breadth (ie, addressing satisfaction with care during evaluation of screening abnormalities and treatment), 2) the ability to address many of the challenges confronted by poor and minority individuals receiving cancer-related care, and 3) relevance for evaluation of care among both navigated and un-navigated patients.

MATERIALS AND METHODS

Development of the Patient Satisfaction With Cancer Care

The scale development team included investigators from different Patient Navigation Research Program sites with content and technical expertise in clinical care of patients from diverse cultural and socioeconomic backgrounds, as well as measurement development and psychometrics. The team reviewed existing patient satisfaction measures, considered various domains of satisfaction (access/logistical, interpersonal/relational, communicational/informational, and coordination of care), and selected and modified existing items for inclusion in the new Patient Satisfaction With Cancer Care scale. One additional item was administered only to participants with a confirmed diagnosis of cancer: "My treatment was explained in a way I could understand."

Response Options and Scoring

Patients responded to each scale item on a 5-point Likert scale (1 = Strongly Agree to 5 = Strongly Disagree). A total scale score was obtained by adding scores on all items, with lower scores indicating higher satisfaction with cancer care.

Participants

The Patient Navigation Research Program methods have been previously published.[18] Briefly, the Patient Navigation Research Program is a cooperative program funded by the NCI and the American Cancer Society to rigorously evaluate the role and benefits of patient navigation among participants with abnormal cancer screening findings or diagnosed cancer-breast, cervical, colorectal, or prostate cancer within 9 largely racial/ethnic minority and low-income communities across the country. Study design and type of cancer differ by participating site.

The satisfaction items were administered to a subsample of the 8075 participants in the Patient Navigation Research Program. In all, 891 English-fluent participants from the multisite NCI-sponsored Patient Navigation Research Program completed the Patient Satisfaction With Cancer Care measure. Survey participants were similar in age, but more likely to be female, minority, lower income, and less educated.

Procedures

Medical staff at the Patient Navigation Research Program recruiting sites (eg, clinics or hospitals) was informed about the study and referred eligible patients to speak with a trained research assistant or patient navigator about participating in the study. To minimize possible effects of low literacy, surveys were read out loud to participants in English.

Eligibility and Exclusion Criteria

Eligibility for the present study included having an abnormal breast, cervical, colorectal, and prostate cancer test finding or a new diagnosis of these cancers without any prior history of cancer treatment other than nonmelanoma skin cancer.[18]

Additional Measures

Demographic characteristics

Demographic characteristics included age, sex, race, ethnicity, primary language, income, education, marital status, and whether the patient received care related to evaluation of cancer screening abnormalities or treatment of cancer, and type of cancer being evaluated or treated (breast, cervical, colorectal, or prostate).

Communication and Attitudinal Self-Efficacy–Cancer

The Communication and Attitudinal Self-Efficacy–Cancer is a psychometrically validated multidimensional measure (ie, understanding and participating in care, maintaining a positive attitude, seeking and obtaining information) of communication and attitude. Structural analysis of the Communication and Attitudinal Self-Efficacy–Cancer revealed high internal consistency and construct validity.[26] Given overlap in constructs, we expected that the Patient Satisfaction With Cancer Care would correlate with the Communication and Attitudinal Self-Efficacy–Cancer.

Data Analysis

Dimensionality analysis of the Patient Satisfaction With Cancer Care

Latent structural and psychometric validation analyses were conducted using the SPSS version 17.0 statistical software package for Microsoft Windows (SPSS Inc., Chicago, Ill). Data from our multisite sample were randomly divided into 2 separate datasets (Sample 1, $N_1 = 453$; Sample 2, $N_2 = 438$) using SPSS. One dataset was used to test the latent structure of the Patient Satisfaction With Cancer Care, and the second dataset was used to validate the said structure. We had a very large sample that facilitated calculation of reliable correlation coefficients for the Patient Satisfaction With Cancer Care. This approach is in accordance with guides on sample sizes for factor analysis/principal components analysis.[27,28] In addition, the principal components analysis (PCA) solutions include many high variables markers and therefore could have facilitated stable and reliable estimates of correlation coefficients with even a smaller sample size.[29] Before conducting the PCA, suitability of the data for dimensionality analysis was assessed using various criteria (eg, examination of the correlation matrix for correlations of.30 and above). The PCA was conducted to reduce the data to a few components that could be more easily described. We performed an initial PCA, using Sample 1 data, without rotation to facilitate extraction and examination of meaningful components, based on eigenvalues and scree plot criteria that more accurately describe the latent structure of the Patient Satisfaction With Cancer Care. The Kaiser-Meyer-Olkin value (KMO), an index of sampling adequacy, was used to determine the suitability of the data for dimensionality analysis.[30,31] In addition, we examined the scree plot of eigenvalues to help determine the number of components to retain. We subsequently rotated the initial factor solution using the VARIMAX technique. Items from Sample 2 were also subjected to a PCA to replicate and test the evidence of the structure of the PCA obtained from Sample 1 through successive unconstrained exploratory procedures. We conducted similar PCA for Sample 2 (N_2) as described above for Sample 1 (N_1).

Measurement reliability analysis

Scale reliability assessment was conducted to determine the degree to which items of the Patient Satisfaction With Cancer Care represent a coherent set that measures the same underlying construct. Cronbach coefficient alpha was used as an index of internal consistency of the Patient Satisfaction With Cancer Care. Measurement reliability analysis was conducted separately for Sample 1 and Sample 2.

RESULTS

The mean age of the analytic sample was 51 years (range, 18-98 years). Most of the sample was female (approximately >80%) and included participants from diverse racial/ethnic backgrounds, including white (43%), black (32%), Hispanic/Latino (23%), Asian (1%), American Indian/Alaska Native (0.5%), and other (0.5%). Half of the sample reported only a high school education or less. Participants presented with abnormal test findings or diagnosis from various types of cancer, including approximately 64% breast, 11% cervix, 12% colorectal, 13% prostate, and 0.5% multiple concurrent cancer sites. Detailed demographic and clinical characteristics of study participants are provided in Table 1. All participants provided informed consent for participation. The institutional review board of all participating institutions approved this study.

Sample 1, N1—Testing of Patient Satisfaction With Cancer Care Latent Structure

Suitability for factor analysis (Sample 1, N1)

Examination of the items correlation matrix revealed the presence of many correlation coefficients of.30 and higher. In addition, the KMO value was 0.95, exceeding the recommended value of 0.60.[30,31] The Bartlett Test of Sphericity also reached statistical significance (chi-square [2378] = 7850.920; $P = .001$), which also supported the appropriateness of dimensionality analyses of the correlation matrix.[32] Values were skewed toward favorable ratings, with a mean coefficient of skewness of 1.45 (range, −2.2 to −0.5).

Table 1. Demographic and Clinical Characteristics of 891 Participants

Characteristic	No.	Mean (SD)
Age, 18-98 y	843	51.43 (13.77)

Construct validity (Sample 1, N1)

The initial unrotated PCA revealed the presence of 5 components with eigenvalues >1 (λ>1): 12.698, 1.734, 1.383, 1.087, and 1.081, which explained 45.35%, 6.19%, 4.94%, 3.88%, and 3.86% of the total cumulative variance (64.22%), respectively. Inspection of the scree plot revealed a clear break after the second component. Cattell's scree plot test and the eigenvalues criteria suggested that 2 components could be retained for further investigation.[33] The components matrix showed that approximately 82% of the items (the first 23 items) loaded on the first component, with factor or component loadings ranging from 0.51 to 0.86. Of these 23 items, 5 loaded on factors 3 to 5, with component loadings ranging from −0.31 to 0.44. Another set of 5 additional items loaded moderately to strongly on factors 2 to 4, with component loadings ranging from 0.33 to 0.92. This second set of 5 items seems related primarily to time waiting at the hospital, transportation and money concerns, and explication of medical tests and health condition. Subsequently, we removed items with moderate loadings on multiple components because of plausible overlapping contributions. We also decided to not include components defined by just 1 or 2 variables, because such components are unstable, generally account for a very small percentage of the variance, and are difficult to correctly interpret.[34] On the basis of these criteria, we ended up with a 1-dimensional 18-item Patient Satisfaction With Cancer Care measure, as indicated by a single-component structure with items forming a coherent set that explained 62% of the variance in patient satisfaction with cancer-related care (Table 2). The results of our psychometric analyses support the validity of Patient Satisfaction With Cancer Care for this sample.[34,35]

Sample 2, N2—Validation of Patient Satisfaction With Cancer Care Latent Structure

Suitability for Factor Analysis (Sample 2, N2)

We tested the emergent structure of the data in Sample 1 by conducting another PCA on data from Sample 2. This approach is based on the notion that successful replication through successive unconstrained exploratory procedures will substantiate the underlying structure of the Patient Satisfaction With Cancer Care beyond any constrained confirmatory procedure. Similar to Sample 1, examination of the correlation matrix for Sample 2 revealed the presence of many correlation coefficients of .30 and higher. In addition, the KMO value was 0.95, exceeding

Table 2. Component Loadings for Sample 1 ($N_1 = 453$) and Sample 2 ($N_2 = 438$): Correlations Between Individual Items and the Underlying Component

Patient Satisfaction With Cancer Care Scale Items	Component Loadings	
	Eigenvalue (λ) 14.58	Eigenvalue (λ) 15.25
	Sample 1	Sample 2
1. I felt that my health concerns were understood.	0.782	0.756
2. I felt that I was treated with courtesy and respect.	0.762	0.739
3. I felt included in decisions about my health.	0.816	0.751
4. I was told how to take care of myself.	0.741	0.725
5. I felt encouraged to talk about my personal health concerns.	0.758	0.715
6. I felt I had enough time with my doctor.	0.774	0.790
7. My questions were answered to my satisfaction.	0.805	0.815
8. Making an appointment was easy.	0.549	0.577
9. I knew what the next step in my care would be.	0.670	0.745
10. I feel confident in how I deal with the health care system.	0.744	0.791
11. I was able to get the advice I needed about my health issues.	0.817	0.851
12. I knew who to contact when I had a question.	0.695	0.747
13. I received all the services I needed.	0.798	0.780
14. I am satisfied with the care I received.	0.855	0.829
15. The doctors seemed to communicate well about my care.	0.830	0.792
16. I received high-quality care from my regular doctor.	0.723	0.752
17. I received high-quality care from my specialists.	0.811	0.803
18. My regular doctor was informed about the results of the tests I got.	0.541	0.630

Extraction method: principal components analysis.

the recommended value of 0.6.[30,31] The Bartlett Test of Sphericity also reached statistical significance (chi-square [2378] = 7853.56; $P = .001$), supporting the appropriateness of dimensionality analyses of the correlation matrix.[32]

Construct validity (Sample 2, N2)

The initial unrotated PCA revealed the presence of 5 components with eigenvalues >1 (λ>1): 13.12, 1.76, 1.39, 1.20, and 1.03, which explained 46.87%, 6.31%, 4.96%, 4.28%, and 3.66% of the total cumulative variance (66.09%), respectively. Inspection of the scree plot revealed a clear break after the second component. Cattell's 1966 scree plot test and the eigenvalues criteria supported the retention of 2 components for further investigation.[33] Similar to the PCA for Sample 1, the components matrix showed that approximately 82% of the items (the first 23 items) loaded on the first component, with factor or component loadings ranging from 0.48 to 0.86. Of these 23 items, 8 loaded on factors 2, 4, and 5, with component loadings ranging from −0.41 to 0.47. Another set of 5 additional items loaded moderately to strongly on factors 2 to 5, with component loadings ranging from −0.62 to 0.68. Similar to the structure of the Patient Satisfaction With Cancer Care in Sample 1, the second set of 5 items in Sample 2 seemed to involve time waiting at the hospital, transportation and money concerns, and explication of medical tests and health condition. As previously described for Sample 1, we removed items with moderate loadings on multiple components (2 or more) because of issues related to overlapping contribution in Sample 2. Just as in Sample 1, we did not include components defined by just 1 or 2 variables, because such components are unstable, account for a small percentage of the variance, and are difficult to reliably interpret.[34] On the basis of these criteria, we also ended up with an 18-item 1-dimensional measure for Sample 2 as indicated by a 1-component structure (Table 2). Results of our structural analyses supported the use of the Patient Satisfaction With Cancer Care as a valid measure for this sample and more importantly confirmed the underlying structure of the Patient Satisfaction With Cancer Care through successive unconstrained exploratory procedures.[34,35]

Patient Satisfaction With Cancer Care Reliability and Convergent and Divergent Validity

Scale reliability assessment conducted for the 18-item Patient Satisfaction With Cancer Care

Internal consistency—the degree to which items that make up this scale represent a coherent set that measures the same underlying construct—was evaluated using Cronbach coefficient alpha. The results showed Cronbach coefficient alphas of approximately 0.95 and 0.96 based on standardized items for the Patient Satisfaction With Cancer Care for Sample 1 and Sample 2, respectively. The

scale reliability assessment supported the use of the Patient Satisfaction With Cancer Care as a reliable tool of satisfaction with cancer care for this sample.[36]

Convergent and divergent validity

The Patient Satisfaction With Cancer Care total score for Sample 1 ($N_1 = 453$) correlated with subscales of the Communication and Attitudinal Self-Efficacy–Cancer (Understand and Participate in Care [$r = 0.40$, $P = .001$] and Seek and Obtain Information [$r = 0.32$, $P = .004$]). The results, however, did not reveal any statistically significant correlation between the Patient Satisfaction With Cancer Care total score and age, primary language, marital status, and scores on the REALM long form (all P values $>.05$). Likewise, the Patient Satisfaction With Cancer Care total score for Sample 2 ($N_2 = 438$) positively correlated with subscales of the Communication and Attitudinal Self-Efficacy–Cancer: Understand and Participate in Care ($r = 0.51$, $P = .001$), Maintain a Positive Attitude ($r = .30$, $P = .01$), and Seek and Obtain Information ($r = 0.39$, $P = .001$). Again, the analysis revealed no statistically significant correlation between the Patient Satisfaction With Cancer Care total score and age, primary language, or marital status (all P values $>.05$). Convergent and divergent validity analyses examined the degree to which the Patient Satisfaction With Cancer Care correlates with measures that assess related constructs (eg, the Understand and Participate in Care and the Seek and Obtain Information subscales of the Communication and Attitudinal Self-Efficacy–Cancer) and differ from measures or indices of other unrelated constructs (eg, age, primary language, or marital status), hence confirming that the items of the Patient Satisfaction With Cancer Care formed a coherent set that assesses the specific construct of patient satisfaction with the cancer-related care they received.

DISCUSSION

We designed the Patient Satisfaction With Cancer Care to be a simple and easy to administer tool to assess satisfaction with cancer-related care for individuals from diverse cultural and socioeconomic populations. An important goal for developing the Patient Satisfaction With Cancer Care was to ensure that the measure assesses experiences common to all patients regardless of whether they were navigated. This approach is expected to ensure the applicability and relevance of this measure to people from comparable racial, ethnocultural, and socioeconomic backgrounds.

The results of our structural analysis and psychometric validation revealed a parsimonious and reliable 1-component solution for the Patient Satisfaction With Cancer Care. This measure provides a milieu-specific patient-oriented approach for assessing perceived relevance and satisfaction with cancer care for individuals from diverse racial, ethnocultural, and socioeconomic backgrounds. The Patient Satisfaction With Cancer Care demonstrates high construct validity. The degree to which the items of the Patient Satisfaction With Cancer Care constitute a coherent set that assesses the underlying construct of patient satisfaction with cancer care was demonstrated by high indices of internal consistency and reliability.

The Patient Satisfaction With Cancer Care differs from previous generic scales in that it focuses on satisfaction with cancer-related care rather than the broader concept of healthcare in general or the narrower concept of cancer treatment for a particular cancer, disease stage, or location (hospital or ambulatory).[37-40] The Patient Satisfaction With Cancer Care addresses the broad domain of cancer-related care, including diagnostic testing in addition to treatment rather than focusing on particular or specific aspects of cancer care.[41-43]

The limitations of these findings merit comment. First, we adapted and modified items from existing instruments, but we did not conduct cognitive interviewing.[44] However, a pilot study of the questionnaire revealed no problem that would have indicated a need to modify questionnaire items to help improve participants' understanding or interpretation of the items. In addition, the Patient Satisfaction With Cancer Care scale was administered orally to minimize effects of low literacy; therefore, it is not certain that similar results would be obtained from participants who self-administer the scale.

Second, consistent with previous satisfaction measures, we observed significant skewing or a tendency toward the higher end of satisfaction.[45] Whether this represents truly favorable experiences or reflects low expectations is unknown.[3] We did not specifically query patients about expectations. For many patients, their abnormal screening/diagnosis may have been their first experience with cancer-related care. Thus, they may have used a priori general healthcare experiences to form their expectations, which could explain the trend toward the higher end of reported satisfaction. This could also represent a social desirability response bias related to interview format.[46] Further studies are needed to help determined if

this finding will remain if patients respond anonymously and whether this ceiling effect will affect the sensitivity of the scale.

Furthermore, about 80% of the sample were women. Further studies are needed to confirm generalizability of the Patient Satisfaction With Cancer Care to men. Also, the Patient Satisfaction With Cancer Care accounted for 60% of the variance in patient satisfaction. Follow-up studies are needed to identify plausible factors that could account for the unexplained portion of this variance.

Lastly, we did not assess the responsiveness of the measure to change and/or how well it matches clinical impression. That is, we do not know how well the Patient Satisfaction With Cancer Care will capture differences in healthcare processes. Some aspects of care such as interpersonal processes may have a much greater impact on satisfaction than technical aspects.[46-48]

The strengths of the study include psychometric assessment of the Patient Satisfaction With Cancer Care measure with medically underserved and underrepresented individuals from racial/ethnic minorities and lower socioeconomic populations across different types of healthcare systems (eg, community health centers, Veterans Administration, and university- and community-based oncology practices). The development of the Patient Satisfaction With Cancer Care represents an initial attempt to develop and assess the validity and reliability of a context-specific measure of satisfaction with cancer-related care that is applicable to underserved and traditionally underrepresented racial/ethnic minorities and lower income individuals who face a variety of barriers to cancer care.

Validation of this Patient Satisfaction With Cancer Care measure will facilitate examination of the impact of patient navigation on cancer-related care.[12] Further studies should examine the predictive validity of the Patient Satisfaction With Cancer Care for treatment-related outcomes within longitudinal research settings. Our analyses showed divergent and convergent capabilities of the Patient Satisfaction With Cancer Care. Additional studies that examine divergent and convergent characteristics of the Patient Satisfaction With Cancer Care with other relevant psychometrically valid and reliable health measures will provide evidence of the strength of the Patient Satisfaction With Cancer Care and further inform the underlying structure and validity of this measure for cancer patients. This scale, the Patient Satisfaction With Cancer Care, should prove useful for evaluation of patient navigation not only in the participating 9 sites of the NCI funded Patient Navigation Research Program, but in other cancer navigation programs as well.

Validity of Selected Patient Safety Indicators: Opportunities and Concerns

Haytham MA Kaafarani, MD, MPH, Ann M Borzecki, MD, MPH, Kamal MF Itani, MD, FACS, Susan Loveland, MAT, Hillary J Mull, MPP, Kathleen Hickson, RN, MN, Sally MacDonald, RNC, Marlena Shin, JD, MPH, Amy K Rosen, PhD

BACKGROUND: The Agency for Healthcare Research and Quality (AHRQ) recently designed the Patient Safety Indicators (PSIs) to detect potential safety-related adverse events. The National Quality Forum has endorsed several of these ICD-9-CM-based indicators as quality-of-care measures. We examined the positive predictive value (PPV) of 3 surgical PSIs: postoperative pulmonary embolus and deep vein thrombosis (pPE/DVT), iatrogenic pneumothorax (iPTX), and accidental puncture and laceration (APL).

STUDY DESIGN: We applied the AHRQ PSI software (v.3.1a) to fiscal year 2003 to 2007 Veterans Health Administration (VA) administrative data to identify (flag) patients suspected of having a pPE/DVT, iPTX, or APL. Two trained nurse abstractors reviewed a sample of 336 flagged medical records (112 records per PSI) using a standardized instrument. Inter-rater reliability was assessed.

RESULTS: Of 2,343,088 admissions, 6,080 were flagged for pPE/DVT (0.26%), 1,402 for iPTX (0.06%), and 7,203 for APL (0.31%). For pPE/DVT, the PPV was 43% (95% CI, 34% to 53%); 21% of cases had inaccurate coding (eg, arterial not venous thrombosis); and 36% featured thromboembolism present on admission or preoperatively. For iPTX, the PPV was 73% (95% CI, 64% to 81%); 18% had inaccurate coding (eg, spontaneous pneumothorax), and 9% were pneumothoraces present on admission. For APL, the PPV was 85% (95% CI, 77% to 91%); 10% of cases had coding inaccuracies and 5% indicated injuries present on admission. However, 27% of true APLs were minor injuries requiring no surgical repair (eg, small serosal bowel tear). Inter-rater reliability was >90% for all 3 PSIs.

CONCLUSIONS: Until coding revisions are implemented, these PSIs, especially pPE/DVT, should be used primarily for screening and case-finding. Their utility for public reporting and pay-for-performance needs to be reassessed. (J Am Coll Surg 2011;212:924–934. © 2011 by the American College of Surgeons)

Since publication of the Institute of Medicine's 2 landmark reports, "To Err is Human" and "Crossing the Quality Chasm" in 2000, patient safety has become a national health care priority.[1,2] The number of studies aimed at measuring adverse events, safety-related events, errors, or patient harm has increased exponentially in the last few years. Medical record review promises richer clinical detail in identifying adverse events, but is resource-intensive and expensive.[3] Traditional mortality and morbidity conferences show less than 25% sensitivity in detecting adverse events when compared with the large chart-based quality measurement initiatives such as the National Surgical Quality Improvement Program (NSQIP).[4,5]

Recently, in an effort to improve and increase detection of potentially preventable safety events in acute-care hospitals, the Agency for Healthcare Research and Quality (AHRQ) designed a set of evidence-based ICD-9-CM-based algorithms called Patient Safety Indicators (PSIs). The PSIs represent a significant advance in the field of patient safety because they use readily available hospital discharge data that can be risk adjusted to screen for safety-related events in the inpatient setting.[6] The PSIs were ini-

pPE/DVT = postoperative pulmonary embolus and deep vein thrombosis
PPV = positive predictive value
PSI = Patient Safety Indicator
VA = Veterans Health Administration
VTE = venous thromboembolism

tially intended as screening tools to identify safety-related events or as case-finding tools for internal quality improvement purposes. However, in the last several years, they have been used by multiple organizations for hospital profiling and pay-for-performance purposes.[7,8] Eight of the PSIs have been endorsed by the National Quality Forum (NQF) as hospital performance measures, and 4 (plus 1 composite measure) have been adopted by the Centers for Medicare and Medicaid Services (CMS) for hospital comparisons of quality and safety and financial reimbursement.[9,10]

With the increased use of PSIs for quality assessment, public reporting, hospital profiling, and reimbursement,[8,11] many clinicians, policymakers, and researchers have raised concerns over the validity of PSIs, given that the PSI algorithms are based on administrative data that are well known for their variability and inconsistency in the coding of diagnoses and procedures. Some of these coding issues include ambiguity in ICD-9-CM coding guidelines, variation in coding practices across different hospitals, and the codes' inability to differentiate between events that happened de novo versus those that were present on admission.[12,13] Although the current literature suggests that PSIs examined to date have moderate to high sensitivities and specificities, their measured performance has been found to depend on the nature of the specific PSI, the nature of the adverse events it targets, and the method of validation used to test its performance. In these multiple validation attempts, the calculated positive predictive values (PPVs) of PSIs against chart abstraction as the "gold standard," ranged between 44% and 91%.[14-20]

Although the criterion validity of several PSIs against the gold standard has been examined in the private sector, little is known about whether these results are reliable in other health care settings, such as the Veterans Health Administration (VA). In this study, we examined the positive PPV of 3 surgical PSIs against medical record review: postoperative pulmonary embolus and deep vein thrombosis (pPE/DVT), iatrogenic pneumothorax (iPTX), and accidental puncture and laceration (APL). These 3 PSIs have all been endorsed by the National Quality Forum as quality measures; APL and iPTX have been adopted by CMS.

METHODS

We applied the AHRQ PSI software (v.3.1a) to VA fiscal year 2003 to 2007 (October 1, 2002 to September 30, 2007) administrative data from a sample of 28 VA hospitals to identify (flag) patients suspected of having a pPE/DVT, iPTX, or APL. To determine rates of true and false positives for each PSI, trained nurses conducted a retrospective chart review of 336 flagged charts (112 charts per PSI) using standardized chart abstraction tools and guidelines developed by the AHRQ and modified for the VA's electronic medical record. Inter-rater reliability testing of the 2 nurse abstractors was also performed. The required Institutional Review Board (IRB) approvals from the Bedford VA Medical Center and the VA Boston Healthcare System were obtained to conduct this study.

PSI overview and definitions

PSIs are calculated as rates: the numerator consists of all discharges with diagnoses, procedures, and/or other attributes indicating the occurrence of the particular adverse event; the denominator includes all discharges at risk for the adverse event, with certain exclusions. All denominators include patients aged 18 and older and exclude patients with Major Diagnostic Category (MDC) 14 (pregnancy, childbirth, and puerperium).[21]

Postoperative PE/DVT detects the occurrence of postoperative venous thromboembolism (VTE) by identifying discharges that have any of the ICD-9-CM codes for PE or DVT in a secondary diagnosis field. The denominator includes all surgical discharges as defined by specific Diagnosis-Related Groups (DRGs) and an ICD-9-CM code for an operating room procedure, narrowing the denominator to those cases most likely to be preventable. It excludes all patients with pre-existing (principal diagnosis or secondary diagnosis present on admission, if known) PE or DVT and patients who underwent a procedure to interrupt the vena cava either as the only operating room procedure during admission or before or on the same day of the index operating room procedure.

The occurrence of iPTX is targeted by identifying discharges with the ICD-9-CM code 512.1 in any secondary diagnosis field. The denominator includes all surgical and medical discharges of patients with specific DRGs. It excludes patients with the code 512.1 in a primary diagnosis field; a code for diaphragmatic surgery repair; a cardiac surgery DRG; a thoracic surgery or lung or pleural biopsy code; and a diagnosis code for chest trauma or pleural ef-

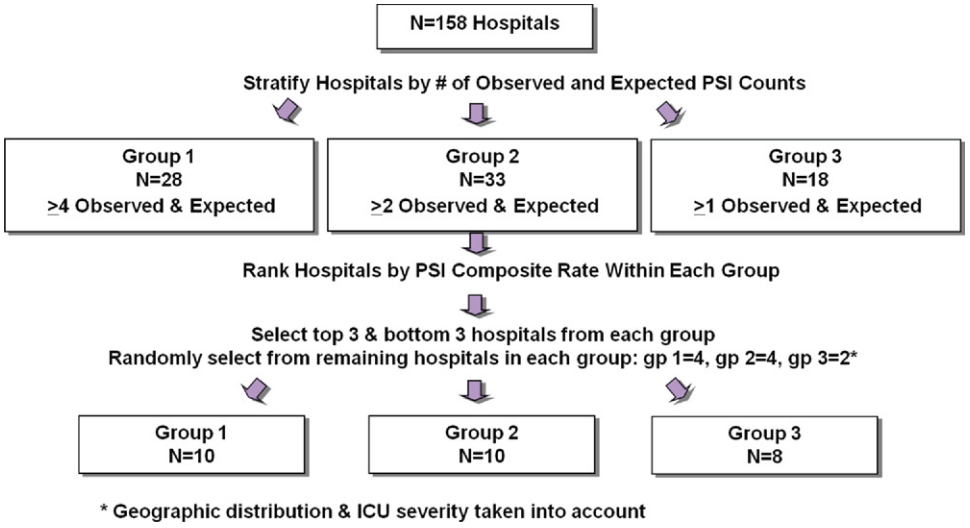

Figure 1. Hospital sampling strategy. PSI, Patient Safety Indicator.

fusion. Iatrogenic pneumothoraces caused by procedures performed within 72 hours before admission are included. Similar to pPE/DVT, the denominator was purposely restrictive in order to capture the most "preventable" cases.

APL captures the occurrence of accidental cut, puncture, perforation, or hemorrhage during medical care (ICD-9-CM codes E870.0 through E870.9) or accidental puncture or laceration during a procedure (ICD-9-CM code 998.2) in a secondary diagnosis field. The denominator includes all surgical and medical discharges excluding patients whose APL was present on admission or in a primary diagnosis field.

Hospital selection

Our initial hospital sample included 158 acute-care VA hospitals. To obtain a manageable number of hospitals for chart review, and to minimize variation in coding across hospitals, we selected a sample of hospitals from the 158 that represented a broad spectrum of PSI rates. We grouped the 158 hospitals into 3 tiers based on their observed and expected rates of PSIs, exclusive of PSI 5 (foreign body left during procedure) and PSI 8 (postoperative hip fracture), both of which had low incidence rates across most hospitals. The expected number of PSI events of a specific facility was calculated as the national VA PSI rate multiplied by the PSI denominator of that specific facility. The first group of hospitals included facilities that had a numerator of at least 4 safety-related events in both the expected and observed numerators of each PSI. The second group had at least 2 safety-related events in the expected and observed numerators of each PSI. The third group had at least 1 safety-related event in the expected and observed numerators of each PSI. Hospitals with less than 1 safety-related event in the expected and observed numerators in any of the PSIs were excluded, yielding a final sample of 79 hospitals. Within each tier of hospitals, facilities were ranked using the AHRQ PSI composite rate.[21] The top 3 and bottom 3 hospitals were included in the hospital sample. We then randomly selected from the remaining hospitals within each stratum to obtain a sample of 28 hospitals. To assure balanced geographic representation, 3 hospitals were replaced by the next hospital in rank, for a final sample of 28 hospitals representing diverse geographic regions of the US. The hospital selection process is shown in Figure 1.

Case selection

Four flagged medical records per PSI (pPE/DVT, iPTX, APL) were randomly selected from each of the 28 hospitals for a total of 336 medical records. Based on previously reported PPV estimates, 112 cases per PSI were selected to ensure reasonably narrow PPV confidence intervals (range 10% to 20%). When a certain facility had less than 4 flagged records for a specific PSI, flagged records were reviewed from the next facility within the stratum, for a maximum of 8 records total per hospital.

Medical record abstraction

Two trained nurses used standardized abstraction instruments to review medical records for occurrence of a safety-related event (pPE/DVT, iPTX, or APL); demographics, comorbidities, and risk factors of the patient population; clinical circumstances surrounding the safety-related event; and patient outcomes after the event. Nurse training included several sessions discussing the rationale behind each PSI, the likely sources of information needed from the electronic medical record, and a systematic chronology for

chart abstraction. When the nurse abstractors were uncertain about any item, the medical record was referred to the research team physicians (HK, AB, KI) for resolution.

Inter-rater reliability

After completion of nurse training, we initiated inter-rater reliability (IRR) testing, as recommended in the literature, to obtain a standardized and reliable method of abstraction.[22] At least 10% of the medical records were reviewed by both nurses, and IRR was measured as the percentage of agreement on select key questions of each abstraction tool, such as ascertainment of the safety-related event. Records were abstracted in groups of 5 until >90% agreement was obtained; this typically occurred after the first or second round of IRR, and then nurses were instructed to proceed by abstracting separate charts. After each round of IRR (including the round achieving >90%), a discussion of disagreements took place in the presence of the clinical physicians (HK, AB, KI) with resulting instrument revisions and/or guideline clarifications as appropriate. An additional round of IRR was performed on 5 records toward the end of the abstraction process to check for potential abstractor drift.

Positive predictive value

For each of the 3 PSIs, we calculated PPV as the rate of true positives divided by the number of medical records reviewed and derived 95% confidence intervals for that estimate.

True positive analysis

For patients with a confirmed pPE/DVT, iPTX, or APL, we performed descriptive analyses of multiple continuous and categorical variables including demographics (age, gender, and race or ethnicity), comorbidities, relevant risk factors, and the nature of the surgical procedure and outcomes. For example, for pPE/DVT, the location of the DVT and the index procedure preceding the PE or DVT were identified. For iPTX, we examined the cause of the pneumothorax (eg, subclavian or internal jugular central line insertion, ventilator-associated barotrauma) and the training level of the staff involved in the procedure (attending vs trainee). For APL, we examined the nature of the surgical procedure, the type of puncture or laceration (eg, bowel injury, durotomy, and splenic injury), and the training level of the staff primarily involved in the procedure. All statistical analyses were performed using SAS version 9.1.

False positive analysis

All false positive cases underwent further detailed review to better understand why they were incorrectly flagged by the PSI algorithms.

RESULTS

Of 2,343,088 admissions, 6,080 were flagged for pPE/DVT (0.26%), 1,402 for iPTX (0.06%), and 7,203 for APL (0.31%).

Postoperative pulmonary embolus or deep vein thrombosis

Positive predictive value

Of 112 cases, 48 were true events of postoperative PE or DVT, yielding a PPV of 43% (95% CI 34% to 53%). IRR between chart abstractors was measured at 94%.

True positive analysis

As shown in Table 1, the patient population was entirely male, with a mean age of 70 years. Seventy-one percent were white, non-Hispanic patients. The mean number of comorbidities per patient was 1.6: 17% of the patients were diabetic, 17% had chronic pulmonary disease, 13% had a malignancy, and 8% had congestive heart failure. Twenty-two of the 48 true pPE/DVT patients had only a DVT diagnosis (46%), 19 patients had only a PE diagnosis (40%), and 7 patients had both a DVT and a PE diagnosed (15%). Of the total of 29 DVTs, 23 involved the lower extremity (79%), and only 4 involved the upper extremities (14%). Orthopaedic and abdominal procedures accounted for more than half of the index procedures preceding the VTE events (38% and 21%, respectively); 67% of the index procedures were elective in nature. The median length of stay for these admissions was 22 days. All-cause in-hospital mortality was 19%.

False positive analysis

Of a total of 64 false positive cases, 16 (25%) patients had a PE and/or DVT diagnosis present on admission (diagnosed 6 months or less before admission), 10 patients (16%) had a remote history of PE/DVT (diagnosed more than 6 months before admission), and 14 patients (22%) were diagnosed after admission but before the index procedure. Coding-related inaccuracies accounted for the remaining 24 false positives (38%) (Fig. 2). These included cases of arterial (not venous) thrombosis, superficial (not deep) vein thrombosis or thrombophlebitis, and cases in which a postoperative PE and DVT workup was negative or the etiology for patient postoperative mortality was uncertain (ie, "rule out" PE). Ten of the cases (9%) were considered false positives for diverse reasons (the miscellaneous category). For example, one of the false positive cases had a discharge summary stating: "patient with history and PE compatible with acute appendicitis." It seems likely that, in this instance, the coder mistook the abbreviation "PE" to stand for pulmonary embolus rather than physical examination.

Iatrogenic pneumothorax

Positive predictive value

Out of 112 cases reviewed, 82 were true iatrogenic pneumothoraces, yielding a PPV of 73% (95% CI, 64% to 81%]. IRR between the chart abstractors was measured at 94%.

True positive analysis

As shown in Table 2, the population was 94% male and 62% white non-Hispanic; mean age was 68 years, and the mean body mass index was 24.5 kg/m^2. Hypertension, airway lung disease (eg, asthma, COPD), and diabetes mel-

litus were the most prevalent risk factors in the patient population (38%, 29%, and 23%, respectively). Of 82 cases of true iatrogenic pneumothoraces, 31 were caused by central venous catheter insertions (38%), 15 by transthoracic needle aspirations or biopsies (18%), 15 by cardiac pacemaker or defibrillator placement (18%), 3 by liver biopsies or liver lesion radiofrequency ablation (4%), 3 by mechanical ventilation (4%), and 1 by cardiopulmonary resuscitation (1%). Several miscellaneous procedures (eg, brachial, axillary or intercostal nerve blocks, pericardiocentesis) accounted for 14 pneumothoraces (17%). Forty-five percent of the pneumothoraces occurred during procedures performed by physicians in training; 33% occurred during procedures performed by attending-level physicians alone. The median length of hospital stay for these patients was 12 days, and the all-cause in-hospital mortality was 18%.

False positive analysis

There were 30 false positive cases, including 10 patients with an old history of pneumothorax or pneumothorax present on admission (more than 72 hours before admission), and 20 cases of inaccurate coding (Fig 3). The latter included cases in which the pneumothorax was spontaneous but not iatrogenic; cases in which lung consolidation or collapse due to pneumonia or empyema were mistaken for iatrogenic pneumothoraces; and cases in which the procedure was known a priori to breach the pleural cavity, such as a thoracic procedure or a lung biopsy.

Accidental puncture or laceration

Positive predictive value

Ninety-five of 112 cases represented "true" cases of accidental punctures or lacerations, yielding a PPV of 85% (95% CI, 77% to 91%). IRR between the chart abstractors was measured at 97%.

True positive analysis

As illustrated in Table 3, the population was 96% male and 63% white non-Hispanic; mean age was 67 years, and mean body mass index was 27.8 kg/m^2. The mean number of comorbidities was 1.5, with the most common comorbidities being hypertension (57%), diabetes mellitus (22%), and chronic pulmonary disease (12%). Seventy-nine of the 95 true iatrogenic events involved the chest or the abdomen (83%); 75 of 95 occurred in the operating room (79%). Injury to vascular structures (inadvertent injury to large arteries or veins), bowel (eg, iatrogenic enterotomy), abdominal organs (eg, splenic injury in a colectomy), genitourinary organs (eg, ureteral injury), and spinal dura (eg, durotomy) accounted for 81% of the punctures or lacerations (23%, 17%, 15%, 13%, and 11%,

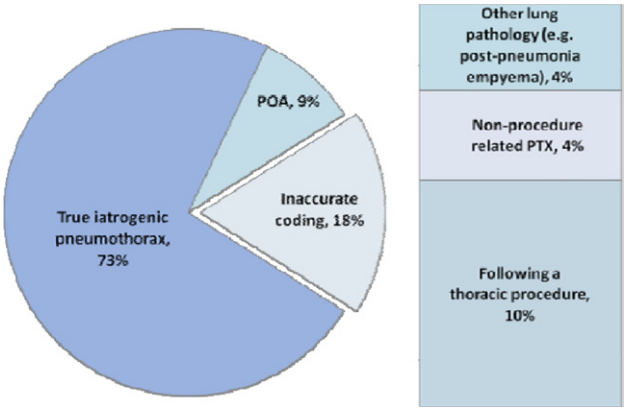

Figure 3. Positive predictive value and analysis of false positives of iatrogenic pneumothorax (iPTX). Numbers might not add to totals due to rounding. The percentages reported in the figure refer to the percentage of the total number of cases; those reported in the text of the manuscript refer to the percentage of the false positive cases only. POA, present on admission.

respectively). Simple serosal bowel tears accounted for 6% of the injuries. When management of these injuries was examined, 26% of them required no surgical management at all (eg, a small serosal bowel tear that was not repaired or a small spinal durotomy that was managed using gelfoam only). Forty-four percent of these injuries occurred during procedures performed by physicians in training; 37% occurred during procedures performed by attending-level physicians alone. In 25% of cases, surgeons reported presence of adhesions or scar tissue; an additional 5% were associated with abnormal anatomy. The median length of stay for patients who sustained these injuries was 8 days. The all-cause in-hospital mortality of these patients was 5%.

False positive analysis

Out of a total of 17 false positive cases, 6 were patients with punctures or lacerations that were present on admission (35%) and 11 were cases of inaccurate coding diagnosis (65%) (Fig. 4). Half of the cases in the latter category were due to the puncture or laceration being nonaccidental (eg, ampulla of Vater "slit" during an endoscopic retrograde cholangiopancreatography to release impacted stones; spontaneous nonprocedure sigmoid colon perforation). The other half involved miscellaneous conditions (eg, suspicion of an intubation-related pharyngeal injury that was later ruled out), including cases in which the reason for coding as an accidental puncture or laceration remained unclear to the chart abstractors.

DISCUSSION

This is the first study to examine the validity of pPE/DVT, iPTX, and APL in the VA. We found that the PPVs of these 3 PSIs varied considerably. Postoperative PE/DVT had a low PPV (43%), iPTX had a moderate PPV (74%), and APL had a moderate-to-high PPV (85%). However, 26% of the accidental punctures or lacerations detected by the APL algorithm were minor injuries that did not require any surgical repair or intervention (eg, serosal bowel tears or dural tears that heal with simple observation or with the use of sealants). Our PPV findings are consistent with those from private sector studies.[14-20,23] Two recent studies estimated the PPV of pPE/DVT to be between 44% and 55%.[14] A separate study estimated the PPV of APL to be around 91%, but similarly noted that 24% of the injuries were "inconsequential," "expected to heal without repair," and for which "the risk may have been acceptable relative to the goals of the procedure."[16] Another recent study estimated the PPV of iPTX to be around 78%, similar to our findings, with 44% of the pneumothoraces resulting from central venous line insertions.[23]

Policy implications

The PSIs we studied show promise as screening tools that can be used to detect patient safety events related to postoperative VTE, iatrogenic pneumothoraces, and accidental punctures or lacerations. Their accuracy can be improved by strategies focused on adjustment of coding guidelines and efforts aimed at educating coders and ameliorating their clinical knowledge. In addition, introduction of "present on admission" flags in administrative data, an intervention already adopted in some states and in many hospitals as of 2007, will clearly improve the PPV of these PSIs by differentiating between new onset diagnoses and those that patients have before admission to the hospital. The ICD-9-CM codes used in the PSI algorithms were initially designed for billing purposes; therefore, using them for clinical and quality of care purposes may require modifications directly to the coding schemes. For example, coding all the "rule out" diagnoses referred to in a physician's note when a postoperative patient experiences shortness of breath (eg, myocardial infarction, pulmonary embolus, pulmonary edema, COPD exacerbation, etc) might make sense from a financial perspective; however, it serves to decrease the specificities and alter the predictive values of the PSIs, which rely heavily on the clinical accuracy of the ICD-9-CM codes. Despite the relative lack of financial incentives in coding in the VA compared with other settings, the fact that our PPVs were similar to or lower than those in the private sector suggests that the shortcomings of the PSIs are inherent to the coding algorithms and practices, and not specific to any one setting. Shifting coding practices to rely on standard accepted clinical criteria rather than physician notes and reports alone will definitely improve the predictive value of PSIs. More importantly, tar-

geted coder education is essential to avoid many of the shortcomings of administrative data in general and the PSIs in specific. Misunderstanding of the nuances of clinical and surgical care was evident throughout this project, where physicians' phrases were occasionally taken out of context, such as with the interpretation of PE as "pulmonary embolus" instead of "physical examination."

Even if the sensitivity and specificity of PSIs were at a theoretical 100%, one also needs to address the conceptual

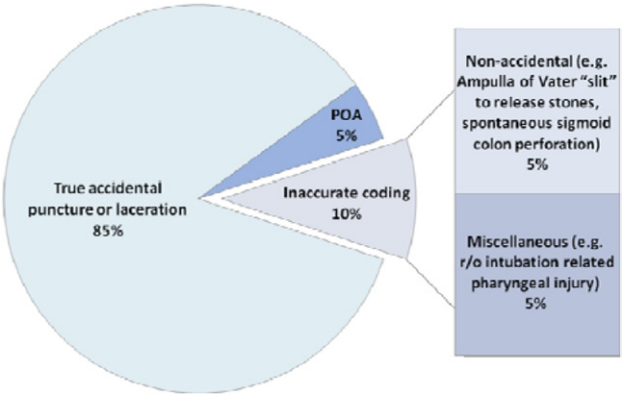

Figure 4. Analysis of false positive cases of accidental punctures or lacerations (APLs). POA, present on admission; r/o, rule out.

framework that correlates the occurrence of an APL, iPTX, or pPE/DVT with suboptimal or poor quality of care. In other words, discussion of what actually makes a good quality indicator or measure goes beyond sensitivities and specificities; it implies a risk-adjusted causal relationship between the provision of certain health services and the occurrence of adverse patient outcomes. This discussion is certainly beyond the scope of this article, which is primarily concerned with examining the criterion validity of the PSIs. The interplay of patient characteristics, hospital/physician/clinical team performance, and the specific circumstances surrounding an episode of care in defining outcomes is far from simple (even with risk adjustment), complicating identification of specific adverse events for the purpose of quality benchmarking and public reporting.

Clinical implications

In addition to the policy implications of the results presented here, analyses of the true safety-related events (pPE/DVT, iPTX, and APL) provide us with significant insights into the nature of the adverse events and the circumstances surrounding them.

Postoperative pulmonary embolus and deep vein thrombosis

Orthopaedic and abdominal procedures accounted for more than half the cases in which a postoperative VTE occurred, stressing the importance of DVT mechanical and pharmacologic prophylaxis in noncardiac surgery in general, and particularly, in orthopaedic and abdominal procedures. It is also notable that 17% of the DVTs diagnosed did not involve lower extremity veins, a classical target for quality improvement efforts. The importance of such a finding stems from the fact that the mechanisms and preventive methods involved in upper versus lower extremity DVTs are essentially distinct. Although sequential compression devices, prophylactic anticoagulation, and early ambulation help prevent lower extremity vein thrombosis, timely removal of central venous access lines, such as central venous catheters or peripherally-inserted central catheters (PICC) lines, is more relevant in the prevention of upper extremity DVTs. We believe that risk-adjusted upper and lower extremity DVTs are both important as potential "quality measures;" therefore, modification of this specific PSI and associated ICD-9-CM codes to separately detect lower and upper extremity DVTs would be useful from a quality improvement perspective. The all-cause inpatient mortality of patients who sustained a VTE was elevated (19%), although it is extremely hard to tease out the mortality risk attributable to the VTE alone because many of these patients had multiple serious medical problems and complications during the same admission.

Iatrogenic pneumothorax

Interestingly, only 38% of the iatrogenic pneumothoraces detected could be attributed to central line insertion, and procedures such as cardiac pacemaker or defibrillator placement, transthoracic needle aspiration, and percutaneous liver biopsy accounted for a significant number of additional pneumothoraces. In addition, the mean body mass index of patients who sustained an iPTX was less than 25 kg/m^2, and a large proportion of patients had airway disease, suggesting that a thin patient with COPD or emphysema might be at higher risk for an iPTX than an obese patient, who might present an otherwise technically challenging body habitus for insertion of a central line or a transthoracic needle drainage. Slightly less than half the procedures causing the pneumothoraces were performed by physicians-in-training, which raises the question of the adequacy of supervision of bedside or interventional procedures, especially central line placements.

Accidental puncture or laceration

As expected, APLs were more common in the chest and abdomen and most commonly involved vascular and intra-abdominal organs. In addition, it seems that this indicator detects a high proportion of injuries occurring during spinal operations (eg, durotomy). Similar to iPTX, a significant number of the injuries occurred when a procedure was being performed by a trainee rather than an attending physician. Such a finding is hard to interpret without conducting further research, but raises issues related to the importance of trainee supervision and the learning curve of complex surgical procedures. More importantly, the nature of the accidental punctures and lacerations detected by this indicator presents serious concerns with regard to the discriminatory ability of this indicator. At least 27% of these "true positive" cases revealed injuries that can be considered to have no real clinical (or surgical) relevance. Correlating an injury, such as a serosal bowel tear during an abdominal procedure characterized by extensive intra-abdominal adhesions, to the quality of care that the surgeon, the surgical team, or the hospital provides seems unfair at the least and even ridiculous at times. Adopting such a PSI before improving its ability to distinguish between clinically relevant and clinically irrelevant injuries will provide surgeons with incentives to avoid noting the occurrence of such minor injuries in their operative notes in fear of equating these with serious accidental injuries as indicated by the PSI. Such unintended consequences will clearly be counterproductive to efforts aimed at improving the quality of surgical care.

Limitations

This study is based on retrospective review of medical records of a limited sample of male veteran patients. One might argue that there is less financial incentive in the VA to strive for accuracy in coding in the VA system compared with the private sector, but previous studies show very good accuracy and reliability of diagnostic and procedural coding in the VA.[24,25] In addition, we had limited objective ability to assess the preventability of the detected adverse events or their association with the quality of care provided. Nonetheless, if the study's results are placed in the context of similar validation efforts taking place in several medical institutions across the nation, a reliable idea of the performance of these indicators can be achieved. The utility of these PSIs, particularly pPE/DVT, as performance measures, needs to be viewed with caution and should be reassessed.

Future directions

As they currently stand, the use of some PSIs (particularly pPE/DVT) as quality measures for hospital safety profiling, public reporting, and pay-for performance is premature. Our research team is currently studying the sensitivity of pPE/DVT, iPTX, and APL and the processes of care that might have contributed to the occurrence of these adverse events; this task is necessary for a full evaluation of PSIs, but requires complex epidemiologic statistical models and extensive medical record review to detect safety-related events that are potentially missed by these indicators.

(*Received 27 April 2010; final version received 18 November 2010*)

The association between smoking and HIV disease progression has been examined in several studies; however, findings have been inconsistent. We examined the effect of recent cigarette smoking on CD4$^+$ T cell count/μl (CD4 count) and HIV RNA concentration (HIV viral load (VL)) among two HIV-infected cohorts with alcohol problems in Massachusetts in the periods 1997–2001 and 2001–2006 using a prospective cohort design and linear mixed models. Smoking groups were defined as: minimal or non-smokers, light smokers, moderate smokers, and heavy smokers. Age, alcohol use, injection drug use, depressive symptoms, gender, annual income, and antiretroviral therapy adherence were considered as potential confounders. Among 462 subjects, no significant differences in CD4 count or VL were found between smoking groups. Using minimal or non-smokers as the reference group, the adjusted mean differences in CD4 count were: 8.2 (95% confidence interval (CI): −17.4, 33.8) for heavy smokers; −0.1 (95% CI: −25.4, 5.1) for moderate smokers; and −2.6 (95% CI: −28.3, 3.0) for light smokers. For log10 VL, the adjusted differences were: 0.03 (95% CI: −0.12, 0.17) for heavy smokers; −0.06 (95% CI: −0.20, 0.08) for moderate smokers; and 0.14 (95% CI −0.01, 0.28) for light smokers. This study did not find an association between smoking cigarettes and HIV disease progression as measured by CD4 cell count and VL.

Keywords: cigarette smoking; CD4$^+$ T cells; viral load; HIV

Introduction

With the major prognostic advance of highly active antiretroviral therapy (HAART; Crum et al., 2006; Detels et al., 1998; Palella et al., 1998), impetus to understand other potential avenues to prevent disease progression among Human Immunodeficiency Virus (HIV)-infected persons has been sought (Baum et al., 1995; Cheng et al., 2007; Cook et al., 2008; Fawzi et al., 2004; Jia et al., 2007). Since smoking is common among HIV-infected persons (Niaura et al., 2000; Webb, Vanable, Carey, & Blair, 2007) its effect on HIV disease progression has merited study. Smoking can suppress the maturation of dendritic cells in the lymph nodes thereby weakening the function of CD4$^+$ T cells (Robbins et al., 2004; Robbins, Franco, Mouded, Cernadas, & Shapiro, 2008). It can also affect the efficiency of peripheral blood mononuclear cells to secrete cytokines (Ouyang et al., 2000). Smoking has also been reported to up-regulate the expression of Fas (cell surface molecules mediating apoptotic cell death) on peripheral blood lymphocytes, rendering them susceptible to apoptosis (Bijl, Horst, Limburg, & Kallenberg, 2001). Other reported possible mechanisms explaining the adverse effects of smoking on immunological function have been described (Abbud, Finegan, Guay, & Rich, 1995; Carrillo, Castro, Cuevas, Diaz, & Cabrera, 1991; Kalra, Singh, Savage, Finch, & Sopori, 2000; Kuniak et al., 1995; Petersen, Steimel, & Callaghan, 1983; Silverman, Potvin, Alexander Jr, & Chretien, 1975; Sopori, Gairola, DeLucia, Bryant, & Cherian, 1985; Sopori & Kozak, 1998; Tollerud et al., 1989a).

Several epidemiologic studies have investigated the relation between cigarette smoking and the course of HIV infection yielding mixed results. Two cohort studies (Conley et al., 1996; Crothers et al., 2005) and two cross-sectional studies (Palacio, Hilton, Canchola, & Greenspan, 1997; Slavinsky III et al., 2002) found an association between smoking and development of opportunistic infections (OIs). In contrast, eight cohort studies (Burns et al., 1996; Coates et al., 1990; Craib et al., 1992; Eskild & Petersen, 1994; Galai et al., 1997; Nieman, Fleming, Coker, William, & Mitchell, 1993; Stephenson et al., 1999; Webber, Schoenbaum, Gourevitch, Buono, & Klein, 1999) and two cross-sectional studies (Gritz, Vidrine, Lavez,

Amick, & Arduino, 2004; Webb et al., 2007) reported a null association. One study (Royce & Winkelstein, 1990) linked smoking with an increase in $CD4^+$ T cells among males although the increase was less pronounced in HIV-infected individuals.

Inconsistent results regarding the effect of smoking on HIV disease progression may in part be attributed to the differing characteristics of the study populations. Adjustment for potential confounders (e.g., alcohol use) did not consistently occur. As most previous epidemiologic studies used the incidence of OIs as a primary endpoint, we considered the other useful biological markers that might complement the observations of clinical outcomes in the examination of whether smoking accelerates HIV disease progression.

We therefore analyzed data from a prospectively assessed two cohorts of HIV-infected patients with alcohol problems to examine the association of cigarette smoking with $CD4^+$ T cell count (CD4 count) and HIV viral load (VL), We hypothesized that smoking would be associated with a lower CD4 count and a higher VL.

Design and methods

Study population

Study participants were from two longitudinal cohorts of HIV-infected persons with alcohol problems: HIV Alcohol Longitudinal Cohort (HIV-ALC) study only (1997–2001; $n = 78$); HIV Longitudinal Interrelationships of Viruses and Ethanol (HIV-LIVE) study only (2001–2006; $n = 230$); and both HIV-ALC and HIV-LIVE studies ($n = 154$). Eligibility criteria and recruitment methods for HIV-ALC (Samet, Horton, Traphagen, Lyon, & Freedberg, 2003) and HIV-LIVE (Samet et al., 2007) were the same with follow-up visits planned every six months. Inclusion criteria included a documented HIV antibody test, a history of alcohol problems as measured by the CAGE questionnaire or a clinical investigator's assessment (Samet, Phillips, & Horton, 2004), age 18 years or older, ability to speak English or Spanish, and at least one contact person to assist with the follow-up. Exclusion criteria included score <21 on the 30-item Mini-Mental State Examination (Folstein, Folstein, & McHugh, 1975; Smith, Horton, Saitz, & Samet, 2006), inability to provide informed consent or answer the interview questions, and plans to move from the Boston area in the subsequent 12 months. For the current analysis, we also excluded those who did not have at least one follow-up visit. Laboratory measurements were obtained at each interview. Additional details on this population have been provided elsewhere (Samet et al., 1995, 2007). The study was approved by the Boston Medical Center and Beth Israel Deaconess Medical Center Institutional Review Boards.

Outcome assessment

The primary outcomes for this analysis were $CD4^+$ T cell count/μl (CD4 count) and log10 plasma HIV RNA/ ml (VL). CD4 count was determined by flow cytometry at the hospital laboratories. VL was measured using a branched-chain assay (lowest detection threshold = 75 copies/ml) or a polymerase chain reaction (lowest detection threshold = 50 copies/ml for ultrasensitive assay, and 500 copies/ml for standard assay; Pachl et al., 1995).

Exposure assessment

Information on smoking was collected at each study visit. Smoking status was categorized per Okuyemi et al. (2002, 2004) as follows: Minimal or non-smoker (smoked less than one cigarette per day); light smoker (smoked one to less than 10 cigarettes per day); moderate smoker (smoked 10 to less than 20 cigarettes per day); or heavy smoker (smoked 20 or more cigarettes per day). We used non-parametric local linear polynomial curves (*loess*) (Cleveland, Grosse, & Shyu, 1992) to verify that the cutoffs were reasonable for our data. We also performed a secondary, confirmatory analysis including smoking categorized based on quintiles of the distribution.

We defined a smoker as someone who answered affirmatively to the question "Do you currently smoke cigarettes?" As a secondary analysis, we defined smoking based on the subject's reported smoking status at two successive visits. That is, the outcome at each time point was modeled as a function of smoking from the current and previous study visit, thus accounting for whether the subjects changed or maintained their recent smoking behavior. In the case of missed visits, smoking status from the last available visit was used. We categorized smoking as follows: consistent smokers (smoked in two consecutive visits); consistent minimal or non-smokers (smoked <1 cigarette per day in two consecutive visits); recent quitters (smoked in the last visit but stopped smoking in the current visit); and new/relapsed smokers (not smoked in the last visit but started or resumed smoking in the current visit). The categorization was based on data from previous studies which suggest that the effect of smoking on the immune system is acute (Hersey, Prendergast, & Edwards, 1983; Sunyer et al., 1996; Tollerud et al., 1989b), with induction period of

about five weeks (Thomas, Holt, & Keast, 1975) to 10 weeks (Chalmer, Holt, & Keast, 1975), and lasts for about 6–35 weeks since quitting (Miller, Goldstein, Murphy, & Ginns, 1982; Radloff, 1977; Thomas, Holt, & Keast, 1975). Since the time elapsed between the last HIV-ALC visit to the first HIV-LIVE visit was too long (range 1–66 months) for some of the subjects enrolled in both cohorts, this secondary analysis was restricted to subjects who participated in HIV-LIVE.

Statistical analysis

We performed descriptive analyses to characterize the study population, overall and by baseline smoking status.

We applied linear mixed effects models to account for correlated measures within subjects. The models included subject-specific random intercepts and slopes, and adjusted for the value of the outcome (i.e., CD4 count and VL) at the previous study visit. We fitted a separate model for each outcome. Graphs illustrating trajectories of HIV disease progression over time were also plotted using outcome estimates from linear mixed effects models.

Age (modeled as a continuous variable), alcohol use (≤ 2 drinks per day, $>2-\leq 4$ drinks per day, and >4 drinks per day), current injection drug use (user vs. non-user), depressive symptoms (CESD score >23 vs. ≤ 23), gender, annual income ($>$median (US$7500) vs. $\leq$ median), and antiretroviral therapy (ART) adherence (not on medication, on medication and adherent, and on medication but not adherent) were considered as potential confounders during analysis. The categories for alcohol use were made narrower than those suggested by Cook et al. (2009) so as to account for residual confounding. The cut-off point for depressive symptoms was determined with Radloff (1977) criteria. ART adherence was measured using the AIDS Clinical Trials Group criteria (Chesney et al., 2000) and defined as a self-report of 100% adherent in the past three days (Samet, Horton, Meli, Freedberg, & Palepu, 2004). Preliminary models were fitted separately for each potential confounder. Confounders were then added sequentially in the models according to the magnitude of their effect on the association between cigarette smoking and outcome. Any potential confounder that changed the point estimate of cigarette smoking by more than 10% was included in the final model. Smoking status and all covariates with the exception of gender and age were analyzed as time-varying variables and updated at each time point. An interaction between smoking and time was included in the models and evaluated for its statistical significance. To assess whether ART modifies the effect of smoking, subgroup analyses were repeated separately for subjects not on ART and for subjects on ART and adherent to medication. Subjects who changed their ART status contributed observations to each stratum depending on the ART status of the observation.

For the primary analysis, undetectable VL was imputed as half the value of the lowest threshold of assay sensitivity. Secondary analyses evaluated the potential bias due to imputing assay values using half the limit of detection (Greenland & Lash, 2008) as follows: The undetectable assay measurements were imputed with plausible values from a logit-logistic distribution (Lesaffre, Rizopoulos, & Tsonaka, 2007) with a scale parameter of 0.8, accounting for the fact that VL values are bounded by 0. The distribution also took into account that 0 VL is unlikely as no current treatment can completely eliminate HIV. This process was repeated in 10,000 simulation runs and 95% simulation intervals (SI) were obtained. Statistical analysis was done using SAS version 9.1 (SAS Institute, Inc., Cary, North Carolina).

Results

The cohort ($n=462$) is described in Table 1 with the following demographic characteristics: black (43%); male (77%); median age 42 years (range 21–71 years); and median annual income of US$7500 or less. In the combined cohort, 77% (358/462) of subjects reported having smoked cigarettes within the last month before enrollment; 23% were minimal or non-smokers, 25% were light, 22% were moderate, and 31% were heavy smokers. The median baseline CD4 count and VL were 380 cells/μl and 1175 copies/ml, respectively. The median follow-up time was 18 months for those enrolled in only HIV-LIVE, 14 months for those in only HIV-ALC, and 40 months for those in both studies. In the overall cohort, the median number of visits was seven (range: 2–14 visits). Subjects who completed the majority of study of visits had higher mean baseline CD4 count (difference = 117.3; $p<0.0001$) and lower mean baseline log10 VL (difference = 0.35; $p=0.03$) than those who did not complete the majority of study visits. There was no significant association between baseline smoking status and whether the subject completed the majority of study visits in this cohort ($\chi^2=0.41$; $p=0.52$). Subjects contributed 3141 observations across all follow-up visits: 827 (26%) classified as minimal or non-smokers, 696 (22%) light smokers, 772 (25%) moderate smokers, and 846 (27%) as heavy smokers.

[a]Minimal or non-smokers are excluded.

The plots in Figure 1 show the unadjusted mean CD4 count or VL over time across smoking categories. The plots suggest potential variation in mean differences in CD4 count or VL over time between smoking categories. However, the smoking-time interaction term was not statistically significant in any

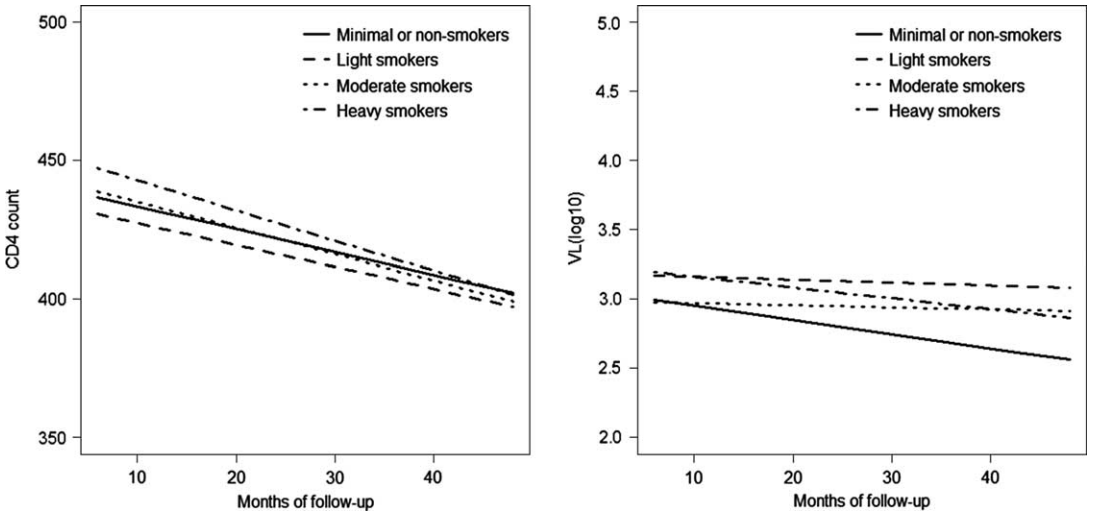

Figure 1. Unadjusted mean CD4 count and VL over time.

of the regression models and was therefore excluded from subsequent analyses.

We did not find any substantial differences in CD4 count or VL across categories of smoking (Table 2). Using minimal or non-smokers as the reference group, the adjusted mean differences in CD4 count were: 8.2 (95% confidence interval (CI): −17.4, 33.8; $p = 0.44$) for heavy smokers; −0.1 (95% CI: −25.4, 5.1; $p = 0.48$) for moderate smokers; and −2.6 (95% CI: −28.3, 3.0; $p = 0.90$) for light smokers. For log10 VL, the adjusted differences were: 0.03 (95% CI: −0.12, 0.17; $p = 0.39$) for heavy

[a]Adjusted analyses controlled for previous CD4$^+$ cell count, ART status, time, and depressive symptoms.
[b]Adjusted analyses controlled for previous log10 HIV RNA, ART status, income, depressive symptoms, injection drug use, age, alcohol, time, and gender.
[c]No. observations was 3141.
[d]ART was removed in the model because we stratified on it.
[e]No. subjects was 291. No. observations was 1026. Included only observations when subject was on ART.
[f]No. subjects was 363. No. observations was 1586. Included only observations when subject was on ART and adhered to medication.
[g]Results are statistically significant.

smokers; −0.06 (95% CI: −0.20, 0.08; $p = 0.83$) for moderate smokers; and 0.14 (95% CI: −0.01, 0.28; $p = 0.06$) for light smokers.

When analysis was stratified by ART status, no clear evidence of an association between smoking with CD4 count or HIV VL was found (Table 2). We observed a small but statistically significant increase in VL for light smokers compared with minimal or non-smokers among subjects who adhered to ART (the adjusted mean difference was 0.24; 95% CI: 0.04, 0.44; $p = 0.01$). However, similar associations were not observed for categories of heavier smoking.

Similarly, no substantial outcome differences were observed for subjects who switched or maintained their smoking behavior (Table 3).

Results (not shown) remained similar in analyses examining the potential bias due to the imputed assay measurements, suggesting that the unobserved values in the lower range did not have a large impact on results. Similarly, the analysis with smoking categorized based on quintiles did not alter the study findings.

Discussion

This study does not provide evidence that cigarette smoking is associated with a decrease in CD4 count or an increase in VL among HIV-infected patients. Specifically, we observed no substantial differences in CD4 count or VL between minimal or non-smokers, light smokers, moderate smokers, and heavy smokers. Moreover, we found no substantial differences in CD4 count or VL when smoking status changed in two consecutive visits.

Our findings are in accordance with previous cohort studies which did not detect an association between cigarette smoking and HIV disease progression (Burns et al., 1996; Coates et al., 1990; Craib et al., 1992; Eskild & Petersen, 1994; Galai et al., 1997; Stephenson et al., 1999; Webber et al., 1999) when using the onset of an AIDS defining condition as a primary outcome. Our design, using CD4 count and VL as markers for HIV disease progression, is well suited for HIV cohorts with less advanced disease, fewer anticipated OIs.

Results from this study are in contrast with findings from two cohort studies which reported that smoking enhances HIV disease progression using OIs as outcomes (Conley, Bush, Buchbinder, & Penley, 1996; Crothers et al., 2005). In one of these studies CD4 counts were also examined (Conley et al., 1996), but not associated with smoking. As smoking may selectively affect target organs (e.g., lungs), the latter study underscores the need to investigate biological markers of immunological dysfunction in addition to OIs in order to assess its impact on the immune system.

Although, we found no evidence of a relation between smoking and HIV disease progression, we could not rule out the potential effect of smoking on CD4 cells or HIV which are not in peripheral blood. As high concentrations of smoke can get trapped in the lungs, it would not be surprising if most of the affected cells are those surrounding the lungs. For example, one study (Wewers et al., 1998) found that, compared to minimal or non-smokers, HIV-infected smokers had a significant depletion in CD4 cells in their *bronchoalveolar lavage* fluid. Analyzing samples of immunological markers derived from sites other than the peripheral blood may shed some light on the issue.

Our study was conducted using a cohort of patients with current or past alcohol problems. As alcohol drinkers tend to smoke more than non-alcohol drinkers (Collins & Marks, 1995), the choice of this cohort ensured availability of ample smokers for analysis. The selection of this cohort came with a caution in that the generalizability of its findings may be limited to a population with alcohol problems. However, given the prevalence of past alcohol

[a]Analysis restricted to HIV LIVE cohort. No. observations was 1974. All p values > 0.05.
[b]Adjusted for CD4 count at previous visit, ART status, age, time, and alcohol use.
[c]Adjusted for HVL at previous visit, ART status, time, and depressive symptoms.

problems among HIV-infected individuals, up to 40% (Samet, Phillips, & Horton, 2004), these findings would still be of importance even if not applicable to a non-alcohol affected HIV population. An interaction term between smoking and current alcohol drinking (categorized by dose) was not statistically significant in regression models.

The main strength of this study was the inclusion of assessments of changes in immunological biological markers over time using repeated measures on the same individuals. We identified the use of such methodology in only one other study (Sunyer et al., 1996) among HIV seronegative subjects in which a positive association existed between smoking and an increase in white blood cells. We performed post-hoc power calculations to assess the differences in CD4 count our study could detect with reasonably high power. While we utilized longitudinal regression methods in the analyses, for the purposes of power calculations we considered a simpler setting utilizing a single time point. Thus, our estimates are conservative as the longitudinal analyses are expected to increase the study power. Assuming a standard deviation of 42 (based on our observed data at baseline), the minimum detectable difference in mean CD4 count between any two smoking groups that our sample size could detect with 80% power was 16 cells/μl. hence this study was adequately powered to detect effect sizes observed previously (Sunyer et al., 1996), a difference in CD4 count of 74 cells/μl between heavy smokers and never smokers. Other strengths included the ability to analyze short term effects of smoking initiation and cessation, information on smoking dosage, and the availability of many important potential confounders.

We note our study had limitations. First, information on cigarette smoking was self-reported. Second, the number of cigarettes smoked may not necessarily reflect the amount of smoke inhaled, underestimating the actual smoking dosage.

In summary, we did not find significant associations between cigarette smoking and CD4 count or VL among HIV-infected patients with alcohol problems. Future epidemiologic studies concerning the impact of smoking on HIV disease progression may provide more insight if focused on this substance's effect on specific tissues and particular immunological systems in addition to immunological markers (i.e., CD4 count and VL) in the peripheral blood.

Minimal Social Network Effects Evident in Cancer Screening Behavior

Nancy L. Keating, MD, MPH[1,2]; A. James O'Malley, PhD[2]; Joanne M. Murabito, MD, ScM[3,4]; Kirsten P. Smith, PhD[2]; and Nicholas A Christakis, MD, PhD[2,5,6]

BACKGROUND: Social networks may influence screening behaviors. We assessed whether screening for breast, prostate, or colorectal cancer is influenced by the actual screening behaviors of siblings, friends, spouses, and coworkers. **METHODS:** We conducted an observational study using Framingham Heart Study data to assess screening for eligible individuals during the late 1990s. We used logistic regression to determine whether the probability of screening for breast, prostate, or colorectal cancer was influenced by the proportion of siblings, friends, and coworkers who had the same screening, as well as spouse's screening for colorectal cancer, adjusting for other factors that might influence screening rates. **RESULTS:** Among 1660 women aged 41-70 years, 71.7% reported mammography in the previous year; among 1217 men aged 51-70 years, 43.3% reported prostate-specific antigen testing in the previous year; and among 1426 men and women aged 51-80 years, 46.9% reported stool blood testing and/or sigmoidoscopy in the previous year. An increasing proportion of sisters who had mammography in the previous year was associated with mammography screening in the ego (odds ratio [OR], 1.034; 95% confidence interval [CI], 1.000-1.065 for each 10% increase). A spouse with recent screening was associated with more colorectal cancer screening (OR, 1.65; 95% CI, 1.39-1.98 vs unmarried). Otherwise, screening behaviors of siblings, friends, and coworkers were not associated with screening in the ego. **CONCLUSIONS:** Aside from a slight increase in breast cancer screening among women whose sisters were screened and colorectal cancer screening if spouses were screened, the screening behavior of siblings, friends, or coworkers did not influence cancer screening behaviors. ***Cancer* 2011;117:3045-52.** © *2011 American Cancer Society.*

KEYWORDS: cancer screening, mammography, prostate specific antigen, social networks.

Screening for cancer has the potential to save lives by identifying cancers at earlier stages, when they may be more amenable to treatment and cure. Nevertheless, many individuals who may benefit do not undergo routine screening.[1-5] Research suggests that individuals' social support networks, including family and friends, or their perception that screening is normative among their peers, may positively encourage screening.[6-12] Such findings have led to interventions using peers and/or other community members or worksite interventions to increase rates of screening.[13-17]

Social contacts can strongly influence a variety of behaviors, including smoking, weight gain, and drinking.[18-20] They might also influence screening behaviors by several mechanisms. Social contacts might provide information or advice about the purpose of specific tests, the benefits of testing, or the need for evaluation of symptoms. They might also provide encouragement to someone who has avoided screening and may provide emotional support to someone concerned about abnormal screening results. They might share their own experiences with screening, which may be more powerful at influencing behavior than sharing less direct knowledge about the tests. Finally, social contacts might assist an individual in finding a doctor or getting to appointments.

Although other studies have suggested benefits of generic social support in encouraging screening behaviors, we are unaware of studies examining whether actual screening behavior of one's peers influence an individual's likelihood of cancer screening. We studied a large network of individuals to assess whether screening for breast cancer, prostate cancer, or

colorectal cancer is influenced by the actual screening behaviors of one's siblings, friends, and coworkers, who may differ in their likelihood of discussing screening and their influence on the ego. We hypothesized that the screening behavior of individuals would be positively influenced by the screening behaviors of their contacts, with the effects being greater for siblings and friends than coworkers. In this study, we were able to measure actual behavior of individuals' social contacts, rather than rely on an index case to inform us about the behavior of others to whom they were connected.

MATERIALS AND METHODS

Data and Subjects

This study used data from the Framingham Heart Study, which, in 1948, enrolled 5209 individuals in the original cohort.[21] Children of the original cohort and their spouses were recruited in 1971 to form the offspring cohort; this cohort included 5124 individuals.[22] In 1994, a minority oversample of 508 individuals was initiated, and in 2002, the third-generation cohort, consisting of 4095 children of the offspring cohort, was initiated.[23] The study protocol was approved by the institutional review boards of Harvard Medical School and Boston University Medical Center.

Network

We focused on the 3807 so-called "egos" in the offspring cohort known to have participated in waves 6 and/or 7 (data collection occurred during 3-year periods centered in 1997 for wave 6 and 1999 for wave 7). The ego is the person whose screening behavior is being analyzed. Any persons to whom these subjects are linked (in any of the Framingham Heart Study cohorts) can serve as social contacts, referred to as "alters." Details of the ascertainment of alters are described in detail elsewhere.[18] Briefly, information was derived from archived, administrative tracking sheets used to identify people close to the study participants to facilitate follow-up. The tracking sheets provided complete information about all first-order relatives (parents, spouses, siblings, and children) and at least 1 "close friend," and these names were linked with the Framingham data to identify ties between egos and alters. Information on address and place of work were used to identify neighbors and coworkers. We classified alters as parents, full sisters, full brothers, friends, and coworkers. We restricted analyses to individuals and their alters who were eligible for screening based on sex- and age-specific screening recommendations (described below). In sensitivity analyses, we repeated all analyses including a small number of half siblings, step siblings, adopted siblings, and foster siblings (5.8% of all siblings). Results were similar and are not presented. We also identified spouses for analyses of colorectal cancer screening.

Screening Behaviors

Data on screening were collected in 2 waves: wave 6 (1995-1998) and wave 7 (1998-2001). Women were asked the year of their last mammogram, men were asked the year of their last blood test for prostate cancer, and men and women were asked the year when stool was last tested for blood and when sigmoidoscopy was last performed.

We assessed screening behavior based on recommendations from national guidelines. For breast cancer screening, we assessed report of mammography within the previous year for women ages 41-70 years[24,25] (results were similar when we restricted to ages 51-70 years, because some guidelines did not recommend mammography for average risk women in their 40s before 1997[26] or later,[27,28] and results were similar when we assessed mammography within the last 2 years). For prostate cancer screening, we assessed prostate-specific antigen (PSA) testing within the previous year among men aged 51-70 years.[25,29] For colorectal cancer screening, we assessed receipt of stool blood testing within the previous year and/or sigmoidoscopy within the past 5 years for individuals aged 51-80 years. Screening guidelines at the time recommended yearly stool occult blood testing or flexible sigmoidoscopy every 3 to 5 years with stool blood testing or colonoscopy;[25,27,30] the survey did not ask specifically about colonoscopy.

Control Variables

We identified factors likely to be associated with cancer risk and/or screening behavior. Specifically, we documented each participant's sex and age and we used data from the prior survey wave (including wave 5 information for subjects whose screening behavior was ascertained in wave 6) to characterize additional participant characteristics, including self-rated health status (excellent/very good, good, fair/poor, unknown), number of years of education, marital status, number of children living (whether in the Framingham Study or not), current employment, number of times per week of intense physical activity, current smoking status, number of alcoholic drinks per week, and presence of diabetes, cardiovascular disease, and/or

pulmonary disease (asthma or chronic obstructive pulmonary disease/emphysema). We used validated data from the Framingham Study to document history of cardiovascular disease and diabetes; presence of pulmonary disease was based on the clinical impression of the Framingham Study clinic examiner. Continuous variables were not categorized.

Analyses

We evaluated testing among eligible participants for each of the waves; hence participants eligible in both waves contributed 2 sets of data to the analyses. We used logistic regression models to assess the proportion of siblings, friends, and coworkers who had the same type of screening test on screening for eligible egos (calculating the effect for each 10% increase in the proportion screened). We also controlled for the number of siblings, friends, and coworkers who were eligible for screening. Models for mammography were limited to female siblings, friends, and coworkers, and those for PSA testing were limited to male siblings, friends, and coworkers. Models also included all control variables described above and survey wave (wave 7 vs 6). The colorectal cancer screening model included men and women, and we included a variable for sex and a variable reflecting marital status and if married whether spouse was screened or not screened. All models used generalized estimating equations, clustering on participants, to account for the possibility that a participant may contribute up to 2 dependent variable observations (1 each wave in the role of ego) or be involved in multiple observations of the predictor variable (in the role of alter).

RESULTS

We identified 1660 women aged 41-70 years, who had 597 sisters, 175 female friends, and 174 female coworkers aged 41-70 years enrolled in the Framingham Heart Study. A total of 1269 women participated in both waves of the survey, so the total number of observations was 2929 women eligible for mammography; of these 71.7% had undergone mammography in the previous year. We identified 1217 men aged 51-70 years, who had 337 brothers, 142 male friends, and 99 male coworkers aged 51-70 years. A total of 804 men participated in both waves of the survey, so the total number of observations was 2021; 43.3% had undergone PSA testing in the previous year. We identified 3045 men and women aged 51-80 years. These individuals had 1426 siblings, 364 friends, and 299 coworkers aged 51-80 years, and 1530 had spouses aged 51-80 years. A total of 2260 individuals participated in both waves, so the total number of observations was 5305; 46.9% had undergone stool blood testing in the previous year and/or flexible sigmoidoscopy in the last 5 years. Characteristics of each cohort are included in Table 1.

Table 2 demonstrates the influence of the screening behaviors of siblings, friends, and coworkers on screening behavior of the ego. For mammography screening, an increasing proportion of sisters who had undergone screening mammography in the previous year was slightly associated with mammography screening in the ego (odds ratio [OR], 1.034; 95% confidence interval [CI], 1.000-1.065 for each 10% increase in the proportion of sisters screened). At an average rate of 71.7% of women being screened, this OR corresponds to a risk ratio[31] of 1.009, suggesting a very small 0.9% increase in screening rates to 72.4% for a 10% increase in the proportion of sisters screened. Women with a greater number of sisters were less likely than women with fewer sisters to undergo mammography (OR, 0.85; 95% CI, 0.72-1.01), although this finding was of borderline statistical significance ($P = .06$). The proportion of female friends and female coworkers who had undergone mammography was not associated with the probability of the ego undergoing mammography screening.

The extent of PSA testing in the previous year among siblings, friends, and coworkers was not associated with PSA testing among egos, nor was the number of brothers, male friends, or male coworkers.

For colorectal cancer screening with stool blood tests and/or sigmoidoscopy, individuals married to a spouse that had been screened were more likely to be screened than those who were unmarried (OR, 1.65; 95% CI, 1.39-1.98), with a risk ratio[31] of 1.296. With 42.6% of unmarried individuals screened, this corresponds to a 12.6% absolute increased risk of screening, to 55.2% for married individuals whose spouses were screened. Individuals married to a spouse who had not been screened or for whom screening status was unknown did not differ from unmarried individuals in screening. The non-overlapping CIs for married patients whose spouses were or were not screened suggest that screening status of the spouse is a more important factor than marital status itself. The proportion of siblings, friends, or coworkers who had been screened was not associated with screening. Individuals with more friends were less likely to undergo colorectal cancer screening (OR, 0.73; 95% CI, 0.58-0.91 for each additional friend in the cohort).

[a] Based on 2929 observations for 1660 women.
[b] Based on 2021 observations for 1217 men.
[c] Based on 5305 observations for 3045 men and women.
[d] Considering heart disease, diabetes, and chronic obstructive pulmonary disease.
[e] Siblings included sisters for breast cancer screening cohort, brothers for prostate cancer screening cohort, and sisters and brothers for colorectal cancer screening cohort who met screening criteria.

In each model, we adjusted for several control variables, some of which had significant effects. Other characteristics of the egos associated with mammography screening included older age (OR, 1.02; 95% CI, 1.01-1.04 for each year of age), being married (OR, 1.63; 95% CI, 1.33-2.00), and being physically active 4 or more times per week (OR, 1.05; 95% CI, 1.00-1.09). Smokers were much less likely to undergo mammography than nonsmokers (OR, 0.56; 95% CI, 0.44-0.71), as were women with more comorbid illnesses (OR, 0.80; 95% CI, 0.65-0.99). Participants surveyed in the wave centered in 1999 were more likely to have mammograms than those surveyed in the wave centered in 1997 (OR, 1.40; 95% CI, 1.21-1.62).

For PSA testing, older men were more likely to be screened than younger men (OR, 1.05; 95% CI, 1.03-1.08). Married men had more PSA tests than unmarried men (OR, 1.73; 95% CI, 1.29-2.31), and men with more years of education were more likely to have PSA testing (OR, 1.08; 95% CI, 1.04-1.12). Smokers were less likely than nonsmokers to have PSA testing (OR, 0.71; 95% CI, 0.54-0.94), as were men with more comorbid illnesses (OR, 0.76; 95% CI, 0.62-0.94). Men surveyed in wave 7 were more likely to report recent PSA testing than those

Table 2. Factors Associated With Recommended Screening in Egos

Survey wave			
Wave 6	1.0	1.0	1.0
Wave 7	1.40 (1.21-1.62)	1.59 (1.35-1.87)	1.52 (1.38-1.67)

All data are presented as odds ratio (95% confidence interval). Values were calculated using generalized estimating equations to account for clustering within participants, because some participants had data from both waves 6 and 7 and/or functioned as alters multiple times. Data were adjusted for participant age, level of education, marital status, number of children, employment status, level of physical activity, smoking status, self-reported health status, coronary heart disease, diabetes, chronic obstructive pulmonary disease, and survey wave. Only female siblings, friends, and coworkers were included in mammography analyses; only male siblings were included in prostate-specific antigen analysis.

[a] Siblings included sisters for mammography analysis, brothers for prostate-specific antigen analysis, and sisters and brothers for colorectal screening analysis who met screening criteria.

[b] $P < .05$.

[c] $P < .10$.

[d] Considering heart disease, diabetes, and chronic obstructive pulmonary disease.

surveyed in wave 6 (OR, 1.59; 95% CI, 1.35-1.87), reflecting the general increase in the use of screening over this time frame.

For stool blood testing or flexible sigmoidoscopy, older participants were more likely to report screening (OR, 1.02; 95% CI, 1.01-1.03). Participants who worked were less likely than those who did not to be screened (OR, 0.85; 95% CI, 0.74-0.98), as were those who smoked (OR, 0.62; 95% CI, 0.51-0.74) and those with more comorbidities (OR, 0.83; 95% CI, 0.73-0.94). Participants surveyed in the wave centered in 1999 were more likely to undergo colon cancer screening than those surveyed in the wave centered in 1997 (OR, 1.52; 95% CI, 1.38-1.67).

DISCUSSION

We examined whether screening behavior of siblings, friends, coworkers, and spouses influenced analogous screening behaviors of individuals. We found that mammography screening increases slightly with an increasing proportion of sisters who have had a mammogram (although women with more sisters were less likely to get mammograms, a finding of borderline statistical significance). PSA testing did not vary by the proportion of brothers, friends, or coworkers who had the test. Colorectal cancer screening was strongly associated with screening among one's spouse, but not with the proportion of friends who were screened.

Several studies suggest that support of others increases an individual's likelihood of participating in cancer screening. For example, women with higher scores on the social network index[6,7] or who report social support from physicians, family, and friends[8] are more likely to undergo mammography and Pap smears. In addition, a study of employed women found that women who perceived that screening is normative among their peers were more likely to undergo regular mammography, although the extent of social support and the size of one's social network was not associated with screening behavior.[9] On the other hand, 2 studies have observed that women reporting explicit encouragement to undergo mammography by social network members were less likely to be screened,[9,32] suggesting that the women who avoid mammography may be more likely to be offered encouragement from others. Perceived risk of cancer is also associated with mammography screening, and this perceived risk is often due to a family history of cancer.[33] In a previous study using data from the Framingham Study, reporting a family history of breast cancer was strongly associated with reporting a mammogram in the last 2 years.[34]

In the current study, we were able to broaden the scope of social contacts examined (to include friends and coworkers), broaden the nature of cancers considered, and, most importantly, trace out direct ties between people and directly query alters about screening behavior rather than merely surveying egos about alters.

Past research suggests that friends can influence mammography behavior with direct efforts. One study randomized individuals to call or not call friends to encourage them to get a mammogram. Friends who received a call had a 15% increase in mammography compared with those who did not receive a call. This effect remained after controlling for demographic characteristics, was effective for black and white women of all ages, and was most pronounced among women with lower household incomes.[35] In addition, women reporting close friends with whom they could discuss their health were more likely to have ever had a Pap smear.[11] Programs have thus been developed that successfully use social support to improve screening for cervical cancer and breast cancer.[36]

Fewer data are available about the impact of interventions on social contacts on prostate cancer screening or colorectal cancer screening. The value of PSA testing for prostate cancer remains controversial,[37] yet research suggests that patients deciding about PSA testing value anecdotes about the decisions of friends, family, or media celebrities.[38] Thus, we had expected that the prostate screening behaviors of alters would influence those of the egos in our study. Consistent with other research,[39] we found that married men were more likely than unmarried men to undergo PSA screening. Men may be encouraged by their wives to obtain more routine and preventive care, or may be persuaded to undergo PSA testing specifically.

Colorectal cancer screening can be inconvenient and invasive, and, for colonoscopy, requires time off from work and someone to accompany the individual to the procedure. These factors may lead to negative attitudes about screening.[40] Nevertheless, support from friends and family has been associated with screening, as have positive attitudes about the screening and beliefs that it is safe.[41] We found a strong association of colorectal cancer screening among spouses of individuals who have been screened, but no associations based on the proportion of siblings, friends, or coworkers who were screened.

Overall, this work again reinforces the distinction between social support and social network effects.[42] The existence of social ties, and the willingness of others to help with health care can affect screening, as suggested by prior work. However, this is a different effect than that of the specific influence whereby an alter's actual behavior influences a similar behavior in an ego. By analogy, it is the difference between the impact on a person's happiness of having many friends versus the impact on a person's happiness of having friends who are themselves happy.[43] We found that the screening behaviors of one's contacts, at least among those contacts included in the study, had little relevance to screening behaviors. Screening behaviors may be less "contagious" because they are not easily observed (unlike smoking, alcohol, obesity, and happiness)[18-20,43] and may not be comfortable topics to discuss. New evidence suggests that ties among friends are influenced by observable characteristics such as obesity and

smoking, but not by less easily observed traits, such as blood pressure and depression score.[44]

Our findings should be interpreted in light of some limitations. First, information on screening was only collected in 2 waves of the Framingham Study, both during the late 1990s. Consequently, we cannot be certain that the findings are relevant to current screening behaviors; screening rates for colorectal cancer have increased since this time,[45] although our study period corresponded with the peaking of mammography rates, which declined in the early 2000s.[46] Second, our study focused on a single community that was lacking in racial and ethnic diversity, so the generalizability of our findings to other populations requires further study. Rates of prostate cancer screening in our cohort were lower than those of colorectal cancer screening, which has not been observed nationally.[47] Third, we could only assess screening behaviors among alters who were included in the Framingham cohorts and of ages that would make them eligible for screening themselves, and our cohort of egos had relatively few alters in the study, limiting our ability to observe effects. Moreover, if an individual had many friends but few were in the Framingham cohorts, then our study would likely underestimate the effects of the other friends' behaviors. Fourth, the survey question about stool blood testing did not distinguish in-office or at-home testing. Finally, self-report of screening may overestimate use.[48]

In conclusion, mammography receipt among sisters and colorectal screening among spouses had some influence on personal screening behaviors, but otherwise screening behaviors of siblings, friends, and coworkers were not associated with increased rates of cancer-specific screening. These observations suggest that while many health behaviors may spread across social ties, not all health behaviors necessarily do. Some behaviors may be intrinsically more "contagious," just as some fashions are easier to adopt and some germs are more contagious than others.

CONFLICT OF INTEREST DISCLOSURES

This study was funded by the National Institute on Aging (grant nos. R-01 AG-24448 and P01 AG-031093) and the National Heart, Lung, and Blood Institute Framingham Heart Study (contract no. N01-HC-25195). N.A.C. has an equity stake in a company, MedNetworks, that is licensed by Harvard to apply some of the ideas embodied in work on social networks.

Substance abuse treatment

ABSTRACT

Background: Substance dependence treatment is often episodic and not well coordinated with healthcare for common comorbidities. Chronic disease/care management (CDM), longitudinal, patient-centered care delivered by multidisciplinary health professionals, may be well suited to treat substance dependence (SD).
Objective: To examine initiation and engagement with CDM care for SD located in a primary medical setting.
Methods: We prospectively studied substance dependent participants enrolled in a trial of CDM addiction care. Primary study outcomes, based upon Washington Circle performance measures, were 14-day initiation of CDM care and 30-day engagement with CDM care. Factors associated with these outcomes were determined using multivariable logistic regression models. We also estimated the proportion of participants who eventually attended at least two visits and four visits by the end of the study (Kaplan–Meier method).
Results: Of 282 participants, approximately half of the cohort (45%, 95% Confidence Interval [CI] 39–51%) met criteria for 14-day initiation and 23% (95% CI 18–28%) for 30-day engagement with CDM care. Most participants attended two or more (81%, 95% CI 76–85%) and four or more CDM visits (62%, 95% CI 56–68%). Major depressive episode (AOR 2.60, 95% CI 1.39, 4.87) was associated with higher odds of 14-day initiation; younger age, female sex, and higher alcohol addiction severity were associated with lower odds of 30-day engagement with CDM care.
Conclusion: : People with SD appear to be willing to initiate and engage with CDM care in a primary medical care setting. CDM care has the potential to improve the quality of care for people with addictions.

1. Introduction

Although substance dependence is often an illness with chronic physiological changes and a relapsing course, most addiction treatment is not structured to manage it as a chronic disease (McLellan et al., 2000; Institute of Medicine, 2006). Traditionally, patients are encouraged to enter addiction treatment for a specified period with the unrealistic expectation of "curing" their substance use disorder (SUD). Most people with SUD do not seek specialty treatment (Cunningham and Blomqvist, 2006; Hasin et al., 2007) and for the few who do, treatment is often episodic and prematurely truncated due to dissatisfaction with care, motivational issues, or program challenges (Substance Abuse and Mental Health Services Administration, Office of Applied Studies, 2008). Medical and psychiatric comorbidities are often neglected, despite their potential to interfere with addiction treatment and contribute to relapse. Patients often need help navigating complex systems of care across addiction, medical, and mental health arenas.

To address these shortcomings, the Institute of Medicine (IOM) and others have called attention to the chronic disease management/chronic care model (CDM) (Wagner, 2000) to improve the health care of individuals with chronic illnesses, including SUD (Institute of Medicine, 2006). Though not unequivocally supported, CDM care has shown promise for other chronic conditions including congestive heart failure, chronic pulmonary disease, and depressive disorders (Roy-Byrne et al., 2001; Simon et al., 2001; Rea et al., 2004; Whellan et al., 2005). Though not as yet reported in randomized trials, CDM care for substance dependence (SD) offers the potential to follow individuals longitudinally, monitor disease progression, and enhance treatment adherence (Saitz et al.,

2008; McKay, 2009). Similar to treatment of other chronic illnesses, adjustments in treatment intensity and modality can be made based upon a patient's functioning, motivation, and clinical course. Multidisciplinary teams with addiction-specific skills can provide direct care, coordinate referrals, communicate with other clinical caregivers, and proactively arrange use of community resources.

CDM care for SD builds upon growing evidence supporting the effectiveness of continuing care interventions to bridge transitions from more intensive treatment (e.g., residential or intensive outpatient treatment) to less intensive treatment (e.g., group counseling). Post-treatment monitoring is effective for facilitating early readmission to treatment for relapses (Scott and Dennis, 2009). Since considerable effort is often required to maintain ongoing attendance (McKay, 2009), alternative modes of treatment delivery such as telephone-based monitoring and brief counseling have been tested and found to be effective for decreasing continuing care dropout and substance use (McKay, 2005).

Some have suggested that primary care may be an optimal setting for providing CDM care for SD (McKay, 2009). Since primary care is meant to deliver longitudinal care, linking CDM care to primary care may facilitate ongoing utilization of CDM care for periodic assessments. Linking CDM care to primary care offers the potential to identify and treat primary care patients with SD who would otherwise not seek substance abuse treatment (Saitz et al., 2008) and to facilitate the coordinating role of the primary care team with respect to the medical, addiction, and psychiatric systems of care.

Although primary care services are theoretically available to patients with SD, these services are often not received for various reasons, such as missed appointments and lack of follow-through for evaluation of medical problems. CDM located in primary care may facilitate the evaluation of comorbid medical problems by encouraging ongoing attendance and engagement with medical care to facilitate actual receipt of services.

Other potential elements of CDM care that are often not part of "real-world" primary care include a focus on SD as a chronic illness, accessible specialty addiction expertise, and a delivery system designed to facilitate coordination of addiction, medical and psychiatric care (Saitz et al., 2008). CDM care is distinct from primary care and substance abuse treatment in that CDM focuses on increasing utilization of care that is potentially available but often difficult to access. It does so by delivering some of this care directly and by actively facilitating and monitoring access to services outside of the CDM clinic.

Although CDM care for SD is potentially effective, whether this type of care is acceptable to patients with SD is unknown. McLellan specified that "a continuing care approach emphasizes making treatments attractive to patients" (McLellan, 2002). Assessing whether patients find CDM care acceptable is important because efficacious addiction treatments are often underutilized, in part, due to lack of patient acceptance (Tucker et al., 2009). Whether patients will initiate and engage with CDM care is an essential component to assessing its potential effectiveness.

The primary objective of this study was to examine the proportion of study participants that initiated and engaged with CDM addiction care when this modality was made accessible. The secondary objective was to assess characteristics associated with initiation and engagement with CDM addiction care. Initiation and engagement were examined using an adaptation of the Washington Circle (WC) performance measures. These performance measures, adopted by the National Committee for Quality Assurance (NCQA) for inclusion in its Health Plan Employer Data and Information Set (HEDIS) (National Quality Forum, 2007) are associated with beneficial outcomes including lower likelihood of arrests/incarcerations (Garnick et al., 2007) and improvements in alcohol addiction severity (Harris et al., 2010).

2. Materials and methods

2.1. Study design and sample

This is a prospective cohort study of patients with alcohol and/or drug dependence enrolled in the Addiction Health Evaluation and Disease management (AHEAD) study, a randomized controlled trial designed to test the effectiveness of CDM for SD located in primary care. This study's analytic sample included only participants randomized to have access to CDM care. Control participants in the AHEAD study were not included in this study's analysis because they did not have access to CDM addiction care and thus, by design, could neither initiate nor engage with CDM care.

Recruitment for the parent study (the AHEAD randomized trial) occurred at an inpatient detoxification unit, primary care clinics and the emergency department at Boston Medical Center, and from the community by advertising on buses and in newspapers.

Eligible participants were adults with alcohol or drug dependence (Composite International Diagnostic Interview Short Form (CIDI-SF)) (Kessler et al., 1998) and current (past-month) drug (heroin or cocaine) or heavy alcohol use (≥5 drinks per day or >14 drinks per week for men; ≥4 for drinks per day or >7 drinks per week for women) who were willing to establish or continue primary medical care at Boston Medical Center (BMC) and attend an outpatient visit in primary care. Patients who were pregnant, had plans to leave the area or a Mini-mental State Examination score <21 (Smith et al., 2006) were excluded. This study's analysis included all parent study eligibility criteria along with one additional criterion: access to CDM addiction care, defined as randomization to have access to the CDM intervention.

Eligible patients were invited to enroll in a study that may include attending an outpatient visit (i.e., the AHEAD clinic) in a primary medical care clinic. Enrollment of study participants was *not* based upon an interest in utilizing CDM care or any other addiction treatment.

After completing the baseline research interview, participants were accompanied to their first CDM visit in the AHEAD clinic. Participants were compensated for study participation after research assessments and the first (intake) AHEAD clinic visit. Thereafter, AHEAD clinic visits were neither compensated nor required for continued participation in the study. Participants were assessed periodically for research purposes but were neither discouraged nor encouraged to attend the AHEAD clinic by research staff. The Institutional Review Board of Boston University Medical Center approved this study. Additional privacy assurances were secured by the issuance of a Certificate of Confidentiality by the Department of Health and Human Services.

2.2. Description of the chronic disease management (CDM) clinic

The main goals of CDM care were to engage patients in longitudinal addiction treatment tailored to patients' needs (including attention to social, medical, and mental health), to re-engage patients in addiction treatments after relapse and/or loss to clinical follow-up, and to improve addiction-related health outcomes. CDM services included clinical case management, motivational enhancement counseling, addiction pharmacotherapy (i.e., buprenorphine, naltrexone, acamprosate and referral for methadone), psychopharmacology, and referrals for addiction, medical, and psychiatric treatment. Although the AHEAD clinic was located in a large primary medical clinic of an urban "safety-net" hospital, the AHEAD staff did not provide primary care. Instead, the clinic encouraged initiation of primary care and adherence to the evaluation and treatment plan for medical problems. Participants could access medical, psychiatric, and substance abuse services provided by the hospital without referral by the AHEAD clinic.

The AHEAD clinic team was comprised of a nurse care manager, social worker, and physicians with addiction expertise (an internist and a psychiatrist). At the first (intake) visit, the team assessed subjects' addiction, medical, and psychosocial needs and negotiated with the patient to prioritize and address short-term needs. While there were overall clinical guidelines for what each patient should be offered in the AHEAD clinic, participants received different interventions based upon need, availability, and patient preference.

After the intake visit, the nurse care manager tried to maintain periodic contact with patients to provide relapse prevention counseling, address social service concrete needs, and facilitate referrals for care. The clinic allowed patients to attend without appointments, regardless of ongoing substance use. Efforts to encourage follow-up included multiple rescheduling attempts (phone, letter) for patients who missed their appointments.

2.3. Measures

2.3.1. Outcomes. Each of this study's main outcomes, initiation and engagement with CDM care, were derived from the Washington Circle (WC) performance measures for outpatient addiction treatment (Garnick et al., 2002). Because the study's objective was to examine initiation and engagement with CDM care, we adapted these measures to only include CDM visits rather than any outpatient treatment service. Initiation of CDM care was defined as two or more AHEAD visits within 14 days of study entry ("14-day initiation") and engagement with CDM care as two or more AHEAD visits within 30 days of initiation ("30-day engagement"). Even though

a significant portion of the study sample was recruited from detox, we did not use the Washington Circle continuity of care measure after detox because we were specifically interested in initiation and engagement with CDM care rather than the effect of CDM care on continuity of care after a detox admission.

Because participants were not specifically seeking CDM care, we also examined the proportion of the study sample who eventually attended two or more AHEAD visits ("linkage with CDM care") and four or more visits ("continuation of CDM care") over the course of the study. AHEAD clinic attendance was prospectively assessed in a standard fashion using templates specifically created for the clinic in an electronic medical record.

2.3.2. Independent variables. Using Gelberg's vulnerable populations modification of Andersen's behavioral model as a guide for the choice of independent variables, we categorized independent variables, all assessed at study entry, as Need, Enabling, or Predisposing factors (Gelberg et al., 2000). Relevant indicators of need for CDM care were conceptualized into four categories: addiction, social, psychiatric, and medical needs. Addiction-related needs were dependence type (alcohol, drug or both) (CIDI-SF) (Kessler et al., 1998); addiction severity (Addiction Severity Index) (McLellan et al., 1992); history of overdose, and patient-assessed treatment need, which although was not directly measured, was partly reflected by a readiness to change scale.

Social needs included homelessness (any night in a shelter or on the street in the past 3 months) (Kertesz et al., 2006) and current legal problems. Psychiatric needs, assessed with the Mini International Neuropsychiatric Interview (MINI) (Sheehan et al., 1998), were major depressive episode and post-traumatic stress disorder. Medical needs were reflected by two self-report comorbidity questionnaires, one validated by Katz et al. (1996) and another assessing substance-related medical conditions (De Alba et al., 2004).

Enabling variables were: unfavorable social network (most or all of the people that the participant spends time with are either heavy/problem drinkers or drug users); health insurance; and health services utilization of (1) residential addiction treatment (excluding care for detoxification), (2) mutual-help (such as Alcoholics, Cocaine, or Narcotic Anonymous), (3) psychiatric care (counseling or therapy for emotional/psychological problems including full-day treatment, partial hospital program, or treatment by a psychiatrist); and (4) medical hospitalizations.

Predisposing variables included age, sex, and race/ethnicity. To account for potential changes in clinic practices at different points in the study, we included the time of participant enrollment with respect to the first day of cohort recruitment ("study enrollment month").

2.4. Statistical analysis

We calculated the proportion of the study sample that initiated and engaged with CDM care along with 95% confidence intervals. Descriptive statistics were used to characterize utilization of CDM services, substance abuse treatment (outpatient or inpatient treatment, excluding treatment for detoxification); and addiction pharmacotherapy. The latter two variables were assessed at a 3-month follow-up interview. Separate multivariable logistic regression models were used to identify predictors of 14-day initiation of CDM care and 30-day engagement with CDM care. All regression models were fit including a single independent variable of interest as well as a core set of covariates: age, sex, race/ethnicity, and study enrollment month. If more than one non-covariate independent variable was statistically significant ($P < 0.05$), then a single model was fit to include all statistically significant variables, again with core covariates. We verified that no pair of independent variables included in a regression model was highly correlated (i.e. >0.40), minimizing the potential for collinearity. Due to the exploratory nature of the analyses, no adjustments were made for multiple comparisons.

As secondary outcomes, we calculated the proportion of the study sample who met criteria for linkage with CDM care and continuation of CDM care using the Kaplan–Meier estimator to account for differential lengths of follow-up. To evaluate predictors of these CDM care utilization measures, we used a model-building approach similar to the one described above using Cox proportional hazards models. All statistically significant independent variables ($P < 0.05$) were combined into a single model with the same core covariates listed above. All analyses were completed using SAS/STAT software, Version 9.1, SAS Institute Inc. Cary, NC.

3. Results

3.1. Study subjects

This study's analytic sample was derived from participants enrolled in the AHEAD study randomized trial. Among 650 eligible individuals, 87% ($n = 563$) enrolled in the AHEAD randomized trial, and 282 were randomly assigned to have access to CDM addiction care comprising the sample for this study.

The baseline sociodemographic and health characteristics of the study sample ($n = 282$) are displayed in Table 1. Recruitment was largely from an inpatient detoxification unit (73%, 206/282). Most of the sample met criteria for both alcohol and drug dependence (56%), fewer (27%) for drug dependence only, and 17% for alcohol dependence only. Social problems, psychiatric and medical comorbidities were common including homelessness

[a] Composite International Diagnostic Interview Short Form (past year) and past 30 day drug use or heavy alcohol use.
[b] Overdose includes accidental and deliberate overdose of illegal drugs, over the counter medications, prescription medications, or alcohol.
[c] Readiness to change drinking or drug use: "How are ready are you to change your drinking or drug use?" using a scale from 1 to 10 with 10 indicating more readiness to change.
[d] Any shelter use or night on the street in the past 3 months.
[e] On probation, parole, pretrial release, or in diversion program (Drug Court).
[f] Mini International Neuropsychiatric Interview (MINI).
[g] Past month.
[h] Past 2 weeks.
[i] Katz Comorbidity Questionnaire.
[j] Includes seizures, heart failure, atrial fibrillation, rapid heat beat, hepatitis, cirrhosis, peripheral neuropathy, cancer of mouth/esophagus/stomach, skin infections, pneumonia, tuberculosis, gastritis, pancreatitis, anemia, septic arthritis, endocarditis, or blood clots.
[k] Environment favoring substance use defined as most or all of the people that you spend time with are either heavy/problem drinkers or heavy/problem drug users.
[l] Alcoholics Anonymous, Narcotic Anonymous, or Cocaine Anonymous.
[m] Past 3 months.
[n] Excludes admission for detoxification.
[o] Any counseling or therapy for emotional/psychological problems including full-day treatment, partial hospital program, or treatment by a psychiatrist.
[p] Standard deviation.
[q] Month of participant enrollment with respect to the first day of Addiction Health Evaluation and Disease management (AHEAD) cohort recruitment (September 11, 2006).

(56%), legal problems (36%), post-traumatic stress disorder (36%), major depression (78%), and substance-related medical conditions (67%).

Approximately half of the cohort (45%, 95% Confidence Interval [CI] 39–51%) met criteria for 14-day initiation and 23% (95% CI 18–28%) for 30-day engagement with CDM care (Table 2). By the end of study follow-up, more than three-fourths (81%, 95% CI 76–85%) of the cohort met criteria for linkage with CDM care and almost two-thirds (62%, 95% CI 56–68%) with continuation of CDM care.

Among those with CDM care linkage, the range of time from study enrollment to the second AHEAD visit was wide (1–458 days), however, the median was 12 days (interquartile range [IQR] 5, 34) and most (72% [164/227]) did so within 30 days of study entry. Similarly, among those with four or more AHEAD visits, the range of time from study enrollment to the fourth AHEAD visit was also remarkably wide (6–1059 days), but the median was 49 (IQR 21, 116) and most (67%) attended at least four AHEAD visits within 90 days.

Utilization of CDM care did not end with engagement. Participants who engaged with CDM care attended a median of 17 AHEAD visits (IQR 8, 27) over an extended period of time (median 514 days, IQR 180, 873). Participants with CDM continuation attended a median 14 visits (IQR 7, 25) over more than a year (median 550 days, IQR 287, 876).

We conducted a supplemental analysis to test whether engagement with CDM was associated with receipt of addiction treatments. Relative to those who did not engage with CDM care, a higher proportion of participants who engaged with CDM services utilized addiction treatment (79% vs 56%. respectively, P value = 0.001) and addiction pharmacotherapy (39% vs 18%, respectively, P value < 0.001).

3.2. Multivariable regression results

Major depressive episode was the only factor associated with initiation of CDM care (Table 3). Participants with major depressive episode had almost twice the odds of initiating CDM care (AOR 2.60, 95% CI 1.39, 4.87). Female sex was associated with lower odds of linkage with CDM care over the course of the study (Adjusted HR 0.67, 95% CI 0.49, 0.90).

Results of analyses (Tables 3 and 4) examining 30-day CDM engagement and CDM continuation were similar: younger age, female sex, and higher alcohol addiction severity were associated with lower odds of 30-day CDM engagement and a lower risk of CDM continuation. Later study enrollment was also associated with the latter CDM measure. Major depressive episode, while significant in the preliminary model, was not significant in a final model that combined all statistically significant factors and core covariates.

Since the sample was composed of individuals with alcohol dependence, drug dependence, or both alcohol and drug dependence, those with lower alcohol addiction severity may have been more likely to be primarily drug users who were seeking services available at the CDM clinic like office-based opioid therapy. We accounted for this possible confounding factor by adding a covariate for past 30-day opioid use, which did not substantially alter results.

4. Discussion

In this cohort of adults with substance dependence with access to CDM care located in primary care, approximately half initiated and a quarter engaged with CDM addiction care in the time frame specified by Washington Circle performance measures. Broadening the time interval, about three quarters of the sample made at least two CDM visits and about two-thirds at least four CDM visits over the course of the study. Regardless of the interval of time used to define these measures, most participants who engaged with CDM care continued to utilize CDM for more than a year.

An important point to consider is that recruitment of study participants was not based upon interest in utilizing CDM care. Although most of the study sample was recruited from a detoxification unit, they were not specifically seeking CDM care, or for that matter, any addiction treatment. Instead, they agreed to participate in a study that included an outpatient CDM clinic visit within primary care (i.e., the AHEAD clinic) or simply a referral to primary care. Therefore, participants in this study who were introduced to CDM care at study entry might return to utilize services in their "own time" instead of utilizing services within the timeframe specified in the WC performance measures. Accordingly, we found that most of the study sample returned to the clinic and CDM services during the follow-up period. Since engagement is considered to be a measure of patients' assessment of the appropriateness and attractiveness of treatment (McLellan et al., 2007), most participants appear to view CDM care favorably.

Because participants were not specifically seeking CDM care, initiation and engagement results approaching those of standard addiction treatment should be considered favorable. This study's initiation estimates are comparable to those reported by Massachusetts public sector addiction treatment sites and by the NCQA in an analysis of Medicaid data (42% for initiation and 27% for engagement) (Garnick et al., 2009). This study's engagement estimate was also comparable to Massachusetts public treatment sites but higher than the Medicaid rates reported by the NCQA (43% and 12%, respectively) (National Committee for Quality Assurance, 2010). Other treatment systems have reported higher treatment engagement rates (Kilbourne et al., 2006; Garnick et al., 2007).

A secondary objective was to evaluate predictors of initiation and engagement. Surprisingly, very few of the long list of variables we examined were significantly associated with initiation and engagement including factors associated with utilization of other types of addiction treatment, such as homelessness, legal problems, and readiness to change. Several of the variables associated with lower odds of ongoing CDM utilization have been noted with other types of addiction care. The association of younger age with lower likelihood to engage with CDM care is consistent with many others including one using WC performance measures (Garnick et al., 2007). As in the National Survey on Drug Use and Health, female gender has been associated with less addiction treatment (Wu et al., 2003). Since women living with children are less likely to use substance abuse treatment (Kertesz et al., 2006), women may have been unable to access ongoing addiction CDM due to family responsibilites, difficulty arranging transportation, and/or child care. Future CDM efforts may need to focus on women with substance dependence, possibly by providing child care, making home visits, or using alternate modalities to clinic visits like telephone contacts (McKay, 2009; Godley et al., 2010).

We also found that higher alcohol addiction severity was associated with lower odds of CDM engagement and continuation. The reasons for this are not clear. A few studies have found an association between higher alcohol addiction severity or higher frequency of alcohol use and less continuity of care after discharge from residential addiction treatment (Greenberg et al., 2002; Harris et al., 2006). As all participants in this study had substance dependence, those with lower alcohol severity may have been more likely to have comorbid opioid dependence; as those individuals would have been the comparison group for this characteristic, their desire to return to the clinic to access opioid pharmacotherapy may account for this finding. However, these results were similar even after

Table 2
Utilization of CDM care for substance dependence.

Outcome	Definition	Proportion (95% CI)
14-day initiation of CDM care[a]	≥2 CDM visits within 14 days after study entry	45% (39, 51)
Linkage with CDM care[b]	≥2 CDM visits between study entry and the end of the follow-up period[c]	81% (76, 85)
30-day engagement with CDM care[a]	≥2 CDM visits within 30 days after "14-day initiation" criteria are met	23% (18, 28)
Continuation of CDM care[b]	≥4 CDM visits between study entry and the end of the follow-up period[c]	62% (56, 68)

[a] Adapted from Washington Circle performance measures for initiation and engagement with outpatient addiction treatment.
[b] Kaplan–Meier survival estimate.
[c] Median follow-up was 550 days with interquartile range of 287–876.

Bolded values indicate an association at $P < 0.05$.
[a] ≥2 CDM visits within 14 days of study entry.
[b] ≥2 CDM visits between study entry and the end of the follow-up period.
[c] ≥2 CDM visits within 30 days of achieving "14-day initiation".
[d] ≥4 CDM visits between study entry and the end of the follow-up period.
[e] Odds ratio from logistic regression models predicting 14-day initiation of CDM care and 30-day engagement with CDM care (separate models for each independent variable of interest, all adjusted for core covariates: age, gender, race/ethnicity, and study enrollment month).
[f] Hazard ratios from Cox proportional hazards models predicting CDM linkage and CDM continuation (separate models for each independent variable of interest, all adjusted for core covariates).
[g] Categories represent tertiles of Addiction Severity Index score (0-1) with 1 indicating higher severity.
[h] $P = 0.08$.

adjusting for past 30-day opioid use. Hence, these findings suggest that those with higher alcohol addiction severity may require additional effort (e.g., motivational enhancement therapy, contingency management, more desirable pharmacotherapies) to engage and continue with CDM care.

4.1. Limitations

The importance of these findings depends upon whether CDM care is found to be effective. There is growing evidence that integrated medical and addictions care is more effective than either

Table 4
Factors associated with "30-day engagement" and "CDM continuation" in the final multivariable model[a].

Independent Variable	30-day engagement		CDM continuation

[a] Results from one multivariable logistic regression model predicting "30-day engagement" with CDM care and one multivariable Cox proportional hazards model predicting "CDM continuation." Both models include all variables listed in the table.

alone (Weisner et al., 2001; Bartels et al., 2004; Saitz et al., 2005) and CDM care contains effective components of addiction treatment (e.g., case management) endorsed by the IOM and others. Even if CDM care per se is not found to be effective, these findings are of interest, given the growing interest in transforming a system of time-limited episodic addiction care to one that spans different stages of substance use recovery (McLellan et al., 2007) and even a lifetime.

Generalizability of the study's results is another consideration when interpreting these findings. Since CDM care is a type of care that likely does not exist in many places, the results of this study are not applicable to models of care now in widespread use. However, there are several reasons that these findings may be applicable to urban general healthcare settings where such clinics could be implemented. First, this study had broad eligibility criteria to allow individuals with significant social, psychiatric, and medical needs to participate in the study regardless of readiness to change or desire for specialty addiction treatment, and most who were eligible enrolled; these were individuals that one might find in general medical practice or populations often excluded from efficacy studies (Humphreys et al., 2008). Second, the AHEAD clinic was located within primary care but was not dependent upon addiction training of the primary medical care staff. Third, many services commonly needed by individuals with SD were subject to the usual financial, administrative, and limited availability constraints. These services included addiction pharmacotherapy, specialty addiction treatment, primary medical care, diagnostic testing, and all other medical treatment provided by the hospital. In sum, the CDM clinic itself had no barriers but for any services outside the clinic, there were constraints, and in those circumstances, CDM clinicians worked to facilitate receipt of those services. CDM is a treatment model that could be implemented in other sites, albeit with variation in local available specific treatments outside the clinic.

4.2. Implications

This study's findings are relevant to recent efforts to provide longitudinal rather than episodic addiction care to improve the quality of care (McLellan et al., 2005; Institute of Medicine, 2006; McKay, 2006; Dennis and Scott, 2007). Evidence is growing for the utility of continuing care interventions to maintain progress from an initial, more intensive treatment and facilitate earlier re-entry into addiction treatment with relapse (Patterson et al., 1997; McKay et al., 2005; Bennett et al., 2007). CDM care shares this longitudinal perspective of care and goes further by facilitating access to a range of addiction treatment modalities including addiction pharmacotherapy, engaging with patients to acquire self-management skills, and addressing comorbidities. CDM care for substance dependence co-located with primary care has the potential to address the needs of the overwhelming majority of individuals with SD who would otherwise not seek any addiction treatment (Saitz et al., 2008; McKay, 2009). Sustaining participation with CDM care is likely to be instrumental to its efficacy (McKay, 2005). Knowing more about factors associated with CDM initiation and engagement can help clinicians target those who are more likely to drop out of care.

In summary, patients with substance dependence appear to be willing to initiate and follow-up with CDM care, although often not in time frames specified by performance measures developed to evaluate the quality of outpatient addiction care. CDM has the potential for improving the quality of addiction care for people with addictions.

Role of funding source

Funding for this study was provided by the National Institute on Alcohol Abuse and Alcoholism (grant R01 AA010870) and the National Institute on Drug Abuse (grant R01 DA010019). This work was also supported, in part, by the Boston University Translational Science Institute from the National Center for Research Resources (UL1-RR025771). Dr. Samet receives support from NIAAA: K24 AA015674.

The sponsors had no further role in study design; in the collection, analysis, and/or interpretation of the data; in the writing of the report, or in the decision to submit the paper for publication. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institute on Drug Abuse, the National Institute on Alcohol Abuse and Alcoholism or the National Institutes of Health.

Statement of the American Society of Addiction Medicine Consensus Panel on the Use of Buprenorphine in Office-Based Treatment of Opioid Addiction

Mark L. Kraus, MD, FASAM, Daniel P. Alford, MD, MPH, FACP, Margaret M. Kotz, DO, Petros Levounis, MD, FASAM, Todd W. Mandell, MD, Marjorie Meyer, MD, Edwin A. Salsitz, MD, FASAM, Norman Wetterau, MD, FASAM, and Stephen A. Wyatt, DO

Objectives: Opioid addiction affects over 2 million patients in the United States. The advent of buprenorphine and the passage of the Drug Addiction Treatment Act in 2000 have revolutionized the opioid treatment delivery system by granting physicians the ability to administer office-based opioid treatment (OBOT), thereby giving patients greater access to treatment. The purpose of this consensus panel was to synthesize the most current evidence on the use of buprenorphine in the office-based setting and to make recommendations that will enable and allow additional physicians to begin to treat opioid-addicted individuals.

Methods: Literature published from 2000 to 2009 was searched using the PubMed search engine and yielded over 375 articles published in peer-reviewed journals, including some that were published guidelines. These articles were submitted to a consensus panel composed of researchers, educators, and clinicians who are leaders in the field of addiction medicine with specific expertise in the use of OBOT. The panel discussed results and agreed upon consensus recommendations for several facets of OBOT.

Results: On the basis of the literature review and consensus discussions, the panel developed a series of findings, conclusions, and recommendations regarding the use of buprenorphine in office-based treatment of opioid addiction.

Conclusions: Therapeutic outcomes for patients who self-select office-based treatment with buprenorphine are essentially comparable to those seen in patients treated with methadone programs. There are few absolute contraindications to the use of buprenorphine, although the experience and skill levels of treating physicians can vary considerably, as can access to the resources needed to treat comorbid medical or psychiatric conditions—all of which affect outcomes. It is important to conduct a targeted assessment of every patient to confirm that the provider has resources available to meet the patient's needs. Patients should be assessed for a broad array of biopsychosocial needs in addition to opioid use and addiction, and should be treated, referred, or both for help in meeting all their care needs, including medical care, psychiatric care, and social assistance. Current literature demonstrates promising efficacy of buprenorphine, though further research will continue to demonstrate its effectiveness for special populations, such as adolescents, pregnant women, and other vulnerable populations. Since the time of this review, several new studies have provided new data to continue to improve our understanding of the safety and efficacy of buprenorphine for special patient populations.

Key Words: buprenorphine, office-based treatment, opioid addiction

ISSN: 1932-0620/11/0504-0254

DOI: 10.1097/ADM.0b013e3182312983

Since 2002, a large body of evidence has become available, reflecting the experience of US researchers and

clinicians. This evidence is reflected in articles published in peer-reviewed journals, as well as in guidelines issued by various organizations and agencies (Health Resources and Services Administration, 2004; McNicholas, 2004; Wedam et al., 2007; Center for Substance Abuse Treatment, 2006a; Center for Substance Abuse Treatment, 2006b; Gordon and Krumm, 2008; Baxter, 2009).

To make this information more readily available to practicing physicians, as well as to encourage additional physicians to begin treating opioid-addicted persons, members of the American Society of Addiction Medicine consensus panel engaged in a critical examination of the scientific literature and employed their considerable clinical experience in reaching consensus as to recommended patient care practices. In doing so, panel members recognized that advice is not an adequate substitute for the knowledge and skills of practicing physicians who are engaged in developing treatment regimens tailored to the needs of individual patients.

The panel also recognized that not all treatment providers would be able to conform to each of the strategies recommended here. Instead, providers are encouraged to consider the panel's findings, conclusions, and recommendations in the context of the individual patient and their overall practice. Information and recommendations provided in this document are not intended to create a legal standard of care for any physician or to interfere with his or her clinical judgment or practice of medicine.

METHODS

Literature published from 2000 to 2009 was the subject of a PubMed search. The search yielded 376 articles published in peer-reviewed journals. Consensus reports from the federal Center for Substance Abuse Treatment and other authoritative sources also were included in the review.

Articles and published guidelines were submitted to a consensus panel composed of researchers, educators, and clinicians who have expertise in the use of buprenorphine. On the basis of the literature review and consensus discussions, the panel developed a series of findings, conclusions, and recommendations regarding the use of buprenorphine in office-based treatment of opioid addiction. Members agreed on the evidence for buprenorphine's overall efficacy and safety, as well as contraindications to its use.

Multiple drafts of the consensus panel's work were submitted to a national peer review panel, whose members were asked to evaluate the documents for scientific accuracy and clinical relevance. That work is presented here.

RESULTS

Patient Management With Buprenorphine

Induction

Patients who are currently physically dependent on opioids should be in moderate opioid withdrawal before the first buprenorphine induction dose. Patients are instructed to stop taking their opioid, and wait until they develop moderate spontaneous withdrawal. If a patient is not in withdrawal, and is given buprenorphine, precipitated withdrawal may occur. The Clinical Opioid Withdrawal Scale is a useful and validated assessment tool. The initial dose is 2 to 4 mg, and the total first day dose is up to 12 to 16 mg (Johnson et al., 2003; McNicholas, 2004; Batki, 2005; Marsch et al., 2006; Stephen, 2006; Baxter, 2009). During induction, patients should be frequently assessed for signs of overmedication. There is no data as to the specific time interval during which overmedication should be assessed. Therefore, it should be approached based on an individual patient basis.

Patients requesting transfer from methadone to buprenorphine should gradually taper their methadone dose to 30 to 40 mg and remain clinically stable on that dose before starting buprenorphine induction. Because methadone has a long and variable half-life, patients will need to discontinue methadone for at least 36 hours and often up to 72 hours to experience moderate withdrawal before proceeding with buprenorphine induction (McNicholas, 2008).

Patients should be advised to avoid driving or operating other machinery until their dose is stabilized and they are familiar with the effects of buprenorphine.

During induction and stabilization, patients should be assessed frequently for signs of overmedication or undermedication, and dose adjustments should be made accordingly (Johnson, 2003; McNicholas, 2004; Batki, 2005).

Consensus of the Panel

The buprenorphine/naloxone combination product should be used for induction as well as for stabilization and maintenance. The exception is pregnant women who are candidates for buprenorphine treatment, who should be inducted and maintained on the buprenorphine monoproduct (see the discussion of pregnancy).

In opioid dependent patients undergoing induction who exhibit signs of precipitated withdrawal, the physician has 2 options:

1. Continue with buprenorphine induction by continuing to give additional doses of buprenorphine up to 16 mg or until signs and symptoms of withdrawal abate;
2. Or to stop induction when the patient exhibits withdrawal symptoms, treat withdrawal symptomatically (eg, clonidine, antidiarrheals, nonsteroidal anti-inflammatory drugs) and instruct the patient to continue to abstain from opioids and return the following day for reassessment of induction.

The timing of buprenorphine induction requires care to avoid overdose (eg, in a patient who has been using central nervous system depressants such as alcohol or benzodiazepines in addition to opioids) or underdose (eg, triggering a re-emergence of opioid craving).

Stabilization

The stabilization phase is focused on finding the optimal dose for the individual patient. This dose should eliminate all withdrawal symptoms, decrease opioid craving, eliminate other opioid use, and provide maximal functional status (Joseph et al., 2000; Baxter, 2009).

Most patients stabilize on 8 to 24 mg/day (Comer et al., 2005a; Comer et al., 2005b). Rarely, there is a need to go up to 32 mg for the highly tolerant patient. The primary concern

in going to these larger doses is the much greater potential for diversion.

Certain medical factors may cause a patient's dosing requirements to change. These include (but are not limited to) starting, stopping, or changing the dose of other prescription medications; onset and progression of pregnancy; onset of menopause; progression of liver disease; and significant increase or decrease in weight (Baxter, 2009).

Relapse should always be ruled out as a reason for loss of stability. Continued or resumed use of short-acting opioids during treatment with buprenorphine may increase tolerance and render the buprenorphine dose inadequate (Stephen, 2008). If a short-acting opioid of abuse produces euphoria, the buprenorphine dose may be increased to block this effect. A dose increase also may help to suppress drug cravings (Leavitt et al., 2000). Ideally, receipt of opioids from multiple providers should be avoided. However, in cases where this is not so, coordination with other prescribing physicians to limit the number of short-acting opioids obtained by prescription is essential (Baxter, 2009).

Consensus of the Panel

There is no precise way to determine in advance the optimal dose for a particular patient. Because buprenorphine has a long plasma half-life and an even longer duration of action at the mu opioid receptor, 5 days should be allowed between dose adjustments to assess the effect. While most patients stabilize on a dose of 8 to 24 mg/day as demonstrated by the data, many will not need a dose higher than 16 mg/day. This is further supported by Comer et al. in their study noting that brain mu receptors are approximately 90% saturated at a dose of 16 mg/day demonstrated on neuroimaging.

Detoxification/Medically Supervised Withdrawal Management

Few studies have evaluated predictors, mediators, and moderators of treatment success for medically supervised withdrawal from opioids conducted in outpatient settings.

Consensus of the Panel

Detoxification using buprenorphine is not technically difficult, but long-term abstinence following such detoxification appears as difficult to achieve as with other medications. Arguably, detoxification is best conceptualized not as definitive treatment, but as a preparatory and stabilizing introduction to other forms of care.

The most effective withdrawal method involves stabilizing the opioid dependent patient with buprenorphine and then tapering the dose over time by 2 mg every 5 days until the taper is completed. Evidence comparing buprenorphine with methadone is limited, but it appears that completion of withdrawal may be more likely with buprenorphine and withdrawal symptoms may resolve more quickly with buprenorphine than with methadone (Gwoing et al., 2006; Gowing et al., 2009).

Maintenance Treatment

Except in patients whose addictive disorders are of brief duration, the best outcomes occur with long-term medication maintenance with methadone or buprenorphine accompanied by appropriate psychosocial interventions (Collins and McAllister, 2007; Kleber, 2007; Soeffing et al., 2009; Stotts et al., 2009; World Health Organization, 2009). The optimum duration of maintenance is unclear, but may involve long-term or even lifetime medication use (Kleber, 2007; World Health Organization, 2009). This is similar to the treatment of other chronic diseases, such as hypertension, diabetes, or asthma. In the maintenance treatment paradigm, the goal is not to "get off" the buprenorphine, but rather to achieve maximal function both at home and at work.

Generally 8 to 24 mg/day of buprenorphine will be an adequate maintenance dose. Some patients may require a higher dose up to 32 mg or a lower dose as noted above. In positron emission tomographic scan studies, approximately, 92% of mu opioid receptors were occupied by buprenorphine at a dose of 16 mg/day (Comer et al., 2005a; Comer et al., 2005b). It is unclear how positron emission tomographic scan images translate into clinical outcomes such as withdrawal, craving, and treatment retention (Johnson et al., 2003; Sporer, 2004). Doses higher than 24 mg should prompt a thorough review of the patient's rehabilitation status. To evaluate patient progress and success of maintenance therapy, physicians should assess patients regularly for relapse and instability. In managing these challenges, some of the consensus panel recommendations include:

- Increasing frequency of visits
- Adding additional psychosocial interventions
- Increasing drug dose (if not higher than the maximum daily dose already)
- Decrease prescription interval
- Increase level of care
- Initiate a unilateral involuntary taper toward medication discontinuation
- Consider switching medication management to methadone

Consensus of the Panel

As Kleber (Kleber, 2007) has noted, medications are available to treat opioid addiction although none are curative. Medications can, however, markedly diminish withdrawal symptoms and craving, and block opioid euphoric effects if patients relapse, and enhance the efficacy of psychosocial interventions.

Relapse Prevention

Among the major challenges confronting patients in treatment is the prevention of relapse, which is a risk even with successful treatment interventions (White, 2007).

Specific precipitants of relapse vary substantially from one experience to the next, even in the same individual (Connors et al., 1996). Attributing causality is even more complex in patients who have co-occurring medical or psychiatric disorders. In a survey, Daley and colleagues identified factors that contributed to relapse including inability to manage stress or negative emotional states (69%); interpersonal conflicts with family or others (29%); poor adherence to the treatment regimen (25%); negative thinking (11%); and insufficient motivation to change (10%) (Daley et al., 1998).

Consensus of the Panel

The following principles, which are common to many models of relapse prevention (Marlatt and Gordon, 1985; Tims and Leukefeld, 1987; Dimeff and Marlatt, 1995; Amato et al., 2008a; Amato et al., 2008b), can minimize the risk of relapse and attenuate the severity of a relapse episode:

1. Identifying environmental cues and stressors that act as relapse triggers.
2. Learning to identify and manage negative emotional states.
3. Working toward a more balanced lifestyle.
4. Developing skills to cope with stressful life events.
5. Understanding and managing craving.
6. Learning to identify and interrupt lapses and relapses.
7. Developing a recovery support network, such as joining a self-help group.
8. Utilizing clinical resources available to patients, such as counseling.

PATIENT SELECTION

Patient Assessment

The assessment should include:

1. Establishment of the diagnosis (such as, the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition) of opioid dependence including the duration and severity of the illness.
2. Discussion of current opioid use history in terms of when, what and how much opioid the patient most recently used.
3. Documentation of the patient's substance use history, including alcohol and other drugs of abuse.
4. Identification and referral of patients who need medically supervised withdrawal management from alcohol, benzodiazepines, or other sedatives.
5. Identification of comorbid medical and psychiatric conditions and disorders and to determine how, when and where they will be addressed.
6. Screening for communicable diseases and address them as needed.
7. Assessment of the patient's access to social supports, family, friends, employment, housing, finances, and legal problems.
8. Evaluation of the patient's readiness to participate in treatment.

Laboratory tests should include; liver function tests, human immunodeficiency virus (HIV) and viral hepatitis serologies, pregnancy test for women and urine toxicology screening for naturally occurring opioids (eg, such as heroin which is detected as morphine), synthetic and semisynthetic opioids (methadone, oxycodone), and other commonly abused drugs such as cocaine, amphetamines, and benzodiazepines (Gordon and Krumm, 2008).

Consensus of the Panel

Consensus opinion is that an initial patient assessment is of higher quality when it includes a medical and psychiatric history, a substance abuse history, and an evaluation of family and psychosocial supports, as well as pregnancy testing for all women of childbearing age. The physical examination should be focused on evaluating neurocognitive function and identification of sequelae of opioid addiction or severe hepatic dysfunction (Gordon and Krumm, 2008). The decision to initiate medication-assisted therapy begins with an evaluation of the patient to confirm the diagnosis of opioid dependence. An ideal candidate for office-based treatment with buprenorphine is an individual who will comply with each issue noted in the patient consent form such as withdrawal symptoms, risks of combining buprenorphine with other medications, directions for taking medication, cost of medication, and potential side effects (McNicholas, 2004).

Relative Contraindications to the Use of Buprenorphine

Concurrent Use of Sedative-Hypnotics (Including Alcohol)

Individuals with current, active alcohol dependence rarely are appropriate candidates for office-based treatment with buprenorphine (Fishman et al., 2005; McNicholas, 2008).

The combination of buprenorphine with sedative-hypnotic medications has been associated with deaths (Lavie et al., 2005). If concomitant treatment is deemed necessary, the doses of both medications may need to be reduced.

Elevated liver function tests: patients with elevated liver function 3 to 5 times above normal should not be considered for buprenorphine.

Consensus of the Panel

Patients who are dependent or abusing sedative hypnotics, alcohol, or both are rarely appropriate for office-based opioid treatment (OBOT) with buprenorphine. These patients should undergo careful clinical evaluation and should be considered for OBOT only if all of the following apply: clinical indication; willingness to discontinue sedative hypnotics, alcohol, or both by undergoing medically supervised withdrawal; and success in discontinuing hypnotics, alcohol, or both. In addition, patients with elevated liver functions tests 3 to 5 times greater than normal should not be considered for treatment with buprenorphine. These patients may be considered if they are willing to and have successfully discontinued sedative hypnotics, typically through medically supervised withdrawal.

Adolescents

Few studies have systematically evaluated buprenorphine in the treatment of adolescents, although there is good evidence that patients younger than 18 years are at particularly high risk for serious complications of addiction, including overdose deaths, suicide, HIV and other infectious diseases (Levy et al., 2007; Fiellin, 2008). Woody and colleagues (Woody et al., 2008) conducted 12-week clinical trials at 6 community programs for patients aged 15 to 21 years who were randomized to either 12 weeks of buprenorphine/naloxone treatment or a 14-day taper. Adolescents in the treatment group remained in counseling/ancillary treatment longer than those that were rapidly tapered (70 vs 20.5%, $P = 0.001$). Woody and colleagues concluded that continuing treatment with buprenorphine/naloxone improved outcomes compared with short-term detoxification, although further research is needed to assess the

efficacy and safety of longer-term treatment with buprenorphine for adolescents.

Consensus of the Panel

Buprenorphine/naloxone may be considered in adolescents for whom the balance of risks/benefits is considered favorable, considering such factors as: severity of addiction, previous failure, or low likelihood of success of other treatment approaches and overall risk of relapse. Furthermore, risks and benefits of using buprenorphine in adolescents should be discussed between providers and patients (and parents or guardians if patient is less than 18 years of age) on an individual basis.

Pregnant Women

Until recently, in the United States, methadone was the standard of care for pregnant women addicted to opioids. Since this review was conducted, however, new research has demonstrated promising safety and efficacy data for use of buprenorphine in pregnant women (Jones et al., 2009). Pregnant women should be offered either methadone or buprenorphine. Methadone has been shown to be safe and effective for both the pregnant woman and the neonate (Anderson and Kearney 2000; Jones et al., 2005; Vavrinková and Binder 2007). Buprenorphine (as is methadone) has been labeled as a Category C because there was insufficient evidence to establish its safety during pregnancy. Since the release of the 2009 study, buprenorphine monotherapy is a reasonable choice and appears to be as safe as methadone in pregnancy.

Buprenorphine maintained pregnancies also suggest that there is a lower severity of neonatal abstinence syndrome. Several studies have recently been published that have demonstrated that buprenorphine offers a substantial efficacy advantage over the current standard of care with oral morphine (Kraft et al., 2011; Unger et al., 2011). Other potential treatment of neonatal abstinence syndrome is methadone (Bio et al., 2011). This consensus panel review did not evaluate alternative delivery forms other than sublingual tablets (Note: more information and data maybe found in the references cited).

Breast-feeding

The safe use of buprenorphine during breast-feeding is not clearly delineated. However, the benefits of breast-feeding are multiple, including a natural strengthening of the maternal-child bond, which is of particular importance for this patient population. Further research will continue to clarify details regarding the use of buprenorphine in breast-feeding but until then the risks and benefits should be discussed and balanced on an individual patient basis (Lejeune et al., 2005; Briggs et al., 2008).

Consensus of the Panel

Short-term data on pregnancy and neonatal outcomes at the time of this review may indicate buprenorphine monotherapy for treatment of opioid dependent pregnant women is safe. Studies released since this review demonstrate promising safety and efficacy for the use of buprenorphine in pregnant women.

Although the available data are insufficient to firmly establish the safety of breast-feeding for mothers maintained on buprenorphine, the low theoretical risk should be balanced against the well-documented benefits of breast-feeding to both mother and neonate.

Pregnant patients require extensive counseling and community resources for recovery and parenting success. Integration of services and communication among all providers is essential for office-based treatment. The buprenorphine provider should work with the obstetric and pediatric providers to plan all aspects of care within the community. Since these consensus statements were written, additional research has been published that has demonstrated and supported the safety of buprenorphine in pregnant patients. Initial outcomes from these studies are positive demonstrating good outcomes for both mothers and neonates. A full discussion of this research is beyond the current scope of these guidelines, but readers should refer to the referenced literature to obtain further details (Jones et al., 2010).

Patients with Acute and Chronic Pain

In the United States, the parenteral formulation of buprenorphine is approved by the Food and Drug Administration for pain but not addiction treatment, while the sublingual formulation is approved for addiction but not pain treatment. Small studies in Europe and Asia demonstrate analgesic efficacy of the sublingual formulation (0.2-0.8 mg q 6-8 h) in opioid naïve postoperative pain (Edge et al., 1979; Moa and Zetterstrom, 1990). Parenteral analgesic potency is about 30 times that of morphine.

Consensus of the Panel

Several possible approaches exist for treating acute pain requiring opioid analgesia in the patient on buprenorphine therapy. With such limited clinical experience, mutiple treatment approaches based on pharmacologic principles have been published (Alford et al., 2006). The most effective approach will be elucidated with increased clinical experience. Currently there are insufficient data to recommend sublingual buprenorphine for the treatment of acute or chronic pain in patients with a history of opioid dependence.

Patients with HIV Disease

Buprenorphine should be used cautiously in combination with HIV antiretroviral medications that may inhibit, induce, or be metabolized by the cytochrome P450 3A4 enzyme system. Protease inhibitors inhibit cytochrome P450 3A4. Metabolism of buprenorphine, the antiretroviral medications, or both may be altered when they are combined. In some cases, therapeutic blood levels of antiretrovirals may need to be monitored (McCance-Katz, 2005; McCance-Katz et al., 2006a; McCance-Katz et al., 2006b).

Consensus of the Panel

While buprenorphine may be effectively used to treat patients with HIV, its use should be with caution concerning possible but as yet not clinically relevant drug-drug interactions. While drug/drug interactions remain a consideration with buprenorphine, they are likely less of a concern than when treating patients with methadone. Furthermore, successful use

of buprenorphine to treat HIV-infected, opioid-addicted patients has been demonstrated in multiple studies (Moatti et al., 2000; Berson et al., 2001; McCance-Katz, 2005).

Patients With Hepatitis and Other Liver Disorders

Viral hepatitis (especially infection with hepatitis B virus or hepatitis C virus) is common among individuals with up to 60% to 90% of injection drug users being infected with hepatitis C (Berson et al., 2001; Cazorla et al., 2005; Bruce and Altice, 2006). Therefore, patients with viral hepatitis who have opioid dependence and should be evaluated and treated appropriately (Backmund et al., 2001).

Consensus of the Panel

Buprenorphine treatment is not contraindicated by mildly elevated liver enzymes, although liver enzyme levels should be monitored. The threshold for elevated liver function for starting or discontinuing buprenorphine therapy is an elevated liver enzyme level of 3 times above normal. Patients with a history of injection drug use should be strongly encouraged to undergo immunization for hepatitis A and B, taking into account individual patient factors and appropriateness for vaccination.

Patients With Other Medical Conditions and Complications

Buprenorphine may be superior to methadone for the treatment of opioid dependence for patients with underlying cardiopulmonary disease or at risk for respiratory compromise, as it is less likely to cause respiratory depression (Gordon and Krumm, 2008).

Consensus of the Panel

Medical comorbidities may complicate the treatment of opioid addiction. Buprenorphine may be preferrable to methadone for specific medical conditions, though the evidence does not necessarily support which specific conditions.

Patients With Psychiatric Comorbidities

Coexisting psychiatric disorders are present in 20% to 60% of the persons entering addiction treatment, especially older individuals, those living in urban areas, patients who are incarcerated, or patients of a lower socioeconomic status (Robins et al., 1991; Kessler et al., 1994; Room, 1998; Sacks and Ries, 2005).

Patients with co-occurring psychiatric disorders have more difficulty engaging in, participating in, and completing addiction treatment, and generally have poorer prognoses than patients with diagnoses of either substance use or mental disorder alone (Kessler et al., 1994; Dausey and Desai, 2003). Untreated or inadequately treated psychiatric disorders can interfere with the effective treatment of addiction (Ziedonis et al., 2003; Khalsa et al., 2008. Patients with major depression or dysthymia are more likely to use illicit drugs during treatment than patients who do not suffer from depression (Sacks and Ries, 2005).

The presence of comorbid psychiatric disorders should not exclude patients from admission to office-based treatment with buprenorphine if outpatient treatment of both diseases can be accomplished (Sacks and Ries, 2005).

Consensus of the Panel

It is important to determine whether psychiatric symptoms are independent of the substance use or are substance-induced as this may inform treatment approach. Regardless, all patients with psychiatric symptoms should be evaluated and adequately treated. In the latter case, stability in the addiction treatment regimen should be the first therapeutic step (Ziedonis et al., 2003).

However, in patients with very severe psychiatric disease, the reverse treatment sequence may be more reasonable. In these patients, treatment using maintenance buprenorphine should be considered following stabilization of illness.

DISCUSSION

Although almost 2 million persons in the United States abuse or are addicted to opioids—prescription and illicit-–recent data suggest that nearly 80% do not receive treatment for their disorder (Kleber, 2007; Becker et al., 2008; Tetrault et al., 2008).

The use of buprenorphine and buprenorphine/naloxone combination in office-based primary care has improved access to care. Multiple studies have shown that buprenorphine treatment of addiction can be successfully integrated into office practice by physicians who are not addiction specialists (Fiellin et al., 2008).

In most cases, treatment is required for a long period or even throughout life (Kleber 2007; World Health Organization, 2009). Such long-term care, which is common to many medical conditions, should not be seen as a failure of treatment but as a cost-effective way to prolong life and improve quality of life by supporting the natural and long-term process of change and recovery. While the consensus panel did not make a formal recommendation on the frequency of monitoring and the use of varying methods for monitoring patient progress, we agreed that this is often dependent on physician preference as well as the individual patient. Therefore, urine toxicology, prescription supply/interval, etc, may be considered for each individual patient case.

Recent studies indicate that buprenorphine can be used safely and effectively to treat people with specialized needs, such as persons with co-occurring psychiatric conditions, adolescents, older adults, and persons with HIV and liver disease. Each of these conditions imposes specific requirements that must be addressed through careful patient selection, monitoring, and adjunctive services. There is little data on efficacy and safety to support the use of buprenorphine monotherapy to treat breast-feeding women. However, the benefits of breast-feeding are multiple, including a natural strengthening of the maternal-child bond, which is of particular importance for this patient population. The decision to place breast-feeding women on buprenorphine requires a balance of the risks and benefits and a discussion between provider and the individual patient, as a lack of data does not necessarily imply a risk of harm to the neonate. Populations not discussed by this panel remain of importance in treating opioid dependence, including

homeless populations, homosexual and bisexual populations, as well as patients with other medical comorbidities. Though beyond the scope of this review, these populations should be considered individually regarding treatment plans for opioid addiction.

CONCLUSIONS

Based on a review of the available evidence by a consensus panel with considerable clinical expertise and experience in the use of buprenorphine, the following recommendations are offered:

1. Medication-assisted therapies such as buprenorphine have been shown to be more effective than any other type of treatment for opioid dependence, particularly when used in concert with psychosocial interventions, such as counseling and other psychosocial therapies.
2. As in the treatment of most chronic diseases, pharmacotherapy of opioid dependence should be expected to take place over an extended period of time to achieve continued effective management of the underlying disorder. Most successful patients receive maintenance medication for years, whereas only a minority successfully taper off medication.
3. Therapeutic outcomes for patients who self-select office-based treatment with buprenorphine are essentially comparable to those seen in patients treated with methadone programs. While data thus far demonstrate that buprenorphine is almost as effective as methadone at promoting treatment retention, reducing illicit use of heroin and prescription opioids, reducing risky behaviors that transmit HIV and hepatitis, and is superior to methadone in terms of safety, further clinical data are still needed.
4. There are few absolute contraindications to the use of buprenorphine. However, the experience and skill levels of treating physicians can vary considerably, as can access to the resources needed to treat comorbid medical or psychiatric conditions—all of which may make the use of buprenorphine more complex.
5. Some patients who could benefit from treatment with buprenorphine may face challenges to successful treatment through office-based care, either because they require the structure afforded by a methadone program or because they lack access to office-based treatment or such care is not covered. It is important to conduct a targeted assessment of every patient to confirm that the provider has resources available to meet the patient's needs.
6. Patients should be assessed for a broad array of biopsychosocial needs in addition to opioid use and addiction, and should be treated, referred for help, or both in meeting all their care needs, including medical care, psychiatric care, and social assistance. In addition to the benefit they obtain directly from medication, patients should be encouraged to develop relapse prevention skills and to make active changes in their life circumstances to reduce relapse risk.
7. Most patients are likely to stabilize on 8 to 24 mg of buprenorphine per day, although some may need doses of up to 32 mg/day. In the absence of specific contraindications, the buprenorphine/naloxone combination is preferred to the monoproduct.
8. Although drug interactions with buprenorphine do occur, they are not always clinically relevant in a particular patient and do not necessarily prohibit the concomitant administration of buprenorphine with other drugs (although adjustment of the buprenorphine dose may be necessary). In any case, patients should be informed of the potential for drug interactions.
9. Physicians who wish to use buprenorphine should seek a level of comfort with this treatment approach. This encompasses knowledge of applicable practice standards and guidelines, familiarity with the evidence supporting recommended treatment strategies, protocols for treatment or referral of patients with complicating conditions (eg, severe depression, pain, or pregnancy), and an understanding of applicable federal, state, and local laws and regulations.
10. Physicians who treat opioid-dependent patients with buprenorphine should engage in continued medical education and other professional activities to keep current with the evolving knowledge base regarding optimal use of medication-assisted therapies in general with a particular focus on buprenorphine.

ACKNOWLEDGMENTS

The consensus panel and national peer review panel acknowledge with gratitude the support and encouragement of the Officers and board of directors of the American Society of Addiction Medicine, and of ASAM's Executive Vice President, Eileen McGrath, JD. Deep appreciation also is due consensus panel chair Mark L. Kraus, MD, FASAM, for his unwavering leadership, and to ASAM staff members Tracy Gartenmann, Angela Warner, and Darlene Williams for the exceptional skill with which they administered the project.

Consensus Panel. *The consensus panel developed the findings, conclusions, and recommendations found in this report. Members of the panel are:*

Daniel P. Alford, MD, MPH, FACP, Associate Professor of Medicine, Boston University School of Medicine, and Medical Director, Office-Based Opioid Treatment and MASBIRT Programs, Boston Medical Center, Boston, Massachusetts

Margaret M. Kotz, DO, Professor of Psychiatry, Case Western Reserve University School of Medicine, and Director of Addiction Recovery Services, University Hospitals of Cleveland, Cleveland, Ohio

Mark L. Kraus, MD, FASAM, Assistant Clinical Professor of Medicine, Yale University School of Medicine, New Haven, Connecticut; Primary Care General Internal Medicine/Addiction Medicine, Westside Medical Group, PC, Waterbury, Connecticut, and Chief Medical Officer, Connecticut Counseling Centers, Danbury, Connecticut

Petros Levounis, MD, MA, FASAM, Director, The Addiction Institute of New York, and Chief, Division of Addiction

Psychiatry, St Luke's & Roosevelt Hospitals, and Associate Clinical Professor of Psychiatry, Columbia University College of Physicians & Surgeons, New York, New York

Todd W. Mandell, MD, Chief Medical Officer, Community Substance Abuse Centers, Inc, Westfield, Massachusetts

Marjorie Meyer, MD, Director, Opiate Treatment Program During Pregnancy and Associate Professor, Ob/Gyn, University of Vermont Medical Center, Burlington, Vermont

Edwin A. Salsitz, MD, FASAM, Medical Director, Office-Based Opioid Therapy, Department of Medicine, Beth Israel Medical Center, New York, New York

Norman Wetterau, MD, FAAFP, FASAM, Private Practice of Family Medicine, Tri-County Family Medicine, Dansville, New York

Stephen A. Wyatt, DO, Medical Director, Dual Diagnosis Program, Middlesex Hospital, Middletown, Connecticut

National Peer Review Panel. Members of the national peer review panel reviewed multiple drafts of this article and supporting documents and made numerous suggestions to improve its clarity, scientific accuracy, and clinical utility. The consensus panel is indebted to the peer reviewers for their many contributions.

Peter Banys, MD, MSc, Health Sciences Clinical Professor of Psychiatry, University of California at San Francisco, and Director, Substance Abuse Program & Substance Abuse Physician Fellowship, VA Medical Center, San Francisco, California

ABSTRACT

Purpose: Attributes of the organisational culture of residency training programmes may impact patient safety. Training environments are complex, composed of clinical teams, residency programmes, and clinical units. We examined the relationship between residents' perceptions of their training environment and disclosure of or apology for their worst error.

Method: Anonymous, self-administered surveys were distributed to Medicine and Surgery residents at Boston Medical Center in 2005. Surveys asked residents to describe their worst medical error, and to answer selected questions from validated surveys measuring elements of working environments that promote learning from error. Subscales measured the microenvironments of the clinical team, residency programme, and clinical unit. Univariate and bivariate statistical analyses examined relationships between trainee characteristics, their perceived learning environment(s), and their responses to the error.

Results: Out of 109 surveys distributed to residents, 99 surveys were returned (91% overall response rate), two incomplete surveys were excluded, leaving 97: 61% internal medicine, 39% surgery, 59% male residents. While 31% reported apologising for the situation associated with the error, only 17% reported disclosing the error to patients and/or family. More male residents disclosed the error than female residents ($p=0.04$). Surgery residents scored higher on the subscales of safety culture pertaining to the residency programme ($p=0.02$) and managerial commitment to safety ($p=0.05$). Our Medical Culture Summary score was positively associated with disclosure ($p=0.04$) and apology ($p=0.05$).

Conclusion: Factors in the learning environments of residents are associated with responses to medical errors. Organisational safety culture can be measured, and used to evaluate environmental attributes of clinical training that are associated with disclosure of, and apology for, medical error.

INTRODUCTION

Everyone makes mistakes. Over the past decade, the medical profession has started to apply a systems approach to patient safety, recognition that coordination of individual, team, and organisational forces are needed to promote patient safety. Analysis of the root causes of an error can prevent future errors by identifying and correcting problems.[1] However, in order to learn from mistakes and develop safer systems, errors must first be identified and reported.

Unfortunately, many errors are never reported. In one study, merely half of the house officers told their attending physicians about the most serious errors they committed.[2] Underreporting of adverse events is estimated to range from 50% to 96% annually.[1 3 4] Rather than dealing with mistakes constructively by reporting and learning from them, studies indicate that physicians typically respond to their mistakes defensively, blaming the system, other members of the healthcare team, or even the patient.[2 5–7] Possible explanations for underreporting medical errors include fear of litigation acting as a deterrent,[8–10] and the professional medical culture that limit an individual's willingness to discuss error.[5 11]

While elements of professional medical culture are hypothesised to lead to widespread underreporting of medical errors, few studies have elucidated and measured aspects of medical culture that are associated with a failure to disclose, particularly in the learning environments of clinical training programmes. In contrast to medical culture, non-medical industries such as aviation and nuclear safety have traditionally valued a professional 'culture of safety', which facilitates reporting of errors, so that individuals operating in groups within an organisation can learn how to prevent future errors.[12] Medical educators have recently attempted to incorporate system-based thinking into their curriculum, in order to incorporate aspects of a safety culture that, along with enquiry and trust, were previously lacking in

residency settings.[2 7 12] Although there is recognition of the need to create a learning culture of safety for residents,[13] measuring educational culture has proved to be a challenge. In addition to the complexities of quantitatively measuring an abstract concept of 'organisational culture',[14] residents train in multiple environments which are dynamic and divergent: their individual clinical teams (which often rotate), the academic residency training programme, and the clinical institution(s) (usually a hospital) each contributing to a trainee's overall sense of culture.

This study endeavours to measure a trainee's perception of their training environment as it relates to safety, and their response to committing an error. By collecting data on both these elements, we explore the relationship between the culture of the training environment and individual behaviour. Specifically, we hypothesised that house officers would be more likely to disclose and apologise for an error if they rate their clinical team as having an environment in which they can report errors without fear of punishment or rejection; rate their training programme as having positive attitudes about reporting and coping with errors in the workplace; and rate the hospital as having a high level of commitment to patient safety. Secondary aims of our study were to evaluate the association between individual characteristics of clinical trainees and, first, disclosure of a medical error, and second, apology for the error.

METHODS

Study design and survey administration

Anonymous, self-administered surveys were distributed to medicine and surgery residents at Boston Medical Center during educational conferences and department meetings in 2005. The distribution and retrieval procedures of the surveys ensured privacy and anonymity of the residents. The researchers (who were also attending physicians) were blinded as to which residents completed the survey, which ensured no conflict of interest for the researchers if asked to evaluate residents. The residents were assured that their privacy and anonymity would be protected, and that the researchers would remain blinded to their participation status. Specifically, the researchers approached a group of housestaff during an educational conference or meeting, explained the purpose of the survey, and then left the room and building. Residents who choose to participate completed the surveys and returned them in sealed envelopes to a box in the room. Those who chose not to participate returned blank surveys in sealed envelopes. At the end of each conference, a research assistant returned to the room to collect the box with the sealed envelopes. All participants received a $10 honorarium, whether or not they completed the survey. The survey, database, and protocol were de-identified. To further protect participants in the event of an accidental breach of anonymity, a certificate of confidentiality was obtained from the National Institutes of Health. The project was carefully reviewed and approved by the institutional review board.

Survey content

Our survey focused on three levels of environment that had the most face validity of microculture constructs within a resident's learning environment. Questions were selected from three validated surveys of organisational culture, adapted for this study to focus on the organisational environment of housestaff. Since the full survey instruments were deemed too high a respondent burden, the authors carefully considered and then selected items from each survey most relevant to the study. The microenvironment of the immediate clinical team was examined with five of seven questions from the Team Psychological Safety Survey, which assesses the belief that well intentioned actions will not lead to punishment or rejection by the team (see online appendix).[15] The macroenvironment of the residency programme was assessed with 10 of the 37 items from the Error Orientation Questionnaire; the items selected assess attitudes to errors and approaches to coping with errors in the workplace (see online appendix).[16] Perception of hospital management's commitment to patient safety on the clinical unit was assessed with four of 19 items from the Patient Safety Survey (see online appendix).[17] Responses were coded with six-point Likert scales, and summed to derive a total score for each survey. For all three scales (Team Psychological Safety, Residency Programme Error Orientation, and Managerial Safety Commitment), higher scores correlated with more positive aspects of culture. In relation to error, participants were asked to recall the circumstances of and share details regarding their most significant medical or surgical error using open-ended text. In a multiple choice format, participants were specifically asked about the following: consequences for the patient; consequences for the resident; if and to whom they disclosed the error; if they had apologised for the error; and perceived causes for the error. Responses to each question were constructed from the results of a previous survey of residents regarding medical error, conducted by Wu *et* al.[2] In addition, residents were asked to characterise their own level of distress from the error using a 10-point Likert scale.

Analysis

Univariate analysis was used to describe demographics, residency type, reporting rates (to colleagues and friends), apology and disclosure rates (to patients),

emotional responses of residents, types of mistakes, and consequences to and responses of both the residents and patients. Errors were classified from the written responses into one of the following categories: procedural, medical management, laboratory test follow-up, delayed diagnosis, or other/not classifiable. We used χ^2 to evaluate differences between categorical variables and Wilcoxon rank sum methods for the three organisational culture scales. In order to compare the subscales with each other, the raw score was converted to a scaled score, by dividing each raw score by the maximum possible score of each subscale, and multiplying by 33.3. We then calculated an overall Medical Culture Summary score, by summing the three scaled subscores, that is, each subscale contributes one-third of the overall Medical Culture Summary score.

RESULTS

Surveys were distributed to 109 residents and 99 surveys were returned, making an overall response rate of 91%. Two residents' surveys were excluded because they reported no mistake, leaving a final population of 97 residents, 59 (61%) from internal medicine residents and 38 (39%) from surgical residents. There were 57 (59%) male residents, of which 33 (58%) were internal medicine residents and 24 (42%) were surgical residents. Two surgical residents did not report their gender, and were excluded from analyses which included gender. The most significant medical or surgical error that was the focus of residents' responses typically occurred in an inpatient setting and during the first year of training (table 1).

Table 1 Characteristics of residents and setting where error occurred

	Total N=97 N (%)
Gender	
Men	57 (59)
Women	38 (39)
Unknown	2 (2)
Programme	
Medicine	59 (61)
Men	33 (56)
Surgery	38 (39)
Men	24 (63)
Training year	
First year	64 (66)
After first year	32 (33)
Unknown	1 (1)
Setting	
Ward	63 (65)
Ambulatory clinic	3 (3)
Operating room	5 (5)
Intensive care unit	22 (23)
Emergency department	4 (4)

Seventy-five per cent of the residents were extremely distressed by their mistake. While 41 (42%) did not provide an adequate description of their error to be classified, 26 (27%) were classified as medication related, 12 (12%) as procedural, 11 (11%) due to delayed diagnosis, and 9 (9%) due to inadequate follow-up to a laboratory test.

Although 20 (21%) of the involved patients had no reported consequences resulting from the errors, common consequences included delayed treatment for 23 (24%), delayed diagnosis for 22 (23%), prolonged hospital stay for 17 (18%), medical complications for 13 (13%), and death for 13 (13%) patients. The errors resulting in patient death were largely errors involving anticoagulants, potassium balance (either not checking blood work or inadequate management of blood potassium level), or insulin. There were no consequences for 60 (62%) of the residents due to the error, but 30 (30%) reported some form of reprimand, 16 (16%) presented the case at a morbidity and mortality conference (which was reported as a consequence), 6 (6%) reported their work and family life was affected, and 1 (1%) was named in a law suit. The most common attributions for the error reported by residents included being too busy (32, 33%) and inexperience (31, 32%). Many residents also attributed their error to having inadequate knowledge, hesitating before acting, or being too tired (table 2). While 30 (31%) reported apologising for the situation associated with the error, only 17 (18%) reported disclosing the error to patients and/or their family. Five residents both disclosed (29% of those who disclosed) and apologised (17% of those who apologised table 3).

Correlates of disclosure and apology

The disclosure rate was higher among surgery residents (24%) than internal medicine residents (14%), but this difference was not statistically significant (p=0.2). Of the residents who disclosed their error, 32 (33%) reported that it was unsupervised. Three (3%) residents reported being told by their attending not to discuss the error with the patient. Female internal medicine residents were significantly less likely to disclose their worst medical error to patients or their families than their male counterparts (p=0.03). In contrast, more female surgery residents, 7 (58%), apologised for their error compared with male surgery residents 7 (29%), though the difference did not reach statistical significance (p=0.1). Of the 13 errors that resulted in a patient's death, only 3 (23%) of the residents disclosed the error to the patient and/or the patient's family, but 6 (46%) residents apologised to the patient's family. More residents who made errors in medication management (8 of 26, 31%) disclosed their error than those who made

errors with procedures (3 of 12, 25%) or delayed diagnosis (2 of 11, 18%) (p=0.05).

Correlates of organisational culture measures

The Safety Culture Summary score was positively associated with disclosure of medical error to the patient and/or patient's family (p=0.04) and apology for the error (p=0.05). There was a trend of association between disclosure and higher scores on the subscales clinical Team Psychological Safety (p=0.07) and Residency Programme Error Orientation scales (p=0.07), but not for Managerial Safety Commitment (p=0.2). Report of apology to the patient and/or patient's family was not associated with the clinical Team Psychological Safety score (p=1.0) but was positively associated with scores on the Residency Programme Error Orientation (p=0.05) and Managerial Safety Commitment (p=0.01). There were no significant gender differences in scores for each of the subscales as well as the summary measure of safety culture. Surgery residents had higher scores on the Residency Programme Error Orientation (p=0.02) and Managerial Safety Commitment scales (p=0.05) compared with medicine residents, but there was no significant difference between programmes in the Safety Culture Summary score (table 4).

CONCLUSIONS

Only 17% of the residents we surveyed reported disclosing their most significant error to their patient and/or patient's family, and only 31% of the residents reported apologising for their most significant error. Our results suggest that factors in the learning environments of the clinical team and residency programme are associated with error disclosure and apology among residents. Individual factors, such as gender and type of error, also appear to be associated with error disclosure

and apology, and more residents apologised for the error than disclosed it.

Our findings of discordance between apology and disclosure of medical error are consistent with previous studies exhibiting residents may be more willing to apologise for a bad outcome than to reveal that they played a role in causing the bad outcome, resulting in a 'partial disclosure'.[18 19] Collectively, these findings imply that factors that facilitate apologising for an error may differ from influences that facilitate disclosing an error. These findings are reflected in State laws that distinguish different components of conversations with patients about unanticipated outcomes: 'expression of sympathy' (apology), 'explanation' (disclosure), and 'admission of fault', which does not cleanly translate into either category.[20] Additional explanations for the discordance may include the social context in which the error occurred. For example, apologising for a systemic error that occurred would likely be easier than disclosing personal responsibility for an error, which could have greater legal and professional consequences.[19]

The relationships of gender to our outcome measures are complex. More male residents disclosed error (driven mostly by male internal medicine residents) while more women apologised (driven mostly by female surgical residents). With our small sample size, definitive conclusions about the interactions among gender, specialty and disclosure are difficult to ascertain from our data. Previous studies[2 9] have also demonstrated that individual attributes, such as gender and emotional response to the error, influence the reporting rate of the error. However, in contrast to our results, women in a previous study were *more* likely to discuss their errors with their patients and make constructive changes in their practice.[2] Although the female residents in our study were less likely to disclose their error, the female surgical residents were more likely to apologise, consistent with past reports of greater empathy among female physicians.[21] Our results suggest that there are barriers to disclosure in the learning environments of clinical trainees that affect men and women differently. Further research will be needed to elucidate which barriers to disclosure and apology affect genders differentially. For example, possible barriers to disclosure may be attitudinal— women may feel they have more to lose than men by disclosing in order to be professionally successful, or emotional— women may feel more of a sense of helplessness and loss of control once information is disclosed.

We found surgery residents to have higher scores on the residency programme's Error Orientation Scale and the clinical unit's Managerial Safety Commitment Scale than medicine residents, but not on the Safety Culture Summary score. This is consistent with a previous survey of residents, which found that presentations of errors causing adverse events occurred 18% of the time in internal medicine ground rounds compared with 42% in surgery.[22] The differences between these two fields are likely due to divergent regulatory and cultural factors. Historically, morbidity and mortality rounds have served as a forum where surgeons learn from poor outcomes and aspire to identify their errors,[23] but this tradition is weaker in medicine training programmes.[24] The Accreditation Council for Graduate Medical Education (ACGME) requires that surgery morbidity and mortality conferences present and discuss 'all deaths and complications that occur on a weekly basis'. Historically, there has been no similar requirement for internal medicine.[24] Without a specific requirement to do so, adverse events and errors occurring in the medicine service may not be generally discussed.[21]

Several medicine residencies have developed programmes to address the current ACGME competency on Systems Based Practice,[13] by teaching systems-based thinking using root cause analysis of medical errors,[25] which require residents to develop an awareness of working in multidisciplinary teams to enhance patient safety, and participate in identifying system errors and implementing potential solutions.[13] Several studies have demonstrated the benefits of such educational

interventions,[26–29] although to our knowledge, no study has attempted to measure changes in learning environment as a result of such interventions. Although such programmes are helpful, current ACGME guidelines do not require training programmes to address a thorough behavioural process of managing medical mistakes: accepting responsibility; discussing with colleagues; disclosing and apologising to patient; conducting an error analysis; and making changes in a practice setting designed to reduce future errors.[1 2 5 6 11 30]

The ability of residents to cope with medical error may be dependent on reassurance and learning opportunities provided by medical colleagues and supervisors.[26] Our findings would support this assertion, given the positive association between our derived Medical Culture Summary score and reporting of disclosure and apology. However the low frequency of disclosure and apology suggests that more work needs to be done within our training programmes to mitigate the negative effects of error to individuals, and gain potential benefits from more thorough processing of errors for individuals and the healthcare system.

There are several issues germane to housestaff and errors that are not addressed by our study. Some believe that an effective apology includes offering some form of reparation for the mistake.[31] We did not examine the issue of reparation. While the literature suggests that resident physicians who accept responsibility for their errors and discuss them are more likely to report other improvements in their medical practice,[2] we did not examine this phenomenon. Furthermore, while disclosure in a timely and appropriate manner may influence a patient's decision to pursue legal action,[1–3] we did not explore the relationship between our findings and legal action. In addition, though a doctor's emotional reaction to an error can last for years[32] and negative emotional responses are associated with increased odds of future self-perceived errors,[33] we did not evaluate emotional reactions or predict the future likelihood of error. Lastly, we did not directly examine the extent to which subjects were trained regarding coping with medical error, and hence could not determine if this training influenced their behaviour.

This study has several limitations. First, residents at only one academic medical centre were surveyed, so the results may not be generalisable. In addition, the residents were surveyed during 2004–2005, so it is possible that these results may no longer be accurate. During the past 6 years, the ACGME training requirements have increased their focus on systems-level thinking and training programmes have increasingly focused on reduction of error. However, the authors feel that the key findings of this study are relevant today. The rate of safety culture change is relatively slow, as demonstrated

Kronman AC, Paasche-Orlow M, Orlander JD. *BMJ Qual Saf* (2011). doi:10.1136/bmjqs-2011-000084

by a recent hospital survey administered by the Agency for Healthcare Research and Quality: average composite change in safety culture to change 1% over 1–2 years.[20] An increased focus on reduction in error does not translate directly to increases in individual accountability, apology or disclosure of error. Second, the modest sample size, limits opportunity for multivariable analyses as well as statistical power to detect potential associations. Third, our survey directed residents to consider a single error. We did this to focus respondents' attention on the details of an event that they would remember clearly to gain insight into aspects of organisational culture. This specific error may not be representative of most errors. In addition, as most of these errors occurred during the residents' first year of training, the expectation for disclosure and apology may be different than for the other years of training. However, a prior study that included trainees at our institution suggested that the responsibility of delivering bad news often falls to junior members of the team, including first-year trainees and medical students.[34] Fourth, the scales of organisational culture we used have rarely been used in healthcare settings. As such, the clinical significance of our observed score differences are unclear.

Despite the limitations, we successfully adapted survey tools previously used in a business environment to measure aspects of the learning environment of clinical trainees which are associated with disclosure and apology for medical error. This instrument needs to be validated in other institutions before proving its value as a metric in residency programme safety culture. If validated, such an instrument could be a valuable tool to assess changes in learning environments. Measuring culture and providing such feedback to leadership and staff is one of the safe practices recommended by the National Quality Forum to promote patient safety and reduce medical error.[35]

Measuring culture change requires a multimodal approach, of which this instrument could make a valuable contribution.[36] Since the ability to measure medical culture, and changes to it, is immature,[37] our study provides baseline measurements to help move the field further along. Developing learning environment metrics will be valuable to other institutions and training programmes in the coming years, as incremental programmatic changes in systems-level thinking and disclosure of medical error continue to impact the learning environments of residents.

Our results suggest a need for training programmes to provide trainees with structured, meaningful ways to cope with errors to prevent negative emotional responses, as well as create learning environments that facilitate disclosure of errors. Attention may need to be paid to explicate potential gender-related differences. All this is particularly important if, as a profession, we are to instil proper values, attitudes and responses to the inevitable occurrence of error in the next generation of physicians. As residency programmes incorporate systems-level thinking into residency education for patient safety and error prevention, it is important not to neglect the humanistic and interpersonal consequences of error for providers and patients. In order to do so, we need to develop measurement tools for learning environments. Further research is needed to identify successful environmental attributes that promote disclosure and healthy processing of medical errors.

Framingham and Boston, Massachusetts; and Rochester, Minnesota

Objectives The aim of this study was to assess the relationship between sex hormones and natriuretic peptide levels in community-based adults.

Background Women have higher circulating natriuretic peptide concentrations than men, but the mechanisms for these sex-related differences and the impact of hormone therapy are unclear. Experimental studies suggest that androgens may suppress natriuretic peptide secretion.

Methods We measured N-terminal pro–B-type natriuretic peptide (NT-proBNP), total testosterone, and sex hormone–binding globulin plasma levels in 4,056 men and women (mean age 40 ± 9 years) from the Framingham Heart Study Third-Generation cohort. Sex/hormone status was grouped as: 1) men; 2) post-menopausal women not receiving hormone replacement therapy; 3) pre-menopausal women not receiving hormonal contraceptives; 4) post-menopausal women receiving hormone replacement therapy; and 5) pre-menopausal women receiving hormonal contraceptives.

Results Circulating NT-proBNP levels were associated with sex/hormone status (overall $p < 0.0001$). Men had lower NT-proBNP levels than women of all menopause or hormone groups, and women receiving hormonal contraceptives had higher NT-proBNP levels than women who were not receiving hormone therapy (all $p < 0.0001$). These relationships remained significant after adjusting for age, body mass index, and cardiovascular risk factors. Across sex/hormone status groups, free testosterone (FT) levels decreased and sex hormone–binding globulin levels increased in tandem with increasing NT-proBNP levels. In sex-specific analyses, NT-proBNP levels decreased across increasing quartiles of FT in men (p for trend <0.01) and women (p for trend <0.0001). Adjustment for FT markedly attenuated the association between sex/hormone status and NT-proBNP concentrations.

Conclusions These findings suggest that lower levels of circulating androgens and the potentiating effect of exogenous female hormone therapy contribute to the higher circulating NT-proBNP concentrations in women. The importance of understanding the effects of sex and hormone therapy on the cardiovascular system is underscored by the pronounced sex differences in the prevalence of cardiovascular disease, the increase in cardiovascular events in women following menopause, and concerns regarding the safety of hormone replacement therapy (HRT) in post-menopausal women (1–3). Studies of circulating cardiovascular biomarkers, such as the natriuretic peptides (NPs) (4–8), may provide a biological basis to better understand these sex-related differences in cardiovascular risk. The NPs exert hormonal (vasodilation, natriuresis, and

aldosterone and endothelin suppression) and autocrine/paracrine (antihypertrophic, antifibrotic, and proangiogenic) protective cardiovascular effects. Sex is one of the strongest determinants of concentrations of circulating B-type natriuretic peptide (BNP) or N-terminal pro–B-type natriuretic peptide (NT-proBNP) in population-based studies, with women having consistently higher circulating levels than men (4–7). Nonetheless, the mechanisms underlying the sex-based difference in circulating NPs have not been established. Further, the effect of menstrual status, menopausal status, or exogenous hormone therapy on plasma NP concentrations in women remains unclear (6,8–10).

Previous studies have suggested that sex hormones play an important role in the regulation of NPs (11). On one hand, estrogens have been shown to exert a stimulating effect on the NP system (9,12) and are therefore postulated to mediate the "NP excess" in women compared with men. On the other hand, recent experimental (13,14) and cross-sectional human data (8,15) suggest that androgens may exert an inhibitory effect on the NP system, thus accounting for the lower NP levels in men and potentially explaining the lack of cardiovascular protection in men compared with women (8). However, prior clinical studies of the influence of androgens on NPs were limited to studying women (8,16) or children (15) and did not fully characterize both endogenous (menstrual phase) and exogenous (hormone therapy) variations. Further, previous investigations did not include measures of insulin resistance, which is a potential confounder because hyperinsulinemia is known to be associated with both sex hormones (hyperandrogenemia) and lowered NP concentrations (17–20).

We aimed to test the hypothesis that free testosterone (FT) is an important determinant of the relationship between sex/hormone status and circulating NPs in adults from the general population. Specifically, we hypothesized that higher FT levels in men compared with women and in women not receiving hormone therapy compared with those receiving hormone therapy may be related to lower circulating concentrations of NPs. To achieve our aim, we measured levels of testosterone and its primary binding protein, NP levels, and insulin measures in a large, community-based sample of predominantly middle-aged adults grouped by sex, menstrual status, and the presence or absence of hormone therapy.

Methods

Study sample. The Framingham Heart Study (21) is a community-based cohort investigation that began in 1948 with the recruitment of the Original Cohort, recruited a second generation in 1971 consisting of offspring of the Original Cohort and their spouses (Offspring Cohort), and most recently added a third generation in 2002 consisting of children of the Offspring Cohort (Third-Generation Cohort). Participants of the youngest cohort (Third-Generation Cohort), in whom plasma NT-proBNP concentrations were measured, were eligible for the current study. Those with prevalent heart failure (prior diagnosis of heart failure based on Framingham criteria [22]), myocardial infarction, or serum creatinine >2 mg/dl were excluded from the present investigation (n = 26). The index examinations took place during April 2002 to July 2005. All women had menstrual histories recorded by trained physicians using standardized questionnaires, including details regarding reproductive history, first day of the last menstrual period, frequency and regularity of menstrual cycles, and current usage of any hormone therapy. Participants were instructed to bring all of their current medications (taken within 1 month) with them to the examination, allowing verification by the examining physician. Anthropometric, blood pressure, and cardiovascular risk factor data were obtained at the index visit using standard protocols. All participants provided written informed consent, and protocols were approved by the Boston University Medical Center Institutional Review Board.

Abbreviations and Acronyms

BNP = B-type natriuretic peptide
FT = free testosterone
HC = hormonal contraceptives
HOMA = homeostatic model assessment
HRT = hormone replacement therapy
IR = insulin resistance
NP = natriuretic peptide
NT-proBNP = N-terminal pro–B-type natriuretic peptide
SHBG = sex hormone–binding globulin

Classification of sex/hormone status. Menopause was defined as the cessation of periods (in the absence of pregnancy) for at least 1 year because of naturally occurring (as opposed to surgical or medical) causes. Among postmenopausal women, those receiving HRT were defined by self-reported current usage of female hormone therapy, as well as validation by direct assessment of all of the participants' current medications by the examining physician. Among pre-menopausal women, those receiving hormonal contraceptives (HC) were defined by self-reported current usage of hormone-containing oral pills, injections, or implants for birth control or medical indications, as well as validation by direct assessment of all of the participants' current medications by the examining physician. Based on these definitions, sex/hormone status was classified into 5 categories (Fig. 1):

- Men
- Post-menopausal women not receiving HRT
- Pre-menopausal women not receiving HC
- Post-menopausal women receiving HRT currently
- Pre-menopausal women receiving HC currently

In secondary analyses, we estimated the menstrual phase (follicular vs. luteal vs. midcycle) at the index visit among pre-menopausal women with regular ongoing menstrual cycles (cycle lengths 28 to 30 days) who were not receiving HC. This determination was based on the fact that the interval from ovulation to menstruation (luteal phase) is fixed at 14 days, whereas the interval from the start of menstruation to ovulation (follicular phase) can vary de-

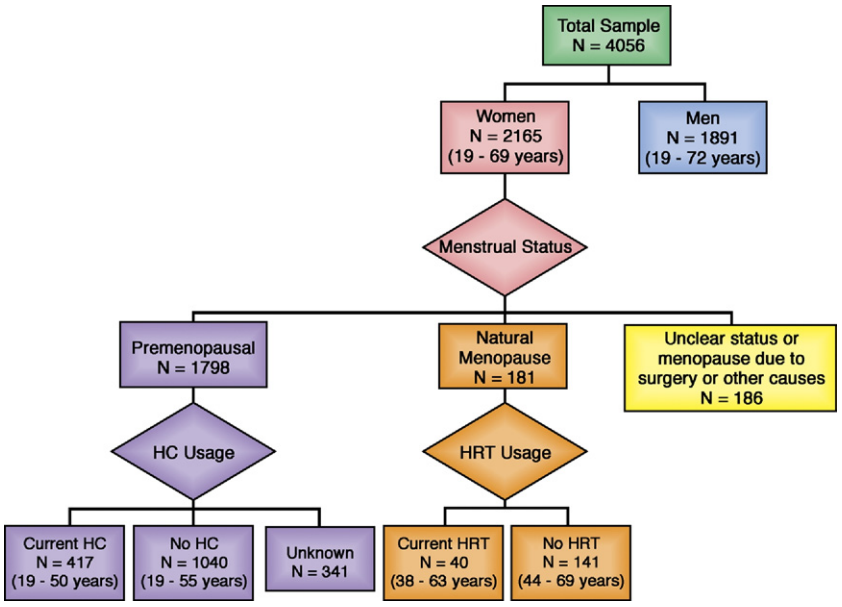

Figure 1 **Classification of Sex/Hormone Status**

The flow chart illustrates the classification of sex/hormone status into 1) men; 2) post-menopausal women not receiving hormone replacement therapy (HRT); 3) pre-menopausal women not receiving hormonal contraceptives (HC); 4) current HRT users; and 5) current HC users. The age range of participants in each group is indicated in brackets.

pending on cycle length, as previously established (23) and widely applied in similar studies (24–27). Thus, using the date of the examination, date of onset of the last menstrual period, and menstrual cycle length (specifically ascertained at the index examination), we derived the duration of the follicular phase in each regularly cycling woman, allowing 4 days between the follicular and luteal phases for the mid-cycle phase. The calculated durations were then used to assess whether NT-proBNP measurement on the date of the index visit occurred in the follicular, midcycle, or luteal phase of the menstrual cycle.

Measurement of circulating NT-proBNP, testosterone, and SHBG. Venous blood was drawn under fasting conditions between 8:00 and 9:00 AM. Samples were immediately stored at −70°C and analyzed in batches in 2009, allowing minimization of interassay variability and effects of temporal drift in the laboratory measurements. Plasma NT-proBNP levels were measured using a standard immunoassay (Roche Diagnostics, Indianapolis, Indiana), with a measurement range of 5 to more than 35,000 ng/l and intra-assay coefficient of variation of 2.7%. Serum total testosterone concentrations were quantified using a validated liquid chromatography–tandem mass spectrometry assay, with a lower detection limit of 2 ng/dl. Sex hormone–binding globulin (SHBG) concentrations were measured using an immunofluorometric assay (DELFIA-Wallac, Inc., Turku, Finland). Total testosterone concentrations are influenced by multiple factors, such as obesity in men and oral contraceptive therapy in women, and may not reflect androgen activity. We thus calculated FT using the law of mass action equation (28,29) and used FT in subsequent analyses.

Measurement of insulin resistance. Insulin resistance (IR) was calculated using the homeostatic model assessment (HOMA) equation: HOMA-IR = (FPG × FPI)/22.5, for which FPG = fasting plasma glucose (mmol/l) and FPI = fasting plasma insulin (mU/l) measured by enzyme-linked immunosorbent assay (Millipore Corporation, Billerica, Massachusetts) (30).

Statistical analyses. The association between log NT-proBNP and sex/hormone status was assessed using general linear models followed by pairwise comparisons between sex/hormone status groups with Bonferroni correction. The model was adjusted for covariates known to influence NT-proBNP concentrations (age, body mass index, systolic blood pressure, diastolic blood pressure, serum creatinine, and presence of antihypertensive medications, diabetes mellitus, and current smoking). We similarly assessed the association of log FT and log SHBG with sex/hormone status. Of a total of 2,165 women (Fig. 1), menopause status was unclear or not due to natural causes in 186, HC usage was unknown in 341, and FT/SHBG measurements or clinical covariates were missing in a further 25, leaving 1,613 women in the final multivariable models for sex/hormone status.

To assess the association between log NT-proBNP and circulating androgens, we used sex-pooled and sex-specific general linear models, in which the dependent variable was log NT-proBNP and predictors were log FT or log SHBG (separately), hormone status (among women; categories 2 to

Table 1 Baseline Characteristics

	All (N = 4,056)	Men (n = 1,891)	Women (n = 2,165)
Age, yrs	40 ± 9	40 ± 9	40 ± 9
Body mass index, kg/m^2	26.9 ± 5.6	28.0 ± 4.7	26.0 ± 6.1
Systolic blood pressure, mm Hg	117 ± 14	121 ± 13	113 ± 14
Diastolic blood pressure, mm Hg	75 ± 10	78 ± 9	73 ± 9
Serum creatinine, mg/dl	0.79 ± 0.15	0.90 ± 0.13	0.70 ± 0.11
Hypertension	16	21	12
Antihypertensive medications	8	10	7
Diabetes mellitus	3	4	2
Smoking	17	18	16
NT-proBNP, ng/l	28.1 (14.1, 52.6)	16.2 (8.1, 28.8)	42.9 (25.7, 72.2)
Log NT-proBNP	3.3 ± 1.0	2.7 ± 0.9	3.7 ± 0.8
FT, pg/ml	5.3 (2.1, 114.5)	119.0 (95.0, 152.0)	2.2 (1.4, 3.2)
Total testosterone, ng/dl	49.6 (23.7, 600.2)	617.7 (487.5, 786.1)	24.6 (17.7, 34.3)
SHBG, nmol/l	55.1 (35.2, 96.1)	37.0 (26.7, 50.2)	89.7 (58.7, 132.7)
HOMA-IR	0.98 (0.70, 1.49)	1.01 (0.78, 1.66)	0.89 (0.65, 1.31)

Values are mean ± SD, %, or median (25th, 75th percentiles). To convert FT concentration to SI units (pmol/l), multiply values in pg/ml by 3.47; to convert total testosterone concentration to SI units (nmol/l), multiple values in ng/dl by 0.0347.

FT = free testosterone; HOMA-IR = homeostatic model assessment of insulin resistance; NT-proBNP = N-terminal pro–B-type natriuretic peptide; SHBG = sex hormone–binding globulin.

5 of sex/hormone status as defined above), and covariates (listed above). We tested for interaction between log FT or log SHBG and hormone status among women and adjusted models for HOMA-IR among participants without diabetes. To further assess the association among sex/hormone status, log NT-proBNP, and circulating androgen levels, we analyzed multivariable models (sex pooled and in women alone), in which the dependent variable was log NT-proBNP and predictors sequentially included clinical covariates (listed above), sex/hormone status groups (defined above), and log FT. We assessed the beta coefficients for each sex/hormone status group, compared with the referent group of pre-menopausal women receiving HC, before and after adding log FT to the model. We also compared the type I sum of squares with the type III sum of squares for the class variable sex/hormone status to assess the percent variability in NT-proBNP levels due to sex/hormone status before (type I sum of squares) and after (type III sum of squares) the addition of log FT to the model, adjusting for all other covariates. Of a total of 2,165 women and 1,891 men, FT measurements were available for 2,144 women and 1,880 men, whereas SHBG measurements were available for 2,147 women and 1,880 men. Of these, there were no missing clinical covariates (age, body mass index, systolic blood pressure, diastolic blood pressure, serum creatinine, antihypertensive medications, diabetes mellitus, and smoking) in 2,123 women with FT measurements, 2,126 women with SHBG measurements, and 1,871 men. In addition to clinical covariates, HOMA-IR measurements were also available for 1,857 women with FT measurements, 1,859 women with SHBG measurements, and 1,650 men.

In the subgroup of pre-menopausal women with regular menstrual cycles in the absence of HC, we compared log NT-proBNP concentrations among menstrual phases (follicular, midcycle, and luteal) using general linear models with Bonferroni correction in pairwise comparisons among phases. We similarly compared log FT and log SHBG concentrations among menstrual phase groups. Models were adjusted for covariates known to influence NT-proBNP concentrations (listed above).

All analyses were performed using SAS software. Statistical significance was determined at a p value of <0.05 (Bonferroni-adjusted significance level required $p < 0.05$ [number of possible comparisons] in cases of multiple comparisons).

Results

Baseline characteristics. Characteristics of the study sample (N = 4,056; mean age 40 years) are shown in Table 1. As expected in a predominantly middle-aged, community-based sample, the prevalence of cardiovascular risk factors was low, and the majority (83%) of women were pre-menopausal (Fig. 1). Among pre-menopausal women, 23% (n = 417) were currently receiving HC; among post-menopausal women, 21% (n = 40) were currently receiving HRT. HRT consisted predominantly of oral combination therapy with estrogen and progesterone (n = 34 [85%]). Of note, the age range of participants was relatively narrow, even among post-menopausal women.

Association between sex/hormone status and circulating NT-proBNP levels. Log NT-proBNP was strongly associated with sex/hormone status (age-adjusted $p < 0.0001$) (Fig. 2A), with the lowest concentrations in men and highest concentrations in pre-menopausal women receiving HC. These relationships remained unchanged after adjusting for age, body mass index, systolic blood pressure, diastolic blood pressure, serum creatinine, and presence of antihypertensive medications, diabetes mellitus, and smok-

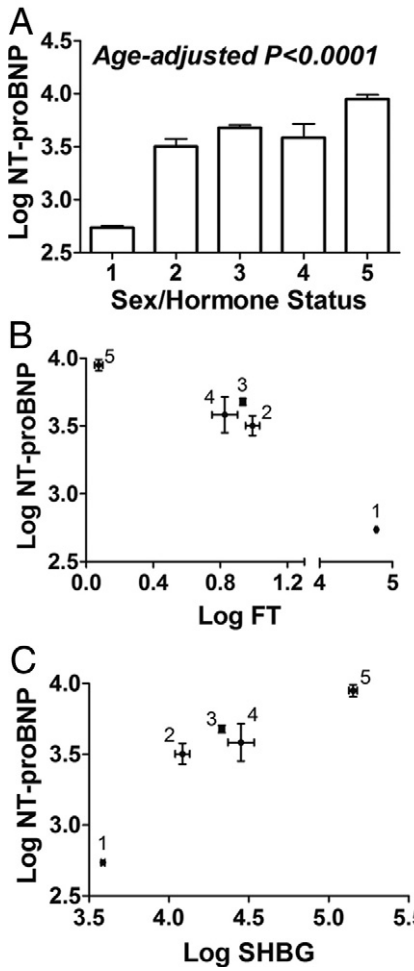

Figure 2 Association of Sex/Hormone Status With Circulating NT-proBNP, Testosterone, and SHBG

(A) Columns and **bars** represent the age-adjusted least squares means and SE of log N-terminal pro–B-type natriuretic peptide (NT-proBNP) by sex/hormone status (1 = men, 2 = post-menopausal women not receiving HRT, 3 = pre-menopausal women not receiving HC, 4 = post-menopausal HRT users, and 5 = pre-menopausal HC users). The p value shown is for the association between NT-proBNP and sex/hormone status overall; for pairwise comparisons within sex/hormone status groups, please refer to the text. **(B)** Bivariate plot showing the age-adjusted least squares means and SE of log free testosterone (FT) **(horizontal axis)** and log NT-proBNP **(vertical axis)** in each sex/hormone status group. **(C)** Bivariate plot showing the age-adjusted least squares means and SE of log sex hormone–binding globulin (SHBG; horizontal axis) and log NT-proBNP (vertical axis) in each sex/hormone status group. Abbreviations as in Figure 1.

ing. In pairwise comparisons, men had lower plasma NT-proBNP levels than women regardless of menopause status or hormone therapy (Bonferroni-corrected $p < 0.0001$). Among pre-menopausal women, levels of NT-proBNP were higher in those receiving HC (Bonferroni-corrected $p < 0.0001$). Among post-menopausal women, there was no difference in circulating NT-proBNP levels between current HRT users and nonusers (multivariable-adjusted $p = 0.39$). In additional analyses including an interaction term between year of blood collection and sex, there was no evidence for an interaction.

Association among circulating NT-proBNP, FT, and SHBG levels. As expected, men had the highest FT concentrations, whereas women receiving HC had the lowest FT and highest SHBG concentrations. Across sex/hormone status groups, FT levels decreased and SHBG levels increased in tandem with increasing NT-proBNP levels (Figs. 2B and 2C).

In sex-stratified analyses, NT-proBNP levels were lower in the highest quartiles of FT in both men (Fig. 3A) and women (Fig. 3B). Log NT-proBNP was inversely related to log FT and directly related to log SHBG in both men and women (Table 2). After adjustments for age, body mass index, systolic blood pressure, diastolic blood pressure, serum creatinine, antihypertensive medications, diabetes, and smoking, the association between log NT-proBNP and log FT was significant in women ($p < 0.0001$) but not men ($p = 0.78$). Each unit increase in log FT was associated with a 20% decrease in NT-proBNP levels among women, adjusting for clinical covariates. Results were similar after further adjustments for HOMA-IR among participants without diabetes. In both sexes, log NT-proBNP was related to log SHBG in multivariable analyses ($p < 0.0001$). Each unit increase in log SHBG was associated with a 19% increase in NT-proBNP levels among men and a 40% increase in NT-proBNP levels among women, adjusting for clinical covariates. There was no interaction between menopause or hormone status and log FT or log SHBG.

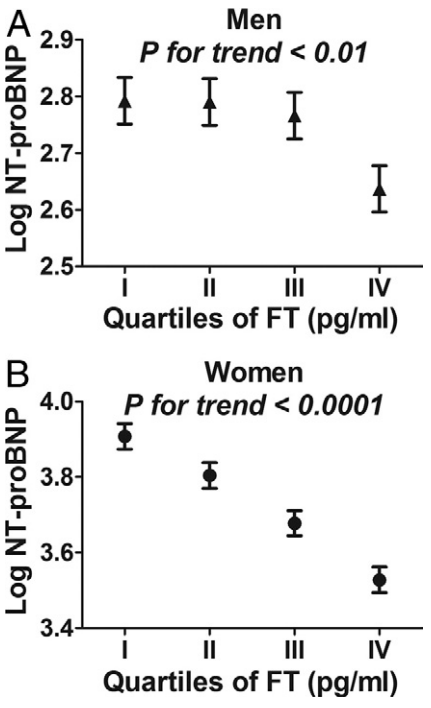

Figure 3 Association Between Circulating NT-proBNP and FT Levels

Least squares means and SE of log NT-proBNP are shown for each sex-specific quartile (I to IV) of FT in men **(triangles; A)** and women **(circles; B)**, respectively. Abbreviations as in Figure 2.

Log SHBG	0.13 (0.03)	0.0001	0.24 (0.02)	<0.0001

*Beta coefficients represent the mean change in log NT-proBNP per 1 SD difference in log FT or log SHBG; For single variable analyses, n = 1,880 in men (both models), 2,144 in women (model containing log FT), and 2,147 in women (model containing log SHBG). †Adjusted for age, body mass index, systolic blood pressure, diastolic blood pressure, serum creatinine, antihypertensive medications, diabetes mellitus, and smoking; n = 1,871 in men (both models), 2,123 in women (model containing log FT), and 2,126 in women (model containing log SHBG). ‡Adjusted for age, body mass index, systolic blood pressure, diastolic blood pressure, serum creatinine, antihypertensive medications, smoking, and HOMA-IR; n = 1,650 in men (both models), 1,857 in women (model containing log FT), and 1,859 in women (model containing log SHBG).

Abbreviations as in Table 1.

In the entire sample, sex/hormone status explained 38% of the variability in NT-proBNP levels in multivariable models adjusted for age, body mass index, systolic blood pressure, diastolic blood pressure, serum creatinine, and presence of antihypertensive medications, diabetes mellitus, and smoking. This effect was larger than the contribution of any other clinical covariate. The addition of log FT to multivariable models adjusted for age, body size, and cardiovascular risk factors led to attenuation of the differences in log NT-proBNP among sex/hormone status groups (Table 3). After log FT was added to the multivariable model, clinical sex/hormone status only explained 1% of the variability of NT-proBNP levels.

In women alone, the addition of log FT to multivariable models similarly led to attenuation of the differences in log NT-proBNP levels among menopause or hormone therapy groups (Table 3). Menopause and hormone status explained 14% of the variability in NT-proBNP levels in women and in multivariable models adjusted for clinical covariates but only 2% after log FT was added to the multivariable model. Thus, the vast majority of the variability in NT-proBNP due to menopause and hormone status in women appeared to be attributable to differences in FT concentrations.

In analyses restricted to participants not receiving any antihypertensive therapy, the associations among sex/hormone status, NT-proBNP, and FT were unchanged (not shown).

Subgroup analysis by menstrual phase. Among 546 premenopausal women with regular menstrual cycles in the absence of HC (Table 4), NT-proBNP levels were lower in the midcycle phase than in the follicular or luteal phase ($p = 0.014$ for midcycle vs. follicular phase; $p = 0.015$ for midcycle vs. luteal phase; Bonferroni-corrected $p < 0.05$ for

both) in multivariable models. There was a corresponding trend toward higher FT levels in the midcycle phase compared with that in the follicular or luteal phase ($p = 0.045$ for midcycle vs. follicular phase; $p = 0.099$ for midcycle vs. luteal phase). When log FT was added to multivariable models, the association between menstrual phase and log NT-proBNP became nonsignificant. There was no association between SHBG levels and menstrual phase.

Discussion

Principal findings. In a large sample of men and women from the general community, sex and exogenous hormone therapy were the largest determinants of variation in circulating NT-proBNP levels. Men had lower plasma NT-proBNP concentrations than women regardless of menopause status or hormone therapy, whereas women receiving HC had higher NT-proBNP concentrations than women without hormone therapy. Among sex/hormone status groups, men also had the highest FT and lowest SHBG concentrations; conversely, women receiving HC had the lowest FT and highest SHBG concentrations. In both sexes, increasing NT-proBNP levels were related to decreasing FT and increasing SHBG concentrations. Accounting for FT greatly attenuated the differences in circulating NT-proBNP levels among sex/hormone status groups, even after adjustments for known clinical covariates and restricting analyses to women. These findings are consistent with the hypothesis that androgens suppress NT-proBNP and suggest that differences in FT concentrations may largely explain the sex- and hormone-related differences in circulating NPs.

Androgen regulation of NP concentrations. Several lines of evidence suggest that testosterone may exert a suppressive effect on the NP system and thus mediate a "BNP deficiency" in men compared with women. In male rats, orchiectomy produced marked increases in plasma NP levels, and testosterone replacement restored NP concentrations to baseline (14). In isolated perfused rat atria, testosterone suppressed volume-stimulated release of atrial NP (13). However, contradictory results have also been reported regarding the effect of testosterone on atrial NP gene expression (31) and synthesis in cultured rat myocytes (32). In clinical studies, inverse correlations between BNP and FT levels have been observed in women in the Dallas Heart Study (8) and in a small Japanese study (16). Androgen receptor antagonism for prostate cancer has been associated with large increases in levels of NT-proBNP (33). In male children and adolescents, associations of decreasing FT, increasing SHBG, and increasing NT-proBNP levels have been noted (15).

Our findings extend prior observations to a large community-based cohort of middle-aged men and women. The demonstrated association between NT-proBNP and androgens offers a potential unifying explanation for sex and hormonal status-related differences in NP concentrations. In men, low BNP concentrations may be related to the suppressive effects of high concentrations of FT. A nonlinear relationship with NT-proBNP at such high concentrations of FT may explain the failure to detect a statistically significant relationship between FT and NT-proBNP in men following multivariable adjustment. In women, FT concentrations are more than 50-fold lower than that in men and are exquisitely sensitive to SHBG concentrations.

Estrogen regulation of NP concentrations. Previous studies have also shown that estrogens may exert a stimulatory effect on the NP system (11). In female rats, pretreatment with estradiol and progesterone stimulated atrial NP gene expression (31). In post-menopausal women, administration of estrogens produced a rise in plasma levels of BNP (9). A complex interplay of factors has been postulated, in which estrogens modulate NP production via known effects on the renin-angiotensin system (12).

Measurements of estradiol and estrone were not available for the current study, limiting our conclusions regarding the role of estrogens in mediating the observed difference in NT-proBNP levels. However, according to the hypothesis of a stimulatory effect of estrogens on NPs, we would have expected post-menopausal women and men to have similar NT-proBNP levels given their similar estrogen levels, yet NT-proBNP concentrations were much higher in the former. Similarly, based on higher endogenous estrogens in pre-menopausal than post-menopausal women, we would have expected higher NT-proBNP levels in the former, but levels were similar in the 2 groups. Lastly, given that the midcycle (ovulatory) phase of the menstrual cycle is associated with higher estrogen levels compared with the follicular or luteal phases, higher NT-proBNP levels would be expected midcycle; however, levels were paradoxically lower in women at midcycle. Interestingly, each of the above observations can potentially be explained by variation in FT, which is highest in men, comparable in pre- and post-

menopausal women, and higher during the midcycle phase than the follicular or luteal phase. These findings are consistent with prior studies showing that circulating NT-proBNP concentrations are not correlated with measured estradiol concentrations in females (15,16).

Nonetheless, in the absence of direct measurements of estrogens, a role for estrogen-stimulated increases in NT-proBNP cannot be excluded. An explanation based purely on androgen suppressive effects would be inadequate to account for the known rapid fall in NP concentrations during the first year of life or the similar levels of NT-proBNP in male adolescents and male pre-pubertal children (34). In aggregate, it is likely that both the stimulatory effects of estrogens and inhibitory effects of testosterone contribute to the regulation of BNP concentrations during the life course. The relative concentrations of these sex hormones may also be an important factor. Additional population-based studies including pre- and post-pubertal individuals of both sexes are warranted.

Circulating NPs and use of hormone therapies. Previous studies examining the impact of HRT on BNP in post-menopausal women have produced conflicting results (6,8–10), and none have examined the impact of HC on circulating BNP in pre-menopausal women. Our study indicates that usage of HC in pre-menopausal women is associated with higher circulating NT-proBNP levels compared with no usage. This may be due to direct stimulatory effects of estrogens on the NP system, a reduction in FT-mediated suppression of NT-proBNP secondary to increased SHBG from oral estrogens, or indirect effects of oral estrogens and progestins acting via the renin-angiotensin system to modulate NP levels (12). Consistent with previous studies (8,16), we did not detect a significant association between naturally occurring menopause and NT-proBNP concentrations after accounting for age, although the relatively small number of post-menopausal women in our middle-aged sample may have limited our statistical power to detect a difference. We were similarly unable to demonstrate a significant association between usage of HRT and circulating NT-proBNP, in contrast to findings from Olmsted County (6). This could be due to small numbers of HRT users in our current sample because we included younger women who were recruited following publication of the Women's Health Study and the nationwide reduction in HRT prescription rates (2,35). Of note, the effects of exogenous female sex hormone therapies are known to vary with the route of administration (36), formulation (37), and composition; for example, progestogens in HC may exert both androgenic and antiandrogenic effects (38). These details were not available in our study but represent important areas for future study.

Study strengths and limitations. Strengths of this study include the large sample size, community-based design, careful recording of menstrual history, standardized examinations with routine blood collection, and uniform ascertainment of cardiovascular risk factors including IR. Measurements of estrogens and details regarding the individual hormone components of HC were not available. The accurate detection of an ovulatory cycle or hormonal changes in reproductive aging in women requires specific measurements of female sex hormones and gonadotropins. A role for estrogen-stimulated increases in circulating BNP cannot be excluded based on these data. FT was not directly measured, but estimated FT concentrations from total testosterone (by mass spectrometry) and SHBG (by radioimmunoassay) correlate well with direct measurements by equilibrium dialysis (39–42). Biologically active atrial NP (43) and BNP (44) provide physiologically meaningful information but are less practical for measurement in large, ambulatory cohorts composed of predominantly healthy individuals, in part because of the high proportion of values censored by the detection limit of the mature NP assays (4,5). We acknowledge the potential for residual confounding by unmeasured comorbidities and their pharmacological therapies, as well as the limited ability to draw conclusions regarding causality from these observational data. Nonetheless, our findings are consistent with experimental data on the effects of testosterone on NPs.

Conclusions

Circulating NT-proBNP levels were related to sex and exogenous hormone therapy in men and women from the general community. Suppression of NPs by androgens may account for sex- and hormone-related differences in NT-proBNP concentrations. Given the known cardioprotective effects of BNP (45), further studies are warranted to elucidate how these mechanisms may contribute to the well-described sex-related differences in cardiovascular risk.

Comparative *Logic Modeling* for Policy Analysis: The Case of HIV Testing Policy Change at the Department of Veterans Affairs

Erika M. Langer, Allen L. Gifford, and Kee Chan

Objective. Logic models have been used to evaluate policy programs, plan projects, and allocate resources. *Logic Modeling* for policy analysis has been used rarely in health services research but can be helpful in evaluating the content and rationale of health policies. Comparative *Logic Modeling* is used here on human immunodeficiency virus (HIV) policy statements from the Department of Veterans Affairs (VA) and Centers for Disease Control and Prevention (CDC). We created visual representations of proposed HIV screening policy components in order to evaluate their structural logic and research-based justifications.

Data Sources and Study Design. We performed content analysis of VA and CDC HIV testing policy documents in a retrospective case study.

Data Collection. Using comparative *Logic Modeling*, we examined the content and primary sources of policy statements by the VA and CDC. We then quantified evidence-based causal inferences within each statement.

Principal Findings. VA HIV testing policy structure largely replicated that of the CDC guidelines. Despite similar design choices, chosen research citations did not overlap. The agencies used evidence to emphasize different components of the policies.

Conclusion. Comparative *Logic Modeling* can be used by health services researchers and policy analysts more generally to evaluate structural differences in health policies and to analyze research-based rationales used by policy makers.

Key Words. Evidence-based practice, HIV, health policy, Centers for Disease Control and Prevention (U.S.), Veterans Affairs (U.S.)

Health care decision makers have used research evidence to justify adoption of Centers for Disease Control and Prevention (CDC) human immunodeficiency virus (HIV) testing guidelines into a variety of health care settings. In 2006, the CDC released revised HIV testing guidelines for adults and adolescents (Branson et al. 2006). Within the U.S. Department of Veterans Affairs

(VA), reports emerged indicating that HIV testing rates were low (Owens et al. 2007), prompting reevaluation of VA HIV testing practices and policies. As a result, in 2009, the VA adopted CDC recommendations by eliminating written informed consent requirements for HIV testing and making testing a routine part of Veterans' health services (Department of Veterans Affairs 2009).

Translation of specific clinical recommendations and evidence into policies and practice within health care systems is a major challenge. If the structural logic and rationale of the CDC recommendations are not clear, initiatives and resource allocations necessary for a change in testing policy could be difficult to implement. James and Jorgensen (2009) have suggested that research utilization theory offers a robust conceptual framework for assessing the policy process. There is a pressing need to use effective evaluation tools to reveal the evidence-based resources, inputs, and outputs of policy in a systematic, logical, and transparent manner as health care settings implement the CDC guidelines. *Logic Modeling* is a technique that offers a way to analyze and quantify how policy makers use research—how their "research utilization" informs the process and outcomes of translating specific research-based knowledge into evidence-based practice (Rich 1997).

To understand research utilization, we propose a novel application of the logic model. *Logic Modeling* provides a visual representation of input, throughput, and output components that are brought together to produce intended change. While *Logic Modeling* can be used after completion of primary activities as a way of evaluating how well policy was able to meet intended outcomes, it may also be used earlier in institutional change processes to plan for and guide future evaluation. *Logic Modeling* as an evaluation tool has been used widely to examine the resources, inputs, outputs, and outcomes of programs in a clear and systematic fashion. Therefore, we applied

this to better understand the evolution of VA HIV testing and assess how evidence was brought to bear on the policy design.

Over the past 40 years, logic models have largely been applied to evaluations of specific social programs (Wholey 1987), but *Logic Modeling* has also been used in both community-based and systems-level initiatives (Julian 1997; Moyer, Verhovsek, and Wilson 1997; Kaplan and Garrett 2005), in planning (Dwyer 1996; Macaskill et al. 2000), management (Millar, Simone, and Carnevale 2001), and preevaluation to develop indicators and document outcomes (Kellogg Foundation 2004; Innovation Network 2008). *Logic Modeling* can stimulate reflection (Moyer, Verhovsek, and Wilson 1997), enable communication, and promote continued learning toward health service objectives (Kellogg Foundation 2004; Innovation Network 2008).

Policy documents such as the VA HIV directive and CDC HIV recommendations represent endpoints within the decision making process and are particularly relevant to successful replication of policies within other contexts. Used as primary sources for analysis, policy documents can counter the problematic "fuzziness" of health policy by providing insights into the formal rules and intentions of policy measures (Kroneman and van der Zee 1997). James and Jorgensen (2009) have suggested that by working backward from final policy statements, it is possible to reconstruct policy decision making to explore knowledge utilization, a term which encompasses both scientific and nonscientifically generated information sources apparent in the policy making process (Trostle, Bronfman, and Langer 1999; Dobrow, Goel, and Upshur 2004). In this formulation, "research utilization" is a sub-type of knowledge utilization that can describe the development of evidence-based practices.

Use of research data in policy making has previously been characterized as instrumental (i.e., direct, actionable), conceptual (i.e., diffuse, gradually enlightening), or symbolic (i.e., strategic, tactical) (Pelz 1978; Weiss 1979; Trostle, Bronfman, and Langer 1999; Hanney et al. 2003; Almeida and Báscolo 2006). We explore the symbolic use of research evidence. This use can occur to attain political legitimacy, support a position, give confidence, reduce uncertainty, and raise financial resources for policy decisions (Hanney et al. 2003).

Despite the personal, economic, and public health benefits of HIV screening, the revised 2006 CDC guidelines have not been universally adopted. Lack of consensus in how testing policy should be applied may stem in part from lack of transparency in how evidence-based resources, inputs, and outputs have been synthesized, translated, and adopted in different settings. We propose that when informed by research utilization theory, policy *Logic*

Modeling can generate this transparency. Modeling policy alongside causal assumptions allows us to compare across policy settings in order to better understand the rationales of specific policy choices. Where research-based justifications are entirely lacking in the model, there may exist gaps in CDC or VA policy logic. We propose that by generating insights into the policy making process, comparative *Logic Modeling* is thus an effective tool for health policy analysis.

MATERIALS AND METHODS

Using final CDC and VA policy statements on HIV testing (Branson et al. 2006; Department of Veterans Affairs 2009), this case study examines retrospectively the structural logic and research-based rationale of each policy. To describe the structural logic of each agency's policy design, we adopted the *outcomes-based logic model* from W. K. Kellogg Foundation (2004). We used content analysis of agency policy documents to identify elements of the five policy design components presented in the model. These components are resources/inputs, activities, outputs, outcomes, and impact (labeled 1–5 in Figure 1).

Comparison of Design Logic

Resources/inputs include space, technology, equipment, materials, and the human, financial, organizational, and community inputs available to direct toward proposed activities. *Activities* include processes, tools, events, technology, and actions needed to bring about intended change, and encompass the services, products, advocacy, and infrastructures of the intervention. *Outputs* are the direct measurable or tangible products of activities quantified as types, levels, and targets of delivered services. They are not themselves the anticipated change, but they help to assess how well change is being implemented. *Outcomes* are the individual, community, systematic, or organizational changes

Figure 1: Logic Model with Policy Design Components, 1–5, and Research-Based Links, A–D

Source: Adapted from Kellogg Foundation (2004).

to behavior, knowledge, skills, status or level of functioning. *Impact* is the fundamental change that occurs over the longer term (Kellogg Foundation 2004; Innovation Network 2008).

We used these definitions to construct separate logic models for the CDC and VA HIV testing policy statements. First, we categorized direct quotes from the statements according to the components of the logic model, and we cross checked this categorization between researchers. Next, we compared structural components across logic models to determine the extent of policy overlap, and we abbreviated these quotes for the purpose of display (see Tables 1 and 2). Sections of the CDC guidance pertaining to HIV screening for adolescents, pregnant women, and their infants were excluded from the analysis, as maternity care is typically provided outside the VA, and the agency does not provide care for adolescents or infants (Department of Veterans Affairs 2010).

Comparison of Design Rationales

Next, we adapted the logic model to draw specific attention to the presence or absence of a research-based rationale or evidence-based practice for policy design. The research-based policy rationale was described through use of the model arrows or "links" (labeled A–D in Figure 1). These represent causal inferences of the design which connect one policy component to another in an "if-then" statement (Kellogg Foundation 2004). The causal inferences of link B, for example, state that if the policy includes certain *activities*, then it will produce a particular *output*. This causal inference may or may not be supported explicitly by research evidence. While causal inferences may be supported by a variety of information types, our study was concerned only with research-based links.

To quantify research-based causal inferences, we first identified all research references or formal citations in the texts. We then looked to see if these references were used to support causal inferences about any elements within the five policy design components, as determined previously. To be counted as a link, at least two elements belonging to different, adjacent model components had to be present. The number of links for each location (A–D) in the logic model were counted and compared within and across policy designs (see Figure 2).

To assess accuracy and permit possible revision to these coding rules, we piloted them on the proposed rule for Veteran HIV testing policy that was published in the Federal Register on December 29, 2008 (Department of Veterans Affairs 2008). This early draft of the VA policy invited public

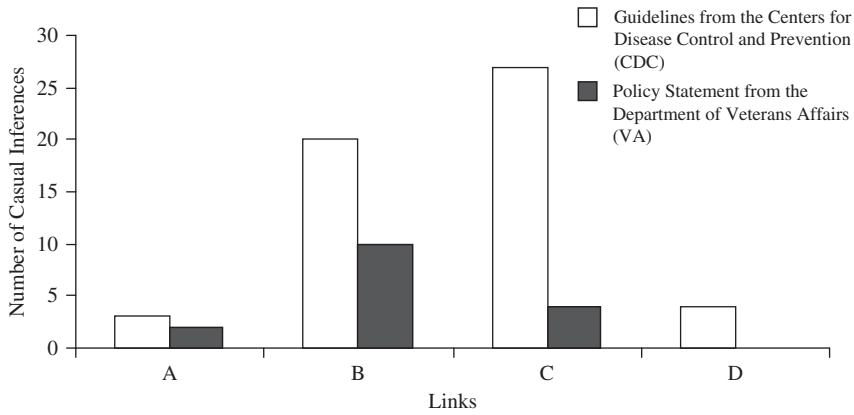
Figure 2: Research-Based Causal Inferences in Two Federal HIV Testing Policy Statements



Here, Link A Represents the Number of Causal Inferences That Linked Resources to Activities; B Links Activities to Outputs; C Links Outputs to Outcomes; and D Links Outcomes to Impact. The CDC's Greatest Relative Research Use Emphasized Resulting Outcomes of Policy Change, While the VA's Greatest Relative Research Use Rationalized the Effect of New Policy Activities upon Outputs.

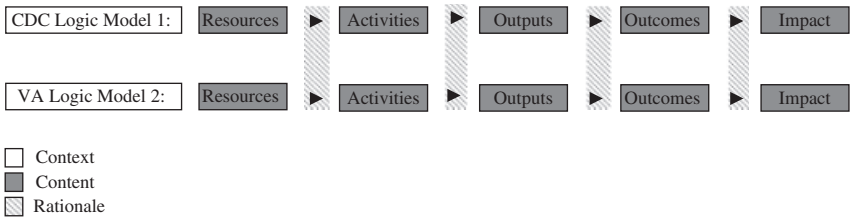
comment prior to the final announcement on July 16, 2009. The result of our pilot evaluation was to assign links occurring between more than two components into all relevant categories; for example, a research-based link between a single output and two or more outcomes would be counted as two pairings for Link C of the model (i.e., both "Output 1 > Outcome 1" and "Output 1 > Outcome 2").

Outcomes of the final comparison were to quantify the number of references given and the number of research-based causal inferences under each link of the model. This was used to determine where agencies were focusing. We incorporated these findings into a conceptual framework connecting policy context, content, and rationale (Figure 3).

RESULTS

CDC and VA HIV testing policy shared design elements under every component of the logic model (see Tables 1 and 2).

Figure 3: Conceptual Framework for Comparative *Logic Modeling* across Two Health Policies



The Structural Components (1) Resources, (2) Activities, (3) Outputs, (4) Outcomes, and (5) Impacts (Gray Boxes) Were Evaluated across the CDC (Top) and VA (Bottom) Logic Models. The Causal Inferences (Black Arrows) Linking Model Components Were Compared with Provide Insights into Research Utilization by Each Agency. Where Supported by Research Citations, These Links Provided a Research-Based Rationale for Comparison across Policies (Diagonal Lines).

Resources

Both agencies invited community input into the design process. Only the CDC mentioned potential barriers to proposed testing activities in the form of human, financial, organizational, and legal resources not be readily available. The VA listed technological resources such as an educational HIV website, electronic medical records, and a computerized provider ordering system that could better enable policy activities.

Activities

Both agencies proposed routine, voluntary HIV testing and removed prior requirements for written consent and pretest counseling. They required oral informed consent and its documentation within the medical record, as well as provision of multilingual educational materials to accompany testing. Both recommended annual repeat testing of patients at high risk for infection. The VA differed from the CDC in that it specifically eliminated a requirement for posttest counseling. The CDC did not require direct personal contact between patient and provider to convey negative test results, but it did recommend counseling referrals for high-risk patients and required efforts that would link patients who test positive to counseling. The CDC proposed additional criteria for screening in populations where HIV prevalence is greater than 1 percent. The CDC noted that where these policy changes were incompatible with existing state laws, steps should be taken to resolve the conflicts.

Outputs

Both agencies anticipated increased screening rates. The CDC recommended that all health care settings implement HIV testing of patients aged 13–64, patients seeking treatment for tuberculosis or sexually transmitted diseases, patients who are starting a new sexual relationship, patients who are sources of occupational exposure, and patients who are thought to be at high risk for infection. The VA made recommendations for Veterans receiving medical care benefits. Here there was a marked difference in policy scope between the disease monitoring agency and VA's health services delivery arm.

Outcomes

Both agencies anticipated a reduction in high-risk behaviors in the short term. Patients who tested positive would be linked to treatment. Long-term goals for both agencies were to reduce HIV-related morbidity and mortality. The CDC foresaw further benefit in removing stigma against HIV testing, ensuring a good patient–provider relationship and achieving cost-effectiveness.

Impact

Both agencies anticipated advancement of public health goals and patient rights.

Research Evidence Application

Both the CDC and the VA used research references to support policy design inferences, but the chosen evidence base differed greatly between these two agencies.

The VA emphasized a need for Veteran-specific research, and, unlike the CDC, cited studies conducted at VA health care facilities and with a primary focus on the U.S. Veteran population. The VA disagreed with public comment that would maintain mandated pre- and posttest counseling because that literature was "drawn from settings outside the VA" (Department of Veterans Affairs 2009).

Whereas the VA was issuing a final rule governing health practices of its own service facilities, the CDC was generating policy recommendations for adoption externally. As such, the CDC required a strong level of transparency to make the guidelines readily adoptable to a variety of U.S. settings.

Consistent with these different policy mandates, we found no overlapping references between HIV testing policy statements, despite similar design components. The VA did not cite the CDC guidelines formally, but stated its

intention to bring procedures in line with current CDC HIV testing recommendations, suggesting that the agency is familiar with the evidence base of CDC policy without the need to reiterate these references.

There were differing quantities of research evidence, with the CDC citing many more references than the VA. It is important to note that this comparison captures only symbolic research references in the final policy statements. The policies may be products of greater instrumental and conceptual research use occurring earlier in the process in order to identify desired evidence-based practices.

We found additional differences between agency policy statements after quantifying and comparing the research-based causal inferences used to link design components. Every link in the CDC logic model was supported with at least one research-based causal inference (Figure 2), but the VA model did not link outcomes to impact. Particular links of the logic model took on greater relative importance according to the agency (Figure 2). In the following, we provided only a few examples of these causal links.

Link A, Resources to Activities

Both agencies cited minimal evidence linking policy resources to activities and focused more on the limitations of resources to produce successful alternatives, such as risk-based screening.

Link B, Activities to Outputs

The VA emphasized this link with the bulk of its research citations. Both agencies believed that an increase in testing rates would result from the elimination of pretest counseling and prior written informed consent requirements.

Link C, Outputs to Outcomes

The majority of research-based causal inferences made by the CDC linked outputs to outcomes. The agency focused on findings of reduced transmission, improved health outcomes, and reasonable cost-effectiveness, which occurred as a result of early HIV diagnosis and treatment. The VA also offered justifications for this model link, stating that research exists which supports an "excellent record of linkage to care" following positive HIV diagnosis.

Link D, Outcomes to Impact

Only the CDC cited research to support an impact to patient rights, justice, and public health over the longer term.

DISCUSSION

Since 2006, the CDC has recommended routine, one-time HIV testing for all U.S. adolescents and adults ages 13–64, in all health care settings except those with undiagnosed HIV prevalence known to be <0.1 percent. Current guidelines support a broad opt-out testing approach under the patient's general consent for medical care, with annual repeat testing of patients at highest behavioral risk (Branson et al. 2006). These guidelines differ from past CDC recommendations that focused screening on those with risk behaviors, required signed, informed consent, and included pre- and posttest behavioral counseling to reduce risk behaviors (Centers for Disease Control and Prevention 2001). The use of *Logic Modeling* as a comparative tool for policy analysis provides a systematic and transparent approach to examine design logic and research use in relating the CDC guidelines to requirements in VA health care facilities that began in 2009.

Prior study has indicated that the policy making and research processes are heavily influenced by context (Rütten et al. 2003; Almeida and Báscolo 2006; Contandriopoulos et al. 2010), and that policy making setting may be a factor in research utilization (Weiss 1978; James and Jorgensen 2009). In this study, we developed a conceptual framework to evaluate context, content, and rationale of the policy process simultaneously (Figure 3).

While we found some differences in CDC and VA policy design and rationale, the agencies' HIV testing policies are largely comparable. The strong overlap of CDC and VA HIV testing policy components in this study suggests that VA policy may be generalizable to other settings considering adoption of, or alignment with, CDC guidelines. The CDC has identified "states, local jurisdictions, or agencies" as the regulatory bodies that oversee HIV screening, in such settings such as "hospital emergency departments, urgent care clinics, inpatient services, substance abuse treatment clinics, public health clinics, community clinics, correctional health care facilities, and primary care settings" (Branson et al. 2006). These settings all stand to benefit from observation of HIV testing policy implementation at the VA.

Content overlap between agencies' policies permitted comparison of research-based causal inferences. Despite similar policy design choices, however, we found no overlapping references between the CDC and VA policy statements. This may indicate the use of other (non-research-based) information types to make policy design choices. But because it reflects symbolic research use by the agencies, this finding provides additional insights into the tactics, formal interests, and design focus of agency policy makers. We found

that the VA cited evidence that was specific to U.S. Veterans in VA health service settings, while the CDC drew from a broader evidence base than the VA, as is reflective of their differing scopes of practice.

We found that the CDC offered evidence in support of all logic model links, while the VA did not justify its claims of a longer-term impact for the proposed policy change. This finding may represent an evidence gap in VA policy rationale, or the agency may be citing supportive evidence as a formality, having already decided to adopt the CDC guidelines. When used symbolically, research utilization in policy statements may be a tactical move designed to create stakeholder buy-in of an earlier, and authoritative, decision making process.

Depending on the agency, particular links of the logic model took on greater relative importance. The majority of the VA's research-based justifications were given to link planned activities to expected outputs, while the CDC placed the most evidentiary emphasis on linking outputs to outcomes, a finding also related to the agencies' different public health missions. The VA is responsible for operations specific to U.S. Veterans' health and has focused on policy throughputs. The CDC is charged with setting broad policy to influence service providers and the public, and it has placed greater emphasis on policy results. These research emphases differ because symbolic research use can achieve different strategic purposes. Policy makers' purpose will determine the need for supportive evidence that justifies the decision. The VA is running a health care system and must directly allocate resources as well as persuade practitioners, patients, and other stakeholders that the new processes and procedures put into place will achieve desired change. Alternatively, the CDC develops and promotes public health policies with the goal of improving care across the U.S. health care system, and it must communicate the wider benefits of adopting new testing guidelines to an array of health care settings.

Our study connects symbolic research utilization to the federal policy making process through HIV testing policy content and rationale. Others have suggested that different types of evidence are useful at different times in the policy process (Bowen and Zwi 2005), and the use of *Logic Modeling* in this study provided a content-based window to compare these contexts, as illustrated by our conceptual framework (Figure 3).

There are several limitations to the approach we have taken here. Policy documents used to reconstruct policy logic are windows into decision making, but they do not capture instrumental or conceptual uses of research. However, it may be valuable to judge the policy at face value—that is, how it is presented in its final form to other agencies, states, service organizations, patients, and

stakeholders who will interpret and apply the policy. Policy statements that provide minimal insight into the intentions, strategies, and rationale of a policy decision are noteworthy for their lack of logic and research-based rationale.

Policy decision making is frequently criticized for a lack of rationality (Buse, Mays, and Walt 2005). This study does not determine if supportive research evidence exists but was not cited, or if policy logic was based on other types of information. Future study might adapt our proposed framework so that logic model links represent multiple information types. Indeed, it is this combination of information sources that is critical to the meaning of evidence-based policy (Bowen and Zwi 2005). Future study also may look explicitly at included and excluded information as it varies across setting with policy design. Others have advocated this approach as context-specific evidence is critical to effective policy making (Bowen and Zwi 2005; James and Jorgensen 2009).

A final limitation of the study is the potential for researcher bias in creating and employing the counts used to quantify research-based links. We reduce such bias by defining our recording units in advance (i.e., the model components and links) and by piloting our coding rules on the proposed VA rule for stability and reproducibility.

CONCLUSION

This case study has compared the 2009 policy change in HIV testing at the VA with existing screening guidelines from the CDC. Through the use of comparative *Logic Modeling* as a tool for policy evaluation, we examined the substance and rationale of policy choices, and the research emphases of these designs in determining an evidence-based practice.

We found considerable overlap in agency policy logic despite dissimilar use of research evidence. The VA largely replicated the CDC HIV testing guidelines, a result which suggests that future evaluation of the VA's policy adoption could be compared to other non-VA health care facilities. In fact, while the VA is unique as one of the world's largest integrated health care systems providing services to U.S. veterans, it is often overlooked as a relevant source of information for other health care organizations. There are often important similarities between the VA and other large health care systems, such as large proportions of older clients in need of chronic disease management, overall size, geographic spread, and level of system integration.

While the CDC and the VA shared policy elements under every component of the logic model, there were no shared research citations used to justify

model links. This difference in research use may be attributable to the distinct missions of the agencies and to the particular focus of the VA on determining evidence-based practice from a Veteran-specific context. This conclusion is further supported by the agencies' different emphases on model links. Recently, *Logic Modeling* was used to evaluate the health policy process in Vietnam across three maternal health case studies (Ha et al. 2010). These research utilization findings suggest that this method may be useful in identifying policy maker interests and intentions in other contexts as well; for example, in comparing policy drafts across legislative bodies, across time and/or settings, such as historical or international comparisons of similar health care services.

The quantification of causal links in *Logic Modeling* is an effective approach to comparing research use in health policy. As we continue to develop new methods for characterizing this research–policy relationship, advancement of our theoretical knowledge through new tools of policy analysis will be critical to the promotion of effective public health policies.

ABSTRACT

Objective: To compare cancer screening and flu vaccination among persons with and without unhealthy substance use.

Design: The authors analysed data from 4804 women eligible for mammograms, 4414 eligible for Papanicolou (Pap) smears, 7008 persons eligible for colorectal cancer (CRC) screening and 7017 persons eligible for flu vaccination. All patients were screened for unhealthy substance use. The main outcome was completion of cancer screening and flu vaccination.

Results: Among the 9995 patients eligible for one or more of the preventive services of interest, 10% screened positive for unhealthy substance use. Compared with women without unhealthy substance use, women with unhealthy substance use received mammograms less frequently (75.4% vs 83.8%; $p<0.0001$), but Pap smears no less frequently (77.9% vs 78.1%). Persons with unhealthy substance use received CRC screening no less frequently (61.7% vs 63.4%), yet received flu vaccination less frequently (44.7% vs 50.4%; $p=0.01$). In multivariable analyses, women with unhealthy substance use were less likely to receive mammograms (adjusted odds ratio 0.68; 95% CI 0.52 to 0.89), and persons with unhealthy substance use were less likely to receive flu vaccination (adjusted odds ratio 0.81; 95% CI 0.67 to 0.97).

Conclusions: Unhealthy substance use is a risk factor for not receiving all appropriate preventive health services.

ARTICLE SUMMARY

Article focus

- Do persons with unhealthy substance use receive breast, cervical and colorectal cancer screening less frequently than persons without unhealthy substance use?
- Do persons with unhealthy substance use receive flu vaccination less frequently than persons without unhealthy substance use?

Key messages

- Women with unhealthy substance use are less likely to receive mammograms than women without unhealthy substance use.
- Persons with unhealthy substance use are less likely to receive flu vaccination than persons without unhealthy substance use.
- Unhealthy substance use is not a risk factor for not receiving cervical or colorectal cancer screening.

Strengths and limitations of this study

- Strengths: the study used validated measures of unhealthy substance use and encompassed a wide range of substance-use severity.
- Limitations: the findings from our sample of an inner-city patient population with health insurance and access to care who receive primary care at an urban safety-net hospital may not be generalisable to other patient populations. The study cannot determine whether unhealthy substance use causes patients not to receive certain services, or whether screening, brief intervention and substance-use treatment led some patients to complete screenings or vaccination. The study did not obtain records of services performed outside Boston Medical Center, and relied on patient self-report of substance use.

INTRODUCTION

Cancer and flu are among the leading causes of mortality in the USA.[1 2] Flu is preventable, in part, through vaccination, and mortality from cervical, breast and colorectal cancer (CRC) can be reduced through routine screening.[3–5] Nevertheless, many eligible US adults do not receive these recommended preventive services,[6] in particular, low-income persons,[7] racial and ethnic minorities,[8–11] the uninsured[12] and the foreign-born.[13] Despite this knowledge, and the implementation of interventions targeting these groups, preventive services are still underused, which has led

some to believe that high-risk 'pockets' of the population may account for gaps in service receipt. Persons with unhealthy substance use (for alcohol, the spectrum that ranges from risky use to dependence; for drugs, the spectrum from any illicit drug use (including prescription drugs) to dependence) may represent one such 'pocket.' Disorganisation, intoxication, comorbid mental illness and low utilisation of primary care among persons with unhealthy substance use[14] might lead to lower use of preventive services.

Prior studies of cancer screening[15–19] and flu vaccination[18 20] suggest that receipt of these services may be low among persons with substance-use disorders (with levels of use that are severe enough to warrant a diagnosis of abuse or dependence). These studies have been limited by their reliance on ICD-9 codes to define substance-use disorders, their exclusion of persons whose substance use is undiagnosed or does not meet criteria for abuse or dependence, and the fact that they have largely been conducted in Veterans Administration (VA) settings, where patients may not be representative of the general population.

We analysed data on unhealthy substance use collected prospectively and systematically by staff whose sole responsibility across a variety of healthcare settings was screening with brief intervention for substance use, and referral to treatment for substance-use disorders. We linked these data to electronic medical record data at eight urban safety-net hospital-based primary care practices to examine preventive service receipt among persons with and without unhealthy substance use. We hypothesised that persons with unhealthy substance use would receive preventive services less frequently than persons without unhealthy substance use.

METHODS

Study setting and sample

Boston Medical Center is an urban safety-net hospital with eight academic primary care practices staffed by 105 primary care practitioners, including both general internists and family practitioners, and staff and resident physicians. The primary care practices predominantly serve a minority and multicultural low-income population. We identified women eligible for breast cancer screening, women eligible for cervical cancer screening, and men and women eligible for CRC screening. Among these groups examined for cancer screening, we also identified individuals eligible for flu vaccination. We linked these four cohorts of patients to unhealthy substance-use screening data that were obtained over a similar time period in the outpatient, inpatient, and emergency department settings.

From 2007 to the present, Boston Medical Center participated in a universal substance-use screening programme supported by the federal government known as the Massachusetts Screening, Brief Intervention, Referral and Treatment (MASBIRT) programme. As part of the programme, trained lay-persons ask the following three questions of all patients in multiple settings to identify unhealthy substance use:

1. In the past 3 months, how often have you had more than four drinks (with alcohol) in a day (for men; women and men 65 years and over were asked about more than three drinks in a day)?
2. In the past 3 months, how often have you used narcotic pain medicines, sedatives (benzodiazepines), or Ritalin/amphetamine without a doctor's prescription or in greater amounts than prescribed?
3. In the past 3 months, how often have you used marijuana, cocaine, heroin or other drugs?

Unhealthy substance use was defined as any response other than 'never' to any of the above questions. In its clinician's guide, the National Institute on Alcohol Abuse and Alcoholism recommends the single-question screen for unhealthy alcohol use (similar to question 1 above).[21] Smith *et al* validated the single-question screen at Boston Medical Center, finding that it is both sensitive and specific for the detection of unhealthy alcohol use.[22] Since brief validated screening questions for illicit drug use or prescription drug misuse in the primary care setting have only recently been published,[23] the MASBIRT programme used screening questions (questions 2 and 3 above) that were derived from the more extensive Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) questionnaire[24] (validated in primary care settings) and the National Household Survey on Drug Use and Health.[25] The MASBIRT programme specifically asked about marijuana, cocaine and heroin, as these are the three most common illicit drugs used in Massachusetts.[26] Instead of past-year use, all screening questions asked about use in the past 3 months to increase the likelihood that a positive test would make logical sense for a clinician to address (current use) and to match the time frame in the ASSIST questionnaire. The ASSIST questionnaire was administered to all patients who reported drug use or risky alcohol use (an affirmative response to question 1 above), providing a measure of current (or risk of developing) substance-related problems. We defined high-risk drug use according to a WHO ASSIST Specific Substance Involvement Score of ≥27, moderate-risk drug use as a score of 4–26 and low-risk drug use as a score of 0–3.[27] Similarly, we defined high-risk alcohol use as a score of ≥27, moderate-risk alcohol use as a score of 11–26 and low-risk alcohol use as a score of 0–10. Patients who screened positive for unhealthy substance use received a single brief counselling intervention and, if indicated, referral for addiction treatment.

We linked clinical information to data on unhealthy substance use among individuals who were screened for unhealthy substance use from 2007 to 2009. We based our eligibility criteria for the cancer-screening measures on modified versions of the corresponding 2007 *Healthcare Effectiveness Data and Information Set* (HEDIS) measures and recommendations of the US Preventive Services Task Force,[3 28–30] and eligibility criteria for flu

vaccination on CDC guidelines.[31] The Boston Medical Center institutional review board approved the study protocol.

Preventive service measures

Using a clinical data warehouse that makes electronic medical records available for research, we identified three groups of patients: (1) female patients aged 21–64 years; (2) female patients aged 42–69 years; and (3) male and female patients age 51–75 years. We chose these age ranges because we sought consistency with the HEDIS measures on cervical- and breast-cancer screening (groups 1 and 2, respectively), and with the United States Preventive Services Task Force recommendations on CRC screening (group 3).[29] Given the questionable value of CRC screening in persons with limited life expectancy,[32] we chose to follow the United States Preventive Services Task Force colorectal cancer recommendations, with age 75 as an upper age limit of screening, rather than age 80, as specified by HEDIS.

We modified the denominator of the cervical cancer screening measure to include any female patient aged 21–64 who had at least one visit to a primary care site at Boston Medical Center in each of the three previous years. We required a minimum of one visit per year to approximate the HEDIS requirement that patients be 'continuously enrolled' in a health plan. The numerator included any patient who received a Papanicolou (Pap) smear in the past 3 years. We excluded women who had undergone a hysterectomy (based on current procedural terminology (CPT) and International Classification of Diseases, version 9 (ICD-9) codes) from both the numerator and the denominator, as Pap smears are rarely indicated in this group.[30]

For the breast-cancer screening measure, we required that female patients aged 42–69 have one visit to a hospital primary care site in each of the two previous years. The numerator included any patient who received a mammogram in the past 2 years. We excluded women who had undergone a bilateral mastectomy or unilateral mastectomy on two separate dates (based on CPT and ICD-9 codes) from both the numerator and the denominator.

For the CRC screening measure, we required that patients aged 51–75 have one visit to a Boston Medical Center primary care site in each of the two previous years. The numerator included any patient who completed home faecal occult blood cards (based on results in the electronic medical record) in the past year, flexible sigmoidoscopy or barium enema in the past 5 years, or colonoscopy in the past 10 years.

We also examined whether patients eligible for cervical, breast and CRC screening who were eligible for flu vaccination were vaccinated. Patients were eligible for flu vaccination as per CDC recommendations during this period if they were aged 65 or older or had one of the following chronic conditions: asthma, chronic obstructive pulmonary disease, congestive heart failure, moderate or severe liver disease, HIV infection, diabetes mellitus or renal insufficiency.

Covariate measures

Guided by Gelberg's adaptation of Andersen's model of health services use,[33] we examined covariates known to affect healthcare utilisation such as gender, race, age, insurance status and language. We defined the burden of medical comorbidity by using the Deyo adaptation of the Charlson Comorbidity Index.[34] Patients were categorised as having significant comorbidity if they had a Charlson–Deyo Score of one or greater. We obtained psychiatric diagnoses from the electronic medical record problem list. In most cases, these diagnoses were made by the patient's primary care provider or by a mental-health specialist. We also examined primary-care utilisation, analysing the number of primary-care visits over the study period.

Statistical methods

Using the SAS computer statistical package, Version 9.1, we performed χ^2 tests to compare differences in preventive-services receipt between persons with and without unhealthy substance use. In exploratory subgroup analyses, we also compared differences in preventive-services receipt between persons with and without unhealthy alcohol use, and with and without any drug use. We used multiple logistic regression to analyse unhealthy substance use as a predictor of receiving each preventive service. Data were missing at random among <5% of all observations. We included all variables in the model based on their a priori clinical significance, and computed adjusted ORs and 95% CIs based on the multiple logistic model. To minimise the potential for collinearity, we examined the variance inflation factor for each covariate. Analyses were conducted using two-sided tests and a significance level of 0.05. We used general estimating equations to account for clustering of patients within clinicians, and clinicians within practices. To detect differences between men and women with unhealthy substance use, we included interaction terms between unhealthy substance use and sex in the multivariable models of CRC screening and flu vaccination.

RESULTS

There were 9995 primary care patients who were eligible for one of the preventive services of interest and had been screened for unhealthy substance use from 2007 to 2009. Table 1 shows the demographic and clinical characteristics of the sample. Patients with unhealthy substance use were slightly younger, and were more likely to be male, English-speaking and of white or black race (vs Hispanic or other race) than were patients without unhealthy substance use. Patients with unhealthy substance use were also less likely to have private insurance and more likely to have Medicaid or Commonwealth Care (a Massachusetts insurance programme for poor and near-poor uninsured adults). Approximately 10% of the sample screened positive for unhealthy substance use. Among these patients, most had unhealthy alcohol use (72.3%), 41.7% had any illicit drug use, and 30.0% had any marijuana

use. Few patients met criteria for high-risk alcohol or drug use (4.1% and 2.5%, respectively). A higher proportion of patients with unhealthy substance use had a mental disorder (p<0.0001) or significant medical comorbidity (p=0.04) relative to patients without unhealthy substance use. Primary care utilisation did not differ among patients with and without unhealthy substance use.

In bivariable analyses, patients with unhealthy substance use were significantly less likely to receive mammograms or flu vaccination than were patients

without unhealthy substance use (table 2). Women with unhealthy alcohol use were less likely to receive mammograms, while patients with any drug use were less likely to receive flu vaccination or mammograms ($p<0.05$ for all comparisons). Patients with and without unhealthy substance use did not differ in their receipt of colorectal or cervical cancer screening. Among women who were eligible for both a mammogram and a Pap smear, fewer women with unhealthy substance use (56.5%) completed both tests when compared with women without unhealthy substance use (64.5%, p=0.02).

In the multivariable model predicting receipt of mammograms, unhealthy substance use was significantly associated with a lower odds of mammogram receipt (OR 0.69, CI 0.59 to 0.80). Unhealthy substance use was also significantly associated with a lower odds of flu vaccination receipt (OR 0.80, CI 0.66 to 0.97). There were no significant interactions between gender and unhealthy substance use for either CRC screening or flu vaccination. Unhealthy substance use was not an independent predictor of receiving the other preventive services assessed (table 3).

DISCUSSION

Among this sample of patients engaged in primary care, women who screened positive for unhealthy substance use received mammography screening less frequently than women who screened negative. Similarly, men and women who screened positive for unhealthy substance use were less likely to receive flu vaccination than other patients. Not withstanding this identified disparity in the provision of preventive services, delivery of appropriate preventive clinical care in this primary care patient sample was remarkably high, when compared with national estimates.[35] We speculate that persons with unhealthy substance use who are not engaged in primary care at the high thresholds used in these analyses may have substantially lower receipt of preventive services.

Notably, patients with any drug use (which in this study was predominantly marijuana) were also less likely to receive mammography screening and flu vaccination. Because marijuana users are more likely to use tobacco,[36] lower receipt of flu vaccination may have particular clinical significance. Despite large numbers of patients with marijuana use, there are very few studies of

marijuana and health-services use.[37] Unexpectedly, the proportions of patients with cervical and CRC screening were not lower among persons with unhealthy substance use. It is possible that substance-using women are more likely to have unprotected sex, contract sexually transmitted diseases and then visit a women's health provider who may offer cervical-cancer screening.[38 39] Further, in the medical care system in which this study was performed, a Pap smear can be carried out at the time it is recommended, whereas a mammogram must be scheduled on a different day. This additional requirement to schedule a new appointment on a different day and arrange transportation, and possibly childcare, may explain why women with substance-use disorders had lower odds of receiving mammograms but were no less likely to receive Pap tests. CRC screening is the most complex of the screening services that we examined, potentially requiring advanced scheduling, administration of the preparation and having someone accompany the patient home after the procedure. Thus, there may be other factors more important than substance use affecting its completion. Furthermore, before stating that unhealthy substance use does not appear to be a barrier to completion of this most involved screening test, alternative possibilities merit examination such as disproportionately high numbers with evaluation of gastrointestinal bleeds in this population compensating for fewer with standard screening evaluations.

Prior studies found lower rates of CRC screening among veterans with substance-use disorders.[17 18] The lack of a difference in completion of CRC screening in our study between those with and without unhealthy substance use may be explained by inclusion of the spectrum from mild to severe in that definition, as opposed to limiting substance use to the most severe, those with substance-use disorders. Our finding of a lower frequency of mammogram and flu vaccination receipt and a similar frequency of Pap smear receipt among women with unhealthy substance use is consistent with prior studies.[15 18–20] Our study also showed a lower odds of mammogram receipt among English speakers. It is possible that unmeasured confounders such as low socio-economic status, low health literacy and lower levels of education may account for this finding. Our observation of a lower odds of mammogram receipt among individuals with psychiatric comorbidity is consistent with prior studies,[15] yet contradicts our prior work.[19] In the latter study, primary care and mental-health services were well integrated, which may have accounted for improved preventive screenings among persons with mental illness. It is also possible that individuals with psychiatric comorbidity are more likely to receive preventive services because of their more frequent contact with the health system. Yet, the presence of psychiatric comorbidity can also decrease the likelihood of receiving services if the service requires patient organisation to attend an appointment or to take a preparation. Our finding of a lower odds of Pap tests among women with medical comorbidity is consistent with prior studies.[40]

This study has several limitations. The findings from our sample of an inner-city patient population with health insurance and access to care who receive primary care at an urban safety-net hospital may not be generalisable to other patient populations. Yet, the fact that patients were insured and engaged in primary care helps to isolate the effect of substance use on service receipt. We also cannot determine whether unhealthy substance use causes patients not to receive certain services, or whether screening, brief intervention and substance-use treatment led some patients to complete screenings or vaccination. Further, the periods during which patients were screened for unhealthy substance use and were eligible to receive preventive services overlapped, but some patients may have been screened for unhealthy substance use before or after primary care visits in which prevention was addressed. For example, a patient may have been screened by colonoscopy several years ago, yet was found to have unhealthy substance use more recently. In such cases, it may be difficult to draw conclusions about the association between obtaining a colonoscopy and having substance use. However, the chronic, relapsing and remitting nature of substance use suggests that such use may influence preventive-healthcare utilisation over time.

We did not obtain any records of services performed outside Boston Medical Center. We believe that it is unlikely that patients receiving primary care at Boston Medical Center would have sought and received primary preventive care elsewhere, with the possible exception of the flu vaccine, which is widely available in the community. But even if patients had received services elsewhere, such use would have been associated with non-differential misclassification bias, as we suspect patients with unhealthy substance use are no more likely than other patients to obtain care in other health systems. In multivariable analyses, we observed higher rates of flu vaccination among those with psychiatric comorbidity. It is possible that such patients are less likely than others to seek preventive care outside Boston Medical Center. We relied on patient self-report of substance use. Others have found that self-report of substance use is valid when there are assurances of confidentiality and when validated tools are used.[23] While we used a validated tool, it is possible that some patients under-reported their substance use in the clinical setting. Such under-reporting would have biased our findings to the null.

CONCLUSION

In conclusion, our findings suggest that unhealthy substance use is a barrier to completion of mammography screening and flu vaccination. Future interventions to promote mammography screening might target women with unhealthy substance use, and those to promote flu vaccination might target both men and women with unhealthy substance use. Clinical interventions could embed mammography screening and flu vaccination in

other services delivered to individuals with substance-use problems. Training interventions could enhance skills and systems for healthcare personnel who screen for substance-use disorders to include referrals for preventive health services.

HEALTH CARE REFORM

Colorectal Cancer Screening Among Ethnically Diverse, Low-Income Patients

A Randomized Controlled Trial

Karen E. Lasser, MD, MPH; Jennifer Murillo; Sandra Lisboa, BA; A. Naomie Casimir, BA; Lisa Valley-Shah, RN, BSN, MM, CGRN; Karen M. Emmons, PhD; Robert H. Fletcher, MD; John Z. Ayanian, MD, MPP

Background: Patient navigators may increase colorectal cancer (CRC) screening rates among adults in underserved communities, but prior randomized trials have been small or conducted at single sites and have not included substantial numbers of Haitian Creole–speaking or Portuguese-speaking patients.

Methods: We identified 465 primary care patients from 4 community health centers and 2 public hospital–based clinics who were not up-to-date with CRC screening and spoke English, Haitian Creole, Portuguese, or Spanish as their primary language. We enrolled participants from September 1, 2008, through March 31, 2009, and followed them up for 1 year after enrollment. We randomly allocated patients to receive a patient navigation–based intervention or usual care. Intervention patients received an introductory letter from their primary care provider with educational material, followed by telephone calls from a language-concordant navigator. The navigators offered patients the option of being screened by fecal occult blood testing or colonoscopy. The primary outcome was completion of any CRC screening within 1 year. Secondary outcomes included the proportions of patients screened by colonoscopy who had adenomas or cancer detected.

Results: During a 1-year period, intervention patients were more likely to undergo CRC screening than control patients (33.6% vs 20.0%; $P<.001$), to be screened by colonoscopy (26.4% vs 13.0%; $P<.001$), and to have adenomas detected (8.1% vs 3.9%; $P=.06$). In prespecified subgroup analyses, the navigator intervention was particularly beneficial for patients whose primary language was other than English (39.8% vs 18.6%; $P<.001$) and black patients (39.7% vs 16.7%; $P=.004$).

Conclusions: Patient navigation increased completion of CRC screening among ethnically diverse patients. Targeting patient navigation to black and non–English-speaking patients may be a useful approach to reducing disparities in CRC screening.

Trial Registration: clinicaltrials.gov Identifier: NCT01141114

Arch Intern Med. 2011;171(10):906-912

COLORECTAL CANCER (CRC) is the second leading cause of cancer death in the United States and is preventable through screening.[1-3] Nevertheless, approximately 40% of eligible adults in the United States and more foreign-born US residents[4] are overdue for CRC screening.[5] Patients at greatest risk for not being screened include racial minorities,[6] patients with Medicaid or no health insurance coverage,[7] those who are foreign born,[8] and patients with low socioeconomic status.[9] Factors that may contribute to low screening rates among the urban poor with health insurance coverage and access to health care include lack of trust in physicians, an absence of symptoms, fatalistic views regarding cancer,[10] and the lack of a recommendation from a physician for screening.[10]

See Invited Commentary at end of article

Patient navigation is a way to address these barriers to screening. Patient navigators are laypersons from the community who guide patients through the health care system so that they receive appropriate services.[11] The navigators perform a wide range of advocacy and coordination activities, such as assisting patients in obtaining health insurance coverage or transportation to appointments.[12] Using flexible problem solving (rather than provision of a discrete set of services), patient navigators educate patients regarding the disease in question and address the needs of the individual patient. Finally, patient navigators provide social and emotional support to patients.

Several nonrandomized studies,[13-17] including our own,[13] have shown that patient navigation can increase rates of CRC

Author Affiliations are listed at the end of this article.

screening among urban, racial minority patients. One prior randomized study[18] of patient navigation for CRC screening was conducted at a single health center serving mostly patients who speak English or Spanish as their primary language. To build on this limited research, we conducted a randomized controlled trial of patient navigation that included immigrants from the Azores, Brazil, Haiti, and Portugal receiving care at 4 different health centers and 2 public hospital–based clinics in the safety-net health care system (ie, a health care system that provides a significant level of care to low-income, uninsured, and vulnerable populations).

METHODS

STUDY DESIGN

We performed a randomized controlled trial of patient navigation to promote CRC screening. We included a sample of patients aged 52 to 74 years who had not completed CRC screening according to US Preventive Services Task Force guidelines[19] (defined as colonoscopy in the past 10 years, sigmoidoscopy or double-contrast barium enema in the past 5 years, or fecal occult blood testing [FOBT] in the past year) and who spoke English, Haitian Creole, Portuguese, or Spanish as their primary language. We randomly assigned patients to receive a maximum of 6 hours of patient navigation in 6 months or usual care. The intervention encouraged FOBT or colonoscopy, the most frequently used screening tests at the study sites. The Cambridge Health Alliance Institutional Review Board approved the study protocol. The board provided a waiver of informed consent because the study was promoting an established screening standard.

SETTING AND PARTICIPANTS

We conducted the study at Cambridge Health Alliance, a primary care practice–based research network[20] composed of 15 community health centers. The health centers serve a multicultural, low-income population in Cambridge, Somerville, and Everett, Massachusetts. After pilot testing our intervention at 1 health center, we selected 6 primary care sites (4 health centers and 2 hospital-based clinics) that were not part of a Massachusetts Department of Public Health Patient Navigation Program to participate in the study. At the time of the study, all study sites used a common electronic health record (Epic Systems Corporation, Verona, Wisconsin) that supports computerized ordering of laboratory tests and referrals. Gastroenterologists perform colonoscopies at 1 of 3 hospital-based endoscopy centers.

We used the electronic clinical data system to identify patients at the primary care sites who were not up-to-date with CRC screening. We recruited patients aged 52 to 74 years who had had 1 visit to a primary care provider (PCP), ie, a physician or nurse practitioner, in each of the 2 previous years at 1 of the study sites. We limited the sample to patients who identified English, Haitian Creole, Portuguese, or Spanish, the most frequently spoken languages at Cambridge Health Alliance, as their primary language. Using explicitly predefined exclusion criteria, 1 of the study investigators (K.E.L.) performed manual medical record reviews, excluding patients if they had acute illness, an end-stage medical disease,[21] severe psychiatric conditions (such as psychosis, bipolar disorder, paranoia, or schizophrenia), active substance abuse, or cognitive impairment. The **Figure** shows the number of patients accrued, randomized, and assessed for the primary outcome. Of the 823 potentially eligible patients, 465 (56.5%) met study entry criteria.

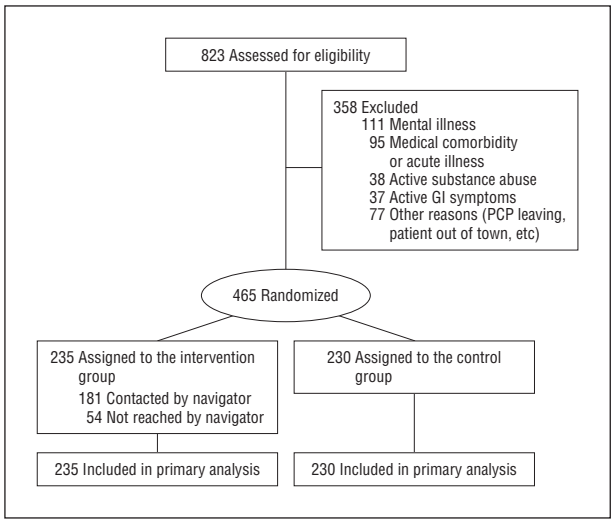

Figure. Consolidated Standards of Reporting Trials study flow diagram. GI indicates gastrointestinal; PCP, primary care provider (ie, a physician or nurse practitioner).

INTERVENTION

We randomly assigned patients to usual care or a maximum of 6 hours of patient navigation during a 6-month period. Some patients required little or no navigation. For example, those who had a previously scheduled colonoscopy appointment and reported that they understood the preparation instructions did not require navigation. For other patients, the maximum of 6 hours was spent contacting patients, educating them regarding CRC and CRC screening tests (FOBT and colonoscopy), motivating them to get screened, helping them decide which test to undergo, helping them obtain health insurance coverage, educating them regarding the correct way to complete FOBT cards, helping them make colonoscopy appointments and finding someone to accompany them home after the procedure, educating them regarding the required bowel preparation, and meeting them on the day of their colonoscopy.

We randomized individual patients, stratified by health center and primary language, using a computer-generated random number table. We enrolled participants from September 1, 2008, through March 31, 2009, and followed them up for 1 year after enrollment. In the intervention group, we sent letters by first-class mail, signed by the PCP of each patient, notifying patients that they were overdue for CRC screening and that a patient navigator would call them. The mailing also included a CRC screening brochure designed by the Harvard Center for Cancer Prevention and the Massachusetts Colorectal Cancer Working Group (*Take Control: Get Tested for Colorectal Cancer*).[22] The brochure, written at a sixth-grade reading level, offered information regarding reasons for screening and different screening modalities. We sent brochures to patients in English, French (for Haitian patients because the brochure was not available in Haitian Creole), Portuguese, or Spanish.

Intervention patients were also eligible to receive navigation from 3 trained navigators who were fluent in English and Spanish, Portuguese, or Haitian Creole. The navigators were based centrally in the Departments of Medicine and Community Affairs. The navigator who worked with Spanish-speaking patients was from Nicaragua, had completed some college-level education, had extensive experience performing community health outreach, and was also a certified nurse assistant. The Portuguese-speaking navigator had a bachelor's degree in clinical psychol-

ogy from Brazil and was an experienced community health worker. The Haitian Creole–speaking navigator was also an experienced community health worker who had completed some college-level education. The navigators were aged 48, 43, and 25 years, respectively. We did not encounter problems matching female navigators with male patients.

The navigators attended a 2-day training program October 4 and 5, 2007, and received additional training on August 22, 2008. The training program included lectures and role-play scenarios concerning the principles of motivational interviewing[23]; CRC and how patients can be screened for it; logistics (eg, how-tos, pros, and cons) of FOBT cards and colonoscopy; CRC prevention (including removal of adenomas); use of open-ended questions, reflective listening, and summarizing; assessment of the readiness of a patient for screening; and approaches for patients who refuse screening (precontemplation), are willing to consider it (contemplation), or are ready to act (action).[23] We based the intervention on a "stages of change" model because other cancer prevention studies[24] have successfully used this model.

During study implementation, the project manager (who also attended the training sessions) audited at least 5 patient calls by each navigator for adherence to a calling script and for motivational interviewing techniques. The patient navigators and the project manager also met on a weekly basis to discuss challenges arising during the outreach calls and to review the use of motivational interviewing techniques.

After randomization, the navigators contacted intervention patients during a 6-month period using a staged rollout procedure by site. Because of financial difficulties, 1 health center closed during the study period (with some patients transferring care to another study health center), and 2 study health centers each merged with other sites that were not part of the study. The navigators continued the intervention with patients at affected sites. Some patients in 2 of the study health centers received mailed outreach material from health center staff regarding CRC screening in early 2009, when planned care outreach became the community standard of care.

During a 3-week period, the patient navigators made as many as 11 attempts to call each patient on different days and times (including evenings and weekends). The navigators also left at least 2 messages for the patient on voice mail or with a family member. If the navigators were unable to contact patients initially, they sent a follow-up letter and made periodic attempts to contact patients during the remainder of the intervention period.

During the initial telephone contact, the navigators educated patients regarding CRC screening, explored barriers to screening, and addressed patients' barriers and their stage of change. For those who were contemplating screening, navigators discussed the screening options of colonoscopy and FOBT cards and the advantages and disadvantages of each test. The navigators presented the screening options in a neutral fashion and did not emphasize the superiority of any test compared with another. The navigators used flexible problem-solving techniques. For example, an elderly patient resisted the idea of colonoscopy because she was concerned that the preparation would make her weak and at risk for a fall. The navigator elicited this concern and suggested the alternative option of FOBT cards.

For patients who chose to complete FOBT cards, the navigator reviewed instructions and mailed FOBT cards and illustrated instructions via first-class mail. If a patient did not return the FOBT cards within 4 weeks, the navigator called the patient to provide support and address barriers to completion. For patients who opted for colonoscopy, the navigators described the test in detail, and the lead navigator contacted the PCP of the patient via the electronic medical record to arrange a colonoscopy referral. Patients with few comorbid medical conditions were referred directly for colonoscopy (also known as open-access colonoscopy); the patient did not require an initial visit with a gastroenterologist but met him or her on the day of the procedure. Patients with conditions such as sleep apnea or a history of problems with anesthesia were referred to a gastroenterologist to discuss colonoscopy. For patients referred directly to colonoscopy, a registered nurse or the lead navigator educated them regarding the procedure and the required bowel preparation, mailed instructions for bowel preparation, and scheduled the procedure.

The navigator worked with the nurse to schedule colonoscopies because the nurse oversaw the colonoscopy schedule. Gastroenterology staff placed reminder calls to all patients 1 day before their colonoscopy. If the navigators were unable to help patients to identify someone to escort them home after the colonoscopy, the navigators advised them to complete FOBT cards instead. For medicolegal reasons, the navigators did not accompany patients home. In some instances, the navigators met patients in the colonoscopy suite to offer emotional support. Some patients were having the first colonoscopy of their life and were fearful about the procedure.

For patients who were not contemplating performing any CRC screening test, the navigators assessed and addressed barriers. For example, for patients who did not have health insurance coverage, the navigators referred them to insurance counselors and worked closely with the insurance department to ensure that eligible patients received coverage. For other patients, the navigators would establish rapport by learning more about the lives of the patients (eg, whether patients were caring for grandchildren or an elderly parent). The navigators motivated some patients to undergo screening by pointing out that by taking care of their own health, patients would be able to continue caring for their family members.

OUTCOME MEASURES

Using a predefined algorithm, 1 study investigator (K.E.L.) performed medical record reviews masked to the intervention assignments to determine CRC screening rates within 1 year of the start of the intervention for all randomized patients. Medical records were reviewed twice to minimize error. We chose to analyze the data at 1 year because the average wait for a screening colonoscopy at the time of the study was approximately 4 months and we assumed that patients would have had sufficient time to complete their colonoscopy during the 1-year period. The primary outcome was completion of CRC screening (colonoscopy, FOBT, flexible sigmoidoscopy, or double-contrast barium enema) within 1 year. Although the navigators focused on helping patients choose between FOBT cards and colonoscopy, PCPs may have chosen to use other accepted screening modalities, namely, flexible sigmoidoscopy or double-contrast barium enema. Secondary outcomes included the proportion of patients screened by colonoscopy and the proportion in whom the screening detected adenomas or cancer. Another secondary outcome was the proportion of patients with high-risk lesions (classified as a dichotomous yes/no variable), defined as 3 or more adenomas of any type, adenomas 1 cm or larger, or adenomas with any villous features.

STATISTICAL ANALYSIS

We calculated that a sample size of at least 197 patients in each group would be required to show a minimum clinically important improvement in CRC screening of 10.0% (10.0% vs 20.0%), with a power of 80.0% and a 2-sided significance level of .05. We conducted all analyses on an intention-to-treat basis. Using χ^2 and Fisher exact tests for dichotomous variables, we performed prespecified subgroup analyses according to the

primary language, age, race, and health insurance coverage status of the patient because these factors are known to affect CRC screening rates.[25] All analyses were performed using SAS statistical software, version 9.1 (SAS Institute Inc, Cary, North Carolina), and we report 2-tailed *P* values or 95% confidence intervals for all comparisons.

RESULTS

PATIENT CHARACTERISTICS

The navigators contacted 181 of the 235 intervention patients (77.0%). The navigators made a median of 8.5 telephone calls (interquartile range, 7.0) to these patients, spending an average of 107 minutes (range, 4-335 minutes) on the telephone with each patient during the 6-month study period. The patient navigators were unable to contact the remaining 54 patients (22.9%) after a median of 10 attempted telephone calls (interquartile range, 7.0), including 34 patients whose telephone service had been intermittently disconnected and 8 patients whose initial outreach letters were returned to sender. Among patients who were and were not contacted, no statistically significant differences were observed in age, sex, race, primary language, or health insurance coverage status.

Table 1 lists the baseline demographic characteristics of the intervention and usual care groups; randomization resulted in groups with similar baseline characteristics. The mean age of the patients was 61.3 years. Most patients were women because women are more likely than men to seek primary care. A substantial proportion of patients were racial minorities and did not have private health insurance coverage. Almost half of patients in both groups spoke English as their primary language (48.2%), with the remainder speaking Portuguese (20.0%), Spanish (13.8%), or Haitian Creole (18.1%).

Table 1. Baseline Patient Characteristics[a]

Characteristic	Intervention, % (n=235)	Control, % (n=230)

Other	1.3	1.3

[a] These characteristics were not statistically significantly different between groups based on χ^2 tests for dichotomous variables and *t* tests for continuous variables. Data are presented as percentages unless otherwise indicated. Percentages may not total 100 because of rounding.

[b] Low-cost or no-cost health insurance coverage program for Massachusetts residents implemented in 2006 as part of the Massachusetts Health Reform Act.

[c] A health insurance coverage program for Massachusetts residents who are not eligible for private coverage or cannot afford it. It replaced the Uncompensated Care Pool (also called Free Care) on October 1, 2007.

OUTCOME MEASURES

A total of 33.6% of intervention patients had been screened by 1 year after study entry vs 20.0% of control patients (**Table 2**; $P<.001$). Intervention patients whom the navigators were able to contact were significantly more likely to be screened than those whom the navigators were unable to contact (39.8% vs 18.6%; $P<.001$). A larger proportion of intervention patients were screened by colonoscopy relative to controls (26.4% vs 13.0%; $P<.001$); similar numbers of intervention and control patients completed FOBT cards (7.2% vs 6.5%; $P=.76$). One control patient had a positive FOBT result that was not followed up with a colonoscopy; the remaining FOBT results were negative. Stratified analyses demonstrated that patient navigation was particularly beneficial for individuals whose primary language was other than English and for patients older than 60 years (Table 2). The intervention was more effective in white and black individuals relative to those of other or unknown race, and a somewhat smaller effect was observed in those with nonprivate vs private health insurance coverage. Because of the small numbers in some race categories, differences between individual race categories should be interpreted with caution.

Intervention patients were more likely to have adenomas detected than were controls (8.1% vs 3.9%; $P=.06$). High-risk adenomas were more frequently detected among intervention patients than among controls (2.5% vs 0.4%; $P=.06$). No colorectal adenocarcinomas were detected in either group.

COMMENT

Patient navigation increased CRC screening rates substantially among racially and linguistically diverse patients served by urban community health centers and public hospital–based clinics. Our study confirms the findings of smaller trials[15,17,20,26,27] and of a recent study[28] of culturally tailored telephone counseling by community health advisers and demonstrates that patient navigation is also effective among patients who speak Haitian Creole or Portuguese as their primary language. Because the Cambridge Health Alliance was undergoing serious financial problems, which led to health center closures and the departure of PCPs, we speculate that our intervention might have had an even stronger effect in a more stable health care system.

The fact that our intervention was effective may reflect the inclusion of several evidence-based components recommended by the Task Force on Community Preventive Services of the Centers for Disease Control and Prevention.[29] These components include client reminders through outreach letters, one-on-one education by the navigators, reduction of structural barriers

Table 2. Receipt of Colorectal Cancer Screening by Intervention Status

related to linguistic and cultural factors, and the inclusion of a mailed educational pamphlet. Although some of the patients in our study may not have been able to read the educational brochure, patients often showed the brochure to their PCP or to a more educated family member. Our intervention also included tailoring to the preferences of patients[30] and informed decision making,[31] elements that may have increased the willingness of patients to be screened. Other possibly beneficial features of the intervention included the lead navigators working closely with the nurse in the gastroenterology center who scheduled colonoscopies; navigators' communicating with PCPs via the electronic medical record, enabling the PCP to place orders for a screening test as soon as a patient chose one; and navigators' working evenings and weekends for greater flexibility in contacting patients. At the time of the intervention, the overall screening rate at the Cambridge Health Alliance was higher than the national average (61% in calendar year 2009) because it reflects patients who are engaged in primary care and who mostly have health insurance coverage. Despite the high baseline screening rate, our intervention was effective.

Strengths of our study are its inclusion of a racially diverse sample of patients from multiple health centers and public hospital–based clinics and its real-world setting. Our study has several limitations. Patients were from 1 geographic area, and some may have obtained CRC screening outside the Cambridge Health Alliance. The navigators were unable to contact 23.0% of intervention patients, which is not surprising given the mobile nature of urban immigrants with low socioeconomic status.[13] In the future, contact rates might be improved by using technology such as text messaging. Patients at some of the intervention health centers began to receive mailed outreach materials regarding CRC screening in early 2009; this may have diminished our intervention effect. We did not have access to data regarding country of birth, citizenship status, length of time in the United States, or level of acculturation for participants. We were also unable to determine which individual components of the intervention were most effective. Prior studies[32,33] have shown that letters have only a limited effect, suggesting that the navigation efforts may have largely accounted for the effectiveness of the intervention. Finally, we excluded patients with active substance use and mental illness documented on the problem list (18.1% of eligible patients); thus, our results may not be generalizable to these patients.

Patient navigation appears to be effective in increasing receipt of colorectal and cervical cancer screening.[34] Yet, clearly, hiring individual navigators for each type of screening would not be feasible. In Massachusetts, as part of a Department of Public Health Program, patient navigators now handle a variety of cancer screenings (breast, cervical, and colorectal) and also provide navigation to link patients to smoking cessation services. Future studies will need to determine whether such dissemination of patient navigation activities, in which an individual patient may receive far less than 1 to 2 hours of patient navigation regarding CRC screening, for example, still results in increased cancer screening. Finally, a need exists to examine the relative efficacy and cost-effectiveness of navigation compared with other viable alternatives (or complements), such as computerized tailored interventions offered in simple and easy-to-understand formats and in the primary language of the user.

As primary care practices are redesigned as medical homes,[35] nonphysician members of the health care team will increasingly take on tasks previously performed by PCPs (eg, counseling and connecting to services). Although the medical home concept is being adopted throughout the United States, its promise requires effective interventions that can be implemented within this new model. Patient navigation is 1 potential intervention that can be integrated into the medical home model. Again, future studies will need to explore whether patient navigation is effective within the context of the medical home.

In conclusion, our findings suggest that patient navigation may represent a powerful tool for increasing CRC screening rates among racially diverse patients. Focusing patient navigation on populations of patients who are black and whose primary language is other than English may be a particularly effective approach to reducing CRC screening disparities for these patients. Future research should assess how health care systems can sustain this benefit when patient navigation is implemented as a routine component of primary care.

Author Contributions: *Study concept and design:* Lasser, Emmons, Fletcher, and Ayanian. *Acquisition of data:* Lasser, Murillo, Lisboa, Casimir, and Valley-Shah. *Analysis and interpretation of data:* Lasser, Emmons, Fletcher, and Ayanian. *Drafting of the manuscript:* Lasser. *Critical revision of the manuscript for important intellectual content:* Murillo, Lisboa, Casimir, Valley-Shah, Emmons, Fletcher, and Ayanian. *Statistical analysis:* Lasser and Ayanian. *Obtained funding:* Lasser. *Administrative, technical, and material support:* Murillo, Lisboa, Casimir, and Valley-Shah. *Study supervision:* Murillo, Emmons, Ayanian, and Fletcher.
Financial Disclosure: None reported.
Funding/Support: This study was supported by Mentored Research Scholar Grant MRSGT-05-007-01-CPPB from the American Cancer Society.
Role of the Sponsors: This study was supported by the American Cancer Society. The funding source had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; or preparation, review, and approval of the manuscript.
Previous Presentations: This work was presented at the Society of General Internal Medicine Annual Meeting; April 30, 2010; Minneapolis, Minnesota; and at the Academy Health Annual Research Meeting; June 29, 2010; Boston, Massachusetts.
Additional Contributions: Meredith Manze D'Amore, MPH, provided assistance in manuscript preparation; Maxim D. Shrayer, PhD, provided comments on an early draft of the manuscript; neither individual was compensated. The Community Outreach and Enrollment Department at Cambridge Health Alliance provided assistance in helping patients obtain health insurance coverage.

INVITED COMMENTARY

Building Blocks of the Patient-Centered Medical/Health Home

The search for the patient-centered medical home resembles the quest for the Holy Grail. Yet no one is sure what this sacred vessel actually looks like. Elements of the patient-centered medical home have been identified by the National Committee on Quality Assurance requirements and meaningful use components from the US federal government (**Table**). Three articles in this issue of the *Archives* provoke thoughts regarding what primary care transformation—the Holy Grail—is all about.

In the study by Lasser et al,[1] patient navigators, who also could be called health care coaches, are community health care workers trained to guide patients through the health care system. Lasser et al found that patients contacted by language-concordant patient navigators are more likely than patients undergoing usual care to be screened for colorectal cancer.
