ANTITHROMBOTIC THERAPY AND PREVENTION OF THROMBOSIS, 9TH ED: ACCP GUIDELINES

Oral Anticoagulant Therapy

Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines

Walter Ageno, MD; Alexander S. Gallus, MBBS; Ann Wittkowsky, PharmD, FCCP; Mark Crowther, MD; Elaine M. Hylek, MD, MPH; and Gualtiero Palareti, MD

Background: **The objective of this article is to summarize the published literature concerning the pharmacokinetics and pharmacodynamics of oral anticoagulant drugs that are currently available for clinical use and other aspects related to their management.**
Methods: **We carried out a standard review of published articles focusing on the laboratory and clinical characteristics of the vitamin K antagonists; the direct thrombin inhibitor, dabigatran etexilate; and the direct factor Xa inhibitor, rivaroxaban.**
Results: **The antithrombotic effect of each oral anticoagulant drug, the interactions, and the monitoring of anticoagulation intensity are described in detail and discussed without providing specific recommendations. Moreover, we describe and discuss the clinical applications and optimal dosages of oral anticoagulant therapies, practical issues related to their initiation and monitoring, adverse events such as bleeding and other potential side effects, and available strategies for reversal.**
Conclusions: **There is a large amount of evidence on laboratory and clinical characteristics of vitamin K antagonists. A growing body of evidence is becoming available on the first new oral anticoagulant drugs available for clinical use, dabigatran and rivaroxaban.**

CHEST 2012; 141(2)(Suppl):e44S–e88S

For many decades, the vitamin K antagonists (VKAs) have been the only oral anticoagulant drugs available for clinical use for the primary and secondary prevention of venous and arterial thromboembolic events. VKAs have been consistently shown to be highly effective in many settings and are now used by millions of patients worldwide. Laboratory and clinical studies have contributed to understanding of the complex pharmacokinetics and pharmacodynamics of VKAs, their interactions, antithrombotic effects, and the risks associated with their use. Several studies have addressed the practical issues related to the management of patients on VKAs treatment, with particular focus on laboratory and clinical monitoring and on reversal strategies.

More recently, new oral anticoagulant drugs, namely the direct thrombin inhibitor dabigatran etexilate and the direct factor Xa inhibitor rivaroxaban, have been approved for clinical use in several countries. A growing body of laboratory and clinical data is becoming available to better understand the mechanisms of action and the optimal management of these new compounds. In this article we summarize the published literature concerning the pharmacokinetics and pharmacodynamics of all oral anticoagulant drugs that are currently available for clinical use and other aspects related to their management.

1.0 Vitamin K Antagonists

1.1 Pharmacology

VKAs produce their anticoagulant effect by interfering with the cyclic interconversion of vitamin K and its 2,3 epoxide (vitamin K epoxide), thereby modulating the γ-carboxylation of glutamate residues (Gla) on the N-terminal regions of vitamin K-dependent proteins (Fig 1).[1-8] The vitamin K-dependent coagulation factors II, VII, IX, and X require γ-carboxylation for their procoagulant activity, and treatment with VKAs results in the hepatic production of partially carboxylated and decarboxylated proteins with reduced coagulant activity.[9,10] Carboxylation is required for a calcium-dependent conformational change in coagulation proteins[11-13] that promotes binding to cofactors on phospholipid surfaces. In addition, the VKAs inhibit carboxylation of the regulatory anticoagulant proteins C, S, and Z and thereby have the potential to be procoagulant.[14] Although the anticoagulant effect of VKAs is dominant, a transient procoagulant effect may occur when baseline protein C and protein S levels are reduced due to the start of VKA therapy and the acute phase of a thrombotic event and before the balanced decrease of vitamin K-dependent clotting factor levels is achieved. Carboxylation requires the reduced form of vitamin K (vitamin KH_2), a γ-glutamyl carboxylase, molecular oxygen, and CO_2.[1] Vitamin K epoxide can be reused by reduction to VKH_2. The oxidation-reduction reaction involves a reductase pair. The first, vitamin K epoxide reductase, is sensitive to VKA, whereas vitamin K reductase is less sensitive.[1-3] Therefore, the anticoagulant effect of the VKAs can be overcome by low doses of phytonadione (vitamin K) (Fig 1).

1.2 Pharmacokinetics and Pharmacodynamics

Warfarin is a racemic mixture of two optically active isomers, the R and S enantiomers. Warfarin is highly water soluble, is rapidly absorbed from the gastrointestinal tract, has high bioavailability,[15,16] and reaches maximal blood concentrations about 90 min after oral administration.[15,17] Racemic warfarin has a half-life of 36 to 42 h[18] (R-warfarin 45 h, S-warfarin 29 h), circulates bound to plasma proteins (mainly albumin), and accumulates in the liver where the two enantiomers are metabolically transformed by different pathways (Fig 1).[18] The S enantiomer of warfarin (2.7-3.8 times more potent than the R enantiomer) undergoes approximately 90% oxidative metabolism, primarily by the CYP2C9 enzyme of the cytochrome P450 system and to a lesser extent by CYP3A4.[19] The less potent R enantiomer undergoes approximately 60% oxidative metabolism, primarily by two cytochrome P450 enzymes, CYP1A2 and CYP3A4, and to a lesser extent by CYP2C19. The remainder of the metabolism of both enantiomers involves reduction to diastereomeric alcohols. The relationship between the dose of warfarin and the response is modified by genetic and environmental factors that can influence the absorption of warfarin, its pharmacokinetics, and its pharmacodynamics.

Other available VKAs include acenocoumarol, phenprocoumon, and fluindione. Like warfarin, acenocoumarol and phenprocoumon also exist as optical isomers, but with different stereochemical characteristics. R-acenocoumarol has an elimination half-life of 9 h, is primarily metabolized by CYP2C9 and CYP2C19, and is more potent than S-acenocoumarol because of faster clearance of S-acenocoumarol, which has an elimination half-life of 0.5 h and is primarily metabolized by CYP2C9.[20] Phenprocoumon is a much longer-acting agent, with both the R- and S-isomers having elimination half-lives of 5.5 days. Both are metabolized by CYP2C9, and S-phenprocoumon is 1.5 to 2.5 times more potent than R-phenprocoumon.[21] Finally, fluindione is an indandione VKA with a mean half-life of 31 h.[22] Unlike warfarin, fluindione is not a chiral compound.[22]

1.3 Interactions

1.3.1 Genetic Factors: A number of point mutations in the gene coding for the CYP2C9 have been identified.[23] These polymorphisms, the most common of which are CYP2C9*2 and CYP2C9*3, are associated with an impaired ability to metabolize S-warfarin, resulting in a reduction in S-warfarin clearance and,

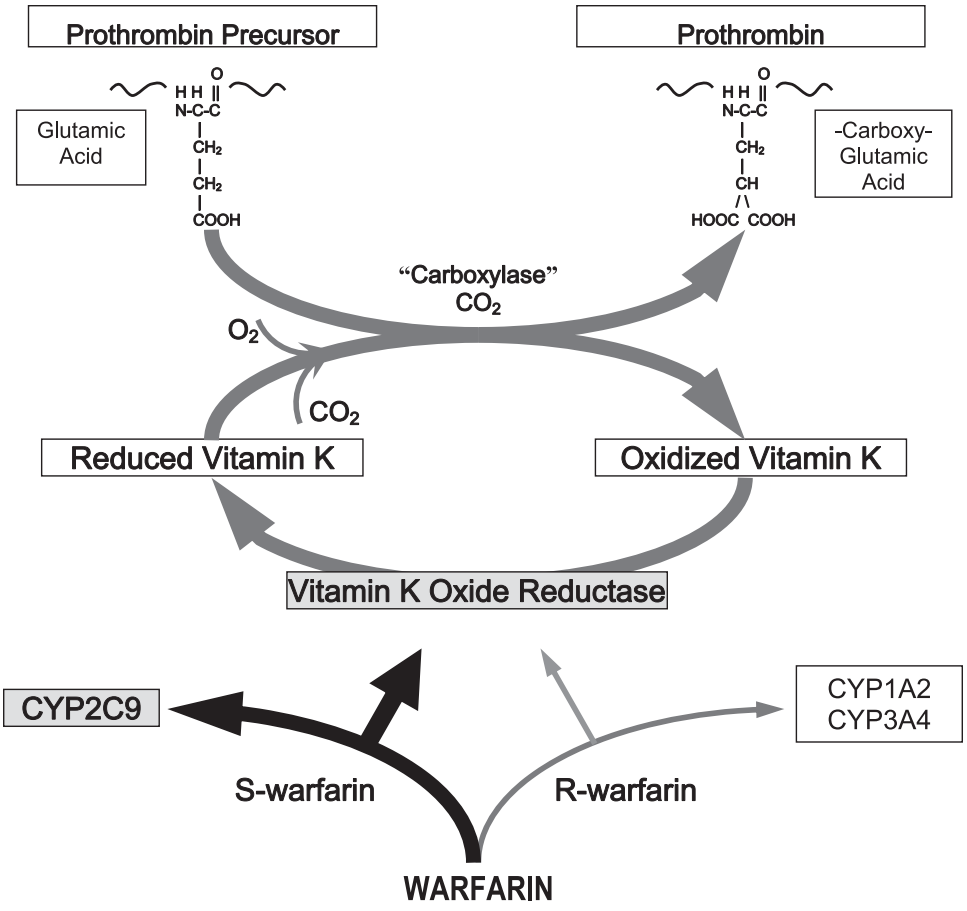

FIGURE 1. [Section 1.1] Vitamin K_1 is reduced to vitamin KH2. The major warfarin-sensitive enzyme in this reaction is the vitamin K oxide reductase mainly inhibited by the S-enantiomer of warfarin. S-warfarin is metabolized by the p450 cytochrome enzyme, CYP2C9. Reprinted with permission from Ansell et al.[8]

as a result, an increased S-warfarin elimination half-life.[24] Mutations in this gene occur with different frequencies in various ethnic groups (Table S1).[25,26] In comparison with patients who are homozygous for the wild-type allele (CYP2C9*1*1), patients with heterozygous (CYP2C9*1*2, CYP2C9*1*3, CYP2C9*2*3) or homozygous (CYP2C9*2*2, CYP2C9*3*3) expression of a variant allele require lower doses of warfarin, as determined by a systematic review of the literature and meta-analysis of studies that assessed the influence of CYP2C9 polymorphisms on warfarin dose requirements (Table S2).[27] Several investigations[25,28,29] have shown that these mutations, as well as others,[30-32] are also associated with an increase in bleeding complications associated with warfarin therapy. Mutations in CYP2C9 also affect acenocoumarol, although to a lesser degree because the anticoagulation potencies of the R and S enantiomers are comparable.[33,34] The effects of CYP2C9 polymorphisms are least pronounced with the use of phenprocoumon.[33,35]

The target for warfarin's inhibitory effect on the vitamin K cycle is the vitamin K oxide reductase (VKOR) enzyme first described in 1974.[36] The gene coding for the VKOR protein is located on the short arm of chromosome 16.[37,38] The gene encodes for several isoforms of a protein that are collectively termed the vitamin K oxide reductase complex 1 (VKORC1). Subsequently, mutations in this gene have been identified leading to enzymes with varying sensitivities to inhibition by warfarin,[38-43] thereby affecting the pharmacodynamics of warfarin. The mutations occur with differing frequencies in various ethnic populations and account, in part, for the difference in warfarin doses required to maintain a therapeutic international normalized ratio (INR) (Table S1) (tables that contain an "S" before the number denote supplementary tables not contained in the body of the article and available instead in an online data supplement; see the "Acknowledgments" for more information).[39-41,44,45]

Genetic mutations in the gene coding for the VKORC1often involve several mutations leading to various haplotypes that cause greater resistance to warfarin therapy. Harrington et al[43] found a warfarin-resistant individual who had high serum warfarin

concentrations and a 196G>A transition, predicting a Val66Met substitution in VKORC1. D'Andrea et al,[39] studying 147 patients, found that those with a 1173CC genotype required a higher mean maintenance dose compared with those with a CT or TT genotype, as did Quiteineh et al,[46] who found that a 1173 C>T polymorphism was significantly associated with the risk of anticoagulant overdose. By identifying a number of noncoding single nucleotide polymorphisms, Rieder et al[40] were able to infer that there are five major haplotypes associated with different dose requirements for maintaining a therapeutic INR. The maintenance dose ranged from a low of 2.7 mg warfarin per day for the sensitive haplotypes up to a high of 6.2 mg per day for the resistant haplotypes. Asian Americans had the highest proportion of sensitive haplotypes, whereas African Americans more frequently exhibited the resistant haplotypes (Table S1).

1.3.2 Drugs: VKAs are highly susceptible to drug-drug interactions. For warfarin, for example, manufacturer-provided product information lists >200 specific agents that may interfere with this agent.[47] Unfortunately, there seems to be little concordance among commonly used drug compendia and product labels with respect to interactions involving warfarin. Indeed, a major problem with the literature on this topic is that many reports are single-case reports and are not well documented. Anthony et al[44] recently reviewed three drug information compendia, Clinical Pharmacology, ePocrates, and Micromedex, and the warfarin sodium (Coumadin) product label approved by the US Food and Drug Administration, for listings of interactions between warfarin and drugs, biologics, foods, and dietary supplements and found that of a total of 648 entries from the four sources, only 50 were common to all the sources.[44] As in the previous edition of this article,[8] Table 1 summarizes a comprehensive list of drugs that potentiate, inhibit, or have no effect on the anticoagulant effect of warfarin based on the results of a systematic review of available evidence completed in 2005, which rated warfarin drug interaction reports according to interaction direction, clinical severity, and quality of evidence, and developed lists of warfarin drug interactions considered highly probable, probable, possible, and highly improbable.[48]

Drugs such as cholestyramine can reduce the anticoagulant effect of warfarin by reducing its absorption. Other drugs potentiate the anticoagulant effect of warfarin by inhibiting its clearance, whereas some drugs may inhibit the anticoagulant effect by enhancing its clearance.[49] These latter effects may be through stereoselective or nonselective pathways,[50,51] (stereoselective interactions may affect the oxidative metabolism of either the S-enantiomer or R-enantiomer of warfarin). The inhibition of S-warfarin metabolism is more important clinically, because this enantiomer is more potent than the R-enantiomer as a VKA.[50,51] Phenylbutazone,[52] sulfinpyrazone,[53] metronidazole,[54] and trimethoprimsulfamethoxazole[55] inhibit the clearance of S-warfarin, and each potentiates the effect of warfarin on the prothrombin time (PT). In contrast, drugs such as cimetidine and omeprazole, which inhibit the clearance of the R-isomer, potentiate the PT only modestly in patients who are treated with warfarin.[51,54,56] Amiodarone is a potent inhibitor of the metabolic clearance of both the S-enantiomer and the R-enantiomer and potentiates warfarin anticoagulation.[57] The anticoagulant effect of warfarin is inhibited by drugs like barbiturates, rifampin, azathioprine, and carbamazepine, which increase its clearance by inducing hepatic metabolism.[58] Azathioprine also reduces the anticoagulant effect of warfarin, presumably through a potentiating effect on hepatic clearance.[59] Long-term alcohol consumption has a similar potential to increase the clearance of warfarin, but ingestion of even relatively large amounts of wine had little influence on the PT in normal volunteers who were given warfarin.[60] The effect of enzyme induction on warfarin therapy has been analyzed in a critical review.[58] Ten hepatic microsomal enzyme agents were assessed. Enzyme induction of warfarin metabolism by rifampin and barbiturates was considered likely, and an interaction with carbamazepine, griseofulvin, aminoglutethimide, nafcillin, and dicloxacillin was considered probable.

Drugs may also influence the pharmacodynamics of warfarin by inhibiting the synthesis of or increasing the clearance of vitamin K-dependent coagulation factors or by interfering with other pathways of hemostasis. The anticoagulant effect of warfarin is augmented by second-generation and third-generation cephalosporins, which inhibit the cyclic interconversion of vitamin K;[61,62] by thyroxine, which increases the metabolism of coagulation factors;[63] and by clofibrate through an unknown mechanism.[64] Doses of salicylates of >1.5 g per day[65] may augment the anticoagulant effect of warfarin. Acetaminophen potentiates the effect of warfarin when used over prolonged periods of time, as demonstrated in a recent randomized, blinded trial.[66-68] Acetaminophen possibly potentiates the anticoagulant effect of warfarin through inhibition of VKOR by a toxic metabolite of the drug,[69] although the accumulation of this metabolite may vary among individuals, thus accounting for a variable potentiating effect.[70] Heparin potentiates the anticoagulant effect of warfarin, but in therapeutic doses produces only a slight prolongation of the PT. The mechanisms by which erythromycin[71] and some anabolic steroids[72] potentiate the anticoagulant effect of

Table 1—*[Section 1.3.2] Drug, Food, and Dietary Supplement Interactions With Warfarin by Level of Supporting Evidence and Direction of Interaction*

Data from Holbrook et al.[48]

warfarin are unknown. Sulfonamides and several broad-spectrum antibiotic compounds may augment the anticoagulant effect of warfarin in patients consuming diets that are deficient in vitamin K by eliminating bacterial flora and aggravating vitamin K deficiency.[73]

Drugs such as aspirin,[74] nonsteroidal antiinflammatory drugs,[75,76] penicillins in high doses,[77,78] and moxalactam[62] increase the risk of warfarin-associated bleeding by inhibiting platelet function. Of these, aspirin is the most important because of its widespread use and prolonged effect.[79,80] Aspirin and nonsteroidal antiinflammatory drugs can also produce gastric erosions that increase the risk of upper GI bleeding. This can occur even with COX-2 inhibitors, which were originally believed to be less likely to predispose to gastric bleeding than nonsteroidal antiinflammatory drugs.[76] In one case-controlled analysis of 98,821 subjects on warfarin identified in linked databases, celecoxib and rofecoxib were associated with a 1.7- or 2.4-fold increased risk of GI hemorrhage, respectively.[76] The risk of clinically important bleeding is heightened when high doses of aspirin are taken during high-intensity warfarin therapy (INR, 3.0-4.5).[74,81] However, low doses of aspirin (ie, 75 to 100 mg daily) combined with moderate-intensity and low-intensity warfarin anticoagulation therapy are also associated with increased rates of bleeding.[82,83] The effect of statins or fibrates on the risk of bleeding in patients on VKAs is controversial. The initiation of a fibrate or statin that inhibits CYP3A4 enzymes was recently reported to increase the risk of gastrointestinal bleeding in warfarin-treated patients, whereas other statins that are mainly excreted unchanged were not found to be associated with such an increased risk.[84] Conversely, other authors reported that long-term statin use is associated with a decreased risk of bleeding complications in patients with atrial fibrillation (AF) on warfarin therapy.[85]

The most effective method to avoid adverse outcomes associated with drug interactions is to try to avoid, when feasible, concurrent use of potentially interacting drugs and to use noninteracting alternatives instead. When noninteracting alternatives are not available, adverse outcomes can be avoided by increasing the frequency of monitoring and adjusting warfarin doses based on INR response. Prospective dosing adjustments are inappropriate because of the unpredictable nature of patient response to drug interactions (see Holbrook et al[86] in this supplement).

1.3.3 Environmental Factors: Nutritional supplements and herbal products are particularly problematic in that warfarin-treated patients often fail to inform physicians that they are using such products and physicians rarely ask. In one survey of 1,200 patients from four large anticoagulation clinics (ACs) in the

United States, one-third of the patients used dietary supplements and one-third of all patients surveyed indicated that their provider failed to discuss potential interactions with them.[87] There is also little or no standardization of the content of such products, especially herbal remedies, and reports of interactions are often anecdotal or single-case reports, without good substantiation.[88-91] Of the higher-quality studies, ginkgo and ginger were shown not to have an effect on the pharmacokinetics and pharmacodynamics of warfarin in healthy subjects in a randomized, open-label, crossover, study,[92] and coenzyme Q_{10} (and ginkgo) was shown not to have an effect on warfarin dosage in a randomized, double-blind, crossover study.[93] Ginseng was shown to reduce the effect of warfarin in a randomized, placebo-controlled trial.[94] Not surprisingly, products such as green tea, with a high content of vitamin K, were shown to reduce the anticoagulant effect of warfarin.[48]

Subjects receiving long-term warfarin therapy are sensitive to fluctuating levels of dietary vitamin K,[95,96] which is derived predominantly from phylloquinones in plant material.[96] Sadowski and associates[97] have listed the phylloquinone content of a wide range of food, and the list can be found on the Internet (http://ods.od.nih.gov/factsheets/cc/coumadin1.pdf). Phylloquinones act through the warfarin-insensitive pathway.[98] Important fluctuations in vitamin K intake can occur in both healthy and sick subjects.[99] An increased intake of dietary vitamin K that is sufficient to reduce the anticoagulant response to warfarin occurs in patients consuming green vegetables or vitamin K-containing supplements, during weight-reduction diets, and in patients who have been treated with vitamin K supplements.[100] Reduced dietary vitamin K intake potentiates the effect of warfarin in ill patients who have been treated with antibiotics and IV fluids without vitamin K supplementation and in patients who have states of fat malabsorption.

In general, a consistent intake of vitamin K-containing foods is advisable, but neither specific restrictions nor additions seem necessary in patients with stable anticoagulant control. Patients should be informed of possible changes in INR, in particular in response to the use of dietary supplements or herbs, or alcohol used chronically or ingested in large quantities.[101,102] More frequent monitoring of the INR should be proposed if dietary habits have substantially changed in response to weight reduction diets, periods following hospitalization, treatment with chemotherapy, sustained diarrhea or vomiting, or in case of anorexia.[103]

A number of other conditions and disease states have been observed to influence anticoagulation with warfarin. Hepatic dysfunction potentiates the response to warfarin through the impaired synthesis of coagulation factors.[104] These patients may appear to be "auto-anticoagulated" with baseline elevated INRs, but the degree of suppression of clotting factors does not mimic that of patients treated with warfarin and is not sufficient to prevent thromboembolism.[105] Hypermetabolic states produced by fever or hyperthyroidism increase warfarin responsiveness, probably by increasing the catabolism of vitamin K-dependent coagulation factors.[70,106] Certain components of cigarette smoke may induce CYP1A2, and warfarin dosing requirements have been observed to decline after smoking cessation.[107,108] Chewing tobacco contains high quantities of vitamin K that can increase warfarin dose requirements.[109] Exacerbations of heart failure can increase responsiveness to warfarin therapy, likely in response to the effect of hepatic congestion on warfarin metabolism.[110] End-stage renal disease is associated with reduced activity of CYP2C9, leading to lower warfarin dosing requirements in these patients.[111] Warfarin dosing requirements decline with advanced age as a result of reduced availability of vitamin K stores and lower plasma concentrations of vitamin K-dependent clotting factors.[112-114] In fact, age may be the single most important easily obtained predictor of warfarin dosing requirement.[115]

1.4 Antithrombotic Effect

The antithrombotic effect of VKAs is attributed to their anticoagulant effect, which in turn is mediated by the reduction of four vitamin K-dependent coagulation factors. The experiments of Wessler and Gitel[116] >40 years ago using a stasis model of thrombosis in rabbits showed that the antithrombotic effect of warfarin requires 6 days of treatment and requires the reduction of prothrombin (factor II), which has a relatively long half-life of about 60 to 72 h, compared with 6 to 24 h for other vitamin K-dependent factors. In a rabbit model of tissue factor-induced intravascular coagulation, the protective effect of warfarin mainly resulted from lowering prothrombin levels.[117] Patel and associates[118] demonstrated that clots formed from umbilical cord plasma containing about half the prothrombin concentration of plasma from adult control subjects generated significantly less fibrinopeptide A than clots formed from maternal plasma. The view that warfarin exerts its antithrombotic effect by reducing prothrombin levels is consistent with observations that clot-bound thrombin is an important mediator of clot growth[119] and that reduction in prothrombin levels decreases the amount of thrombin generated and bound to fibrin, thereby reducing thrombogenicity.[118]

The suggestion that the antithrombotic effect of VKAs is reflected in lower levels of prothrombin forms the basis for overlapping the administration of

a parenteral anticoagulant with warfarin until the PT or INR is prolonged into the therapeutic range during the treatment of patients with thrombosis. Since the half-life of prothrombin is about 60 to 72 h, at least 5 days of overlap is necessary.

1.5 Monitoring Anticoagulant Intensity: the INR

The PT test[120] is the most common test used to monitor VKA therapy. The PT responds to a reduction of three of the four vitamin K-dependent procoagulant clotting factors (ie, II, VII, and X) that are reduced by warfarin at a rate proportional to their respective half-lives. Thus during the first few days of warfarin therapy the PT reflects mainly a reduction of factor VII, the half-life of which is approximately 6 h. Subsequently, the reduction of factors X and II contributes to prolongation of the PT. The PT assay is performed by adding calcium and thromboplastin to citrated plasma. Thromboplastins vary in responsiveness to a reduction of the vitamin K-dependent coagulation factors. An unresponsive thromboplastin produces less prolongation of the PT for a given reduction in vitamin K-dependent clotting factors than a responsive one. The responsiveness of a thromboplastin can be measured by assessing its international sensitivity index (ISI) (see later discussion in this section). Highly sensitive thromboplastins (indicated by an ISI of approximately 1.0) are now available that are composed of human tissue factor produced by recombinant technology and defined phospholipid preparations.

PT monitoring of VKA treatment is not standardized when expressed in seconds, or as a simple ratio of the patient plasma value to that of plasma from a healthy control subject, or as a percentage of diluted normal plasma. A calibration model,[121] which was adopted in 1982, is now used to standardize reporting by converting the PT ratio measured with the local thromboplastin into an INR, calculated as follows:

$$\text{INR} = (\text{patient PT}/\text{mean normal PT})^{\text{ISI}}$$

or

$$\log \text{INR} = \text{ISI}(\log \text{observed PT ratio})$$

where ISI denotes the ISI of the thromboplastin used at the local laboratory to perform the PT measurement. The ISI reflects the responsiveness of a given thromboplastin to the reduction of the vitamin K-dependent coagulation factors compared with the primary World Health Organization (WHO) international reference preparations, so that the more responsive the reagent, the lower the ISI value.[121] It is proposed that patients' samples for calibration should be selected by rejecting samples beyond the 1.5 to 4.5 INR range.[122] Outliers, defined as points with a perpendicular distance greater than three residual SDs from the line of relationship, should be rejected. Selection of patients' samples and rejection of outliers results in a reduction of the between-laboratory variation of calibration.[122]

As the INR standard of reporting was widely adopted, a number of problems surfaced. These are listed in Table 2 and are reviewed briefly here.

The INR is based on ISI values derived from the plasma of patients who had received stable anticoagulant doses for at least 6 weeks.[123] As a result, the INR has not been validated and should be viewed with some skepticism early in the course of warfarin therapy, particularly when results are obtained from different laboratories. Even under these conditions,

Table 2—*[Section 1.5] Potential Problems With the INR (Causes of Erroneous INR)*[8]

Problems	Description
1. Incorrect PTR from erroneous PT determination due to	
Pretest variables (sampling and blood collection problems)	Trisodium-citrate concentration, storage time, storage temperature, evacuated tube effects, inadequate sample, variations in manual technique
Incorrect normal value	From nonuse of MNPT, error in MNPT due to unrepresentative selection, technical faults (see above), nonuse of geometric mean
2. Incorrect ISI of local thromboplastin reagent/test system from lack of reliability of the ISI result provided by the manufacturer	Incorrect choice of IRP, poor distribution of coumarin test samples across treatment range, inadequate numbers of test samples in ISI calibration, incorrect transformation of PTR of test plasmas to INR
3. Drift of ISI since original calibration	
4. Instrument (coagulometer) effects on INR at local site	
5. Lupus anticoagulant effects on some thromboplastin reagents	
6. Lack of reliability of the INR system when used at the onset of warfarin therapy and for screening for a coagulopathy in patients with liver disease	
7. Relative lack of reliability of INR > 4.5 as these values excluded from ISI calibrations	

INR = international normalized ratio; IRP = international reference preparation; ISI = international sensitivity index; MNPT = mean normal prothrombin time; PT = prothrombin time; PTR = prothrombin time ratio.

however, the INR is more reliable than the unconverted PT ratio,[124] and its use is thus recommended during both the initiation and maintenance of VKAs.

The validity of the INR in other conditions of impaired coagulation has been less frequently evaluated. Some authors have recently challenged the use of the INR in patients with liver disease and in particular in prognostic scores such as the Model for End-stage Liver Disease.[125,126] Thus, a new INR specific for liver diseases has been proposed, derived by using plasma from patients with liver diseases to calibrate thromboplastins instead of plasma from patients on oral anticoagulant treatment with VKAs.[125,126]

The accuracy of the INR can be influenced by reagents with different sensitivities[127] and also by the automated clot detectors now used in most laboratories.[128-135] In general, the College of American Pathologists has recommended[136] that laboratories should use thromboplastin reagents that are at least moderately responsive (ie, ISI < 1.7) and reagent/instrument combinations for which the ISI has been established and validated.

ISI values provided by the manufacturers of thromboplastin reagents are not invariably correct when applied locally,[137-139] and this adversely affects the reliability of measurements. Local calibrations can be performed using plasma samples with certified PT values to determine the instrument-specific ISI. The mean normal plasma PT is not interchangeable with a laboratory control PT.[140] Therefore, the use of other than a properly defined mean normal PT can yield erroneous INR calculations, particularly when less-responsive reagents are used. The mean normal PT should be determined for each new batch of thromboplastin with the same instrument used to assay the PT.[140]

The concentration of citrate that is used to anticoagulate plasma may affect the INR.[141,142] In general, higher citrate concentrations (eg, 3.8%) lead to higher INR values,[141] and underfilling the blood collection tube spuriously prolongs the PT because excess citrate is present. Using collection tubes containing 3.2% concentrations of citrate for blood coagulation studies and adequately filling tubes can reduce this problem.

1.6 Practical Issues Related to Initiation and Maintenance

1.6.1 Approaches to the Induction of VKAs: Following the administration of VKAs, an initial effect on the INR usually occurs within the first 2 or 3 days, depending on the dose administered, and an antithrombotic effect occurs within the next several days.[143,144] There is room for flexibility in selecting a starting dose of warfarin. The results of clinical studies suggest that initiation doses between 5 and 10 mg are effective,[143,145,146] with individual responses varying according to the inpatient or outpatient status, age, concomitant treatments, and comorbidities. Thus, starting doses of ≤ 5 mg might be appropriate in the elderly, in patients with impaired nutrition, liver disease, or congestive heart failure, and in patients who are at high risk of bleeding.[112,115,147,148] An initial dose of 2 to 3 mg seems to be appropriate for patients who have undergone heart valve replacement, given their higher sensitivity to VKAs probably caused by the effects of cardiopulmonary bypass and concomitant therapies.[149] Recommendations are provided in Holbrook et al.[86]

As described in section 1.2.1, CYP2C9 genotype and VKORC1 haplotype influence warfarin dosing requirements. In response to these observations, numerous investigators have attempted to assess the combined influence of patient factors on warfarin dosing requirement, with a goal of developing models to predict warfarin dose requirements based on assessment of various environmental and genetic factors.

Sconce et al[42] found that a combination of CYP2C9 and VKORC1 genotypes plus height produced the best predictive model for estimating warfarin dose, whereas Vecsler et al[150] reported that CYP2C9 and VKORC1 genotypes together with age and body weight could explain as much as 63% of the dose variance, and Herman et al[151] could attribute 60% of dose variability to CYP2C9 and VKORC1polymorphisms, age, and body surface area. Limdi et al[152] found that CYP2C9 and VKORC1 polymorphisms accounted for 30% of the variability in warfarin dose among European Americans but only for 10% among African Americans. In a prospective cohort study of 48 consecutive patients starting warfarin for postorthopedic surgery prophylaxis, the patients with a variant CYP2C9 allele had a greater than fourfold increase in the risk of the INR exceeding 4.0. However, this substantial increase in the risk of supratherapeutic INR was observed despite the fact that all patients had their warfarin dose selected using a complex algorithm that considered CYP2C9 genotype.[153]

Gage et al[154] developed a dosing algorithm based on CYP2C9 and VKORC1 polymorphisms along with clinical and demographic factors. In the derivation cohort of 1,015 patients on warfarin therapy, body surface area, age, target INR, amiodarone use, smoker status, race, current thrombosis, VKORC1 polymorphism 1639/3673 G>A, CYP2C9(*)3, and CYP2C9(*)2 were all independent predictors of warfarin therapeutic dose.

Three prospective studies have compared the time in therapeutic range (TTR; see section 1.6.2 "Evaluating the Quality of Monitoring: TTR") of patients using a pharmacogenetics-based dosing strategy with the TTR achieved when patients were managed

without knowledge of genotype.[155-157] Two of these studies showed no difference in TTR, whereas one study reported increased times in range for the pharmacogenetic group but had significant design flaws. More recently, Klein et al[158] developed two dosing algorithms: one based on clinical variables only and one based on both clinical variables and genetic information. The ability of these two algorithms to predict subsequent warfarin doses was then compared in a validation cohort of > 1,000 patients. The pharmacogenetic algorithm more accurately identified patients who required ≤ 21 mg weekly warfarin doses and patients who required weekly doses of ≥ 49 mg in comparison with the clinical algorithm and to a fixed-dose approach, whereas no difference was detected in the prediction of intermediate doses.

A few studies have suggested that certain genotypes are associated with adverse events. Thus, Higashi et al[29] studied 185 patients, 58 with at least one variant genotype of CYP2C9, and found an increased risk of having INRs above range (hazard ratio [HR], 1.40; 95% CI, 1.03-1.90) and of a serious or life-threatening bleeding event (HR, 2.39; 95% CI, 1.18-4.86) in those with variant genotypes. The latter hazard estimate was based on a few events in a very small number of patients with the variant genotypes. Joffe et al,[159] also studying CYP2C9 single nucleotide polymorphisms, found a trend toward increased rates of an INR > 6.0 and of bleeding in patients who were categorized as heterozygotes, or compound heterozygotes/homozygotes, compared with those categorized as wild type, as did Veenstra et al.[30] A similar increased risk of bleeding was seen in patients with these polymorphisms who were taking acenocoumarol but not phenprocoumon.[32] On the other hand, neither CYP2C9 nor VKORC1influenced the risk of bleeding in a more recent study by Limdi et al.[160]

Likewise, the only high-quality, randomized, controlled trial performed to date showed that use of a pharmacogenetic-based dosing strategy did not significantly reduce the risk of adverse events (34.7% in pharmacogenetic group vs 42.4% in control group; OR = 0.72; 95% CI, 0.41-1.28]).[155] This issue is further discussed and recommendations are provided in Holbrook et al.[86]

When rapid anticoagulant effect is required, a rapidly acting parenteral anticoagulant should be started together with the VKA and discontinued after at least 5 days of concomitant therapy and once the INR has been in the therapeutic range for at least two measurements approximately 24 h apart. This allows factors X and II to be reduced to levels sufficient to treat VTE. If there is no urgent need for an immediate anticoagulant effect (eg, in chronic stable AF), warfarin administration can be commenced without the concurrent use of a rapid-acting anticoagulant.

1.6.2 Evaluating the Quality of Monitoring: TTR: The relationship between the intensity of treatment and the risk of an adverse event has been evaluated by examining the frequency of such events as a function of the TTR.[161-163] A strong relationship between TTR and the rates of bleeding or thromboembolic events has been observed across studies[161-173] with different patient populations, different target ranges, different scales for measuring intensity of anticoagulation (ie, PT, PT ratio, and INR), different methods of measuring TTR, and different models of dose management. In a large, retrospective analysis of patients with mechanical heart valves, Cannegieter et al[164] found that risks of major bleeding or thromboembolism were greatly increased during the times when patients were above or below the therapeutic range of INR compared with times when they were within range. A similar relationship has been demonstrated for other groups of patients.[169,174] A recent substudy examined the influence of TTR on the relative effectiveness of warfarin and dual antiplatelet therapy with aspirin plus clopidogrel in patients with nonvalvular AF, in which the overall result favored warfarin.[165] In this large retrospective analysis, the TTR during warfarin therapy appeared to be a major determinant of its efficacy, since the advantage of warfarin over antiplatelet therapy was lost below a threshold TTR of between 58% and 65%.[165] The percentage of INRs or TTR is highly dependent on the quality of dose management as reflected in studies that report TTR. Poor quality of dose management results in a high proportion of low INRs during the first 3 months of treatment following an acute DVT, which in turn predicts a higher rate of subsequent recurrence.[161,175] The TTR reflects the quality of dose adjustment in studies of patients managed in a usual care (UC) setting, by an anticoagulation management service (AMS), by patient self testing (PST) or patient self management (PSM), or in the setting of a randomized trial.

TTR can be determined in different ways, so comparisons between studies may be difficult.[176] TTR is most commonly estimated by using one of three methodologies: calculating the fraction of all INR values that are within the therapeutic range (ie, the number of INRs in range divided by the total number of INR tests); using the "cross-section of the files" methodology, which assesses the fraction of patients with an INR in range at one point in time compared with the total number of patients who had an INR measured at that point in time; or applying the linear interpolation method of Rosendaal et al,[177] which assumes that a linear relationship exists between two INR values and allocates a specific INR value to each day between tests for each patient. Each approach has its advantages and disadvantages.[176] Furthermore, the results of all these methods depend on whether

an exact or an expanded therapeutic range is used,[178] whether INRs obtained during invasive procedures when warfarin therapy might be interrupted are included, and whether different oral anticoagulant preparations (eg, warfarin, phenprocoumon, acenocoumarol, or fluindione) are included.[179,180] Since clinical outcome studies have not compared one methodology with another and correlated their results with adverse events, no one method can be recommended, and the reader should be aware of these differences.

1.6.3 Frequency of Monitoring: In hospitalized patients, INR monitoring is usually performed daily until the therapeutic range has been achieved and maintained for at least 2 consecutive days. In outpatients starting VKA therapy, initial monitoring may be reduced to once every few days until a stable dose response has been achieved. When the INR response is stable, the frequency of testing can be reduced to intervals as long as every 4 to 6 weeks (or possibly longer in particularly stable patients). If adjustments to the dose are required, then the cycle of more frequent monitoring should be repeated until a stable dose response can again be achieved.

The optimal frequency of long-term INR monitoring is influenced by patient compliance, transient fluctuations in the severity of comorbid conditions, the addition or discontinuation of other medications, changes in diet, the quality of dose-adjustment decisions, and whether the patient has demonstrated a stable dose response. The dose required to maintain a therapeutic range for patients >60 years of age decreases with increasing age,[112,115,181,182] possibly because of a reduction in the clearance of warfarin with age.[183] Gender also influences dose, with women requiring less warfarin to maintain a therapeutic INR than men at an equivalent age.[115]

To compare different intervals between measurements of INR in stable patients, Pengo et al[184] randomized 124 patients with prosthetic mechanical heart valves and at least 6 months of a steady dose requirement to INR monitoring at either 6-week or 4-week intervals. They found no differences of time in, above, or below range between the groups, although the actual monitoring intervals were 24.9 days in the 6-week group and 22.5 days in the 4-week group ($P<.0003$).[184] In a retrospective study of $>4{,}000$ patients with chronic AF and $>250{,}000$ INRs, Shalev et al[185] found that time in range increased as the testing interval decreased from every 5 weeks or more to every 3 weeks (41% to 48%, $P<.0005$), and the investigators suggested that patients should be monitored at time intervals no longer than every 3 weeks. However, the strength of the recommendation is reduced by the very poor TTR reported in both arms of the study. More recently, Witt et al[186,187] found that patients with very stable INR levels defined by extremely high TTR rates required fewer visits for INR control and had significantly fewer hemorrhagic and thromboembolic events than patients with a less-stable INR; they suggested that many warfarin-treated patients whose INR values remain within the therapeutic range over time could be safely treated with INR recall intervals >4 weeks. In this study, advanced age predicted stable anticoagulation.

1.6.4 Factors Associated With INR Stability in Long-term Management: Two recent studies have assessed factors associated with very stable INR control during treatment with VKAs.[186,187] In the first study, 2,504 patients with INR values entirely within the INR range for 6 months were compared with 3,569 patients with at least one INR value outside the INR range.[186] In the second study, 533 patients with INR values within the therapeutic range for 12 months were compared with 2,555 control subjects.[187] Independent predictors of stability were age >70 years, the absence of chronic diseases, and (in one study only[187]) male gender. Congestive heart failure, diabetes, and a target range for INR ≥ 3.0 were associated with instability.

Physical activity also seems to play a role in the stability of the response to warfarin. A reduction in the anticoagulant effect has been found to be correlated with a sudden increase in physical activity. An increase in warfarin requirements associated with an increase in physical activity (represented by a daily exercise such as walking) has been described both in patients and in healthy subjects.[188,189]

Changes in dietary vitamin K intake may influence the stability of the INR in patients on VKAs, and a few trials have assessed its impact on therapeutic stability. Sorano et al[190] showed that controlling the intake of dietary vitamin K can achieve a more stable anticoagulant response. Sconce et al,[191] by comparing the daily vitamin K intake in 26 unstable patients and in 26 stable control patients, showed that unstable patients have poorer intake of vitamin K. Kurnik et al[192] showed that in vitamin K-depleted patients, very small amounts of vitamin K-containing vitamins will influence the INR to a greater extent compared with those with an adequate vitamin K status. Schurgers et al,[193] studying healthy volunteers on oral anticoagulation, found that a daily dose of vitamin K of at least 150 μg was needed to alter the INR response. Reese et al,[194] in a retrospective analysis, assessed the effect of a daily dose of 100 μg of vitamin K_1 in nine unstable patients. These patients experienced an increase in the percentage of INRs in range from 32% to 57% in response to the daily vitamin K. In a prospective, open-label, crossover study, Ford et al[195] found that

five of nine patients improved their stability with administration of low-dose vitamin K. As expected, the INR initially decreased in patients given vitamin K, and an increased dose of warfarin was needed to reestablish an INR within the therapeutic range, which took from 2 to 35 days to achieve. In a nested case-control study, Rombouts et al[196] assessed the effect of dietary vitamin K intake on the risk of subtherapeutic INR values and the interaction between usual and recent vitamin K intake. Patients with a high usual vitamin K intake had less risk of a subtherapeutic INR, an effect possibly mediated by a reduced influence on the INR of an incidental consumption of vitamin K-rich food when there is a high usual intake of vitamin K. In these last two studies, variable INR was defined as requiring a minimum of three warfarin dose changes or three INRs outside of the therapeutic range in the preceding 6 months,[195] or an INR SD > 0.5 with at least three warfarin dose changes during the previous 6 months.[196]

Sconce et al[197] conducted the first randomized, blinded trial in 70 unstable patients over a 6-month period. Vitamin K supplementation with 150 μg/d resulted in a significantly greater decrease in SD of the INR compared with placebo (-0.24 ± 0.14 vs -0.11 ± 0.18; $P < .001$) and a significantly greater increase in percentage of time within target INR range (28% ± 20% vs 15% ± 20%; $P < .01$). Finally, Rombouts et al[198] randomized 100 patients treated with phenprocoumon to receive daily doses of 100 μg of vitamin K and 100 patients to receive a placebo. Vitamin K improved the stability of anticoagulant therapy, with a relative risk of maximal stability (where all INR results were in range) in the vitamin K group compared with the placebo group of 1.8 (95% CI, 1.1-2.7).

De Assis et al[199] randomized patients with a recent INR value outside the therapeutic range to a conventional approach based on changes in anticoagulant prescription or to a strategy that adjusted the dietary intake of vitamin K. Patients in the latter group had significantly more INR values within the therapeutic range and significantly fewer episodes of minor bleeding as compared with patients in the former group.

As with any other drug, a patient's nonadherence to prescribed dosing with VKAs is one of the most important causes of INR instability. In a prospective cohort study at three US ACs aimed to determine the effect of adherence on anticoagulation control, patients treated with warfarin were monitored with an electronic system that records each time they open their medication container.[200] There was a high proportion of missed tablets and, as expected, in multivariable analyses there was a significant association between under-adherence and under-anticoagulation. In a case-control study on the most unstable patients from 35 Italian ACs, poor comprehension of the indications and mechanisms of VKAs was the most important predictor of instability among other factors, including working status, type of VKA, and a poor score on a mental test.[161] In a single-center study carried out on outpatients attending an AC in the United States, perceived barriers to compliance with warfarin, marital status, living arrangements, and drug regimen played significant roles in warfarin noncompliance.[201] In a prospective cohort study of adults initiating warfarin at two ACs, independent risk factors for nonadherence were education level, employment status, mental health functioning, and cognitive impairment.[202]

1.7 Data Management

An obstacle to the safety and effectiveness of warfarin therapy is the poor quality of dose management in routine clinical practice. Adequate anticoagulant care with the VKAs requires a system of patient education and careful data management to record and track INR values and to ensure patients are treated with anticoagulants for an appropriate period of time.

1.7.1 The Role of Anticoagulation Clinics: Nonrandomized, retrospective studies have reported better outcomes in patients when anticoagulant therapy is managed by an AMS or an AC compared with management by their personal physicians (ie, UC). Four such studies have reported major bleeding rates ranging from 2.8% to 8.1% per patient-year of UC.[203-206] Rates of thromboembolism with UC were not reported except in two studies in which the event rates were 6.2% and 8.1% per patient-year. Similarly, retrospective and prospective cohort studies of care provided by an AMS reported rates of major hemorrhage or thrombosis ranging from 1.4% to 3.3% and 0.7% to 6.3% per patient-year of therapy, respectively.[164,170,207-210] Three retrospective comparative studies using a before-and-after design of patients managed by UC or an AMS reported significant improvements in the outcomes of hemorrhage or thrombosis with AMS-directed care.[211-213] In contrast, however, two prospective, randomized controlled trials[214,215] comparing UC with the care of an AMS failed to show a significant difference in major hemorrhage or thromboembolism. The study by Matchar et al[214] also failed to show a significant improvement in TTR, although the AMS performed modestly better than UC. Wilson et al[215] did observe a significant improvement in TTR in the AMS group compared with UC (82% vs 76% respectively, $P = .034$). They also noted more high-risk INRs with UC than with an AMS (40% vs 30%, $P = .005$). This latter study had a major

limitation in that all patients were initially managed in an AMS for 3 months until they were stable and then observed for only 3 months after randomization to either receive UC or to continue care by the AMS.[215] The other study[214] suffered from a high turnover of patients, the possibility of selection bias affecting the referral of patients to the AMS, the open nature of the study, and targeted ranges that were sometimes outside recommended guidelines. In a retrospective, multicenter, international cohort study, 1,511 patients were randomly recruited from clinics offering routine medical care (UC) in the United States, Canada, and France, and from ACs in Italy and Spain.[216] Major management differences were detected, especially between AC care and routine medical care, but also among countries. For patients managed by routine medical care, documentation of care was often inadequate. Finally, less time in therapeutic INR range was noted in routine medical care.

In a systematic review of 67 studies representing > 50,000 patients managed by ACs (68%), during clinical trials (7%), or in community practices (24%), van Walraven et al[217] found that the practice setting had the greatest effect on anticoagulation control. TTR (days) varied from 56.7% in community practices to 65.6% in ACs and 66.4% for randomized trials. Compared with randomized trials the absolute reduction of TTR for community practices was −12.2% (95% CI, −19.5 to −4.8). The difference between community practices and ACs was −8.3% (95% CI, −4.4 to −12.1).

1.7.2. Computerized Monitoring: Computer assistance by the use of dedicated programs may improve dose management and TTR. Although programs differ, they typically calculate whether a dose adjustment is necessary from a user-defined table of trend rules for each therapeutic range. If dose adjustment is required, the current INR is compared with the target INR, and a proprietary equation calculates the new dose. The time to the next test is also set by the program using a set of variables comparing the current INR, the interval from the last test, the number of previous changes, and the number of previous INR values within the target range.

A number of early studies[218-220] evaluated computer programs to improve warfarin dosing. The first randomized study in 1993[221] showed that three contemporary computer programs all performed as well as the experienced medical staff of an anticoagulation management service in achieving a target INR of 2.0 to 3.0, but the computer achieved significantly better control when more intensive therapy was required (ie, INR, 3.0-4.5). In another randomized study[222] of 101 patients receiving long-term anticoagulation, computerized warfarin dose adjustment proved comparable to manual regulation in terms of the percentage of INR values maintained within the therapeutic range but required 50% fewer changes of dose. The first multicenter randomized trial, in 285 patients, of one computerized dosage program in 1998[223] showed a 22% overall improvement of control with the program compared with the performance of experienced medical staff. The computer program gave significantly better overall INR control across all target INR ranges. A slight improvement in TTR was also obtained by Italian investigators[224] using a different management program in > 1,200 randomized patients from five centers. A total of 71.2% of patients were in range with computer dosing and 68.2% were in range by manual dosing during the maintenance phase.[224] In both of these studies, the computer's improved results were probably due, in part, to a reduced propensity to reduce warfarin doses when the INR was at the upper limit of the "desired" range.

More recently, the European Concerted Action on Anticoagulation completed the first international, multicenter, randomized, controlled trial aimed to compare the safety and effectiveness of computer-assisted dosing of VKAs, using two computer programs in different centers (DAWN AC; 4S Information Sys, and PARMA; Instrumentation Laboratories), with conventional manual dosing.[225] A total of 13,052 patients treated with a VKA were followed for a total of 18,617 patient-years. Overall, there was a trend toward fewer clinical events with computer-assisted dosage. There was also a statistically significant reduction in clinical events in the subgroup treated for VTE. A subsequent cost-effectiveness analysis found computer-assisted dosing cheaper than manual dosing.[226]

The results of two small clinical trials suggest that computerized dose management can also be at least as effective as manual dosing by trained anticoagulation physicians or nurses during the initiation of anticoagulation therapy.[224,227] However, some computerized programs are unable to manage dosing during the induction phase.

1.7.3 Point of Care INR Testing: Point of care (POC) monitors measure a thromboplastin-mediated clotting time using a fingerstick sample of capillary whole blood or un-anticoagulated venous whole blood.[228] The result is then converted to a plasma PT equivalent by a microprocessor and is expressed as a PT and/or INR. Each manufacturer typically establishes the conversion formula by simultaneously comparing fingerstick or venous whole blood results with an established laboratory method and reagent that is traceable to the international reference thromboplastin.

Numerous studies[229-248] have reported on the accuracy and precision of these instruments and on the ability of patients, both adults and children, to obtain an INR and to use that INR to guide their anticoagulant therapy. However, limitations to the accuracy and precision of POC INR monitors have been documented. Problems identified with POC instruments include greater differences compared with a standard plasma-based methodology as INRs increase above the therapeutic range,[242,243] incorrect calibration of the ISI of the POC instruments,[244] the inability to calculate a mean normal PT,[249] and instrument-specific inaccuracies of the INR in patients with antiphospholipid antibodies.[250] In a recent systematic review of the literature, Gialamas et al[251] concluded that there is still no robust evidence that the use of POC instruments in general practice improves health outcomes or is cost-effective compared with UC and that analytical quality is comparable to laboratory testing. A major problem of comparative studies is the fact that there is a similar lack of correlation of INR results when anticoagulated plasmas are simultaneously compared using different instrument/thromboplastin combinations.[129-135] These differences may be clinically important in that they may lead to different dosing decisions.[128-134] Kaatz et al[252] compared two POC monitors and four clinical laboratories against a secondary reference thromboplastin preparation. They found that laboratories using a more sensitive thromboplastin showed close agreement with the standard, whereas laboratories using an insensitive thromboplastin showed poor agreement. The two POC monitors fell between these two extremes.

Steps are still needed to ensure the conformity of POC PT monitors to the WHO INR PT standardization scheme, but the WHO ISI calibration procedure is not practicable using the monitors. Simpler procedures for ISI calibration of POC monitors have recently been evaluated in a number of multicenter sites by the European Concerted Action on Anticoagulation and the UK National External Quality Assessment Schemes. By using lyophilized plasma calibrants with independently certified INRs, Poller and colleagues[253-255] have shown that verification or recalibration of the ISI of the instrument is possible. However, to obtain reliable ISI values for the two instruments tested they had to develop different ISI calibration methods. It is likely, therefore, that different types of POC monitor systems will require different ISI calibration methods. In a study of proficiency testing of three POC monitors over 6 years in >10 centers, Kitchen et al[256] found in each survey that INR results in 10% to 11% of centers were $>15\%$ different from results in other centers using the same monitors. This compared with a 12% difference for hospitals using conventional INR techniques. The European Concerted Action on Anticoagulation has recently tested 523 Coaguchek monitors at nine clinics and found that 20.3% of the monitors showed significant deviations.[257]

PST or PSM using a POC instrument represents another model of care with the potential for improved outcomes as well as greater convenience.[258] Several systematic reviews have shown improvements in the quality of anticoagulation control (TTR) and/or incidence of adverse events with PST and/or PSM.[259-261] Heneghan et al[261] pooled estimates from 14 randomized trials of PST showing a significant reduction in thromboembolic events (OR, 0.45; 95% CI, 0.30-0.68), all-cause mortality (OR, 0.61; 95% CI, 0.38-0.98), and major hemorrhage (OR, 0.65; 95% CI, 0.42-0.99) vs the comparator. For PST and PSM combined, there were significant reductions in thromboembolic events (OR, 0.27; 95% CI, 0.12-0.59) and death (OR, 0.37; 95% CI, 0.16-0.85) but not major hemorrhage (OR, 0.93; 95% CI, 0.42-2.05). In a recent randomized study from France comparing monthly laboratory monitoring with weekly self testing and monitoring in patients with prosthetic heart valves, self monitoring improved INR stability and reduced the incidence of bleeding, although the study was underpowered to show a true difference in clinical outcomes.[262] Another recent randomized study from Germany compared INR monitoring by the primary care physician with self management in patients with prosthetic heart valves and found greater INR stability and a lower incidence of thromboembolic events in the group of self-managed patients but no differences in bleeding events.[263]

PST and PSM require special patient training to implement.[264,265] This mode of therapy may not be suitable for all patients and may not be practical or cost-effective in certain settings. All participants in PST/PSM programs should participate in a recognized external quality assessment program.

1.8 Optimal Intensity Ranges

The optimal target range for the INR is not the same for all indications. In general, because bleeding is closely related to the intensity of anticoagulation,[164,266-268] there has been interest in establishing the lowest effective therapeutic range for each indication.[268-276]

Investigators have used various methodological approaches to establish the most appropriate range for different indications. These are as follows: (1) randomized trials in which patients are assigned to one of two different target ranges[270-274]; (2) indirect comparisons, in which outcomes are compared between separate randomized trials of VKA therapy that applied different target ranges of INR, and the control

patients received no therapy or another antithrombotic agent (usually aspirin)[277-280]; (3) subgroup analyses of observational studies (including within treatment groups of randomized trials) relating the observed INR or time spent in an INR range at the time of the outcome to either a bleeding event or thromboembolic event[164,207,208,267,268,281]; and (4) case-control studies in which the INR levels at the time of an event are recorded and compared with INR levels in appropriately selected control subjects.[174]

When moderate-intensity INR (approximately 2.0-3.0) was compared with higher-intensity adjusted-dose oral anticoagulation,[269,272-274,278-280] the moderate treatment intensity was shown to reduce the risk of clinically important bleeding without reducing efficacy. Conversely, a lower treatment intensity (eg, INR range 1.5-2.0) appears to be less effective than moderate-intensity therapy. For example, a randomized trial demonstrated that an INR of <2.0 (INR target, 1.5-2.0)[270] reduced the recurrence of venous thrombosis after an initial 3 to 6 months of standard treatment when compared with placebo. A subsequent clinical trial,[271] however, found that maintaining an INR intensity of 2.0 to 3.0 in the same clinical setting was more effective than a lower intensity of 1.5 to 2.0 and was not associated with a greater risk of bleeding. Likewise, in patients with AF, a randomized trial[282] reported that adjusted-dose warfarin therapy (INR, 2.0-3.0) was more effective than the combination of fixed-dose warfarin (3 mg/d) and aspirin; other studies showed that the efficacy of oral anticoagulant agents is reduced when the INR falls to <2.0.[174,207,208,283-285] Warfarin targeted to an INR of <2.0 has also been shown to be ineffective for preventing failure of dialysis access grafts.[286]

The use of fixed minidose warfarin (1 mg daily) has been evaluated in a number of clinical settings. A number of these studies reported that fixed minidose warfarin is ineffective when compared with dose-adjusted warfarin, in particular for the prevention of stroke in patients with AF and for the prevention of thrombosis of central venous catheters.[287-290] There is currently no evidence to support the use of fixed mini-doses of either acenocoumarol or phenprocoumon in any setting. However, the data obtained with fixed minidoses of warfarin cannot be extrapolated to other VKAs because of their different half-lives and the likelihood they would have different pharmacodynamic effects at similar doses. The optimal target range for each indication is discussed specifically in other articles in this supplement pertaining to each indication.

1.9 Significance of Nontherapeutic INRs

Fluctuations in INR may occur because of any one or more of the following conditions: inaccuracy in INR testing, changes in vitamin K intake, changes in the absorption of vitamin K or VKAs, changes in the metabolism of VKAs, changes in vitamin K-dependent coagulation factor synthesis or metabolism, other effects of concomitant drug use, or patient noncompliance. A number of studies have shown that adverse event rates rise sharply as the INR moves above or below the target INR interval.[163,164,174] A recent retrospective analysis of $>3,000$ patients with AF found that the one-third with the poorest INR control (48% of time in range) had twice the rate of stroke, myocardial infarction, major bleeding, and death as did the one-third with the best INR control (83% of time in range).[163]

However, the risk of adverse events associated with a single INR outside the therapeutic range is probably low. For example, although excessively elevated INR values are clearly associated with an increased risk of bleeding, in particular for INR values of >5.0,[164,169,170,268] data from a large registry of warfarin-treated patients suggest that the short-term risk for major bleeding is low for someone with a single INR value between 5.0 and 9.0 (0.96% at 1 month).[291] Similarly, in a retrospective, matched cohort study of 2,597 patients on warfarin therapy, the risk of thromboembolic events at 3 months in patients with stable INRs who experienced a single significant subtherapeutic INR value was low (0.4%) and was not significantly different from the risk observed in patients with persistently stable INRs.[292] Similar rates were reported in a population of 294 patients with mechanical heart valves experiencing a single subtherapeutic INR and in a large cohort of patients who required short-term discontinuation of warfarin to undergo minor outpatient interventions.[293,294]

Before executing a plan for managing an episode of altered anticoagulation effect, important factors relating to the collection and processing of the blood sample must be taken into consideration. For example, a spuriously elevated INR should be suspected when a patient with previously stable INR control presents with a very high INR result in the absence of any explanation for the loss of INR control. Spurious results might also be suspected when abnormalities were encountered during sample collection (eg, the phlebotomist had a difficult time obtaining a sample or combined the contents of two collection tubes, and so forth).[295] Recommendations for the management of patients whose INR is outside the therapeutic range are provided in Holbrook et al.[86]

1.10 Adverse Events

1.10.1 Bleeding Events: The rate of hemorrhagic events must be interpreted in the context of the clinical characteristics of the group studied. Factors that

influence the rate of bleeding include the following: the target INR range; whether patients are mostly new to therapy or have long-term experience with therapy; whether an INR or PT is used to manage therapy; the indication for anticoagulation; the type of VKA; patient-specific risk factors, including concomitant antiplatelet therapy; and the quality of dose management. It is also not appropriate to extrapolate the rates of adverse events from randomized controlled trials to everyday practice, because high-risk patients may be excluded from clinical trials, and monitoring and management of anticoagulation are often better coordinated in clinical trials than in clinical practice.

When bleeding occurs, especially from the GI or urinary tract, the presence of an underlying occult lesion should always be considered. This is important because the patient factor that most consistently predicts major bleeding is a history of other bleeding, particularly from the GI tract.[207] A number of descriptive studies[296-298] have reported on the probability of finding occult lesions. Coon and Willis[296] identified occult lesions that were responsible for bleeding in 11% of 292 patients with hemorrhage. Jaffin et al[297] found a 12% prevalence of positive stool occult blood test results in 175 patients receiving warfarin or heparin compared with 3% in 74 control subjects. There was no difference between the mean PT or activated partial thromboplastin time (aPTT) in patients with positive and negative test results. Among the patients with positive stool occult blood test results, 15 of 16 patients had a lesion that had not been previously suspected, and four patients had neoplastic disease. Landefeld et al[266] found that 14 of 41 patients with GI bleeding had important remediable lesions, of which two were malignant. To perform endoscopy in these patients is an important choice, because endoscopy has been shown in prospective studies to identify the bleeding source in $>50\%$ of patients managed with anticoagulant therapy who present with upper GI tract bleeding and because endoscopic therapy for nonvariceal upper GI bleeding achieves hemostasis in $>90\%$ of patients.[299] This limited information supports the need to investigate patients with occult GI bleeding, as it may herald the presence of an underlying malignancy or other lesion that is frequently rectifiable.

In a 2-year prospective study in which enrolled patients had monthly urinalysis, Culclasure et al[300] found microscopic hematuria in 3.2% of patients receiving oral anticoagulation compared with 4.8% in the control group not receiving anticoagulant therapy. There was no difference in the rate of hematuria with therapeutic or high INRs. Following a second episode of hematuria, 43 patients (32 receiving anticoagulant therapy, 11 control patients) were investigated. Of these patients, 27 receiving anticoagulant therapy (84%) and eight control patients (73%) were found to have significant underlying disease, with three cancers found in the combined group (7%). Other case series[301,302] have reported a higher likelihood of underlying lesions in patients who develop hematuria while receiving anticoagulant therapy.

1.10.2 Factors Predictive of Bleeding Events: The most important factor influencing the risk of bleeding is the intensity of anticoagulant therapy.[162,164,169,170,174,208,266-269,272-275,283-285] The likelihood of bleeding has been reported to rise steeply as the INR increases above 5.0.[164,169,170,268] The optimal target range for each indication and the lowest effective range are discussed specifically in other articles in this supplement pertaining to each indication.

Several patient characteristics are associated with higher odds of bleeding during anticoagulation therapy. The patient factor most consistently predictive of major bleeding is a history of bleeding (especially GI bleeding).[162,208,273] Other factors associated with a higher risk of bleeding include advanced age; the presence of a serious comorbid condition, such as cancer, renal insufficiency, liver disease, arterial hypertension, and prior stroke; alcohol abuse; and the use of concomitant therapies, in particular antiplatelet drugs.[162,203,204,207,303]

A number of prediction models of bleeding risk have been proposed. Dahri and Loewen[304] performed a qualitative review of the published clinical prediction rules that estimated bleeding risk in patients starting on warfarin. The authors found seven studies, of which four presented distinct clinical prediction rules. Because none of these scores exhibited sufficient predictive accuracy or evaluated the impact of their use on patient outcomes, the authors concluded that no existing clinical prediction rules can be recommended for widespread use in practice at present. One prediction model that was prospectively validated in different outpatient populations identified four independent factors associated with an increased risk of bleeding. These factors were age >65 years, history of gastrointestinal bleeding, history of stroke, and at least one of the following variables: myocardial infarction, hematocrit $<30\%$, creatinine >1.5 mg/dL, and diabetes.[203] Another model, derived using registry data from patients with AF, identified prior bleeding, hepatic or renal disease, ethanol abuse, malignancy, age >75 years, reduced platelet count or function, hypertension (uncontrolled), anemia, genetic factors (CYP2C9 polymorphism), an excessive risk of falls, and a history of stroke as risk factors for bleeding.[305]

The impact of age on bleeding risk remains controversial, with older reports finding risk increasing with age,[162,163,181,267,306,307] whereas newer studies have failed

to find this association.[170,205,207,268,282,308-310] The discrepancy may be partly explained by the wide range in the mean age of the patients enrolled in the various studies, the relative lack of representation in most studies of patients > 80 years of age, and the selection and survivorship biases in noninception cohort studies. When investigators attempt to separate the effect of age from comorbid conditions associated with age, some have concluded that age in and of itself is not a major independent risk factor,[112,267,311] whereas others have found it to be an independent risk factor[266,268] even after controlling for the intensity of the anticoagulant effect. Some have suggested that older patients may have a lower risk of bleeding when managed by AMS.[312,313] Even if the overall risk of bleeding is not increased in the elderly, it is clear that the risk of intracranial hemorrhage increases with age.[267,268,314,315]

Warfarin is frequently used concurrently with other antithrombotic agents. A meta-analysis assessing clinical studies comparing warfarin alone and warfarin in association with aspirin found that the combination increased the risk of bleeding by almost one-half compared with warfarin alone (OR, 1.43; 95% CI, 1.00-2.02).[316] A combined analysis of the SPORTIF (Stroke Prevention Using an Oral Thrombin Inhibitor in Atrial Fibrillation) III and V trials involving 481 patients who received aspirin and warfarin compared with 3,172 patients who received warfarin alone demonstrated a significant 1.6% per year increase in major bleeding.[317] Although there are no randomized controlled trials that have compared bleeding rates in patients receiving "triple therapy" (usually warfarin, aspirin, and clopidogrel) with either warfarin alone or with a "dual therapy," a systematic review identified 12 reports involving 3,413 patients treated with oral anticoagulants who underwent percutaneous coronary intervention with stent insertion and subsequently received the combination of aspirin, clopidogrel, and warfarin. The rates of major bleeding in patients receiving triple therapy ranged from 0% to 21% (mean 7.4%) during up to 21 months of follow-up and 0% to 5.9% (mean 2.6%) during 30 days of follow-up.[318] In a Danish nationwide registry of patients with AF, all combinations of warfarin, aspirin, and clopidogrel were associated with an increased risk of nonfatal and fatal bleeding, whereas dual or triple therapy carried a more than threefold higher bleeding risk than warfarin alone.[319]

1.10.3 Reversal Strategies: Strategies to reverse the effect of VKAs may be needed in patients who require urgent invasive procedures, in asymptomatic patients presenting with excessively elevated INR values, and in bleeding patients. Therapeutic options include interruption of VKA treatment as well as the administration of vitamin K (usually vitamin K1, phytonadione) and blood derivatives such as fresh frozen plasma and prothrombin complex concentrates and recombinant activated factor VII.[303,320]

Interruption of VKAs may be sufficient in patients who need an elective invasive procedure or in asymptomatic patients with an elevated INR value and a low risk for bleeding. In this latter case, it must be noted that it takes approximately 2.5 days for an INR between 6.0 and 10.0 to decline to < 4.0.[321] Because acenocoumarol has a much shorter half-life than warfarin, the time required for an effective decline will be less and is probably no more than 1 day for most patients.[322,323] Conversely, the longer half-life of phenprocoumon will probably result in a much slower decline. Finally, the half-life of fluindione is similar to that of warfarin, and thus a similar decline should be expected.

Phytonadione (vitamin K_1, a form of vitamin K derived from plants) has been used in clinical trials that assessed the usefulness of oral vitamin K for the treatment of warfarin-associated coagulopathy.[324] Vitamin K_2 (menaquinone, which is synthesized by bacteria) and vitamin K_3 (menadione) are not widely available and have not been well studied in clinical trials.[324] Low doses of phytonadione can be administered orally in combination with warfarin interruption in patients not requiring urgent reversal. When oral phytonadione is administered in conjunction with temporary interruption of warfarin therapy, approximately 1.4 days are required for an INR between 6 and 10 to decline to < 4.0.[321] When administered intravenously, low doses of phytonadione produce similar reductions as oral phytonadione in the INR value at 24 h, whereas subcutaneous phytonadione appears to be less effective than low-dose oral phytonadione.[325,326] When administered at higher doses for the management of the bleeding patient, intravenously administered phytonadione works more rapidly than either oral or subcutaneous vitamin K_1.[325,327,328] Reduction of the INR begins within 2 h, and a correction to within the normal range is generally achieved within 24 h if hepatic function is normal and if a sufficiently large dose is given.[324] At 24 h, 5 mg of oral and 1 mg or IV vitamin K_1 produce similar effects on the INR.[325] IV phytonadione may cause anaphylactoid reactions. Although frequently reported, and likely more common in patients who receive large IV doses administered rapidly, the true frequency of this complication is about three per 10,000 doses administered, and it may be more likely to occur if formulations containing polyethoxylated castor oil are used to maintain the vitamin K in solution.[329] To minimize the risk of anaphylactoid reactions, vitamin K_1 should be mixed in a minimum of 50 mL of intravenous fluid and administered, using an infusion pump, over a minimum of 20 min.

Fresh frozen plasma remains the most widely used coagulation factor replacement product for urgent reversal of coumarin anticoagulation.[320] Plasma may be a potential carrier of infective agents, and its use is associated with an increased risk of volume overload. Furthermore, it requires a cross-match if group-specific plasma is to be used, and it takes a prolonged period of time to thaw and administer. Given the long half-life anticoagulant effect of warfarin and the short half-life of infused coagulation factor concentrates, phytonadione must also be given to restore the adequate endogenous production of VKA-sensitive anticoagulant proteins. Urticaria occurs frequently with plasma transfusion; anaphylaxis is less common, occurring in about one in 20,000 transfusion episodes.[330] Transfusion-related acute lung injury remains the most feared complication after transfusion and is estimated to occur in about one in 5,000 plasma-containing transfusions.[331]

Nonactivated prothrombin complex concentrates (PCC) are probably more effective than plasma in correcting INR. PCCs do not require a cross-match, are virally inactivated, do not pose a risk of volume overload, and can be infused in 15 to 30 min. PCC may be classified as three-factor products (with adequate levels of factors II, IX, X, and low factor VII levels) and four-factor products, which contain adequate levels of factors II, VII, IX, and X as well as protein C and S.[319,331] Current PCCs are more or less devoid of activated clotting factors and are supplemented with heparin and antithrombin to minimize the risk of thrombosis.[332] Four-factor PCCs are currently not available in some countries (eg, United States).

In patients with life-threatening bleeding, recombinant activated factor VII has been used to control bleeding.[320] Recombinant activated factor VII is able to generate a consistent thrombin burst through both tissue factor-dependent and tissue factor-independent mechanisms and is able to trigger thrombin generation even in the presence of significant platelet dysfunction. Evidence supporting its use in VKA-associated bleeding is currently limited, and its use cannot be recommended except in the setting of life-threatening bleeding when more effective agents are not available.[333] As would be expected based on its potent procoagulant effect, this agent may cause thrombosis. Recommendations to guide the use of these strategies are provided in Holbrook et al.[86]

1.10.4 Nonhemorrhagic Adverse Events: Other than hemorrhage, the most important side effects of warfarin are acute thrombotic complications, such as skin necrosis and limb gangrene. These uncommon complications are usually observed on the third to eighth day of therapy[334,335] and are caused by extensive thrombosis of the venules and capillaries within the subcutaneous fat (in the case of skin necrosis) and massive outflow obstruction of the venous circulation of the limb (in the case of limb gangrene). The pathogenesis of these complications and the reason for the localization of the lesions are not well understood. An association between warfarin-induced skin necrosis and protein C deficiency[336-339] and, less commonly, protein S deficiency[339] has been reported, but this complication also occurs in nondeficient individuals. A pathogenic role for protein C deficiency is supported by the similarity of the lesions to those seen in neonatal purpura fulminans, which complicates homozygous protein C deficiency. A variant of this syndrome also attributed to a severe warfarin-induced depletion of protein C is the occurrence of venous limb gangrene during warfarin treatment of cancer-associated DVT[340] and in some patients with heparin-induced thrombocytopenia started on warfarin after withdrawal of heparin.[341,342] The management of patients with warfarin-induced skin necrosis who require lifelong anticoagulant therapy is problematic. Therapy with warfarin is considered to be contraindicated, and long-term heparin therapy is inconvenient and is associated with osteoporosis. A reasonable approach in such patients is to restart warfarin therapy at a low dose (eg, 2 mg), under the coverage of therapeutic doses of parenteral anticoagulants, and to gradually increase the warfarin dose over 1 or more weeks. This approach should avoid an abrupt fall in protein C levels before there is a reduction in the levels of factors II, IX, and X, and it has been reported to not be associated with the recurrence of skin necrosis in a number of case reports.[337,338,342]

The purple toe syndrome may very rarely occur in association with the initiation of VKA treatment. It is a nonhemorrhagic, cutaneous complication due to cholesterol emboli that usually develops 3 to 8 weeks after the start of warfarin therapy and is characterized by the sudden appearance of bilateral, painful, purple lesions on the toes and sides of the feet that blanch with pressure.[343,344]

The VKAs also interfere with the carboxylation of Gla proteins that are synthesized in bone.[345-348] Although these effects contribute to fetal bone abnormalities when mothers are treated with a VKA during pregnancy,[349,350] it is unclear how they might affect children. There are two uncontrolled cohort studies that describe reduced bone density in children on warfarin for >1 year, but the role of the underlying disorders in reducing bone density remains unclear.[351]

Finally, by preventing the activation of G1a proteins and growth arrest-specific gene 6 (Gas-6), VKAs may also induce vascular calcification.[352] However, this relationship in humans is conjectural and is based on case reports.[352]

2.0 Direct Thrombin Inhibitors: Dabigatran Etexilate

Dabigatran is a selective, reversible, direct thrombin inhibitor given as dabigatran etexilate, an orally absorbable prodrug, since dabigatran itself is a strongly polar molecule that is not absorbed from the gut. Phase 3 clinical studies reported to date have evaluated the use of dabigatran etexilate for the prevention of VTE after elective total knee or hip arthroplasty, for therapy of VTE, and to prevent stroke or systemic embolism in nonvalvular AF. The drug is approved in many countries for the prevention of VTE in patients undergoing total hip or knee replacement surgery and in the United States and Canada for the prevention of stroke or systemic embolism in nonvalvular AF. Dosing schedules are 150 mg and 220 mg once daily when used to prevent VTE (starting with a half dose given soon after surgery) and 110 mg and 150 mg bid in patients with AF, although only the latter dose was approved for this use in the United States. The 150 mg bid dose was also used for the treatment of VTE. Dabigatran etexilate remains under evaluation for the secondary prevention of VTE and in the management of acute coronary syndromes. Melagatran (given as its prodrug Ximelagatran) was the first of the orally available direct thrombin inhibitors to be clinically evaluated and was effective for both the prevention and treatment of VTE and in AF but caused unacceptable liver toxicity.[353-355]

2.1 Pharmacology

Direct thrombin inhibitors, such as dabigatran, the hirudins, and argatroban, do not require a cofactor, which differentiates them from the indirect coagulation inhibitors like the heparins, other glycosaminoglycans, and the synthetic pentasaccharide that must form a complex with plasma antithrombin before they can accelerate inhibition of thrombin and/or factor Xa.[356] Clot-bound thrombin is relatively protected from heparin-like anticoagulants in vitro but is freely accessible to direct thrombin inhibitors.[119]

Dabigatran (initially referred to as BIBR 953) is a small synthetic molecule of 471.5 d with strongly basic functional groups that is a concentration dependent, competitive, highly selective and reversible direct thrombin inhibitor with a Ki of 4.5 ± 0.2 μM (which is comparable with that of melagatran).[357,358] The inhibitor prevents access to the active site of thrombin by forming a salt bridge between its amidine group and Asp 189 and through hydrophobic interactions.[357] Like melagatran and argatroban, dabigatran is a univalent inhibitor that interacts with the active site of thrombin alone, whereas hirudin, lepirudin, and desirudin also bind to a substrate recognition site (exosite 1).[356] Because the highly polar and lipophobic dabigatran molecule is not absorbed from the gut, its oral availability required the synthesis of an absorbable prodrug, dabigatran etexilate (BIBR 1048; 627.7 d).[357] On absorption, this esterified, hexylated, and more lipophilic prodrug is rapidly converted to dabigatran (the mechanism is ester cleavage catalyzed by serine esterase enzymes, via two intermediates—BIBR 1087E and BIBR 951 CL).[357,359] As would be expected from a direct thrombin inhibitor, dabigatran prolongs the thrombin clotting time (TCT), PT, aPTT, and ecarin clotting time (ECT) of plasma from humans, rats, rabbits, dogs, and rhesus monkeys and also inhibits thrombin generation in human plasma.[358] The ECT has been a preferred measure of anticoagulant effect for r-hirudin and other direct thrombin inhibitors; ecarin is a metalloprotease enzyme obtained from venom of the saw-scaled viper (*Echis carinatus*) that generates meizothrombin from prothrombin.[360,361]

Dabigatran prevents thrombin-induced platelet aggregation but not platelet aggregation by arachidonic acid, collagen, or adenosine diphosphate.[358] Administration of oral dabigatran etexilate or IV dabigatran causes concentration-dependent reductions of thrombosis provoked in rats and rabbits by venous stasis plus tissue factor infusion or venous stasis plus endothelial damage. Thrombus inhibition peaks within 30 to 60 min of an oral dose, then persists for 2 to 3 h in rats and about 7 h in rabbits, and correlates well with prolongation of the aPTT.[362,363] In rats, the intravenous dabigatran dose required to prolong the tail bleeding time is 5 to 10 times greater than the maximally effective antithrombotic dose of 0.1 mg/kg.[363]

2.2 Pharmacokinetics and Pharmacodynamics

Dabigatran etexilate is now formulated as a capsule containing multiple small pellets, each of which is composed of drug coated on a tartaric acid core to create an acid microenvironment that favors drug dissolution and preserves gut absorption even when the gastric pH is high (solubility is best at a low pH).[364] Systemic bioavailability of oral dabigatran etexilate has been measured at 7.2% in healthy young volunteers and estimated at 6% to 7% in healthy older subjects.[359,364] Oral bioavailability of the capsules is comparable to that of tablets used in the phase 1 and early phase 2 evaluations.[365,366] Plasma dabigatran concentrations peak within 2 hours after a dose of dabigatran etexilate and then decrease by $>70\%$ during an initial 4- to 6-h distribution phase that is followed by a much slower elimination phase. With repeated dosing, the terminal elimination half-life is 12 to 17 h, the peak and trough concentrations are dose-proportional, and it takes 2 to 3 days to reach

steady-state levels. The terminal half-life following a single dose is about 9 h in healthy volunteers.[359,361,364] The summary of pharmacokinetic parameters in Table 3 was derived from Stangier.[367] Rapid conversion of dabigatran etexilate to dabigatran ensures that plasma concentrations of the etexilate and two intermediate prodrugs barely reach detectable levels.[359] Approximately 35% of circulating dabigatran is protein-bound, regardless of concentration. After a 5-mg dose of IV dabigatran in healthy volunteers, the distribution volume was measured at 69 to 90 L, which exceeds the volume of body water, and plasma clearance was 149 mL/min.[359] About 15% of available dabigatran is conjugated to form pharmacologically active but unstable glucuronides that account for about 20% of the total drug exposure.[359] Eighty-five percent of the dose is excreted by renal clearance, almost all as unchanged dabigatran.[359] Pharmacokinetic data from the phase 2 studies, together with population modeling, predict average steady-state peak and trough plasma dabigatran concentrations of 99 and 14 ng/mL after daily dosing with 150 mg dabigatran etexilate,[368] 183 and 37 ng/mL after 220 mg/d,[369] and 184 and 90 ng/mL after 150 mg bid (Table S3).[369] Apart from dose, the systemic exposure to dabigatran is related to age and renal function. When older but apparently healthy volunteers aged 65 to 87 years received 150 mg dabigatran etexilate bid, the steady-state area under curve (AUC) was 1.7 to 2 times greater than that observed in a previous study of younger men aged 18 to 45 years. The increase in drug exposure was explained by reduced renal clearance and was more obvious in older women (in whom the AUC was 3% to 19% above that in older men).[364,367] In a separate parallel group volunteer study, the AUC∞ after 150 mg dabigatran etexilate was 1.5, 3.2, and 6.3 times higher in people with mild, moderate, or severe renal impairment (creatinine clearance of 51-80, 31-50, and ≤ 30 mL/min) than in healthy control subjects. The corresponding levels of peak plasma concentration (Cmax) were 109, 138, and 205 ng/mL, compared with 85 ng/mL when renal function was normal. The terminal half-life was doubled to 28 h in severe renal failure, from 14 h in control subjects.[370] Strong effects of renal function on drug concentrations were also demonstrated in patients having a hip or knee replacement, in whom dose-effect modeling predicted a steady-state Cmax of 100 ng/mL during bid dosing with 150 mg if the creatinine clearance was >90 mL/min, increasing to 140, 180, and 240 ng/mL as creatinine clearance diminished to 60 to 90, 40 to 60, and <40 mL/min.[366,367] Moderately severe liver dysfunction (Child-Pugh classification B) appears to have little effect on dabigatran pharmacokinetics, since peak plasma concentrations were reduced by 15% after 150 mg dabigatran etexilate in twelve affected subjects, when compared with 12 healthy age- and sex-matched control subjects, whereas time to Cmax, the elimination half-life, AUC, distribution volume, and extent of glucuronidation remained unchanged. Effects on blood clotting test results were similar in the two study groups.[371] The effects on blood coagulation tests closely mirror plasma dabigatran concentrations. Peak prolongation coincides with the Cmax, and clotting times decrease as dabigatran leaves the circulation. Unlike warfarin and other vitamin K inhibitors, which have long-lasting effects on the INR, the relatively short half-life of dabigatran means that time between dosing and blood sampling is a critical determinant of drug effect. Effects on the aPTT, INR, TCT, and ECT were studied in healthy volunteers and in patients having a hip or knee replacement. In the placebo-controlled volunteer study, wherein healthy men aged 18 to 45 years received one dose of 10 to 400 mg dabigatran etexilate or eight hourly doses of 50 to 400 mg for 6 days, the

Table 3—*[Section 2.2] Pharmacokinetic Characteristics of Dabigatran Etexilate*

Population and Dosage	Tmax or Tmax, ss, h	Cmax or Cmax, ss, ng/mL/mg	Cmin or Cmin, ss, ng/mL/mg	AUC∞ or ss, (ng/h/mL)/mg	$t_{1/2}$, h

od	6.0[a]	0.41[a]	0.13	6.41[a]	
bid	2.7	1.06	0.45	15.9	

The results recorded for bid or tid dosing are at ss. Cmax, Cmin and AUC are normalized to a 1-mg dose of dabigatran etexilate. Results are mean or median. AUC = area under the curve; AUC∞ = AUC from time zero to infinity; Cmax = peak plasma concentration; Cmin = minimum plasma concentration; od = once daily; ss = steady state; tmax = time to reach the peak plasma concentration; $t_{1/2}$ = terminal half-life. (Modified with permission from Stangier et al.[364])

[a]Measured after first oral dose of dabigatran etexilate following surgery for hip or knee replacement.

drug was given as a dry powder dissolved in dilute tartaric acid[361] and caused dose-dependent prolongations of aPTT, INR, TCT, and ECT. The coagulation test results correlated with plasma dabigatran concentration, the maximum clotting times coincided with Cmax, and effects persisted for 8 h or longer except for the aPTT and INR at the lowest doses. The peak clotting time ratios after 200 to 400 mg of dabigatran etexilate were >55 for the TCT, >5 for the ECT, 1.5 to 1.9 for the INR, and 1.8 to 2.1 for the aPTT. The TCT, ECT, and INR increased in linear proportion with plasma dabigatran levels, but the aPTT concentration-response curve was curvilinear and flattened above concentrations of 200 ng/mL.[361,369] Plasma dabigatran levels also correlated closely with effects on the ECT and aPTT in the BISTRO trial, a safety study of dabigatran etexilate in patients having an elective hip or knee arthroplasty, wherein escalating doses of dabigatran etexilate were given for 6 days in tablet form after surgery. The doses were 12.5 mg rising to 300 mg bid or 150 mg to 300 mg once daily.[368] Bid dabigatran etexilate raised the peak aPTT and ECT ratios from 1.08 to 1.91 and from 0.96 to 5.17 as the dose increased from 12.5 mg to 300 mg, whereas the mean trough levels of aPTT ratio rose from 1.0 to 1.65.[368] Concentration-effect relationships were linear for the ECT but nonlinear for the aPTT, with better sensitivity and precision for the ECT.[366] A nonlinear dose-effect on the aPTT was also found in patients with AF taking bid doses of up to 300 mg.[372] Different aPTT reagents appear to have similar sensitivities to dabigatran, as does the activated clotting time.[369] The likely impact of reduced renal function on blood clotting test results in patients given 150 mg dabigatran etexilate bid was estimated through population modeling of data from the BISTRO I study. This predicted a maximum aPTT of 47.4 s with normal renal function, increasing to 54.2, 61.9, and 78.3 s in patients with mild, moderate, or severe reductions in creatinine clearance (the corresponding predictions for maximum ECT were 55.2, 77.4, 108, and 183 s).[367] The modeling is consistent with results when otherwise healthy volunteers with a creatinine clearance <30 mL/min received a 150-mg dose of dabigatran etexilate: maximum aPTT, ECT, INR, and TCT ratios were 3.45, 3.26, 4.14, and 12.5, compared with 1.85, 1.89, 1.4, and 6.87 in healthy control subjects.[370] This emphasizes the need to avoid dabigatran etexilate in patients with severe renal failure and the importance of renal function when considering the choice of dosing regimen. It remains possible that dabigatran may activate platelets in patients with AF, as urinary excretion of 11-dehydrothromboxane B2 (an end product of thromboxane A2 metabolism) was increased by roughly 20% during 12 weeks of treatment in a dose-ranging trial, and that effect was suppressed by aspirin.[372]

2.3 Interactions

2.3.1 Factors Interfering With Absorption: Absorption of dabigatran etexilate is influenced by gastric pH as affected by proton pump inhibitors, food, the postoperative state, and also by drugs that inhibit or induce activity of the cell efflux transporter P-glycoprotein (P-gp). Dabigatran etexilate has a low aqueous solubility that is further reduced by increased pH,[373] as is observed in patients taking the gastric proton pump inhibitor pantoprazole. Twice-daily pretreatment with 40 mg pantoprazole for 48 h in a crossover study reduced geometric mean levels of Cmax and AUC after 150 mg dabigatran etexilate by 40% and by 32% in healthy male volunteers aged 18 to 55 years.[365] Bioavailability (steady-state AUC) was also reduced by 20% to 40% in a parallel group study in which older volunteers, aged ≥65 years, took 40 mg pantoprazole with 150 mg dabigatran etexilate bid for 6 days; pantoprazole raised the gastric pH from 2.2 to 5.9, and pH correlated with AUC. Small corresponding changes in Cmax, ECT, and aPTT were not believed to have clinical importance.[364]

Taking 150 mg dabigatran etexilate after a high-fat, high-calorie breakfast prolonged the time taken to reach Cmax from 2 h to 4 h in the crossover study described above, although Cmax and total drug exposure remained unchanged.[365] Absorption of doses taken 4 to 8 h after a hip replacement was slowed and reduced, compared with 2 to 10 days later, such that time to reach the peak plasma concentration was delayed to 6 h and both Cmax and AUC were greatly diminished (Table 3); the changes were attributed to early effects of surgery on GI motility and gastric acidity.[366]

2.3.2 Other Drug-Drug Interactions: Important drug-drug interactions most often result from changes in drug metabolism that are due to induction or inhibition of CYP3A4 and other enzymes of the microsomal cytochrome P450 complex or from changes in drug bioavailability mediated by the adenosine diphosphate-dependent cell efflux transporter, P-glycoprotein (P-gp).[374] Potential drug interactions with dabigatran etexilate have been explored in studies in which volunteers received dabigatran etexilate together with drugs known to provoke such mechanisms. Many drugs may interact through more than one pathway.

Because cytochrome P450 enzymes have almost no role in the metabolism of dabigatran and are not affected by dabigatran in vitro, this becomes an unlikely mechanism for drug-drug interactions,[359] and volunteer studies confirm the lack of a clinically important interaction with atorvastatin (a substrate for CYP3A4 and substrate/inhibitor of P-gp) and diclofenac (a substrate for CYP2C9 and uridine

glucuronyltransferase 2b7, and also a substrate and weak inhibitor of UGT1A).[367] When 22 volunteers aged 43 ± 15 years took 80 mg atorvastatin together with 150 mg dabigatran bid for 4 days in an open-label crossover study, the steady-state AUC of dabigatran was reduced by 18%, whereas the Cmax and AUC of atorvastatin increased by 15% and 23%.[375] Cmax and AUC of dabigatran remained unchanged in a similar study of 24 volunteers aged 18 to 55 years who took one 50-mg dose of diclofenac after 4 days of bid dosing with 150 mg dabigatran etexilate, whereas Cmax of diclofenac and its main metabolite decreased by 11% to 17%.[376] The changes were believed to be small and clinically unimportant.

In vitro studies find that dabigatran etexilate (but not dabigatran) is a substrate for P-glycoprotein (P-gp, MDR1) with a medium affinity when tested using the Caco-2 cell-line1, which makes it a potential target for P-gp-related drug interactions.[377] The bioavailability of P-gp substrates like dabigatran may be raised or reduced through inhibition or induction of P-gp: the P-gp inhibitors include amiodarone, verapamil, ketoconazole, quinidine, and clarithromycin, whereas P-gp inducers include rifampicin and St. John's wort (*Hypericum perforatum*).[377]

In formal interaction studies with amiodarone, a first dose of 600 mg raised the AUC and Cmax of dabigatran by about 50% and 60%, an interaction that may persist for some weeks after stopping amiodarone due to the long half-life of this drug.[373] The effects of verapamil depend on its dosing schedule and drug formulation.[373] The first dose of an immediate-release formulation, when given 1 hour before 150 mg dabigatran etexilate, increased the Cmax and AUC of dabigatran by about 180% and 150%, but these elevations were reduced to about 60% and 50% after repeated dosing and to about 90% and 70% when taking an extended-release formulation. The interaction became negligible (increases of 10% in Cmax and 20% for AUC) if verapamil was taken >2 h after dabigatran etexilate when dabigatran absorption was essentially complete. Twice-daily coadministration of 500 mg clarithromycin increased the AUC and Cmax of dabigatran by about 19% and 15%, respectively.

The strong P-glycoprotein inhibitors quinidine and ketoconazole are contraindicated when taking dabigatran etexilate because they markedly increase exposure to dabigatran.[373] The approved product information advises caution when considering coadministration of strong P-gp inducers like rifampicin or St. John's wort, which may significantly decrease the Cmax and AUC.[373]

The P-gp substrate digoxin is used to probe P-gp mediated drug-drug interactions. After 4 days of dosing with once-daily digoxin plus bid 150 mg dabigatran etexilate, there was little effect on the pharmacokinetics of either drug in a three-way crossover study of 23 healthy volunteers aged 18 to 65 years.[378]

Drug interactions that may change the Cmax and AUC of dabigatran have not been correlated with clinical outcomes. Very large increases of Cmax and AUC, like those of quinidine and systemic ketoconazole, are likely to raise the bleeding risk. Moderate increases, like those provoked by amiodarone or verapamil, may become important if combined with old age or reduced renal clearance. The concern about strong P-gp inducers like rifampicin is their potential to decrease drug exposure and therefore reduce efficacy.

2.3.3 Dabigatran Etexilate and Antiplatelet Drugs: The added bleeding risk when platelet function inhibitors like aspirin and clopidogrel are taken during anticoagulant therapy is compounded for aspirin and other nonsteroidal antiinflammatory drugs by the increased likelihood of peptic ulceration due to interference with prostaglandin-mediated cytoprotection of the gastrointestinal mucosa.[379] These mechanisms are independent from any pharmacokinetic drug-drug interactions (none was demonstrated between dabigatran etexilate and diclofenac).[376] Aspirin increased the bleeding rate when added to ximelagatran in patients with AF and to warfarin in patients with AF, a prosthetic heart valve, coronary artery disease, or peripheral vascular disease.[82,317,380]

The added effects on bleeding when aspirin is combined with dabigatran etexilate were explored in the Prevention of Embolic and Thrombotic Events in Patients With Persistent Atrial Fibrillation (PETRO) trial, a phase 2, parallel-group, randomized, dose-ranging safety study in 502 patients with nonvalvular AF who also had coronary artery disease and/or one or more other risk factors for systemic embolism. The patients received 12 weeks of treatment with open-label warfarin alone (target INR 2-3) or with blinded 50 mg, 150 mg, or 300 mg dabigatran etexilate bid plus daily aspirin (81 mg or 325 mg) or a placebo, using a 3 × 3 factorial design to allocate study treatments to patient groups of unequal size. Aspirin increased the chances of major or clinically significant nonmajor bleeding in patients given a supratherapeutic dabigatran dose of 300 mg bid, in whom the bleeding rate was 20% with an aspirin dose of 325 mg/d (six of 30), 14.7% if the dose was 81 mg/d (five of 34), and 5.7% (six of 105) in patients given the aspirin placebo. The trends reached statistical significance when the two aspirin groups were pooled. Bleeding risk was not apparently raised when aspirin was added to 50-mg or 150-mg doses of dabigatran, but the sample size was too small to exclude clinically important effects.[372]

Low doses of aspirin (≤ 100 mg/d) were permitted in the Randomized Evaluation of Long-term Anticoagulant Therapy (RE-LY) (nonvalvular AF) and Dabigatran in the Treatment of Venous Thromboembolism (RE-MEDY) (VTE) phase 3 studies of dabigatran etexilate, which compared bid doses of 110 mg and/or 150 mg with warfarin, but subgroup analyses of bleeding risk are not yet available.[381,382] Product information recommends against the combination of dabigatran etexilate with clopidogrel and other thienopyridines, given alone or as dual antiplatelet therapy with aspirin.

2.4 Antithrombotic Effects: A number of recent phase III clinical trials have evaluated the use of dabigatran etexilate for the prevention and treatment of VTE and to prevent systemic embolism in nonvalvular AF. A phase II study explored its dose-response in acute coronary syndromes.

The efficacy and safety of anticoagulant prophylaxis for VTE depends in any given patient population on the dose, timing, duration, and choice of drug therapy (ie, on the treatment regimen as well as the therapeutic agent). The VTE prevention trials of dabigatran etexilate have evaluated two once-daily dabigatran dosing regimens in patients having elective hip or knee arthroplasty: 150 mg/d or 220 mg/d, beginning soon after surgery with a half-dose of 75 mg or 110 mg. In addition, these two dabigatran regimens were compared with one of two standard enoxaparin prophylaxis regimens: 40 mg/d starting on the evening before surgery, or 30 mg bid starting 12 to 24 h after surgery (worldwide, these are the low-molecular-weight heparin prophylaxis regimens most widely used for joint surgery; both are accepted as standard clinical practice). Two of the trials compared both of these dabigatran regimens with the 40 mg/d schedule of enoxaparin in hip or knee arthroplasty,[383,384] one compared both of the dabigatran regimens with 30 mg enoxaparin bid after knee arthroplasty,[385] and one compared only the 220 mg/d dabigatran etexilate regimen with enoxaparin 40 mg/d in hip arthroplasty.[386]

In all prophylaxis studies, the primary measure of treatment effectiveness was the rate of "total VTE" (a composite of subclinical deep leg vein thrombosis detected with routine bilateral ascending venography done at the end of treatment, confirmed symptomatic DVT or pulmonary embolism (PE), and death from any cause), an outcome that could be evaluated in 73% to 78% of patients. All recorded the presence of major bleeding, clinically relevant nonmajor bleeding, and any adjudicated bleeding.

The two dabigatran prophylaxis regimens were "noninferior" to enoxaparin 40 mg/d in hip arthroplasty and in knee arthroplasty (ie, statistically no less effective),[383,384,387] but each was less effective after knee arthroplasty than 30 mg enoxaparin bid.[385] The first dose of dabigatran etexilate was given 1 to 4 h after surgery in the comparisons with 40 mg/d enoxaparin, but delayed until 12 to 24 h after operation in the comparison with bid enoxaparin. It is likely the bid enoxaparin regimen was superior in part due to the higher daily dose (60 mg), but delaying the start of dabigatran etexilate after surgery may also have contributed to an inferior result. In a subsequent comparison, 220 mg/d dabigatran was again "noninferior" to 40 mg/d enoxaparin in preventing "total VTE" after hip arthroplasty but appeared also to be more effective in preventing "major VTE" (a composite of proximal DVT, nonfatal PE, and death related to VTE).[386] It is now standard practice to start anticoagulant treatment after VTE with a heparin (unfractionated or low molecular weight) together with a VKA, overlap the two drugs for at least 5 days, and stop the heparin only after the INR exceeds 2.0 for > 2 consecutive days.

Dabigatran etexilate was noninferior to warfarin in a double-blind, placebo-controlled and randomized, phase III comparison in patients with deep leg vein thrombosis or PE (the RE-COVER trial) in which study treatment began with at least 5 days of an approved anticoagulant (predominantly unfractionated or low-molecular-weight heparin) plus daily warfarin placebo or warfarin.[382] This study design is unlike that of other (ongoing) evaluations of new oral anticoagulants for VTE, in which the new oral anticoagulant is given alone from the initiation of therapy. The primary measure of efficacy was the incidence of symptomatic and confirmed nonfatal recurrence, or death related to VTE. Randomization in RE-COVER was substratified for a clinical presentation with symptomatic PE (31% of the total) and subgroup analysis suggests this presentation had little or no effect on the relative efficacy of dabigatran. Masking was preserved by using coded POC machines to generate a real or sham INR. Once this exceeded 2.0 for 2 consecutive days, they received dabigatran etexilate 150 mg or its placebo bid (ie, they continued warfarin or started dabigatran). Hence, all patients received at least 5 days of initial treatment with a heparin. However, the median total duration of parenteral therapy before starting dabigatran was 9 days in both of the RE-COVER study groups, which seems longer than the usual clinical practice. INR was within its targeted range of 2.0 to 3.0 for 60% of study time in the warfarin-treated patients.

VKAs are highly effective in preventing embolic stroke from AF, achieving risk reductions of almost 70% when compared with placebo and about 50% when compared with aspirin[387]; their most feared complication is intracranial bleeding, with an added

risk of approximately 0.2% per annum during ongoing warfarin treatment.[388]

Dabigatran dosing regimens of 110 mg and 150 mg bid were compared double-blind with open-label warfarin (target INR, 2.0-3.0) in the RE-LY trial where patients with nonvalvular AF received study treatment of at least 1 year and median of 2 years, and the primary study outcome was ischemic stroke or systemic embolism.[381] On average, the INR in patients taking warfarin was within its target range of 2.0 to 3.0 for 64% of study time. Both efficacy and bleeding risk of dabigatran etexilate depended on the dose. Annual rates of ischemic stroke or embolism were 1.69% with warfarin, 1.53% with 110 mg dabigatran bid (noninferior), and 1.11% with 150 mg dabigatran ($P < .001$ relative to warfarin, $P = .005$ relative to 110 mg dabigatran). The annual incidence of major bleeding was similar, with 150 mg dabigatran and warfarin, but significantly less with 110 mg dabigatran (see section 2.6 "Practical Issues Related to Initiation and Maintenance"). A striking result was the reduced frequency of hemorrhagic stroke with dabigatran compared with warfarin ($P < .001$), regardless of dabigatran dose.

2.5 Monitoring Anticoagulant Intensity

Ex vivo effects on laboratory tests after taking dabigatran etexilate were summarized in section 2.2 "Pharmacokinetics and Pharmacodynamics." Simple widely used coagulation tests have limitations for measuring dabigatran effect: the PT and aPTT are relatively insensitive, the relation between aPTT and dabigatran concentration is nonlinear, and the usual form of TCT is oversensitive. Most promising is the ECT, which has a linear dose-response throughout the range of concentrations expected during prophylaxis or therapy; however, this test is not readily available.[369]

There is no evidence relevant to the possible clinical benefits from laboratory testing, since the phase 3 studies evaluated fixed doses and their reports have not examined clinical outcomes in relation to drug levels or clotting test results. The intent has been to recommend standard doses for most patients; although first principles suggest that laboratory-assisted dose adjustment of this mainly renally excreted drug could add clinical value in selected populations, as in elderly subjects with reduced renal function,[389] it seems unlikely that routine monitoring would yield any wide clinical benefit.[390] Perhaps the most likely role for laboratory testing may be in treated patients who bleed or develop thrombosis, need an acute invasive procedure, or could have taken an overdose. In the setting of major bleeding, or if urgent or emergent surgery is required, a normal TCT rules out the presence of dabigatran. TCT tests are available routinely in many laboratories.

2.6 Practical Issues Related to Initiation and Maintenance

Unlike other new oral anticoagulants, dabigatran etexilate offers a choice between higher and lower dosing regimens, since the schedules evaluated in phase III clinical studies to date were 150 mg and 220 mg once daily when used to prevent postoperative VTE, 150 mg bid for the treatment of VTE, and 110 mg and 150 mg bid in patients with AF.

Dose was important during long-term therapy of patients with AF, in whom 150 mg bid was superior to warfarin and 110 mg bid was noninferior, whereas the rates of major bleeding were similar with 150 mg dabigatran and warfarin but significantly less with 110 mg dabigatran. However, only the 150-mg dose was approved in the United States, whereas in Canada both doses are approved. By contrast, there was less apparent effect of prophylactic dosing level on efficacy or the likelihood of surgical bleeding after major joint replacement, when compared with 40 mg/d enoxaparin.

Subgroup analyses of large clinical studies have provided little evidence to date for clinically important effects of age, gender, or renal function on efficacy or safety within any dosing level. Without such information, the choice between available dosing regimens must rest on individual decisions about the preferred balance between efficacy and bleeding risk and on extrapolations about that risk from pharmacokinetics of this predominantly renally excreted drug. For example, a lower dose may be preferred for elderly patients with a mild to moderate decrease of renal function. In addition, the choice will be influenced by known drug interactions (see section 2.3 "Interactions").

At this time, the only product information approved by European Medicines Agency (EMA) and other regulators is for prophylactic dosing with dabigatran etexilate. Based on clinical study results and pharmacokinetic evidence, EMA recommends a standard daily dose of 220 mg, reduced to 150 mg if patients are aged > 75 years, have a creatinine clearance between 30 and 50 mL/min, or need treatment with verapamil or amiodarone. Ensuring compliance with continued dosing will be a concern for dabigatran etexilate, as it is with any chronic therapy that does not require repeated measurement of drug effect.

2.7 Adverse Events

2.7.1 Bleeding Events: The major potential hazard from dabigatran etexilate is bleeding. After an

elective hip or knee replacement, the risks of major bleeding were small during VTE prophylaxis with dabigatran etexilate and similar to those with prophylactic enoxaparin. The rates were 0.6% to 1.3% in patients given 150 mg/d and 0.6% to 2.0% when the dose was 220 mg/d. These compared with 1.3% to 1.6% with 40 mg/d of enoxaparin and 1.4% with 30 mg of enoxaparin given bid. About 90% of the bleeding events were related to the surgical wound.

Bleeding risk during 6 months of treatment after VTE was less with 150 mg dabigatran bid than with warfarin (target INR, 2.0-3.0). The 6-month rate of "any bleeding" was reduced from 21.9% with warfarin to 16.1% (relative risk, 0.71; 95% CI, 0.59-0.85), and that of "major or clinically relevant but nonmajor" bleeding was diminished from 8.8% to 5.6% (relative risk, 0.63; 95% CI, 0.47-0.84; $P = .002$). Major bleeding was infrequent (1.9% with warfarin and 1.6% with dabigatran).[382]

As indicated earlier, the bleeding risk was dose dependent in the RE-LY study of patients with AF: the annual incidence of major bleeding was 3.4% in patients taking warfarin, 3.1% with 150 mg bid dabigatran (relative risk, 0.93; $P = .31$), and 2.7% if the dose was 110 mg (relative risk, 0.80; 95% CI, 0.69-0.93; $P = .003$); the P value of the difference between dabigatran dosing groups almost reached the conventional level for statistical significance ($P = .052$). Both dabigatran regimens reduced the likelihood of intracranial bleeding by more than one-half compared with warfarin (annual incidence was 0.74% with warfarin, 0.30% with 150 mg dabigatran [$P < .001$] and 0.23% with 110 mg dabigatran [$P < .001$]), whereas annual rates of major extracranial bleeding were little different between the study groups.[381]

Dabigatran etexilate does cause a dose-dependent increase in the incidence of major GI bleeding. This was a statistically significant effect in the RE-LY study; annual rates were 1.02% with warfarin, 1.51% with 150 mg dabigatran ($P < .001$ compared with warfarin), and 1.12% with 110 mg dabigatran.[381] An excess risk was also reported in the RE-COVER trial, in which more patients treated with bid 150 mg dabigatran etexilate had GI bleeding (53 events vs 35 with warfarin).[382]

2.7.2 Nonhemorrhagic Adverse Events: Dyspepsia is a consistently reported adverse effect of dabigatran etexilate. In the RE-LY study, in which warfarin was open label, 11.8% and 11.3% of patients given 110 mg or 150 mg dabigatran complained of dyspepsia compared with 5.8% of patients taking warfarin.[381] Fewer patients reported dyspepsia in the wholly double-blind RE-COVER trial: 2.9% with 150 mg dabigatran bid, and 0.6% with warfarin ($P < .001$).[382]

It is essential to exclude liver toxicity when evaluating new oral anticoagulants, especially because the first orally available direct thrombin inhibitor (ximelagatran) caused unacceptable hepatic toxicity that remains unexplained. About 0.5% of the patients treated with ximelagatran for >35 days developed laboratory evidence of severe liver injury: a greater than threefold elevation of serum alanine transaminase level plus a greater than twofold increase in bilirubin concentration, compared with upper normal limits.[355,391] In one 35-day VTE prevention study, severe hepatic injury with onset after the end of drug exposure was not predicted by regular liver enzyme monitoring during therapy.[392] It has been estimated that ximelagatran may have caused or contributed to fatal liver damage in about 1 in 2,000 patients.[355] No dabigatran study to date has recorded a disproportionate increase of liver enzyme levels or clinically significant liver disease as an adverse effect.

In some ximelagatran studies, short- or long-term treatment was also associated with trends or a statistically significant excess of adverse events related to coronary artery disease.[355] This raised concerns that other new oral anticoagulants might increase the risk from acute cardiac events. Adjudicated coronary events (unstable angina, myocardial infarction, cardiac death) were rare and evenly distributed between study groups in the orthopedic surgery studies of dabigatran etexilate and in the RE-COVER trial, but the RE-LY trial reported an excess of myocardial infarction among the patients treated with dabigatran. The relative risks, compared with warfarin, were 1.35 ($P = .07$) with 110 mg and 1.38 ($P = .048$) with 150 mg dabigatran (the corresponding absolute risks were 0.53%, 0.72%, and 0.74% per annum).[381] There are no ready explanations (although indirect evidence of platelet activation by dabigatran was reported from the PETRO study).[372]

2.8 Reversal of Drug Effect

There is insufficient clinical experience to firmly guide the management of major bleeding, suspected overdose, urgently needed surgery, or urgent invasive diagnostic or therapeutic procedures in patients who are taking this new drug. Pharmacokinetic modeling does, however, indicate how long it takes for drug effects to dissipate after stopping dabigatran etexilate before an elective intervention, although conclusions about the time taken before a return to normal hemostasis remain tentative pending well-documented information about clinical outcomes.

The half-life of dabigatran suggests that drug levels and drug effects should decrease by about 50% at 12 to 18 h after the most recent dose, and the trough levels to 25% of their previous steady state by 24 h

after stopping dabigatran etexilate, so long as creatinine clearance exceeds 50 mL/min. The level at which it is safe to undertake surgery or an invasive procedure is unknown. Moderately severe renal dysfunction (creatinine clearance of 30-50 mL/min) extends the half-life to about 18 h, in which case, or if the surgical bleeding risk is critically high (as with intracranial surgery), it may be better to delay elective procedures until 2 to 4 days after stopping the drug. Measuring the TCT or aPTT should help to estimate the residual level of dabigatran.[369]

In addition to immediately stopping drug administration, the clinical management of major bleeding would require early volume and RBC replacement, urgent assessment for cause, and any local measures that may be required until the bleeding stops (pressure, cautery, suture, or other interventions). It is believed that maintaining an adequate diuresis could help to protect the renal excretion of dabigatran. Although product information for dabigatran etexilate mentions the use of fresh frozen plasma to help control bleeding, this seems unlikely to influence the drug effects. Thus plasma should only be administered in the setting of a documented dilutional coagulopathy.

Dabigatran has no antidote, and the management of life-threatening bleeding remains empirical. Indirect evidence from animal models and in vitro studies suggests that recombinant factor VIIa or a prothrombin complex concentrate may bypass the anticoagulant effects of high dabigatran concentrations.[369] It may also be relevant that hemodialysis removed 62% of circulating dabigatran within 2 h and 68% within 4 h in an open-label study of 12 subjects with end-stage renal failure who received 50 mg dabigatran etexilate.[369,370] In vitro mixing experiments suggest that early administration of activated charcoal might reduce the absorption of dabigatran etexilate.[369]

3.0 Direct Factor Xa Inhibitors: Rivaroxaban

Rivaroxaban is a direct factor Xa inhibitor and is currently approved in many countries, including the United States, for the prevention of VTE in patients undergoing total hip or knee replacement surgery. The drug is undergoing an extensive clinical development program in other clinical settings, including the treatment of VTE and the prevention of acute ischemic stroke in patients with AF. In phase III clinical trials, rivaroxaban was found to be more effective than the low-molecular-weight heparin enoxaparin in preventing VTE after total hip or knee replacement surgery[393-396] and more effective than placebo when given to patients with previous DVT or PE after an initial 6- to 12-month course of standard oral anticoagulant treatment. The doses evaluated were 10 mg once daily in major orthopedic surgery and 20 mg once daily in the long-term secondary prevention of VTE.

3.1 Pharmacology

Rivaroxaban is a selective and competitive active-site-directed, reversible factor Xa inhibitor with selectivity for factor Xa that is > 10,000-fold that for other trypsin-like serine proteases.[397] Rivaroxaban acts through electrostatic interaction with Asp189 in the S1 pocket of factor Xa. This interaction involves the chlorine substituent of the chlorothiophene moiety, which interacts with the aromatic ring of Tyr228 at the bottom of the S1 pocket.[398] Because rivaroxaban is a nonbasic, small molecule (the molecular weight is 436 g/mol) it can inhibit not only free factor Xa but also prothrombinase complex and clot-associated factor Xa.[399,400] This range of activities is unique to small, direct inhibitors because the factor Xa incorporated in the prothrombinase complex is protected from inhibition by antithrombin and by antithrombin-dependent anticoagulants.

Rivaroxaban is minimally soluble in organic solvents and nearly insoluble in water.[398] Binding to plasma proteins, mainly albumin, ranges between 92% and 95%.[398] Rivaroxaban is metabolized via oxidative and hydrolytic pathways involving different classes of enzymes. In humans, CYP3A4 and CYP2J2 are the two enzymes responsible for its oxidative metabolism and contribute to a similar extent.[401] About 66% of rivaroxaban is excreted via the kidneys (36% unchanged), and 28% is excreted in the feces (7% unchanged).

Inhibition of factor Xa activity by rivaroxaban is highly dependent on the concentration of the drug. Rivaroxaban induces prolongation of the PT, aPTT, and heparin clotting time, among other tests.[399,402] On the other hand, rivaroxaban does not affect the bleeding time or platelet aggregation.[399,403] Animal models demonstrated dose-dependent reduction of thrombus formation by rivaroxaban.[399]

3.2 Pharmacokinetics and Pharmacodynamics

In healthy men aged 19 to 45 years, single doses of rivaroxaban administered after a fasting period of 10 h produced a median inhibition of factor Xa activity that ranged from 20% with the 5-mg dose to 61% with the maximum dose of 80 mg.[404] No significant inhibition was observed with doses of < 5 mg. The maximum inhibition of factor Xa activity occurred between 1 and 4 h after drug administration, and the half-life of the biologic effect was 6 to 7 h. Factor Xa activities did not return to normal until after 24 h, when doses > 5 mg were administered.[404] The effect on PT prolongation had a similar profile, as did effects

on the aPTT and HEPTEST (a low-molecular-weight heparin activity assay). Conversely, rivaroxaban had no effect on thrombin and antithrombin activity.[404] Peak plasma concentration of the drug occurred at 2 h, and the terminal half-life was between 7 and 17 h. At doses > 10 mg, the increases in peak plasma concentration and AUC were less than dose proportional. Approximately 40% of the administered dose was excreted unchanged via the kidneys when the 1.25-mg dose was administered; this proportion decreased to 10% with the highest doses tested (ie, 60-80 mg). Finally, inhibition of factor Xa activity and PT prolongation correlated strongly with plasma concentrations ($r = 0.949$ and $r = 0.935$, respectively).[404] When multiple doses were administered at mealtime in healthy male subjects aged 20 to 45 years, the maximum inhibition of factor Xa activity was documented after approximately 3 h and it was dose dependent, ranging from 22% after 5 mg to 68% after 30 mg (Table 4).[405] Inhibition was maintained for 8 to 12 h after 5-mg doses and for approximately 12 h after doses of 10 mg to 30 mg. Daily rivaroxaban doses did not cause a further increase in the maximum inhibition of factor Xa activity. A very similar pattern was observed with PT, aPTT, and HEPTEST prolongation, which was dose dependent for all tests, reached maximum levels after 1 to 4 h, and was comparable after the first and last administered dose.[405] When inhibition of factor Xa activity was compared after once, twice, or three times daily administration of the 5-mg dose, there was no detectable difference between the maximum effect on the first and the last day of administration. The plasma concentrations of rivaroxaban were also dose dependent, with maximum concentrations at 3 to 4 h for all doses and regimens and a half-life of approximately 4 to 6 h on the first day and of approximately 6 to 9 h on the last day of treatment. The correlation between plasma concentrations of rivaroxaban and inhibition of factor Xa activity or PT prolongation was linear, with an r of 0.950 and 0.958, respectively.[405]

Data from this study were later used for population modeling that would predict the behavior of the drug in patients.[406] Results of this model showed that pharmacokinetics of rivaroxaban were linear and dose proportional up to the 30-mg dose and confirmed a strong linear correlation between plasma concentration and pharmacodynamic parameters.

The pharmacokinetics and pharmacodynamics of rivaroxaban were also measured in a population of healthy elderly subjects and in patients with an extremely low or extremely high body weight (Table 4).[407,408] In the first study, healthy subjects aged ≥ 60 years received daily doses ranging between 30 mg and 50 mg after a standard breakfast.[407] It was intended to assess even higher doses of up to 80 mg, but dose escalation was stopped prematurely because of an apparent ceiling effect in pharmacokinetic and pharmacodynamic variables. Maximum inhibition of factor Xa activity ranged from 68.4% after the 30-mg dose to 75.3% and 74.5% after the doses of 40 mg and 50 mg, respectively, and occurred 2 to 4 h after administration. No gender differences were observed. PT prolongation was also greater with the 40-mg dose than with the 30-mg dose, and was not different between the two highest doses, with a maximum effect 2 to 3 h after drug administration. Similar profiles were documented for the aPTT and the HEPTEST. Maximum concentration of rivaroxaban was reached after 4 h in all dose groups, and the half-life

Table 4—*[Section 3.2] Pharmacokinetic Characteristics of Rivaroxaban*[402,404,405]

Population and Dosage	Tmax, h, median	Cmax, μg/L	AUC or AUCτ, μg·h/L	$t_{1/2}$, h
Healthy adults[a]				
5 mg od	3.00	76.4 (18.3)	505.5 (19.7)	8.4 (32.6)
5 mg bid	3.00	85.3 (17.7)	458.5 (13.1)	7.0 (27.8)
5 mg tid	2.00	123.8 (19.7)	557.3 (20.4)	5.8 (35.5)
10 mg bid	2.98	158.0 (18.8)	863.8 (18.6)	7.6 (26.7)
20 mg bid	2.50	318.1 (18.7)	1,903.0 (24.5)	8.0 (40.7)
30 mg bid	3.02	451.9 (10.5)	2,728.0 (14.6)	9.2 (64.1)
Healthy elderly				
30 mg single dose	4.0	392.0 (23.0)	3,531.0 (20.0)	11.7 (63.7)
40 mg single dose	4.0	461.0 (16.8)	4,385.0 (24.1)	13.3 (31.9)
50 mg single dose	4.0	437.0 (32.0)	4,496.0 (33.9)	11.9 (47.8)
Body weight[b]				
≤ 50 kg women only	4.00	178.1 (16.6)	1,172.0 (22.0)	9.6 (36.7)
70-80 kg	3.50	143.4 (26.5)	1,029 (20.1)	7.2 (42.1)
> 120 kg	4.00	149.0 (20.4)	1,155 (15.6)	7.3 (25.4)

Data are presented as geometric mean (geometric coefficient of variation). AUCτ = AUC during a dosage interval at steady state. See Table 3 for expansion of other abbreviations.

[a]Multiple doses.

[b]10 mg single dose.

ranged between 12 and 13 h (Table 4). Excretion via the kidneys was similar among the dosing groups: although women had higher drug concentrations than men after the 30-mg and 40-mg doses, the authors considered that none of the pharmacokinetic parameters showed clinically significant differences between females and males. Finally, the slopes of correlations between plasma concentrations of rivaroxaban and clotting tests were similar in this population of healthy elderly subjects and the population of healthy young men enrolled in a previous study.[407] Other studies have subsequently confirmed the absence of gender-based differences in the pharmacokinetics of rivaroxaban.[409] Pharmacokinetics and pharmacodynamics of rivaroxaban in young and elderly Chinese men and women are comparable to those previously reported in studies of healthy whites.[410,411]

The effects of extreme body weight on a single 10-mg daily dose of rivaroxaban were assessed in a study carried out in men and women aged 18 to 55 years weighing ≤ 50 kg, between 70 and 80 kg, or > 120 kg (Table 4).[408] Peak plasma concentrations were higher in the low body weight group than in the other two groups, with a Cmax value that was significantly increased by 24% as compared with the normal body weight group. On the other hand, there was no difference in plasma concentrations between subjects with a normal or high body weight, and the AUC was similar among all three groups. The half-life of rivaroxaban was increased by 2 h in the low body weight group. Inhibition of factor Xa activity was similar in the three groups, with a maximum effect that occurred after 3 to 4 h and was slightly lower in the group of patients weighing > 120 kg than in the other two groups. The maximum prolongation of PT, aPTT, and the HEPTEST decreased significantly with increasing body weight, although overall all these changes were small.[408]

Finally, to define the pharmacokinetics and pharmacodynamics of rivaroxaban in a population of patients undergoing major orthopedic surgery, blood samples were obtained from patients enrolled in phase II randomized trials.[412,413] The first study analyzed data from two trials that assessed bid doses of rivaroxaban ranging from 2.5 mg to 30 mg administered at mealtimes.[412] Exclusion criteria from these trials were body weight < 45 kg, creatinine clearance < 30 mL/min, and severely impaired hepatic function. The authors found substantial variability in the pharmacokinetics of rivaroxaban on the first postoperative day for all doses, possibly attributed to the presence of "slow" and "fast" absorbers. Overall, absorption was fast, with a Cmax within 1 to 2 h. Absorption status was unrelated to gender, food, anesthesia, or the use of comedications. The variability at steady state was only moderate, and the increase of exposure was dose dependent. Between 14% and 31% of rivaroxaban was excreted unchanged via the kidneys. The clearance of the drug was consistently affected only by renal function, with a creatinine clearance of 30 mL/min resulting in a 15% to 35% higher drug exposure in these two trials.[412] Based on the results of subsequent simulations of various scenarios for patients with different extremes of covariates, it was estimated that plasma concentrations of rivaroxaban would have exceeded the 90% CI of the average patient only in a 90-year-old patient weighing 30 kg, suggesting that one dose of the drug could be administered to all patients regardless of their age, gender, and body weight. The second study compared data from two phase II clinical trials, both carried out in patients undergoing total hip replacement surgery, one assessing bid doses and the other assessing single daily doses.[413] Overall, the pharmacokinetics were similar after once-daily or bid dosing, since only the steady-state area under the plasma concentration-time curve over 24 h was higher with once-daily doses than with bid doses[413] (Table S4). PT prolongation strongly correlated with plasma concentrations when rivaroxaban was given once daily or bid.[413] Simulations of plasma concentration expected after a 10-mg once-daily dose in model subjects with extreme demographic characteristics showed that plasma concentration-time profiles would fall within the predicted 90% CI of the average patient.

3.3 Interactions

3.3.1 Drugs: In humans, CYP3A4 plays a pivotal role in the oxidative metabolism of rivaroxaban.[401] Drugs that inhibit or induce CYP3A4 have the potential to interact with rivaroxaban. However, only drugs that act as strong inhibitors of both CYP3A4 and of P-glycoprotein, a transporter protein of which rivaroxaban is a substrate, have been shown to cause important reduction of the clearance of the drug, thus provoking a significant increase in plasma concentrations. These drugs include azole antimycotics and HIV protease inhibitors. The concomitant administration of rivaroxaban with ketoconazole 400 mg once daily or with ritonavir 600 mg bid resulted in an approximately 2.5-fold increase in the mean AUC and 1.7-fold increase in the mean Cmax of rivaroxaban, together with significantly increased effects on clotting tests.[414] Thus, the use of rivaroxaban in patients receiving ketoconazole, itraconazole, voriconazole, and posaconazole or any HIV protease inhibitor is currently not recommended.[414] Rivaroxaban should be used with caution when given together with other drugs that strongly inhibit only CYP3A4 or only P-glycoprotein. These drugs include clarithromycin, which at the dose of 500 mg bid leads to a

1.5-fold increase in the mean AUC and to a 1.4-fold increase in the Cmax of the drug, and erythromycin, which at the dose of 500 mg three times daily causes a 1.3-fold increase in both the AUC and the Cmax.[414] On the other hand, reduced plasma concentrations of rivaroxaban can occur when strong CYP3A4 inducers are coadministered. These include rifampicin (which causes a 50% decrease in the AUC), phenytoin, carbamazepine, phenobarbital, or St. John's wort.[414] The concomitant administration of rivaroxaban with substrates of either CYP3A4 or P-glycoprotein, such as atorvastatin, digoxin, or midazolam, did not result in clinically relevant interactions.[415,416]

The concomitant administration of rivaroxaban and aspirin was tested in a randomized, two-way crossover study.[403] Healthy men aged between 18 and 55 years were randomized to receive aspirin alone at the dose of 500 mg on the first day and 100 mg on the second day, rivaroxaban alone at the dose of 15 mg, or aspirin and rivaroxaban at the same dosages. Patients receiving rivaroxaban alone were subsequently treated with rivaroxaban and aspirin and vice versa. Maximum levels of inhibition of factor Xa activity and maximum prolongation of the PT, aPTT, and the HEPTEST were similar in patients treated with rivaroxaban alone and in patients treated with rivaroxaban plus aspirin. Collagen-stimulated platelet aggregation was inhibited in the aspirin-alone group and in the aspirin plus rivaroxaban group but not in the rivaroxaban-alone group. Inhibition of platelet aggregation with aspirin was 89.3% greater than with rivaroxaban alone, and with aspirin plus rivaroxaban it was 97.4% greater than with rivaroxaban alone. Bleeding time was not affected by rivaroxaban alone, but was prolonged to 1.46 times the baseline by aspirin alone and to 1.96 times the baseline by adding aspirin to rivaroxaban. The combination of aspirin with rivaroxaban prolonged bleeding time more than aspirin alone. Pharmacokinetic parameters of rivaroxaban were not altered by the coadministration of aspirin.

The concomitant administration of rivaroxaban and a nonsteroidal antiinflammatory drug was also tested in a randomized two-way crossover study.[417] Healthy men aged between 18 and 45 years were randomized to receive 15 mg of rivaroxaban alone or 15 mg rivaroxaban plus naproxen 500 mg. After 14 days all subjects crossed over. Maximum inhibition of factor Xa activity and maximum prolongations of the PT, aPTT, and HEPTEST were similar between the two groups. Bleeding time was significantly increased by the combined use of rivaroxaban and naproxen as compared with rivaroxaban alone. Plasma concentrations of rivaroxaban were slightly increased, by 10% for both the AUC and the Cmax after the coadministration of naproxen. Finally, the concomitant administration of drugs that alter the gastric pH, such as the histamine H2 antagonist ranitidine or the antacid aluminum-magnesium hydroxide, had no effect on the plasma concentrations or pharmacodynamics of rivaroxaban.[418]

3.3.3 Environmental Factors: The effect of food on the absorption of rivaroxaban was tested in healthy male subjects aged 18 to 45 years.[418] After a single dose of 5 mg, the absorption of rivaroxaban was found to be slower in the fed state than the fasting state, with a delay in the median time to reach the peak plasma concentration from 2.75 h to 4.0 h. The AUC and the Cmax both increased with the concomitant administration of food, by 28% and 41%, whereas the terminal half-life remained unchanged. The fed state increased the time to maximum prolongation of the PT and maximum inhibition of factor Xa activity and also the maximum effect on these clotting tests. Thus, absorption of rivaroxaban was moderately increased after the administration of food, with a resulting increase in pharmacokinetic and pharmacodynamic parameters. In addition, concomitant food intake reduced interindividual variability, whereas elimination remained unchanged. No pharmacokinetic differences were documented when high-fat, high-calorie meals were compared with high-carbohydrate meals. These food effects have been attributed to a prolonged length of stay in the stomach that is possibly related to the lipophilicity and limited aqueous solubility of the drug.[418]

3.4 Antithrombotic Effect

Rivaroxaban acts as a competitive inhibitor of the amidolytic activity of factor Xa. In vitro, the inhibitory effect is concentration dependent, with an inhibitory constant against factor Xa of 0.4 ± 0.02 nM.[399] The selectivity of rivaroxaban for factor Xa is 10,000-fold greater than for other serine proteases, including factor Va, factor IXa, factor XIa, thrombin, and activated protein C. The onset of action is rapid and reversible, as shown by the kinetic association rate constant of 1.7×10^7 mol/L^{-1}/s^{-1} and kinetic dissociation rate constant of 5×10^{-3}/s^{-1}.[419] The inhibitory effect is maintained when factor Xa is complexed with factor Va and Ca^{2+} on a phospholipid membrane (prothrombinase bound) as shown by a concentration-dependent inhibition of thrombin generation[399] and also when factor Xa is bound to the clot.[420]

In plasma, endogenous human factor Xa is inhibited by rivaroxaban to cause dose-dependent prolongation of both the PT and aPTT, with the PT being more sensitive than the aPTT.[399] In whole blood and in platelet-rich plasma, rivaroxaban has a dose-dependent effect in prolonging the initiation phase of thrombin generation after activation of the tissue

factor pathway, reduces the maximum concentration of generated thrombin, and decreases the endogenous thrombin potential.[400] The effect on the initiation and propagation phases of thrombin generation is greater than the effect on the decay phase, expressed by the endogenous thrombin potential. High concentrations of rivaroxaban are able to prevent thrombin generation almost completely, due to inhibition of factor Xa bound to the prothrombinase complex.[400] The effect of rivaroxaban on platelet-induced thrombin generation in vivo was tested in a randomized, placebo-controlled, crossover study of 12 healthy male subjects aged 27 to 37 years.[397] The prothrombinase-induced clotting time, a plasma clotting assay based on the activation of coagulation using factor Xa, phospholipids, and an enzyme that activates factor V, was prolonged dose dependently by rivaroxaban, with a maximum effect after 2 h. Thrombin generation in platelet-rich plasma was markedly reduced by rivaroxaban, with an 80% to 90% decrease (by 5-mg and 30-mg doses, respectively) of the peak collagen-induced endogenous thrombin potential at 2 h. There was a close correlation between plasma concentration of rivaroxaban and its effects on factor Xa activity inhibition, prothrombinase-induced clotting time prolongation, and endogenous thrombin potential reduction.[397]

Rivaroxaban has no effects on platelet aggregation induced by collagen, adenosine diphosphate, or thrombin.[403,421,422] An indirect effect on platelet aggregation induced by tissue factor, determined by the inhibition of thrombin generation, has been reported in defibrinated plasma.[423]

In venous thrombosis models and in arteriovenous shunt models, rivaroxaban was shown to cause dose-dependent reduction of thrombus formation, inhibition of factor Xa activity, and prolongation of the PT.[399] The antithrombotic effective doses of rivaroxaban did not prolong bleeding time in animal bleeding models.[399]

3.5 Monitoring Anticoagulant Intensity

The predictable pharmacologic profile of rivaroxaban allows the administration of the drug at fixed doses without the need for routine laboratory monitoring or dose adjustments. However, there may be rare situations, as in the case of overdose or unexpected bleeding, assessment of compliance, evaluation of drug interactions, or assessment of drug accumulation in renal or hepatic impairment, when the availability of a quantitative clotting assay might be valuable. Despite the predictable, dose-dependent effects of rivaroxaban on the PT and (to a lesser extent) the aPTT, and on tests measuring thrombin generation, there are currently no validated laboratory assays that can be recommended to monitor rivaroxaban or any recommendations for dose adjustments based on observed test results. For instance, the thromboplastins used for PT clotting assays have differing sensitivities to factor Xa inhibitors, and the INR introduced to correct for differences in PT sensitivity when monitoring the VKAs does not adequately correct for differences in assay sensitivity to direct factor Xa inhibitors. Smith and Morissey[424] evaluated the effects of five commercial thromboplastin reagents on sensitivity of the PT to rivaroxaban and its correlation with the INR. PT ratios (ie, PT with drug/PT without drug) were measured using normal human plasma to which rivaroxaban 1 μg/mL was added in vitro. PT ratios varied from 2.25 to 7.32 with the different thromboplastins; subsequent conversion to an INR further exacerbated the observed differences in sensitivities to rivaroxaban between the various PT assays.

Recently, Samama et al[402] carried out a study that aimed to identify a clotting test suitable for monitoring rivaroxaban activity by evaluating the effects on a number of different assays of increasing the drug concentration in pooled citrated normal human platelet-poor plasma. There was a concentration-dependent prolongation of the PT and aPTT, but the increases in clotting times varied depending on the thromboplastin reagent used.[402] The effect of rivaroxaban on the aPTT was weaker than that on the PT. Rivaroxaban also prolonged the thromboelastograph parameters. Standard methods for the HEPTEST and the prothrombinase-induced clotting time resulted in paradoxical responses. Tests used to measure anti-factor Xa activity of the low-molecular-weight heparins showed dose-dependent effects but were associated with some degrees of variation. Finally, rivaroxaban also caused a dose-dependent increase of the diluted Russell viper venom ratio. Specific calibration of some of these tests may lead to the availability of an appropriate assay to monitor the pharmacodynamic effects of the drug. Neither the PT (expressed either in seconds or as a ratio) nor the aPTT should be used to monitor the anticoagulant effect of rivaroxaban.

3.6 Practical Issues Related to Initiation and Maintenance

Rivaroxaban is currently approved in many countries for the prevention of VTE in patients undergoing total hip replacement surgery and total knee replacement surgery based on the results of four phase 3 clinical trials.[393-396] For this indication, the approved dose is 10 mg once daily. Treatment should be started between 6 and 10 h after surgery, and the duration of treatment should vary from 2 weeks in patients undergoing total knee replacement surgery

to 5 weeks in patients undergoing total hip replacement surgery, although approved durations may vary among countries. Rivaroxaban is currently not approved for use in patients with severe renal failure and a creatinine clearance of < 15 mL/min, in patients with hepatic disease associated with coagulopathy, and in patients receiving concomitant systemic treatment with azole-antimycotics or HIV protease inhibitors.[414] Rivaroxaban is also not approved for use in children or adolescents < 18 years of age because of the absence of clinical data, in pregnant women because of the potential for reproductive toxicity (observed in animals) and the evidence that the drug passes the placenta, and during breast-feeding because the drug is secreted into milk.[414]

Future additional indications are expected following the results of recently published clinical trials. In particular, more information on the long-term administration of rivaroxaban now originates from studies carried out in patients with VTE or AF in whom the drug was administered for a minimum of 6 months and up to a maximum of 40 months.[425,426]

To date, the results of a phase III clinical trials assessing the use of rivaroxaban in the treatment of DVT have been published. In the EINSTEIN study, > 3,400 patients with acute symptomatic proximal DVT were allocated to rivaroxaban 15 mg bid for 3 weeks followed by 20 mg once daily or initial therapy with enoxaparin (1 mg/kg bid) and simultaneous warfarin administered to a target INR of 2.0 to 3.0.[425] The primary outcome measure was symptomatic recurrent VTE, which occurred in 36 rivaroxaban-treated patients and 51 low-molecular-weight heparin/warfarin-treated patients (HR, 0.68; 95% CI, 0.44-1.04; $P < .0001$ for noninferiority). Patients who had completed 6 to 12 months of anticoagulant treatment with either a VKA or rivaroxaban (if also enrolled in the acute-phase rivaroxaban treatment study) after an acute episode of VTE were randomized to receive rivaroxaban 20 mg once daily or matching placebo for additional 6 to 12 months. The study showed superior efficacy of rivaroxaban over placebo in the prevention of recurrent venous thromboembolic events, a nonsignificant increase in major bleeding, and an increase in clinically relevant, nonmajor bleeding events.[425]

More recently, the results of the Rivaroxaban Once Daily Oral Direct Factor Xa inhibition Compared with Vitamin K Antagonist for the Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET) study comparing rivaroxaban 20 mg once daily (15 mg once daily if patients had a creatinine clearance between 30 and 49 mL/min) with warfarin in patients with AF and at least two additional risk factors for embolic events were published. In this randomized, double-blind, controlled trial, rivaroxaban was noninferior to warfarin in the prevention of ischemic stroke or systemic embolism, with a similar rate of major bleeding events but with fewer intracranial and fatal bleeding events.[426]

Other recently completed phase III trials include a study on the prevention of VTE in medical patients (Multicenter, Randomized, Parallel Group Efficacy and Safety Study for the Prevention of VTE in Hospitalized Medically Ill Patients Comparing Rivaroxaban with Enoxaparin [MAGELLAN] study), in which rivaroxaban is administered at the same 10 mg once-daily dose used in the Regulation of Coagulation in Major Orthopedic Surgery Reducing the Risk of DVT and PE (RECORD) program; and the EINSTEIN PE study, in which patients with hemodynamically stable PE are treated for the first 3 weeks with a 15 mg bid dose of rivaroxaban followed by a 20 mg once-daily dose. Finally, a phase III study in patients with acute coronary syndromes is assessing rivaroxaban doses of 2.5 mg and 5.0 mg bid.[427]

3.7 Adverse Events

3.7.1 Bleeding Events: Data on the incidence of bleeding complications with the use of rivaroxaban are currently available from the results of phase II and phase III clinical trials only. As of yet, no published phase IV studies or reports from clinical practice have been published. Reported rates must take into account the definition of bleeding used in each study, given the variability of definitions used among clinical trials assessing different compounds.

The reported rates of any bleeding with rivaroxaban in the four phase III clinical trials carried out in patients undergoing total hip and total knee replacement surgery range from 4.9% to 10.5%[393-396] and are comparable to the rates observed in patients treated with enoxaparin. Rates of major bleeding events vary from < 0.1% to 0.7%, and the rates of clinically relevant nonmajor bleeding events vary from 2.6% to 3.3%, again with no statistically significant differences between the rates observed in the rivaroxaban groups and the rates observed in the comparator groups (ie, the low-molecular-weight heparin enoxaparin in all studies).[393-396] A pooled analysis of the four RECORD studies reported that the concomitant use of nonsteroidal antiinflammatory drugs, aspirin, or other antiplatelet agents was not associated with an increased rate of bleeding events.[428]

The rate of any bleeding event in patients with a previous episode of VTE treated with rivaroxaban 20 mg once daily for 6 to 12 months after the initial standard course of anticoagulant therapy was 23%; major bleeding and clinically relevant nonmajor bleeding occurred in 0.7% and 5.4% of patients, respectively.[425]

3.7.2 Nonhemorrhagic Adverse Events: None of the four phase III clinical trials found evidence of drug-associated liver toxicity in patients treated with rivaroxaban for up to 5 weeks.[393-396] Overall, the proportion of patients with elevated liver enzymes was low in all studies and was similar between rivaroxaban and enoxaparin. The incidence of cardiovascular events was low while on treatment with rivaroxaban, ranging between 0.1% and 0.7%, and was similar to that seen with enoxaparin. Drug-related adverse events occurred in 12% to 20% of patients in the four RECORD trials; these rates were similar to those observed with enoxaparin. The most frequent adverse events were nausea, vomiting, and constipation.

3.8 Reversal

There is currently no specific antidote available to antagonize the effects of rivaroxaban. In case of overdose, the use of activated charcoal to reduce absorption is suggested.[414] Because of the high plasma protein binding, rivaroxaban is unlikely to be dialyzable. In case of active bleeding, possible strategies currently include discontinuation of treatment and administration of blood products or component transfusion if required to treat an identified deficiency.[414] However, there is currently no direct evidence in humans to support the efficacy of blood product transfusion or other interventions in improving hemostasis when patients have received rivaroxaban. Recently, Perzborn et al[429] reported the results of a study carried out in rats treated with high-dose rivaroxaban, which aimed to assess the efficacy of prothrombin complex concentrate. After determination of baseline mesenteric bleeding time, rats were initially treated with IV rivaroxaban and subsequently received four-factor prothrombin complex concentrates at 25 U/kg or 50 U/kg. Prolongation of the bleeding time was almost completely abrogated by higher dose of prothrombin complex concentrates, whereas the lower dose was ineffective. The use of recombinant factor VIIa is also suggested in the presence of life-threatening bleeding based on some preclinical data.[414] A reconstructed recombinant factor Xa has been recently proposed as a potential antidote for factor Xa inhibitors.[430] This is a catalytically inactive factor Xa that has no procoagulant or anticoagulant activity and does not interfere with the prothrombinase complex but maintains high affinity for factor Xa inhibitors. In plasma, the addition of the antidote dose-dependently reversed factor Xa inhibition as measured by anti-factor Xa units, tissue factor-initiated thrombin generation, and clotting assays. In vivo, the antidote completely reversed PT prolongation induced by intravenous infusion of rivaroxaban in rats.

Conclusion

Over the last decades, a large amount of research has been addressed to improve the understanding of the mechanisms of warfarin, acenocoumarol, and phenprocoumon and to improve the management of patients treated with these VKAs. Several studies have in particular identified some genetic factors associated with the individual responses to VKAs and several drugs, foods, and environmental factors that can interact with these compounds. Several induction and maintenance strategies have been compared, and management studies have evaluated different approaches for the monitoring of patients on VKAs, including AMS and AC, computer programs, and POC for INR testing. The results of all such studies have greatly contributed to improve the efficacy and safety of oral anticoagulant therapy and to increase the number of patients who can be deemed eligible for such treatment. Finally, a number of trials have also addressed the management of patients on VKA treatment who are at increased risk of bleeding or are actively bleeding, and a number of therapeutic strategies have been proposed, although additional research may be warranted in particular to further improve the management of the bleeding patient.

The new oral anticoagulant drugs have the potential to overcome several drawbacks of the VKAs. These drugs can be administered at fixed doses and do not require laboratory monitoring, thus offering a clear advantage over the VKAs. It is hoped that new studies will provide us with further information on the role of specific laboratory tests for the monitoring of the activity of these new classes of drugs, when requested, and on the optimal management of drug-related adverse events.

Acknowledgments

Author contributions: As Topic Editor, Dr Ageno oversaw the development of this article, including any analysis and subsequent development of the information contained herein.
Dr Ageno: contributed as Topic Editor.
Dr Gallus: contributed as a panelist.
Dr Wittkowsky: contributed as a panelist.
Dr Crowther: contributed as a panelist.
Dr Hylek: contributed as a panelist.
Dr Palareti: contributed as a panelist.
Financial/nonfinancial disclosures: In summary, the authors have reported to *CHEST* the following conflicts of interest: Dr Ageno has received fees for steering committee or safety advisory boards membership from Bayer Health Care, sanofi-aventis, and Thrombogenics; research grants from GlaxoSmithKline, Alexion Pharmaceutical, Pfizer, and Bayer Health Care; honoraria for speaking activities at national or international meetings and for advisory boards from Bayer Health Care, GlaxoSmithKline, sanofi-aventis, Pfizer, BMS, and Boehringer Ingelheim. Dr Gallus has received fees for steering committee membership from BMS, Pfizer, sanofi-aventis, Bayer, ASTELLAS, Daiichi Sankyo. Dr Crowther has served on various advisory boards, has assisted in the preparation of educational materials, has sat on data and safety monitoring boards, and his institution has received research funds from the following companies: Leo Pharma, Pfizer, Boehringer Ingelheim,

Bayer, Octapharm, CSL Behring, and Artisan. His personal total compensation for these activities over the last 3 years totals less than $10,000. Dr Hylek has served on advisory boards (Bayer, Boehringer Ingelheim, Bristol-Myers Squibb, Daiichi Sankyo, Johnson & Johnson, Merck, Ortho-McNeil, and Pfizer; total dollar amount less than $10,000). She has served on the Executive Steering Committee-ARISTOTLE trial sponsored by Bristol-Myers Squibb and Pfizer (dollar amount less than $10,000). She has also served on the Executive Steering Committee-ORBIT AF Registry sponsored by Ortho-McNeil (dollar amount less than $10,000). She has participated in a symposium sponsored by Boehringer Ingelheim (dollar amount less than $10,000). Drs Wittkowsky and Palareti have reported to *CHEST* that no potential conflicts of interest exist with any companies/organizations whose products or services may be discussed in this article.

Role of sponsors: The sponsors played no role in the development of these guidelines. Sponsoring organizations cannot recommend panelists or topics, nor are they allowed prepublication access to the manuscripts and recommendations. Guideline panel members, including the chair, and members of the Health & Science Policy Committee are blinded to the funding sources. Primary care physicians can help drug-dependent patients mitigate adverse drug use consequences; instruments validated in primary care to measure these consequences would aid in this effort. This study evaluated the validity of the Short Inventory of Problems—Alcohol and Drugs modified for Drug Use (SIP-DU) among subjects recruited from a primary care clinic (n = 106). SIP-DU internal consistency was evaluated using Cronbach's alphas, convergent validity by correlating the total SIP-DU score with the DAST-10, and construct validity by analyzing the factor structure. The SIP-DU demonstrated high internal consistency (Cronbach's alpha for overall scale .95, subscales .72–.90) comparable with other SIP versions and correlated well with the DAST-10 (r = .70). Confirmatory factor analysis suggested an unacceptable fit of previously proposed factors; exploratory factor analyses suggested a single factor of drug use consequences. The SIP-DU offers primary care clinicians a valid and practical assessment tool for drug use consequences. (Am J Addict 2012;21:257–262)

INTRODUCTION

Primary care physicians are in a position to identify drug users years before they have medical complications or present for drug treatment. During the clinical encounter, primary care physicians can detect and then provide early intervention to help their patients become aware of and prevent adverse effects of drug use.[1] The individual consequences of drug use and dependence can be severe and may include loss of self-worth; loss of employment; loss of spouse, friends, and family; incarceration; as well as the development or worsening of chronic medical and/or psychiatric disorders. Understanding drug use consequences is central to addressing drug use and can provide motivation to the patient to address the problem. Understanding the severity of problems can also help a clinician determine what, if any, intervention is required (eg, a brief intervention in primary care for patients with milder symptoms or more intensive treatment for the dependent patient). Drug use instruments validated in a primary care setting are important; most such instruments were developed in specialty care settings and may not be appropriate for use in primary care.

One instrument that has been adapted to measure the consequences of alcohol and drug use combined is the Short Inventory of Problems (SIP). Originally developed and validated to measure alcohol consequences, the SIP has been modified to assess individual consequences related to substance (alcohol and other drug) use disorders (SIP-SUD), alcohol and other drug use (SIP-AD), drugs alone (SIP-D), and even bipolar disorder (SIP-BD).[2–4] None has been validated in primary care settings. The original SIP for alcohol is a 15-item instrument created by selecting representative items from the Drinker Inventory of Consequences (DrInC) to assess the self-attributed consequences of drinking in five domains (Physical, Intrapersonal, Social

Received March 11, 2011; revised March 31, 2011; accepted May 3, 2011.

Responsibility, Interpersonal, and Impulse Control) using two time frames (lifetime and recent consequences).[5] The Physical domain assesses acute and chronic physical states resulting from heavy drinking. The Intrapersonal domain asks about personal states of feeling associated with drinking such as guilt or shame. The Social Responsibility domain asks about consequences observable by others such as failing to do what was expected because of drinking. The Interpersonal domain assesses an individual's damage to or loss of personal relationships, including concern about drinking from family and friends. Finally, the Impulse Control domain asks about impulsive actions, risk-taking, increased use of other substances, and legal problems.[5,6]

The Inventory of Drug Use Consequences (InDUC) represented a next step in meeting the need for a standardized measure of both alcohol and other drug use consequences. The InDUC was created by taking the identical items used in the DrInC but modifying the wording from "drinking" to "drinking or using drugs." The InDUC is available in two versions: one that assesses lifetime consequences of substance use and another that assesses the frequency of recent problems (ie, past 3 months).[5] Like the DrInC, the InDUC was subsequently shortened to 15 items (of which 12 items are the same as those used in the SIP for alcohol) to enhance its clinical utility and became known as the SIP for alcohol or drugs (SIP-AD).[2]

It is this version of the SIP that was modified for this study to focus on other drug problems, and we hypothesized that it would have similar properties of internal consistency and validity as its recently developed cousin instrument, the SIP for alcohol modified for other drugs (SIP-D).[3] However, since the instrument used in this study is descended from a different branch of the SIP family tree than the SIP-D with three items that were not part of the SIP for alcohol, this instrument shall be referred to as the Short Inventory of Problems—Alcohol and Drugs modified for Drug Use (SIP-DU) to distinguish it from the SIP-D (Figure 1). Since no previous versions of the SIP have been validated exclusively in a primary care sample, the main objective of this study was to evaluate the validity of the SIP-DU in a sample of primary care patients.

MATERIALS AND METHODS

Participants

The study was conducted between October 2006 and June 2007 in the waiting room of a primary care clinic at an urban safety net hospital. To help minimize biased selection, subjects were systematically approached daily by one research associate according to a predetermined pattern based on waiting room seating, which was varied each day. Patients who were under the age of 18 were excluded, as were those who, in the judgment of the research associate, would be unable to complete the questionnaire because of limited English, cognitive impairment, or acute illness. People in the waiting room accompanying patients but who reported not themselves being patients of the clinic were also excluded. Eligible subjects were interviewed either before or after their primary care visit, or were scheduled to return at a later time for a research interview conducted in a private setting. All data were recorded anonymously without any unique identifiers.

Assessments

Subjects were first asked the single screening question validated in primary care to detect drug use, "How many times in the past year have you used an illegal drug or used a prescription medication for non-medical reasons?"[7] A cross-sectional assessment of alcohol and drug use was then conducted including the Drug Abuse Screening Test (DAST-10), a computerized version of the Composite International Diagnostic Interview (CIDI) Substance Abuse Module and the SIP-DU.[8,9] The questions included in the DAST-10 ask about possible involvement during the past 12 months with drugs by drug class, not including alcohol (eg, the use of prescribed or over-the-counter drugs in excess of the directions, any nonmedical use of drugs). As part of the CIDI, subjects were asked about past year use of illicit drugs (marijuana, cocaine, heroin, stimulants, or hallucinogens) and about past year non-medical use of prescription drugs. The SIP-DU asked questions about lifetime consequences of drug use (1 = Ever/0 = Never); subscale scores and the total score were then calculated by summing the item responses. All interviews were conducted by trained research staff (author PS trained the research associate by role play and by using the CIDI materials) in a private setting and data were recorded anonymously. All study procedures were reviewed and approved by the Institutional Review Board of Boston University Medical Center. Informed consent was given by all subjects before participating in the research.

Data Analysis

All analyses were conducted using SAS version 9.1 (SAS Inc., Cary, NC, USA). Scores were calculated for the total SIP-DU and each of the five subscales using the questions that asked about drug use consequences over the past 3 months. Cronbach's alpha (α) was used to assess internal consistency, or how closely related the set of questions are, and to evaluate how well the SIP-DU subscales measured distinct underlying constructs of drug use consequences. Internal consistency estimates were compared with published results from other SIP instruments.[4,5,10,11] The non-parametric Spearman's rho (ρ) was used to assess correlation of the SIP-DU with the DAST-10, a measure of drug involvement that is conceptually related (convergent validity). To evaluate whether the SIP-DU questions correspond to the previously proposed five concepts of Physical, Social, Interpersonal, Intrapersonal, and Impulse control consequences (construct validity) a confirmatory factor analysis was performed. The following criteria

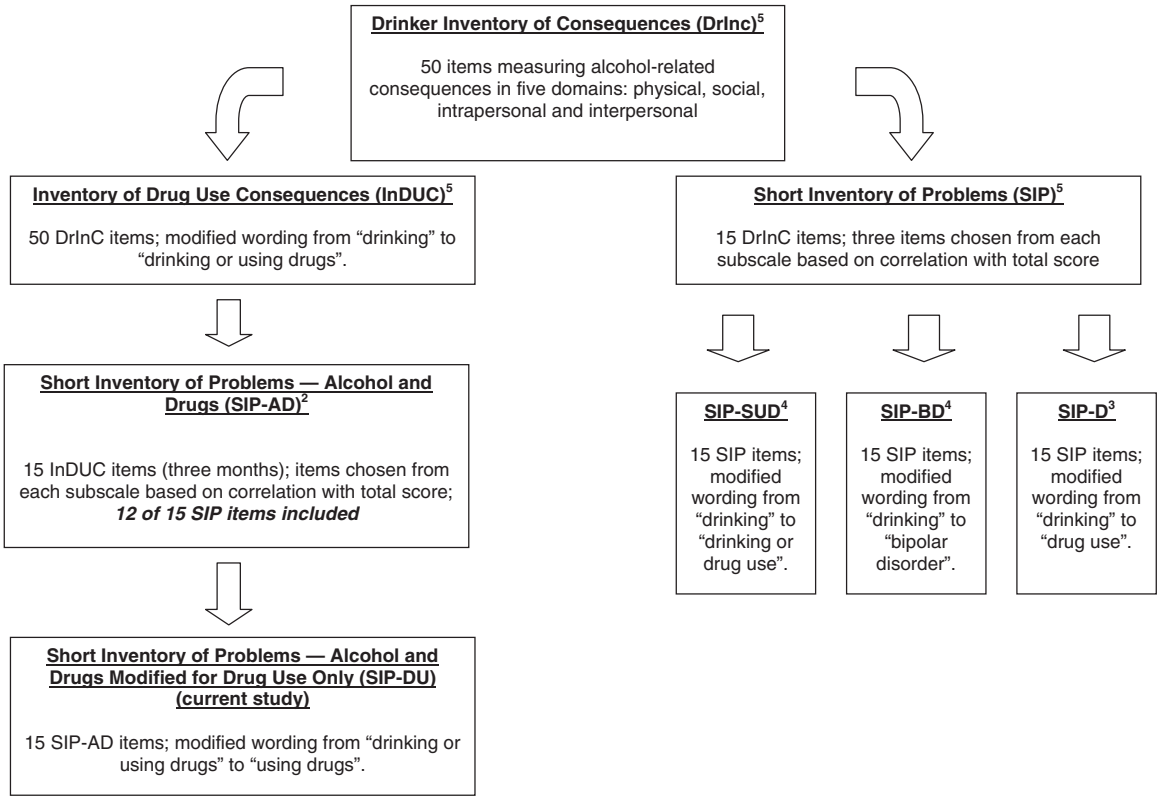

FIGURE 1. Derivation of the short inventories of problems. DrInC = Drinker Inventory of Consequences; InDUC = Inventory of Drug Use Consequences; SIP = Short Inventory of Problems; SIP-AD = Short Inventory of Problems—Alcohol and Drugs; SIP-SUD = Short Inventory of Problems—Substance Use Disorder; SIP-BD = Short Inventory of Problems—Bipolar Disorder; SIP-D = Short Inventory of Problems—Drugs; SIP-DU = Short Inventory of Problems—Drug Use.

were used to assess whether the model fit of the confirmatory factor analysis was acceptable: chi-square test (p-value .05); root mean square error of approximation (RMSEA) <.05; goodness of fit index (GFI) >.95; adjusted goodness of fit index (AGFI) >.90. If the analyses suggested an unacceptable model fit, an exploratory factor analysis was planned to further evaluate the possible underlying constructs of the SIP-DU. For the exploratory factor analysis, the number of factors to retain was determined based on the scree plot and the interpretability of the resulting factors. The exploratory factor analysis was performed using oblique rotation to allow for possible correlation among factors.

RESULTS

Sample Characteristics

Of 1,781 patients approached for screening 903 agreed to be screened and 394 were eligible for the study. Of the 394 eligible subjects, 303 arrived for the research interview and consented to participate in the study; 286 subjects completed the research interview. The sample for this analysis was limited ($n = 106$) to subjects who were identified as drug dependent based on their responses to the CIDI since they represent a relevant primary care population for assessment of drug use consequences (and the original SIP was derived from people with dependence). Study participants were predominantly male with a median age of 46 (range 22–74 years, Table 1). A majority was African American (58%), high school educated (73%), and reported English as their primary language (82%).

Scale Internal Consistency and Convergent Validity

Table 2 presents the scale internal consistency of the SIP-DU and, for comparison, those from the previously published DrInC and previous versions of the SIP, the SIP for alcohol use consequences, and the SIP for substance use disorders (SIP-SUD). These previous studies assessed versions of the SIP in several different populations including outpatients diagnosed with substance use and bipolar disorder, problem drinkers recruited from the community, and Emergency Department patients presenting with alcohol-related injuries.[4,5,10,11] Overall SIP-DU scale internal consistency was high (Cronbach's $\alpha = .95$) and the SIP-DU subscales had moderate-to-strong alphas (Physical = .71;

TABLE 1. Sample characteristics ($n = 106$)

Values are represented as *n* (%) except where otherwise noted; SD = standard deviation.

Social = .89; Interpersonal = .85; Intrapersonal = .86; Impulse = .82). Overall and across all five domains the SIP-DU internal consistency appeared as good as that previously reported for the related SIP measures by other studies. The total SIP-DU score had moderate-to-strong correlation with a conceptually related instrument, the DAST-10 (Spearman's $\rho = .71$), demonstrating convergent validity.

Construct Validity

Confirmatory factor analysis revealed that the five-factor structure did not provide an acceptable fit to the data based on each of the four fit indexes (chi-square $p < .0001$; RMSEA = .17; GFI = .74; AGFI = .58). An exploratory factor analysis was therefore conducted to further evaluate the possible underlying constructs of the SIP-DU. The scree plot suggested two underlying factors. In evaluating the two-factor model, each factor had multiple items with strong loadings and there was only one item that loaded on more than one factor. However, these factors were unable to be interpreted as distinct concepts of drug use consequences and did not correspond with the hypothesized subscales (Table 3). A three-factor model was then considered; however, this model demonstrated poor loadings on the third factor (data not shown). A single-factor model was then fit; all items demonstrated acceptable loadings (.598–.855) and the single-factor model explained 82% of the variance. Cronbach's alpha was .95 for the single-factor model suggesting a high degree of internal consistency. These results suggested a single-factor model provided the best fit to the data.

DISCUSSION

Recent initiatives to promote screening and brief intervention have resulted in improved screening tools for drug use and dependence in a variety of patient populations.[7,12,13] However, it is also important to assess the consequences of drug use once it is identified. Certainly reducing the negative physical, social, and personal consequences of drug use is an important quality of life issue for drug users,[14,15] and the involvement of primary care physicians in helping the patient find ways to reduce these consequences has the potential to improve both quality of care and outcomes. In fact, evidence suggests that higher quality primary care has the potential to reduce the odds of substance use.[16] The purpose of this study was to validate a version of the SIP that can be used in the primary care setting for drug use consequences. The SIP-DU and a single screening question about drug use provide time-efficient tools for primary care teams in identifying and caring for drug-using patients.[7]

Previous research has shown that the SIP and its variants (eg, the SIP-AD) are valuable measurement tools that can reliably assess negative consequences in patients with alcohol or drug use disorders.[2] Although one instrument that summarizes consequences of both alcohol and drug use can

SIP-DU = Short Inventory of Problems—Drug Use. Values in boxes indicate which items distinctly loaded onto either Factor 1 or Factor 2.

be useful as a global measure, tools that are more specific are needed for individual clinical care. Previous versions of the SIP have assessed consequences due to alcohol or drug use without distinguishing whether consequences were due to one or the other. This level of specificity is important when having a discussion with a patient about substance use consequences and when monitoring clinical progress of treatment outcomes in primary care. Having the ability to attribute consequences to alcohol and drugs separately may help clinicians and patients considering treatment options to prioritize and individualize interventions to mitigate the negative consequences experienced by the patient.

The results of this study suggest that the SIP-DU retains strong internal consistency when administered in primary care and that this is comparable to those reported in earlier studies.

The observed correlation of the SIP-DU with the DAST-10 is sufficiently high to suggest that the SIP-DU is measuring an independent construct of drug use consequences. This further highlights the potential usefulness of the SIP-DU in primary care settings with drug-using patients. This study also provides additional evidence that the original SIP can be successfully modified to separately assess consequences of drug use and alcohol use.

The unacceptable fit of the originally proposed five-factor structure for the SIP-DU is consistent with findings reported by Gillespie et al.[17] When they conducted confirmatory factor analysis with their data, they discovered that the loadings of the SIP-AD items were not consistent with a five-factor structure and concluded that a single-factor structure was most appropriate. The exploratory factor analysis findings of this study are consistent with those results.

This primary care sample was recruited from a single urban medical center, which may limit the generalizability of the findings. The patients at this medical center tend to be more socioeconomically disadvantaged, more racially and ethnically diverse, and may have more severe drug use or dependence than that seen at other hospitals that are not in urban underserved settings. Generalizability may also be limited to English-speaking patients willing to participate in a research study.

Since this was designed as a cross-sectional study, neither test-retest reliability nor the responsiveness of the SIP-DU to change over time could be evaluated. In addition, the sample size for this study was small and may not have been adequate to determine the true SIP-DU factor structure. Finally, unlike the full versions of the DrInC and InDUC, neither the original SIP for alcohol nor the SIP-DU contains a control subscale to detect careless responding.

As part of a growing interest in developing substance use measures relevant to primary care, the present study evaluated the validity of the SIP-DU in a primary care sample. As was recently found with the SIP-DU's cousin instrument, the SIP-D,[3] this analysis provides evidence of the SIP-DU's validity in measuring drug use consequences in a primary care setting. Consistent with previous research, a five-factor structure for the SIP-DU could not be confirmed by this study. Instead, the results suggested a possible single-factor structure for the SIP-DU. Future research might include additional psychometric analysis of the SIP-DU in other clinical settings and other geographical regions with larger sample sizes, and might also test use of the SIP-DU for identifying consequences of drug use among patients without dependence. Nevertheless, the SIP-DU offers clinicians a practical assessment tool for drug use consequences in a primary care setting.

Data collection and data analysis were supported by grant DA010019 from the National Institute on Drug Abuse, Bethesda, MD (Dr. Samet) and by grant AA010870 from the National Institute on Alcohol Abuse and Alcoholism, Rockville, MD (Dr. Saitz). The relationship between perceived discrimination and coronary artery obstruction

Brian J. Ayotte, PhD, [a] **Leslie R.M. Hausmann, PhD,** [b,c] **Jeff Whittle, MD, MPH,** [d,e] **and Nancy R. Kressin, PhD** [f,g]

Background Chronic stressors such as perceived discrimination might underlie race disparities in cardiovascular disease. This study focused on the relationship between perceived discrimination and risk of severe coronary obstruction while also accounting for multiple psychosocial variables and clinical factors.

Methods Data from 793 (629 white and 164 black) male veterans with positive nuclear imaging studies were analyzed. Participants were categorized as being at low/moderate or high risk for severe coronary obstruction based on results of their nuclear imaging studies. Hierarchical logistic regression models were tested separately for blacks and whites. The first step of the models included clinical factors. The second step included the psychosocial variables of optimism, religiosity, negative affect, and social support. The final step included perceived discrimination.

Results Perceived discrimination was positively related to risk of severe obstruction among blacks but not among whites after controlling for clinical and psychosocial variables. Similar results were found in patients who underwent coronary angiography (n = 311).

Conclusions Perceived discrimination was associated with risk of severe coronary obstruction among black male veterans and could be an important target for future interventions. (Am Heart J 2012;163:677-83.)

Cardiovascular disease affects disproportionately more blacks than whites in the United States.[1] However, the sources of this disparity are not clearly understood. One proposed mechanism underlying race differences in cardiovascular health is differential exposure to chronic stressors,[2] which includes racial discrimination.[3,4] As an unpredictable and uncontrollable stressor, perceived racial discrimination can elicit physiologic responses (eg, increased blood pressure) that can degrade health over time and result in cardiovascular disease over the long term.[5]

A growing body of literature suggests that perceived discrimination is related to diverse markers of cardiovascular disease. (Discrimination, while a real and objective dynamic, is most often measured by asking individuals their perceptions of whether/how discrimination occurred. We posit that such perceptions are the most important aspect to measure, because if discrimination occurs objectively but is not perceived by an individual, it may have less of an impact on health outcomes. For this reason, throughout the paper we will refer to 'perceived' discrimination, as that is the focus of this work.) Among blacks, but not whites, perceived racial discrimination was associated with higher levels of endothelin-1, which contributes to vascular remodeling, atherosclerotic plaques, renal dysfunction, and ultimately, hypertension and heart failure.[1] Chronic discrimination was also associated with coronary calcification, which is related to coronary obstruction, among a sample of black women.[6] In addition, perceived discrimination was positively associated with diastolic blood pressure reactivity and heart rate among black, but not white, women.[7] Although not all findings support the relationship between perceived discrimination and cardiovascular health,[8] there is significant evidence that perceived discrimination is related to cardiovascular health, particularly among black women.

A number of other psychosocial factors are associated with risk of cardiovascular disease. Negative affect, which includes a number of aversive mood states including disgust, nervousness, and anger,[9] is related to the development and expression of cardiovascular disease

and may be a mediator between perceived discrimination and cardiovascular disease.[10,11] Several protective psychological and social factors, including optimism, social support, and religiosity, have also been identified. *Optimism*, defined as the general expectation that good things will happen, is related to decreased mortality because of cardiovascular disease in black and white women.[12] Systematic reviews of the literature also suggest a consistent relationship between social isolation or low levels of social support and coronary artery disease.[13] Finally, religiosity is associated with positive health outcomes,[14] including the regression of coronary obstruction.[15] These factors have not been included in past studies examining the association between perceived discrimination and cardiovascular outcomes. Thus, it is unclear whether the influence of perceived discrimination on cardiovascular health persists after accounting for these other factors.

The objective of this study was to investigate the association of perceived discrimination with risk of severe coronary obstruction in a sample of white and black male veterans who had positive nuclear imaging studies. We hypothesized that increased levels of perceived discrimination would be related to greater risk of severe obstruction only among blacks even after controlling for clinical and behavioral risk factors (eg, smoking and high blood pressure) and psychosocial variables associated with cardiovascular health (ie, negative affect, optimism, social support, and religiosity). We also examined how the above variables were related to severity of coronary obstruction in the subset of veterans from our sample that underwent coronary angiography.

Methods

Study population

We used data from the Cardiac Decision Making Study, an observational cohort study of white and black veterans who had a cardiac nuclear imaging study performed between August 1999 and January 2001 at 1 of 5 Department of Veterans Affairs (VA) Medical Centers with on-site catheterization laboratories.[16] Overall, 2,335 of the 5,278 patients who were screened had a positive nuclear imaging study. Of these, 981 patients were excluded because they were unable to be contacted (n = 456), had a cardiac procedure in the preceding 6 months (n = 209), were not black or white (n = 102), had impaired mental status (n = 78), were in another study that would influence treatment of their coronary artery disease (n = 32), or other reasons (eg, impaired hearing, patient was a nonveteran, nuclear imaging study was performed for compensation and pension evaluation; n = 104). A total of 1,025 of the 1,354 eligible veterans agreed to participate, of which 793 (629 whites and 164 blacks) had complete data. We also collected coronary anatomy data in a subset of 311 patients (259 whites and 52 blacks) who had coronary angiography within 90 days of their imaging study.

Data

Sociodemographic information. Patients self-reported race, age (in years), and education (0, <12 years of education; 1, ≥12 years). Only patients who responded that they were white/Caucasian (coded as 0) or black/African American (coded as 1) were included in the study.

Clinical variables. Trained nurses abstracted clinical information, including diagnosis of hypertension and diabetes, current smoking status, prior revascularization, and prior myocardial infarction. These variables were coded as 1 if the conditions were present and 0 if they were not. We also collected data on a history of a diagnosis of hypercholesterolemia and if the participants were on antiplatelet or lipid-lowering therapy.

Perceived discrimination. Perceived discrimination was assessed with an adaptation of a previously published 7-item measure asking if the participant has ever been treated unfairly, been kept from doing something, or been made to feel inferior because of his or her race, ethnic group, or skin color in several domains, including (1) school, (2) getting a job, (3) at work, (4) getting medical care, (5) getting housing, (6) from the police or in the courts, or (7) on the street or in a public setting.[17] Because our patient population consisted of military veterans, we adapted the original measure by breaking the medical care question into "getting medical care at the VA" and "getting medical care outside the VA," and added "in the military" as an additional domain. The "yes" responses were counted to create a perceived discrimination score. Overall, the 9-item measure had good internal reliability among white (α = .75) and black (α = .88) participants. We also conducted the analyses using the original 7-item scale and found the same pattern of results, so only results using the 9-item scale are reported.

Psychosocial variables. *Negative affect* was assessed using a 9-item version[18] of the emotionality scale of the Eysenck Personality Inventory.[19] Participants responded "yes or "no" to items such as "Are you often uneasy, feeling that there is something you want without knowing it." The number of "yes" responses was counted to create a negative affect score. *Optimism* was assessed using a 10-item measure that asked participants to rate their agreement on items such as "In uncertain times, I usually expect the best" on a scale of 1 (strongly disagree) to 5 (strongly agree).[20] Responses were summed to create an optimism score. *Social support* was assessed using a validated 4-item scale,[21] which asked about satisfaction with family relationships, frequency of social contact with friends and relatives, and frequency of contact with someone the patient trusts and can confide in. Scores reflect the number of items to which the respondent answered "yes." *Religiosity* was assessed using the sum of 3 items asking about how often patients attended religious services; watched or listened to religious programs on TV or radio; or prayed, meditated, or studied the Bible or other religious text (0 = never/almost never, 7 = daily/more often).

Risk of severe coronary obstruction. We categorized risk of severe coronary obstruction using a modification of the methods of Bateman et al,[22] described in detail elsewhere.[23] Briefly, a board-certified general internist and a cardiology fellow classified the severity of each nuclear imaging study based on review of the official report, which did not include

information on patient race. We considered patients with reversible lesions in the distribution of left anterior descending coronary artery or in both the right coronary artery and left circumflex artery to be at high risk, along with patients with increased lung uptake or transient ischemic dilation with exercise or pharmacologic stress. We considered patients with reversible lesions in just 1 of the right coronary artery or left circumflex artery to be at moderate risk and patients whose defects were very small or minimally reversible to be at low risk. For the current analysis, we collapsed patients into 2 categories; patients at moderate or low risk of severe coronary obstruction and those at high risk.

We also examined severity of coronary artery obstruction among participants who underwent coronary angiography. We classified coronary obstruction as severe if there was a stenosis of ≥70% in the left main coronary artery or all 3 major coronary systems. We classified nonsevere obstruction as moderate if there was at least 70% obstruction of the proximal left anterior descending artery. We defined mild obstruction as at least 1 coronary artery obstruction >70%, but not moderate or severe. We classified obstruction as none if there was no obstruction of >70%. For the current analysis, we collapsed obstruction into 2 categories: moderate/severe and mild/none.

Statistical analyses

We first examined race differences in all study variables using *t* tests or χ^2 tests. We then used hierarchical logistic regression models to examine the association between perceived discrimination and risk of severe coronary obstruction separately for blacks and whites. We chose to stratify the analyses by race because the experiences and consequences of racial discrimination are likely to be qualitatively different for blacks and whites, and the analytic strategies of including race as a covariate or attempting to adjust for variables confounded with race often can produce results that obscure racial differences.[24] Stratifying analyses by race is a recommended analytic technique that treats race as a "marker for differential experiences and exposures" (p. 303) and is less prone to mask important race differences.[25]

Each hierarchical model included 3 steps. Step 1 included sociodemographic and clinical characteristics that are known to differ by race or were associated with race in our sample (ie, age, education, hypertension, diabetes, prior revascularization, prior myocardial infarction, and current smoking status). We tested the impact of including additional clinical variables (receipt of antiplatelet or lipid lowering therapy, hypercholesterolemia), but they were not significant, so we omitted them from the final model. In the second step, we

added several psychosocial variables that are related to cardiovascular health (ie, negative affect, optimism, social support, and religiosity). We added perceived discrimination in the final step. We repeated these steps for the analysis of coronary obstruction in the subsample of veterans who underwent coronary angiography.

The predictive power of the models was examined by use of the area under the receiver operating characteristic curve (ie, the *c* statistic). Values near 0.50 reflect a model with no apparent accuracy, values between 0.70 and 0.80 are considered good, values between 0.80 and 0.90 are considered excellent, and values above 0.90 are considered outstanding.[26]

Results

Descriptive statistics

Characteristics of the full sample are presented in Table I. Compared with blacks, whites were significantly older and less likely to be diagnosed with hypertension but were more likely to have had prior revascularization or prior myocardial infarction. Whites reported significantly less discrimination, negative affect, and religiosity, but significantly more social support than blacks. There were no race differences in education, optimism, and diabetes. Overall, 43.9% of participants were at high risk for severe coronary obstruction, based on their nuclear imaging studies; this percentage was similar in blacks and whites. Among the 311 patients who underwent coronary angiography, whites were significantly more likely than blacks to have moderate/severe coronary obstruction (39.0% vs 25.0%).

Logistic regressions

The final logistic regression models for the nuclear imaging study results are presented in Table II. Among blacks, step 1 (c_{model} = 0.66, χ^2_7 = 14.86, $P < .05$) indicated that prior myocardial infarction and smoking were positively associated with high (vs low/moderate) risk of severe coronary obstruction. In step 2 (c_{model} = 0.70, χ^2_4 = 10.36, $P < .05$), optimism was negatively related to risk of severe coronary obstruction. Finally, step 3 (c_{model} = 0.77, χ^2_1 = 13.45, $P < .05$) indicated that perceived discrimination was associated with an increase in risk of severe coronary obstruction after accounting for the variables in the first 2 steps of the model. Prior myocardial infarction, smoking, and optimism remained significant in the final model.

Among whites, smoking and myocardial infarction were related to high risk of severe coronary obstruction in step 1 ($c_{model} = 0.59$, $\chi^2_7 = 15.04$, $P < .05$). In step 2 ($c_{model} = 0.61$, $\chi^2_4 = 14.04$, $P < .05$), optimism was related to lower risk of coronary obstruction. Perceived discrimination was not related to risk of coronary obstruction among whites in step 3 ($c_{model} = 0.63$, $\chi^2_1 = 1.27$, $P > .05$).

The final logistic regression models for blacks and whites who underwent coronary angiography are presented in Table III. For blacks, step 1 ($c_{model} = 0.66$, $\chi^2_7 = 11.23$, $P < .05$) indicated that smoking was significantly related to the likelihood of moderate/severe coronary

obstruction among blacks. In step 2 ($c_{model} = 0.79$, $\chi^2_4 = 13.46$, $P < .05$), optimism was related to a lower likelihood of moderate/severe obstruction. In step 3 ($c_{model} = 0.91$, $\chi^2_1 = 13.08$, $P < .05$), perceived discrimination was significantly related to increased likelihood of moderate/severe obstruction. Among whites, myocardial infarction and smoking were related to an increased likelihood of moderate/severe obstruction in step 1 ($c_{model} = 0.61$, $\chi^2_7 = 15.88$, $P < .05$). In step 2 ($c_{model} = 0.65$, $\chi^2_4 = 10.79$, $P < .05$), optimism was again related to a decreased likelihood of moderate/severe obstruction. Perceived discrimination was not associated with obstruction among whites in step 3 ($c_{model} = 0.68$, $\chi^2_1 = 1.01$, $P > .05$).

Discussion

In this study of black and white male veterans with abnormal nuclear imaging studies, we found that, among black men, greater perceptions of racial discrimination were related to increased risk for severe coronary obstruction and to angiographic coronary obstruction after controlling for clinical and psychosocial factors that are related to cardiovascular health. In addition, smoking, prior myocardial infarction, and optimism were related to nuclear imaging study results and coronary angiography results for blacks and whites.

These findings support and extend previous research linking perceived discrimination to indicators of cardiovascular disease[1,6,27,28] and are consistent with previous work that found these associations mostly among blacks.[1] Our results strengthen the evidence for a relationship between racial discrimination and cardiovascular disease in men, as previous work tended to focus on women. In addition, we controlled for psychosocial factors related to cardiovascular outcomes that have not been examined in previous research on the health correlates of perceived discrimination. Finally, by examining the association between perceived racial discrimination and coronary obstruction, we shed light on 1 possible causal pathway for the black-white disparity in cardiovascular deaths.

There are several possible explanations for the relationship we report. Chronic stress such as perceived discrimination is related to increased activation of the hypothalamic-pituitary-adrenocortical axis,[29,30] which results in increased production of cortisol. Cortisol, in turn, is independently related to risk of coronary artery disease and stenosis.[31,32] Research also suggests that perceived discrimination is related to hypertension[1] and increased cardiovascular reactivity,[7] which are both related to coronary obstruction.[33] In our results, perceived discrimination was associated with greater risk of severe coronary obstruction although we accounted for hypertension. Other possible contributors include increased endothelin-1 (a vasoconstrictor implicated in the development of vascular disorders[1,34]), e-selectin (an endothelial adhesion molecule associated with atherosclerosis[35]), and C-reactive protein (a marker of inflammation that is associated with cardiovascular disease[36]), all of which are related to perceived discrimination.

This study went beyond past studies of discrimination and cardiovascular disease indicators by including a number of psychosocial variables that are associated with cardiovascular health. Among blacks and whites, optimism was negatively related to the risk of severe coronary obstruction. Optimism might be related to cardiovascular health through factors such as hypertension,[37] as well as through other psychosocial factors (eg, increased social support, coping ability).[12]

This study found no significant associations of social support, negative affect, or religiosity with nuclear imaging study results or the results from coronary

angiography. One possible reason for these null findings is that our sample was restricted to persons with evidence for clinically significant coronary ischemia on nuclear imaging studies; these associations might be found in a sample that included persons without such evidence. It is also possible that these factors are not associated with coronary obstruction, per se, although they have been associated with other indicators of cardiovascular health. We chose to control for these variables in the current study, although it is possible that they might serve as moderators of the relationship between perceived discrimination and cardiovascular health because of their stress-buffering potential. We tested this possibility in supplemental analyses and found no evidence that optimism, negative affect, religiosity, or social support moderated the relationship between perceived racial discrimination and the nuclear imaging study results or the results from coronary angiography. With this being the first study to examine the relationships of these variables to nuclear imaging results, additional research is needed to determine whether the lack of significant relationships observed in the current study is seen in other populations.

These findings should be interpreted in the context of several limitations. First, our sample included only men with positive nuclear imaging study results—a population selected to be at high risk for coronary disease. This may explain why diabetes and hypertension, known risk factors for coronary artery disease, were not associated with the imaging results. Although physicians presumably included these clinical risk factors in their clinical decision making, it is unlikely that they incorporated perceptions of racial discrimination (or optimism). Thus, to the extent that perceived discrimination affects measurable risk factors for coronary artery disease, our estimates of the impact of perceived discrimination may be conservative. Future research should examine these relationships in people who are at low risk for coronary disease.

Second, our data were cross-sectional, thus precluding any causal interpretations. Third, we did not account for a number of clinical variables that are associated with risk of coronary obstruction (eg, various cholesterol subsets). Fourth, the sample size of black patients was relatively small, resulting in relatively large confidence intervals around our effect size estimates.

Finally, we assessed only racial discrimination, which was seldom a significant concern for white participants. This nonsignificant relationship between discrimination and risk of coronary obstruction should not suggest that discrimination is unimportant for whites. Previous studies indicate that nonracial discrimination is associated with cardiovascular outcomes, suggesting that it may be unfair treatment in general, rather than racial discrimination in particular, that leads to negative health effects.[38]

Despite these limitations, these results add to the growing literature on the relationship between perceived discrimination and cardiovascular health by investigating the relationship between perceived discrimination and risk of severe coronary artery obstruction. This is important because coronary artery disease is the most common form of heart disease and is the leading cause of death in the United States. Our findings underscore the possible negative health consequences of perceived discrimination among blacks. Future research should focus on identifying potential modifiable mediators of the relationship between perceived discrimination and cardiovascular disease so that the negative health consequences of perceived discrimination can be reduced.

We are pleased to present this special issue on health literacy of the *Journal of Health Communication*. The journal continues to demonstrate a deep commitment to this important topic, offering a venue to exhibit leading health literacy research for the third year in a row. We hope that this special issue helps guide the overall direction of the field and serves as a springboard for lively discussion, innovative research, and practice initiatives.

As in the past, this special issue includes findings presented at the Health Literacy Annual Research Conference (HARC III), which was held on October 17–18, 2011 in Chicago, Illinois and was attended by more than 200 health literacy investigators. The 2011 conference was unique, as it was co-located with the International Conference for Communication in Healthcare (ICCH), an event dedicated to presenting cutting-edge research and educational strategies to improve how information and ideas are exchanged in health care settings—topics that are clearly related to the health literacy agenda. The coordination of these two conferences allowed researchers from countries around the world to share findings and build collaborations for the future. In doing so, it offered an exceptional opportunity for HARC to fulfill its primary objectives of (a) professional development, (b) advancing the science of health literacy

research, and (c) promoting interdisciplinary research. We look forward to continuing our pursuit of these goals during HARC IV, which will be held on October 22–23, 2012 in Bethesda, Maryland.

The expansion of HARC, along with the growth in health literacy research, has led to the largest health literacy special issue yet. This issue includes over 20 articles and commentaries from across the United States and Europe, covering a number of key themes. Recognizing the growing diversity of the United States, multiple articles explore the links between health literacy, culture, and language proficiency. This includes a commentary from McKee and Paasche-Orlow calling for greater collaboration between researchers studying low health literacy and those focusing on limited English proficiency, as well as a conceptual framework by Lie, Carter-Pokras, Braun, and Coleman that integrates the concepts of health literacy and cultural competence for the purpose of improving education for health care professionals. An original research article from Shaw, Armin, Torres, Orzech, and Vivian explores the relationship between culture, health literacy, and chronic disease self-management among patients from four ethnic groups, while another from Sentell and Braun examines health status by health literacy and English proficiency among an ethnically and linguistically diverse study sample.

There has been increased recognition by researchers, clinicians, and government agencies of the importance of promoting patient-centered care and considering patient preferences in the design and implementation of interventions. Three articles in this issue respond to this movement by describing patients' preferences for receiving health information. Cawthon and colleagues discuss which components of their PILL-CVD intervention were considered beneficial according to patients, particularly those with low health literacy. Gaglio, Glasgow, and Bull report findings from an in-depth study on patients' preferred sources of health information. Finally, Guise, Koonce, Storrow, Kusnoor, and Ye reveal the importance of personalizing health education interventions by patients' preferred learning style and literacy skills.

As in the past, this special issue also includes articles focused on the conceptualization and measurement of health literacy. Squiers, Peinado, Berkman, Boudewyns, and McCormack introduce a conceptual framework for health literacy that builds on prior frameworks, but emphasizes a full pathway from the development of literacy skills to resulting health outcomes. Haun, Luther, Dodd, and Donaldson report on the conceptual and measurement variations between three commonly used measures of health literacy. Helitzer, Hollis, Sanders, and Roybal introduce the TALKDOC, an instrument designed to measure multiple health literacy competencies within the context of HPV and cervical cancer. Rubin presents an article on the construct of "listenability" (versus readability) as part of health literacy. Finally, Bann, McCormack, Berkman, and Squiers describe the validation of a shortened, 10-item version of their Health Literacy Skills Instrument. While development and validation activities for these tools should continue, next steps include incorporating these measures into future and ongoing research. This is essential to advance the field and ensure that validated, theory-based instruments are being used in practice.

This special issue expands upon the existing literature by including studies that further explore the association between health literacy and various health outcomes. Mitchell, Sadikova, Jack, and Paasche-Orlow assess the link between health literacy and re-hospitalization, while Mosher, Lund, Kripilani, and Kaboli examine the relationship between health literacy and medication-related outcomes, including

medication knowledge, adherence, and adverse drug events. Arnold and colleagues assess the role of health literacy in colorectal cancer screening knowledge, beliefs, and experiences. From an international perspective, Sahm, Wolf, Curtis, and McCarthy consider the prevalence and potential effects of limited health literacy in Ireland. Together, these articles serve to identify areas where additional research is needed; such findings have the potential to inform the design and implementation of future interventions.

Three articles describe efforts to improve the design, content, and efficacy of written materials from a health literacy perspective. Boxell and colleagues present information on the development and testing of a gynecological cancer information pamphlet in the United Kingdom, while King et al. evaluate the benefit of using symbols on prescription medication information leaflets. Liu and Rawl examine the role of text cohesion on the understandability of print materials, and Kaphingst et al. describe the development and testing of the Health Literacy INDEX, a tool that measures the health literacy demands of written health information materials. These articles highlight the ways in which written information can be enhanced, but also show the limitations of using print material alone to convey health information to patients.

Finally, a few articles in this special issue address topics that are of particular salience to health care organizations and providers. Weaver, Wray, Zellin, Gautam, and Jupka describe a process of assessing organizational health literacy in health centers serving vulnerable populations. Jager and Wynia examine how often physicians ask patients to "teach-back" information provided during clinical encounters; this article specifically examines the sociodemographic characteristics of patients who receive this health literacy via best practice versus those who do not. Finally, Bickmore and Paasche-Orlow discuss the potential impact of health information technology on health disparities and caution that greater inequalities will result without significant advances in health information technologies that are usable and accessible for people with low health literacy. The study by Gazmararian, Yang, Elon, Graham, and Parker explores this concern by examining the role of health literacy on women's ability to enroll electronically in the Text4Baby intervention.

Overall, this special issue covers a variety of topics, methods and perspectives. It takes a truly interdisciplinary approach, incorporating research from public health, medicine, nursing, anthropology, and communication science, among others. It includes perspectives of insurers, clinicians, patients, and researchers from the United States and Europe, using quantitative and qualitative methodologies to examine some of the most pressing questions in health literacy research. This issue acknowledges the limitations of a still relatively new field, exhibits a continued discussion about the conceptualization of health literacy and the use of imperfect measures—yet also shows great promise and progress. To move forward, we must continue to engage in this interdisciplinary dialogue, confronting and addressing our challenges, with the ultimate objective of advancing this important discourse.

■ **Abstract:** With the increases in complexity of care for breast health concerns, there is a growing need for efficient and effective clinical evaluation, especially for vulnerable populations at risk for poor outcomes. The Breast Health Center at Boston Medical Center is a multidisciplinary program, with internists providing care alongside breast surgeons, radiologists, and patient navigators. Using a triage system previously shown to have high provider and patient satisfaction, and the ability to provide timely care, patients are assigned to either a breast surgeon or internist. From 2007 to 2009, internists cared for 2,408 women, representing half of all referrals. Women served were diverse in terms of race (33% black, 30% Hispanic, 5% Asian), language (34% require language interpreter), and insurance status (51% had no insurance or public insurance). Most presented with an abnormal screen (breast examination 54% or imaging 4%) while the remainder were seen for symptoms such as pain (26%), non-bloody nipple discharge (4%), or risk assessment (7%). A majority of final diagnoses were made through clinical evaluation alone (n = 1,760, 73%), without the need for additional diagnostic imaging or tissue sampling; 9% (n = 214) received a benign diagnosis with the aid of breast imaging; 19% (n = 463) required tissue sampling. Only 4% went on to see a breast surgeon. Internists diagnosed 15 incident cancers with a median time to diagnosis of 19 days. Patient and provider satisfaction was high. These data suggest that a group of appropriately trained internists can provide quality breast care to a vulnerable population in a multidisciplinary setting. Replication of this model requires the availability of more clinical training programs for non-surgical providers. ■

Key Words: breast, diagnostic, health services, prevention, screening

Increased attention to the early detection of breast cancer has resulted in more women participating in breast cancer screening (1). Concurrently, new and changing screening guidelines, imaging options, risk assessment methodologies, preventive strategies, and diagnostic algorithms and techniques have made the early detection of breast cancer increasingly complex. As available screening methods are not highly specific, abnormal findings are common and often require clinical expertise, such that the demand for specialists in breast health has increased (2,3). Yet, the number of breast cancers diagnosed as a result is quite low; the average positive predictive value (proportion of women with abnormal screening exams who have breast cancer) is approximately 2.0% for women below age 50, and 4.7% for women over age 50.

The complexity of breast care can lead to failures in the process of care, which lead to lapses or discontinuation of breast health care that have the potential to impact survival for those found to have a malignancy (4,5). Lack of access to timely appointments with breast care subspecialists has been shown to contribute to such delays (6). The delivery of these services to underserved populations introduces additional complexity as a result of the additional burden of well-documented socio-cultural barriers to accessing care (7–9). Indeed, delays in diagnosis after an abnormal screening test for these underserved populations,

Battaglia, MD, MPH, Associate Professor of Medicine Women's Health Unit, Section of General Internal Medicine, Evans Department of Medicine, Boston Medical Center and Women's Health Interdisciplinary Research Center, Boston University School of Medicine. 801 Massachusetts Ave, Suite 470, Boston, MA 02118, or e-mail: Tracy.Battaglia@bmc.org.

DOI: 10.1111/j.1524-4741.2011.01179.x

including those from racial/ethnic minority and low socioeconomic groups, have been found to contribute to worse breast cancer outcomes (10–13).

A number of societies have promoted guidelines to address the management of women with breast problems (14–17). While many of these guidelines suggest that diagnostic evaluation requires expertise of surgical oncologists or breast surgeons, there is a lack of evidence that this model is required for quality care (18). As many women in need of breast health consultation do not have surgical needs, alternative care models are needed to improve access for those who do. Therefore, we describe here a new care model for breast health and breast concerns that incorporates general internists with an expertise in women's health. This clinical practice, previously shown to improve adherence to timely follow-up of screening abnormalities (19), provides services to a disproportionate share of vulnerable and traditionally underserved women. We provide a description of the program structure and function along with evaluation metrics as evidence of its impact on quality care.

Origin

The Breast Health Program at Boston Medical Center (the teaching hospital of Boston University School of Medicine) was created in 1989 through collaboration between the Women's Health Unit (within the Department of Internal Medicine), Surgical and Medical Oncology, and Breast Imaging. It was developed out of the recognition that diagnostic evaluation for breast disease requires knowledge and skills beyond the level of traditionally trained internists, yet surgical providers were inundated with non-surgical referrals. As a result, breast surgeons had fewer appointments available for those truly in need of their service.

Philosophy

The Breast Health Program at Boston Medical Center is a multidisciplinary and interdisciplinary diagnostic evaluation program. The goal of the program is to provide efficient and comprehensive diagnostic services and prevent delay in cancer diagnosis and care. Our multidisciplinary team includes seven internists, three breast surgeons, 2–4 radiologists specializing in breast imaging, and three pathologists with expertise in cytopathology and/or surgical pathology. Interdisciplinary support is available with nurses, genetic counselors, social workers, patient navigators, medical assistants, and breast imaging technicians. Providers aim to deliver comprehensive services at each visit to minimize potential gaps in care, while addressing a wide range of breast conditions and barriers to care as they present in the clinical setting.

Features

Communication Communication between providers is facilitated by several features (1). Space: When the practice began, there was no allocated space for all providers, so patient evaluation and care were accomplished through a "virtual center." With growth and documented success of the program (19,20), space for all clinical consultation and breast imaging was created in a dedicated facility to allow for real time communication and improve opportunities for formal and informal consultation on cases (2). Schedules: Schedules are coordinated to ensure that both an internist and breast surgeon staff the center during each available clinical session, at which time a full spectrum of screening and diagnostic breast imaging services are also available (3). Regular conferences: A multidisciplinary breast conference, which includes representation from internal medicine as well as all oncology specialists (surgical, medical, and radiation oncology, pathology, and clinical trials), meets weekly to review all cases with ambiguous or inconclusive cytopathology as well as all newly diagnosed cancer cases to create comprehensive diagnostic and treatment plans. Special seminars are also organized quarterly to discuss challenges in management of benign breast disease, such as protocols for use of screening MRI among high-risk populations (4). Meetings: Leadership from internal medicine, surgery, and radiology meet monthly with nursing and administrative staff, to review organizational and management issues along with quality metrics. Additional interdisciplinary monthly meetings include IT staff, internal medicine, program coordinator, and patient navigators to review quality indicators and refine reporting systems and clinical protocols.

Triage System The Breast Health Program developed a central intake system to triage referrals to either a surgeon or internist based on patient risk of cancer. The aim was to ensure that women most likely to need surgical intervention are initially seen by a breast surgeon (Fig. 1). Triage decisions are made by an experienced practice triage nurse, and

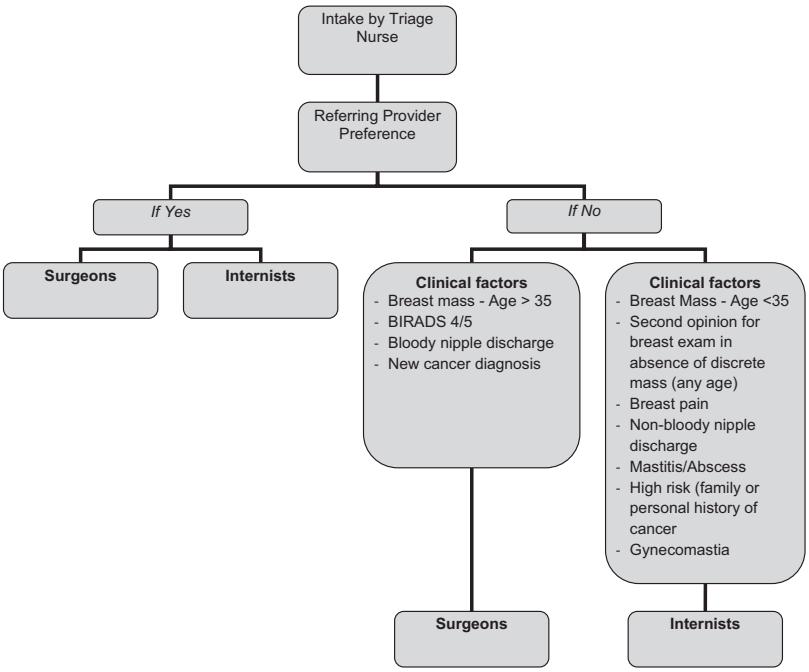

Figure 1. Breast health program triage system.

result in an equal distribution of patient referrals being scheduled with internists and surgeons. We have previously shown that this triage system minimizes referral error, decreases time to surgical appointment for those with a malignancy, and satisfies referring providers (20). A preclinical review includes assessment of potential need for diagnostic imaging or other services at the initial or follow-up visit. Interdisciplinary staff will consult with providers to schedule this additional diagnostic imaging to coincide with the patient visit.

Patient Navigation Breast Health Patient Navigators have provided care management services to help our vulnerable patients access needed services with funding from the Avon Foundation since 2001 (21). Two full-time patient navigators identify women referred to the practice, conduct outreach to identify barriers to care, work with providers to develop an individual action plan to overcome those barriers, and utilize the electronic medical record to track all women until diagnostic resolution. Their daily activities are documented in a log within patient charts in the Electronic Medical Record (EMR). Patient navigators are nonclinical personnel usually with bachelor or master's level training, who have experience caring for inner-city, low income patients and/or are from one of the communities served by the medical center.

Tracking Prospective tracking by navigators ensures that patients are followed through completion of all diagnostic workup and treatment as recommended by their provider. Once patients have been referred into our practice, we utilize the hospital EMR to retrieve detailed patient information, including demographics, appointment scheduling, navigator outreach, visits with providers and diagnostic procedures. This information is consolidated into one automated data tracking system, which provides patient navigators with a list of active patients in need of specific services, such as additional imaging (mammograms, MRIs or ultrasound), pending cytology or pathology. Navigators work directly with the internists to ensure that timely resolution is achieved. Navigator supervisors review tracking logs weekly to ensure resolution of outstanding cases. This database also provides quality improvement evaluation data to guide our program management (19,22).

Services Provided by Internists

Internists provide a wide range of services, including (a) counseling on evidence for additional surveillance, breast cancer risk assessment, and discussion of genetic testing, fertility planning, and preventive strategies, including prophylactic surgery, and chemoprevention; (b) clinical evaluation of abnormal breast findings such as nipple discharge or breast masses; and (c) management of symptomatic benign disease,

including breast pain, cysts, acute and recurrent mastitis/abscess. Internists include Fine Needle Aspiration biopsies (FNAB) and Core biopsies into their clinical competencies for two reasons: (a) to facilitate rapid diagnosis should a cancer be present; and (b) to complete diagnostic evaluation on patients not requiring surgical intervention.

Training of Internal Medicine Physicians Most internists, including those with a focus on women's health, have insufficient training and skills to conduct a comprehensive breast health assessment (23). We developed a training system, which pairs trainees with an experienced internal medicine breast provider in the clinical setting for 4–8 hours weekly over a 3–4 month period to provide consulting in a supervised setting. These trainees, all of whom have previously completed internal medicine residency training, also shadow surgical providers. Trainees review all breast imaging with radiologists to develop skills in correlating clinical findings with diagnostic imaging. Trainees practice FNAB and core needle biopsies (with the support of pathologists and cytopathologists) and must demonstrate proficiency in these procedures before they perform them independently. For the first year of practice, trainees are paired with each of the practicing internists on a rotating basis in an effort to increase exposure to multiple practice styles.

EVALUATION METHODS

We report on data collected from the EMR for all patients seeking care from January 1, 2007 through December 31, 2009. Patient demographics are retrieved from the electronic scheduling system (SDK©; Esker Inc., Madison, WI), while all clinical information is retrieved from the medical charts in EMR (General Electric (GE); Centricity^{EMRTM}, https://www2.gehealthcare.com/portal/site/usen/menuitem.e8b305b80b84c1b4d6354a1074c84130/?vgnextoid=5bb454fbded30210VgnVCM10000024dd1403RCRD&vgnextfmt=default&productid=4bb454fbded30210VgnVCM10000024dd1403). Reason for referral to the breast practice is documented in the EMR by the Triage Nurse at the time of intake, along with the referral source. Final diagnosis was determined from pathology and cytology reports, from diagnostic imaging if no pathology or cytology was performed, and from ICD-9 billing diagnoses when no additional imaging or pathology was performed. To ensure that no cancer diagnoses were missed, all patients seen were cross referenced with the Boston Medical Center Cancer registry. Patient satisfaction was continually measured using the institution-wide Press Ganey survey (Press Ganey Associates, South Bend, Indiana), a commercial survey sent to a random subset of all patients with a response rate that represents 20% of the population served. IRB approval was obtained for all data collected.

RESULTS

Patient Population

Patient volume for the Breast Health Program has increased from 651 unique patients in 2001 to 901 unique patients in 2009 as a result of the expansion of internists into the practice. From January 1, 2007 through December 31, 2009, 3,110 patient visits

occurred for a total of 2,408 unique patients seen by medical internists. As described in Table 1, the populations served are diverse and reflective of the urban population seeking care at an inner-city safety-net institution. As would be expected from the triage protocol (see Fig. 1), the majority of women seen by internists were under age 65 (95%), and over half between 19 and 39 years of age (63%). A majority of women were of minority race or ethnicity (33% Black, 30% Hispanic, 5% Asian); while 23% were non-Hispanic White. Thirty-four percent required a language interpreter during their visit, and over half (51%) had publicly funded or no health insurance at the time of their referral.

Table 1 also shows the referral network for those patients seen by internists. About 60% of referrals come from a network of over 15 affiliated community health centers, and about 30% from practices within the Boston Medical Center, including the emergency department, obstetrics and gynecology, family medicine, primary care internal medicine, and geriatrics. The remaining are referred from outside providers, with few self-referrals. The two most frequent reasons for referral triaged to internists are abnormal breast exam (54%) and breast pain (26%), followed by family history of breast cancer, abnormal imaging, and nipple discharge (Table 1).

Services Rendered and Final Diagnoses

Table 2 shows that a majority of final diagnoses were made through clinical evaluation alone (n = 1,760, 73%), without the need for additional diagnostic imaging or tissue sampling. Nine percent (n = 214) received a benign diagnosis with the aid of breast imaging, most commonly from ultrasonography, followed by diagnostic mammography and rarely Magnetic Resonance Imaging. The remaining 19% of final diagnoses (n = 463) were made as result of tissue sampling, obtained mainly via percutaneous tissue sampling, while only 4% went on to see a breast surgeon for further evaluation. Of those referred to surgeons, the median age was 33 years (range 15–74 years) and the most common reason for referral was an abnormal clinical breast exam (55%), followed by abnormal imaging and patient preference for surgical excision of a benign process. A total of 15 women never returned to complete recommended care after an initial evaluation. For many, there was evidence that they transferred care to other institutions.

From 2007 to 2009, a total of 15 breast cancers (Table 3) were diagnosed among all the patients initially referred to internists, versus 502 cancers diagnosed by an initial breast surgeon evaluation during the same time period. Median age of these 15 women was 55 years (range 32–76) and most were Non-White (n = 10). The most common presenting symptom was an abnormal examination (n = 6), which ranged from asymmetry to a discrete mass. The majority of women (n = 9) were being followed by internists for long-term breast health care in the setting of either elevated cancer risk, pain, or in the context of an established primary care relationship with the internist, which explains why some were not ''triaged'' directly to a surgeon according the existing triage protocol. As a result, most women (n = 9) obtained a percutaneous tissue diagnosis prior to

†Patients went to outside institutions for cancer treatment.

being referred to a surgeon. The median time from initial referral to cancer diagnosis was 19 days (range 3–69 days). For one outlier, 69 days elapsed from referral to cancer diagnosis; during that time period, there are 15 documented attempts by the patient navigators to schedule for follow-up care, along with evidence of other active comorbid medical conditions. Most women were Stage 0 or 1 at the time of diagnosis (n = 8), while 5 did present with Stage 2 or 3 disease. Cross referencing with the hospital cancer registry revealed no additional cancer diagnoses on patients seen by internists during this time period.

Satisfaction with Care

Press Ganey data collected by Boston Medical Center indicates that over 90% of patients report being satisfied or very satisfied with access to care and confidence in provider. This figure remained constant over the 3 years. Referring provider satisfaction with the program has previously been shown to be high (20). Our surgeons have found this to be a very useful model in that it allows them to take care of patients more likely to be surgical and avoid backing up their practices with non-surgical cases.

DISCUSSION: IMPACT OF OUR MODEL

We present comprehensive process and outcomes data for a model of care that delivers diagnostic services by including a group of dedicated internists focused on breast care working collaboratively alongside breast surgeons. Our data demonstrate that appropriately trained internists can provide timely, quality evaluation using a team approach with surgical specialists and an evidence-based triage protocol. Therefore, we believe that this model of care for breast health is worthy of adoption at other sites.

While many models of care for management of breast masses state the need for a surgical oncology evaluation, no data support this need (24). To the contrary, several of our findings support that the use of non-surgical providers may be both reasonable and appropriate. First, we have shown here and in our prior work (20), using an evidence-based triage protocol results in successful risk stratification such that internists are evaluating a population with an inherently low probability of malignancy. Furthermore, even among the 3–4% with a cancer diagnosis, there were no delays in diagnosis that may be attributed to the system and none of the nearly 3,000 women served went on to a breast cancer diagnosis over the ensuing few years to suggest any missed diagnoses. It is also worth noting that the majority of patients were given a final diagnosis with only a clinical diagnosis, while only 19% required cytopathologic or tissue sampling, most of which was performed prior to a surgical consultation. With the support of pathologists, Internists are trained to perform these non-invasive procedures. Finally, this model has potential to improve access to breast surgeons by high-risk patients, thus preventing delays in surgery. This potential impact is supported by the average time to surgical evaluation at our institution of 2 days. The high rates of Stage 2 and 3 cancers among those diagnosed by internists are reflective of the overall rates of advanced cancer seen among the population of mostly minority, low-income patients served at our institution, and not linked to any delays in access to diagnostic services.

The American Society of Breast Disease recently developed a framework of quality indicators related to multidisciplinary and interdisciplinary care (25). These quality indicators include the same outcome measures our program monitors, including early diagnosis, decreased time to visit for most at risk, patient satisfaction, and provider satisfaction. The ability of our program to deliver quality indicators recommended by leading authorities is further evidence that it is worthy of replication in other settings.

While internists are not traditionally trained or prepared to conduct diagnostic breast health evaluation,

our findings support their ability to provide quality care. Our patient population is reflective of the vulnerable patients served at other safety net intuitions who are at high risk for presenting with late-stage disease. Our diverse population presented with unusual manifestations of common and rare diseases, including diabetic mastopathy, mammary tuberculosis, breast sarcoidosis, cat scratch disease, abscesses, and recurrent nonlactating mastitis that often require complex medical management. Having a broad background in pathophysiology and disease management is critical for these rare and/or comorbid conditions. Lastly, this group can provide surveillance to high-risk women, for prevention and screening options—areas in which internists are well trained.

There are limitations to our evaluation metrics. First, we do not have data prior to implementation of this model to allow for an historical comparison. Also, we do not have cost or cost effectiveness data. Future research should address the financial implications of similar models, as it is likely that improving timely access for all patients, especially those with cancer, along with the provision of comprehensive services in one visit with an internist, is likely to have financial benefits to the health care system.

In summary, a model of specifically training internists to provide comprehensive breast health services within a multidisciplinary breast cancer center is a novel and effective model that results in high-quality care that is worthy of adoption when serving similar vulnerable populations. More clinical breast health training programs are needed for non-surgical providers to replicate this type of multidisciplinary program.

Acknowledgments

Feasibility of Chronic Disease Patient Navigation in an Urban Primary Care Practice

Tracy A. Battaglia, MD, MPH; Lois McCloskey, MPH, DrMPH; Sarah E. Caron, MPH; Samantha S. Murrell, MPH; Edward Bernstein, MD; Ariel Childs, MPH; Hannah Jong, MPH; Kelly Walker, MPH; Judith Bernstein, PhD, RNC

Abstract: The purpose of this study was to evaluate the feasibility of incorporating chronic disease navigation using lay health care workers trained in motivational interviewing (MI) into an existing mammography navigation program. Primary-care patient navigators implemented MI-based telephone conversations around mammography, smoking, depression, and obesity. We conducted a small-scale demonstration, using mixed methods to assess patient outcomes and provider satisfaction. One hundred nine patients participated. Ninety-four percent scheduled and 73% completed a mammography appointment. Seventy-one percent agreed to schedule a primary care appointment and 54% completed that appointment. Patients and providers responded positively. Incorporating telephone-based chronic disease navigation supported by MI into existing disease-specific navigation is efficacious and acceptable to those enrolled. **Key words:** *chronic disease prevention, mammography, motivational interviewing, patient navigation, primary care, screening, vulnerable populations*

IN RESPONSE TO the fragmented and complex nature of cancer care, patient navigation was designed to help vulnerable patients overcome barriers to accessing cancer care services through the support of a lay health care worker connected to the clinical team (Dohan & Schrag, 2005; Freeman et al., 1995). In 2007, a study conducted by the Health Resources and Services Administration identified "navigator" as one of the 5 prevailing models for community health work and 18% of employers reported patient navigation as a specific strategy they use to conduct community health work (Health Resources and Services Administration, 2007). Navigators, now a standard of care in some practice settings (American College of Surgeons, 2009), assist patients with scheduling, transportation,

insurance, childcare, translation, and any other issues that interfere with timely access to health care. Successful navigation programs traditionally target a specific disease such as breast cancer (Battaglia et al., 2007; Freeman et al., 1995) without taking into account competing medical comorbidities, patient health priorities, or patient preferences. The majority of programs target single-site cancers (Bastani et al., 2010; Battaglia et al., 2007; Burhansstipanov et al., 2010; Chen et al., 2008; Ell et al., 2007; Percac-Lima et al., 2009) in specialty practice settings, while few target multiple cancer sites in a primary care setting (Dietrich et al., 2006; Ford et al., 2006; Guadagnolo et al., 2010).

More recently, the patient-centered medical home (PCMH or "medical home") is emerging as a promising health care delivery model that will help transform the US health care system to improve quality of care delivered and reduce costs (Stange et al., 2010). The principles of the medical home (American Academy of Family Physicians, American Academy of Pediatrics, American College of Physicians, American Osteopathic Association, 2007) build on the primary care model by incorporating the evidence-based chronic care model along with the use of office systems and health information technology (Scholle et al., 2010). This model of care is also patient-centered with an emphasis on ensuring that patients get the care they need where and when they want it. Patient navigation, as a care coordination process, fits well within many of the domains of the medical home, including care coordination, access to care, communication, and tracking and registry. Researchers are beginning to assess the feasibility and acceptability of chronic disease and primary care navigation (Ferrante et al., 2010; Lubetkin et al., 2010). However, little is known about the feasibility of expanding the role of disease-specific navigation to target chronic disease navigation.

Motivational interviewing (MI) is a form of patient-centered counseling directly tailored to enhance readiness to change behavior. It was originally developed for use by psychologists in the context of substance abuse treatment (Bernstein et al., 2005, 2007, 2009a, 2009b; Hettema et al., 2005; Kaner et al., 2007; Stein et al., 2009; Whitlock et al., 2004) but has been widely adapted to address screening and intervention (both primary and secondary preventions) for other behaviors that affect health status (Brug et al., 2007; Kressin et al., 2009; Mason, 2009; Ockene et al., 1999). Motivational interviewing is based on the principle that exploring and resolving ambivalence about taking action is the central motivational task that prepares people for change.

The objective of this study was to evaluate the feasibility of expanding a primary care breast navigation program to address additional medical comorbidities and allow patients to set their own priorities for action through the use of brief motivational interview skills (B-MI). We hypothesize that incorporating multiple chronic disease screenings into navigation outreach is feasible and patients will respond positively. We believe that incorporating MI, with its emphasis on patient choice, into the current navigator model will facilitate agenda-setting and behavior change.

METHODS

This feasibility study (Bowen et al., 2009) was designed as a clinical quality improvement initiative and thus did not have a continuous control group. We conducted a small-scale demonstration study, using mixed methods to determine the (1) practicality (ability to carry out the intervention), (2) limited efficacy (intended effects on clinical care), and (3) acceptability (satisfaction, intent to use) of telephone-based chronic disease navigation in an urban safety net primary care practice. All participants received the B-MI intervention March-July 2010, and we used electronic medical record (EMR) chart abstraction, navigator logs, and qualitative interviews, respectively, to measure outcomes. The Boston Medical Center institutional review board approved this study.

Theoretical framework

Brief motivational interview is an adaptation of standard motivational techniques to the time pressures of the clinical visit

and delivery by both clinicians and outreach workers. Motivational interviewing teaches health care providers to follow a specific algorithm for a conversation about decreasing risk factors for disease, enhancing patients' and providers' self-efficacy for behavioral change (Ockene et al., 1996), and facilitating referral for mental health and other treatment if indicated (Bernstein et al., 2005). The literature (Apodaca & Longabaugh, 2009) suggests that effect on outcomes is directly related to the amount of change talk produced during such conversations. When individuals believe that they will be successful (effective) at making desired changes in their behavior, it is more likely that they will actually be able to do so (Bandura, 1977). The role of the patient navigator in this study of chronic disease navigation is to use B-MI skills via telephone contact to foster self-efficacy, thus increasing the probability of keeping a mammogram appointment and enhance the likelihood of making effective contact with a primary care physician to discuss other prevention issues such as weight management, depression risk, and smoking.

The importance of patients' participation in their own medical care and decision making is well documented, particularly for those with chronic illness (Greenfield et al., 1985, 1988; Kaplan et al., 1989). A key element in a participatory style of patient care is soliciting the patient's priorities and preferences during the medical visit (Kaplan et al., 1995; Marvel et al., 1999). Thus, our MI intervention also included prompts for patients to identify their priorities and set the agenda for their future primary care visit.

Study population

This study was conducted in Boston at an urban safety net hospital serving low-income, racial/ethnic minority residents. Female patients of the internal medicine practice aged 51-70 years with a documented primary care visit in the past 24 months were eligible if they had at least 1 prior mammogram and more than 18 months had elapsed since their most recent documented mammogram. Because of limited resources, non-English speakers were excluded. In addition, patients were excluded if their primary care provider deemed them ineligible on the basis of the presence of comorbidities that impaired their ability to participate, including a current diagnosis of breast cancer or travel out of the country during the study period.

Navigator training

Five experienced primary care–based breast health patient navigators participated in this study. In addition to clinical navigation experience, each completed certification for the core competencies of a community health care worker offered by a regional education center. Each completed an intensive 2-week training workshop led by the Brief Negotiated Interview-Active Referral to Treatment Institute (BNI-ART) (http://www.ed.bmc.org/sbirt/). The training covered basic clinical information about obesity/weight management, smoking cessation, and depression; how to screen patients for weight, smoking, and depression; and how to apply motivational intervention techniques to screenings. Navigators engaged in role-playing and other experiential learning activities. A booster training was held 1 month after study enrollment began.

Intervention protocol

Navigators contacted eligible patients by phone. Multiple attempts to contact patients were made at varying times and days of the week. If contact was not made after 6 attempts, the patient was deemed "unreachable." If contact was made, verbal consent to participate was obtained. The navigator then conducted the B-MI intervention. The conversation included discussions on smoking status, depression, obesity, and participant health priorities, as well as mammography screening. Participants were asked whether weight was a concern for them and whether they were currently a smoker and were screened for depression using the Patient Health Questionnaire-2 (Kroenke et al., 2003; Lowe et al., 2005). Navigators also asked participants to list their top health priorities. Navigators worked with each participant to schedule mammography and primary care appointments and recorded the reason if participants were unwilling to schedule

appointments. Navigators offered to accompany participants to appointments. Reminder calls were made by navigators prior to scheduled appointments to discuss any barriers to attendance and to work with participants to overcome those barriers.

Data sources and data collection

Practicality data elements were measured using navigator logs. Navigators documented their activities, including telephone attempts and participant responses on encounter log forms.

Efficacy data and participant characteristics were collected from manual chart abstraction using the EMRs. Research assistants followed a standard operating procedure to obtain participant sociodemographic information, body mass index, current smoking status, and mammogram and primary care appointment information. Clinical data were abstracted up to 30 days after scheduled appointment dates for each participant.

Acceptability data were collected using semistructured qualitative one-on-one interviews with key informants: a subset of participants (n = 11), all navigators (n = 5), and a subset of primary care providers (n = 5). Participants with a scheduled primary care appointment were eligible for the qualitative portion of this study, were consented, and then contacted by a research assistant by telephone to conduct the interviews. These interviews included a 2-part phone call—the first after the initial call with the navigator and the second after the scheduled primary care appointment. Participants were asked about their experiences and the nature of the conversation with the navigator. Likert scales (range 1–5, 5 = most helpful) were incorporated to assess the participant's satisfaction with components of navigation.

The navigator satisfaction interviews were conducted in person and assessed their satisfaction as a motivational interviewer and with providing navigation for other health issues in addition to the usual breast cancer screening. Provider interviews were administered via telephone and assessed the physicians' satisfaction with the role that the navigator had in preparing their patients for the primary care visit.

All interviews were digitally recorded and transcribed. The research team read the transcripts multiple times and, using an iterative process, developed a coding scheme to reflect the key concepts raised in the narratives. The team coded each transcript independently, using HyperRESEARCH software (ResearchWare, Inc, Randolph, Massachusetts). The team then met to discuss the coded narratives and the major themes and subthemes that emerged.

Measures

The following chronic disease screenings were defined as positive:

1. Overweight/obese = a body mass index $\geq$ 25 recorded in the EMR.
2. Current smoker = a positive response to the navigator asking, "Do you smoke?"
3. Depression = score of 3 or more on the navigator administered Patient Health Questionnaire–2 (range: 0-6).

Participant-identified health priorities were elicited by the navigator.

Practicality outcome measures include (1) eligibility rate of female primary care patients, (2) rate of eligible patients successfully reached by telephone outreach, and (3) rate of consent among those reached. Primary *efficacy* outcome measures include (1) completion of a mammography appointment and (2) completion of a primary care appointment. Completion was defined as attending an appointment within 30 days of the original appointment scheduled by the navigator. *Acceptability* outcome measures include (1) participant and provider satisfaction, (2) participant willingness to have navigators accompany them to appointments, and (3) participant willingness to speak with primary care provider about their health priorities.

Statistical analysis

Descriptive statistics were performed using SAS version 9.1. Basic frequencies provided practicality and efficacy outcomes. Chi-square and *t* tests were used to examine associations between enrollment status and sociodemographic characteristics.

RESULTS

Figure 1 displays *practicality* outcomes. An electronic query of the EMR generated a list of 671 active female general internal medicine patients aged 51 to 70 years whose last documented mammogram was 18 or more months prior. These patient charts were reviewed by research staff for enrollment eligibility. Of 671 patients, only 270 (40%) were considered eligible. The most common reason for ineligibility was non-English language (135/401, 39%), while the remainder did not meet the prespecified eligibility criteria, such as age or time since last mammogram. Among those eligible for enrollment, almost a third (87/270, 32%) could not be reached via telephone outreach. When eligible patients were reached, the majority (109/270, 68%) agreed to participate.

The Table shows the sociodemographic characteristics of the eligible cohort reached via telephone. More than half of all participants were blacks, on public health insurance, and most had a documented visit with their primary care doctor within the previous 12 months. Rates of overweight/obese were substantial. Compared with those who declined to participate, those enrolled into the study were younger, more likely to be on public insurance, more likely to be current smokers, and less likely to have had a primary care visit in the past year.

The Table also shows prevalence of chronic disease for the enrolled group. The most prevalent condition was overweight/obesity (25% and 55%, respectively), and about one-third of participants screened positive for both smoking and/or depression. Overall, 93% of participants screened positive for one of the three chronic disease states; 39% had more than 1 condition (33% had 2 conditions, and 6% had all 3 conditions).

Overall, 67% of participants reported personal health priorities when asked. The majority of these participants (85%) reported health priorities that were congruent with the screening program priorities (36% weight/obesity, 10% depression, and 9% smoking). Weight was the most common patient-reported health priority. Diabetes (4%) was the most common patient-reported disease-specific health priority that was not included as a program priority. Symptoms such as pain or discomfort accounted for 13% of reported health priorities. Most (83%) stated that they would be willing to talk to their primary care providers about their health priorities.

Figure 2 shows the clinical efficacy of the pilot intervention. Overall, 93% of participants scheduled a mammogram appointment as a result of a navigator encounter, and after 30 days, 73% completed their mammogram test. Meanwhile, 71% of participants

Obese (≥30)	62 (57%)	42 (57%)	44 (52%)	148 (56%)
Not in chart	3 (3%)	3 (4%)	8 (10%)	14 (5%)
Current smoker[a]	29 (27%)	...	...	...
Depression[a]	31 (28%)	...	...	...

[a]Data are available only for enrolled subjects.

scheduled a primary care visit to follow up on their health priorities, and after 30 days, 54% of participants arrived for a visit with their primary care provider. Manual chart abstraction revealed that 64% of provider visits had documentation that 1 or more of participant's health priorities were addressed during that appointment.

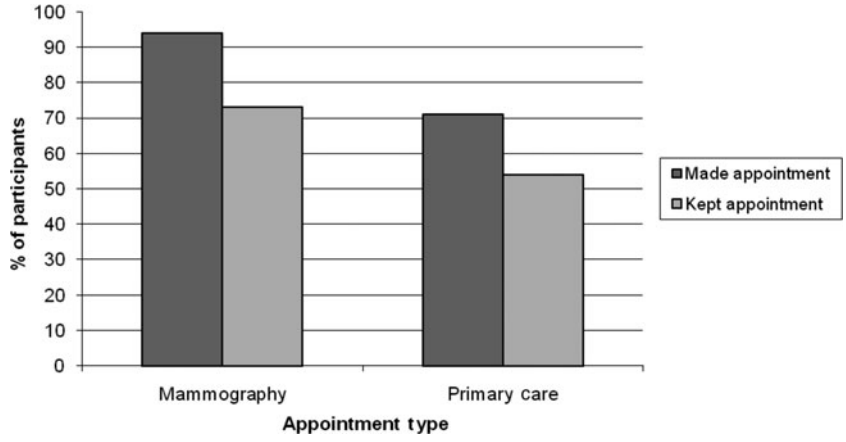

Figure 2. Made and kept appointments (N = 109).

Acceptability outcomes: The patient perspective

Overall, participants reported high satisfaction with the intervention. When asked what they most liked about the conversation with the navigator, participants most frequently noted the opportunity to speak with someone about their health and offering to schedule their appointments, especially concurrent appointments. Several also noted the value of sharing positive examples of their own self-care (eg, weight loss or quitting smoking). The majority of participants had nothing negative to say about the phone call, although one called it "excessive" and one said she would rather speak to someone face to face than over the phone.

Participants generally reported feeling very comfortable with and respected by the navigator (eg, "treated like a human being"). Several noted the importance of being heard by someone other than their doctor. One woman expressed it this way: "Navigators can help people who are in a shell—maybe they'll come out to her and speak to her about certain things. So I think it was a good idea." Another woman said that it would be good for some participants "to know that someone feels that they're special enough to come out and speak to them."

On average, all of the conversations about specific topics (smoking, depression, and weight) were rated above a helpfulness of 4.0, while those about smoking and receiving a mammogram were rated most favorably. All participants were favorable to the idea of combining the mammogram check-in with talk about other health issues. Some said that it gave them a chance to consider health-related issues that are important but that they had forgotten to pay attention to. Overall, participants reported liking the "holistic approach," saying that it was important to focus on the "mind and body" and "the whole picture."

The majority of participants reported that the priority list was helpful in preparation for the primary care visit. One participant stated, "I have a lot of different health issues, and it was very helpful for me to stop and think, well, which of those is the most important to me? You know, it just kind of helps me evaluate where I stand."

Only 2 participants accepted the navigator's offer to accompany her to the primary care visit. Another stated that introducing the navigator into the patient-provider relationship might risk conflicting the already-established rapport: "I don't want you to do that because [my provider has] been trying to get me to see a doctor. And I don't want her to think that I'm asking you and overstepping her."

Participants uniformly spoke positively about reminder calls provided by the navigator before both the mammography and primary care appointments. Several mentioned that the reminder was particularly useful because they tend to forget about scheduled appointments. One said, "I think the reminder was good because I don't like tests and stuff. Her reminding me—and she made the appointment, so that was the same day. So I got everything done. Otherwise, I probably would have said, forget it!"

During the follow-up call, the majority of respondents mentioned that the list of health priorities elicited by the patient herself was useful during the clinical visit with the primary care provider. In regard to the helpfulness of the priority list, 1 woman commented, "It helped me to stay on focus and to be able to do the things and tell the things that—you know because when you go to the doctor's office you go in there and you say, 'Yup, Yup,' [. . .]. Sometimes I do that and really don't say anything." Another remarked, "I think it helped me prioritize and pick the things that were most important in terms of talking to the doctor."

Acceptability outcomes: The navigator perspective

When compared with previous patient navigation approaches, the navigators felt that the incorporation of B-MI and chronic disease created a more personalized experience, which fostered open and honest conversations and a greater sense of patient empowerment. On a scale of 1 to 5, all of the navigators rated

their satisfaction with bundled patient navigation as 3 or higher. Navigators noted that the B-MI intervention gave them a better sense of what each patient needed, and provided them with the resources to address each patient's distinct health priorities. One navigator remarked, "When I reiterate or when I give them a summary or give them a feedback of what they've said, they seem to expand more. And I could feel them, like they take charge of it. A light bulb hits them."

Despite the numerous benefits of enhanced patient navigation, the navigators also identified challenges with the new approach. First, the navigators found that the intervention was unnecessarily excessive for some patients, in which case, the patients just wanted to schedule their appointments and did not want to engage in the B-MI intervention. They noted that the intervention proved to be less useful for the unanticipated high number of patients who had long-standing, positive relationships with their providers, and who felt confident voicing their own health concerns. The navigators uniformly found the depression screening to be an inappropriate screening tool to conduct over the phone with this patient population. They reported that it was often misunderstood or misinterpreted by patients, and these confusions and the stigma attached to depression resulted in some patients being less engaged and open after the depression screening took place.

The navigators also confronted systemic and logistic challenges. Above all, they felt that the commitment involved in this pilot project was too much to tack onto their day-to-day professional responsibilities already in place. They were frustrated by scheduling difficulties and a lack of patient/provider awareness of patient navigation. They recommend that this type of navigation be implemented within an environment that has a stronger foundation to support enhanced patient navigation.

Acceptability outcomes: The provider perspective

Generally speaking, the providers were satisfied with the enhanced patient navigation. Unfortunately, because of the size of their case load and the lapse of time between the patient visits and their interview, it was difficult for the providers to remember specific aspects of the patient navigation that were relevant to the patient visit. The providers were most positive about the navigators' role in eliciting the patient's health priorities. Three of the 4 providers interviewed agreed that many patients come to their visit and have a hard time prioritizing their health needs because they "tend to come in with a bunch of stuff." In the future, the providers recommended that patient navigation be used as a broad-based model, which can be tailored to address patients' specific psychosocial needs. The providers also felt that patient navigation could be a useful tool to support patients in complying with visits and routine health care maintenance.

DISCUSSION

The findings from this chronic disease navigation demonstration project targeting vulnerable participants confirm the feasibility of several aspects of a telephone-based community health worker intervention. The high prevalence of chronic disease in this population in need of a single-site cancer screening (ie, mammography) supports the need to adopt a more patient-centered approach like the one here. We found that almost all participants reached by telephone were willing to engage in the process of navigation and this translated into *effective* delivery of preventive health services for a population at risk for poor outcomes. However, the *practicality* of telephone outreach was limited because of language barriers and inability to reach patients despite multiple attempts. Patients were generally *acceptable* of telephone navigation; however, they did not readily accept face-to-face navigation activities. Navigators struggled with incorporating depression screening. These findings are critical to the planning process for care coordination programs that target similar populations.

Practicality

Perhaps most important is our finding that patient navigation—most frequently conducted in person and focused on a singular condition, such as breast cancer screening follow-up—can also be effectively offered via telephone and successfully combined with screening for carefully selected other health priorities and appointment making. In the context of conversations that were geared first to mammogram appointments, navigators were able to screen for overweight and smoking, both risk factors for breast cancer. Screening for depression proved more difficult, possibly related to the sensitivity of the topic and the awkwardness of the screening tool, particularly when administered by telephone. Navigators found it uncomfortable to ask what they perceived as very personal questions in this context. While some participants did not mind talking about depression, others appeared to be confused about what navigators were actually asking.

The practicality of this navigation program was limited, mainly on the basis of its reliance on telephone outreach. Navigators were able to reach only 68% of eligible patients by telephone, which is similar to telephone-based community health worker interventions targeting similar populations (Lasser et al., 2009; Myers et al., 2008; Percac-Lima et al., 2009; Weber & Reilly, 1997). Studies that were able to reach a larger percentage of patients frequently utilized additional recruitment strategies such as in-person recruitment and incentives for participation (Dietrich et al., 2006; Jandorf et al., 2005; Parker et al., 2007). We recommend that future studies consider additional recruitment strategies to compensate for the difficulties inherent in telephone-based outreach.

Efficacy

Once navigators engaged patients, using B-MI skills, the clinical outcomes were positive and comparable with other navigation studies. This study was conducted with a cohort of women who had not received a mammogram in 18 to 24 months and were thus nonadherent with screening. The ability of the intervention to result in 73% of nonadherent participants completing mammograms is impressive when compared with other intervention studies targeting populations overdue for screening. In a study by Weber and Reilly (1997), 41% of participants overdue for mammograms completed a mammogram in the 10-month intervention period. A study by Burhansstipanov et al. achieved a 55% mammogram completion rate among women who had not been screened within 18 months (Burhansstipanov et al., 2010), and in a study by Fernandez et al., 41% of women who had not had a mammogram in 12 months completed a screening within the 6-month follow-up period (Fernandez et al., 2009). However, because of the lack of a direct comparison group, generalizability of efficacy data is limited.

The full effect of the intervention may also have been limited by the failure of patient health priorities reaching the intended target, the primary care provider. The intervention was intended to prepare participants for their upcoming primary care visit, by discussing priority health concerns in advance. Navigators elicited from patients their list of priority health concerns, a list that was to serve as a springboard for conversation with their provider. While participants reported benefits from generating the list, it did not, in the end, arrive at the providers' offices/records as planned or (be perceived to) exert an impact on the visit. It is likely that this failure was related to the low level of awareness among providers about the intervention, and the long-time lag between the navigation conversation and the primary care visit, and between the primary care visit and the follow-up interview.

Acceptability

Once enrolled, patients talked freely about their health worries and strategies for self-care and reported high satisfaction with the conversation. The fact that they did not readily accept face-to-face navigation services when offered was interesting and may well be related to the finding that the relationships between primary care providers and patients in

this study tend to be long-standing, strong, and open. Thus, the presence of a navigator and even the added information from a patient navigator may not be as critical as it might be in settings where such continuity and strength in provider-patient relationships are not the norm. In fact, providers who participated in follow-up interviews indicated little knowledge that the patient navigation and screening had or had not occurred. When asked about it hypothetically, they were most likely to comment positively on the value of a preset patient-generated priority list, particularly for patients with complex psychosocial needs.

Key lessons learned and recommendations for future telephone-based navigation in this setting include the following:

- Find ways to engage and inform providers early on and in more depth about the intervention and its intent to better prepare patients and providers for their primary care visit.
- Expand hours in which the intervention can be conducted to increase the likelihood of reaching eligible individuals with fewer phone calls.
- Send the patient's priority list to the provider in a clear and recognized way (through the patient, through the navigator, or through the EMR). The priority list also could be effectively revisited when the navigator calls back to schedule or reschedule visits.
- Exclude depression screening in this context.
- Make explicit the "same day mammography/primary care visit" goal for each patient.

LIMITATIONS

Because of the focus on quality improvement and feasibility, we did not include a direct comparison group in this demonstration project. While not ideal, this design is consistent with other feasibility studies that aim to determine whether an intervention should be recommended for efficacy testing (Bowen et al., 2009) and the efficacy demonstrated here is consistent with other navigation evaluation literature. This study was also limited by the restricted inclusion criteria to English speakers only, which is not fully representative of the diverse patient population served at this safety net institution. This limitation underscores the reality of providing culturally appropriate care in resource poor settings and calls for future planning that prioritizes multilingual health workers.

CONCLUSION

As patient navigation becomes a more prevalent form of community health work, in the era of patient-centered health care reform it is crucial to expand navigation beyond the traditional disease-specific cancer setting and provide navigators with tools to effectively address multiple chronic conditions. This study supports the feasibility of chronic disease patient navigation in primary care with some key lessons for program planning and future efficacy testing. This type of feasibility data is critical to incorporating community health workers into the emerging patient-centered medical home model to ensure the delivery of quality care to the most vulnerable populations.

Abstract

Background: Despite close proximity to community health centers, public housing residents are at increased risk of uncontrolled chronic disease, in part because of underutilization of routine health care.

Objectives: To assist in program planning, the Partners in Health and Housing Prevention Research Center (PHH-PRC) used the Community Readiness Model to compare readiness of public housing developments and community health centers to address community-identified health priorities. The model assumes that program success to affect change depends on matching the community's level of readiness to address the issue.

Methods: Key respondent interviews were conducted across 15 communities: Eight housing developments and seven health centers. Interviews were scored across six dimensions on an anchored, 9-point scale and averaged to provide a composite readiness score. Higher scores indicate increasing levels of readiness. Interview transcripts were reviewed for consistent themes.

Results: Health centers scored significantly higher (mean, 5.88) than housing developments (mean, 3.33), corresponding with the Preparation stage of readiness compared with the Vague Awareness stage, respectively. Both scored highest in Existing Programs and Resources and lowest in Knowledge of Efforts. Qualitative analysis revealed a lack of existing partnerships between housing developments and health centers as well as significant social barriers preventing housing residents from engaging in care.

Conclusion: We found a mismatch in readiness to address community health priorities. Although health centers have programs to address health issues, community awareness of programs is limited and barriers to engaging in care persist. The model provided a useful tool for engaging communities into shared program planning.

Keywords

Community-based participatory research, community health partnerships, urban health, urban health services, health disparities, health promotion, health outcomes

Most of the 2 million Americans living in public housing fall below the federal poverty level and face significant social, economic, and physical stressors that negatively impact their health.[1] This is demonstrated by the disproportionately high burden of chronic health problems among public housing residents nationwide, including high rates of asthma, cancer, oral health issues, obesity, hypertension, and diabetes. As a result, public housing residents are more likely than the general population to suffer early morbidity and mortality.[1-5] In Boston, Massachusetts, nearly 10% of residents live in public housing or receive rental assistance.[6] Research has shown that these public housing residents are over three times more likely to report fair or poor health status compared with other Boston residents;

they are more likely to have ever been diagnosed with high cholesterol, hypertension, and diabetes; and report higher current rates of asthma, obesity, smoking, depressive tendencies, disability, and insufficient physical activity.[7] These ongoing health disparities support the need for innovative interventions targeting this vulnerable population.

Public housing residents live in closed multigenerational communities in close physical and social proximity. This creates opportunity for proactive community-based interventions that aim to address problems in the context of community strengths while respecting cultural diversity.[8-10] Engagement of the community is critical to translating scientific advances in healthcare to improved health status, yet numerous barriers exist for vulnerable populations to participate in scientific inquiry, including lack of access and opportunity.[11-13] These challenges limit our understanding of the causes of health disparities and of effective interventions to reduce these disparities among Boston's public housing residents. A community-based participatory research approach is one way to ensure participation of this population in intervention planning.

The PHH-PRC was established in Boston in 2001 as 1 of 33 Prevention Research Centers nationwide, funded by the U.S. Centers for Disease Control and Prevention to create community–academic partnerships aimed at reducing the burden of disease and promoting health among at-risk populations. The PHH-PRC is the only such collaboration that focuses exclusively on public housing, engaging residents in activities and research designed to improve their health and well-being and thus reduce health disparities.[14] The collaboration includes four equal partners: Boston University School of Public Health, Boston Public Health Commission, Boston Housing Authority, and the Community Committee for Health Promotion, representing the residents of Boston Housing Authority's family housing developments. Prior work by the PHH-PRC found that 65% of residents were found to have evidence of at least one life-threatening chronic illness.[15] When followed for 3 months after their screening, only 15% of those with chronic disease had evidence of a follow-up medical appointment,[15] despite close proximity to numerous federally qualified health centers and academic medical centers in Boston. This finding calls for collaborative approaches between the community and local clinical care sites.

Table 1. Community Readiness Model Stages[18-21]

Stage	Description	Goal
1. No awareness	Issue is not generally recognized by the community or leaders as a problem.	Raise awareness of the issue.
2. Denial/resistance	At least some community members recognize that it is a concern, but there is little recognition that it might be occurring locally.	Raise awareness that the issue exists in this community.
3. Vague awareness	Most feel that there is a local concern, but there is no immediate motivation to do anything about it.	Raise awareness that the community can do something.
4. Preplanning	There is clear recognition that something must be done, and there may even be a group addressing it. However, efforts are not focused or detailed.	Raise awareness with concrete ideas to combat condition.
5. Preparation	Active leaders begin planning in earnest. Community offers modest support of efforts.	Gather existing information with which to plan strategies.
6. Initiation	Enough information is available to justify efforts. Activities are underway.	Provide community-specific information.
7. Stabilization	Activities are supported by administrators or community decision makers. Staff are trained and experienced.	Stabilize efforts and programs.
8. Confirmation/expansion	Efforts are in place. Community members feel comfortable using services, and they support expansions. Local data are regularly obtained.	Expand and enhance services.
9. High level of community ownership	Detailed and sophisticated knowledge exists about prevalence, causes, and consequences. Effective evaluation guides new directions. Model is applied to other issues.	Maintain momentum and continue growth.

As preliminary research for interventions that link public housing residents with primary care services, we turned to the Community Readiness Model to assess the level of readiness of the "community" to address a community-identified health priority. The model, developed by the Tri-Ethnic Center for Prevention Research at Colorado State University, is a widely used model for community change[16] that integrates a community's culture, resources, and level of readiness to guide the complex process of community change. The underlying assumption of the model is that overall success of programs to affect change depends on matching the program with a community's level of readiness to address the chosen issue.[17] Community readiness theory combines principles of individual psychological readiness for change (trans-theoretical model) with the principles of community development to provide a framework for implementing changes in community health services,[18,19] then offers practical tools to design, implement, and evaluate programs in community settings.[17] The model defines nine stages of community readiness ranging from no awareness of the problem to a high level of community ownership and action (Table 1). Each stage is characterized by a set of criteria and accompanied by a set of specific goals that facilitate advancing the level or stage of readiness. Originally designed to target substance abuse and drug prevention by the Tri-Ethnic Center,[17,19] the model has since emerged as a tool in other areas,[20] including obesity,[21,22] HIV,[23] and clinical trial enrollment.[24]

The aim of this study was to understand the level of readiness for each community partner (housing developments *and* health centers) to engage in health promotion planning, as a preliminary step toward successful implementation of programs that would engage residents into clinical care. We target both public housing developments and community health centers as "communities" of interest. The aims of this research were to (1) compare the readiness of housing developments versus community health centers to address a chosen health priority, and (2) identify community-specific barriers relevant to bringing residents of public housing developments into primary care services within the community health centers.

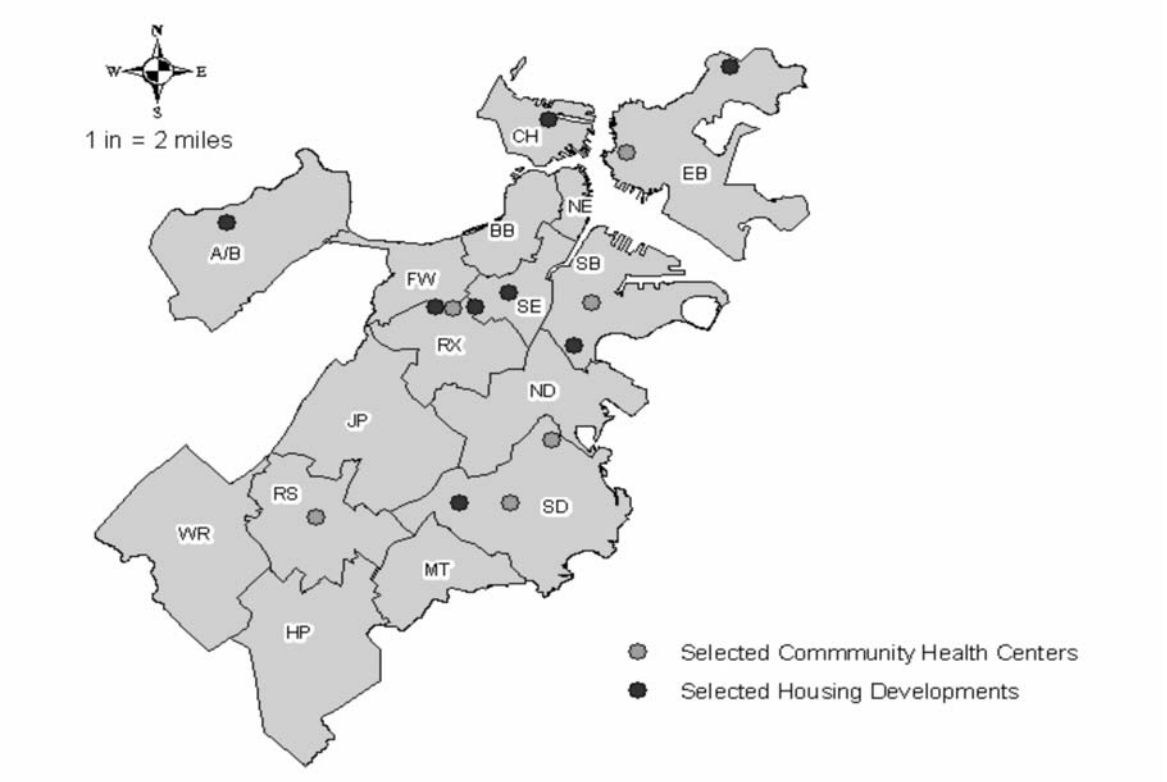

Figure 1. Location of Study Sites by Boston Neighborhoods

Boston neighborhood names: A/B = Allston-Brighton; BB = Back Bay; CH = Charlestown; EB = East Boston; FW = Fenway; HP = Hyde Park; JP = Jamaica Plain; MT = Mattapan; ND = North Dorchester; RS = Roslindale; RX = Roxbury; SB = South Boston; SD = South Dorchester; SE = South End; WR = Roxbury.

METHODS

Utilizing principles of the community readiness theory, we conducted readiness assessments across 15 different communities, including eight public housing developments in Boston and seven federally qualified community health centers in close proximity to the chosen housing developments (Figure 1). Key respondent interviews at each community site were conducted between May and October 2010. The Boston University Medical Center Institutional Review Board approved this study.

Study Sites

For this project, we define a "community" as a group that shares a common residence or clinical care site, as defined by a discrete public housing development or community health center. Rather than a geographic area or cultural group, we view a public housing development or community health center as a distinct community with its own identity.[25] We included health centers and housing developments within the same geographic area as discrete communities because they have independent governing structures, health priorities, and ways of addressing those priorities.

There are a total of 26 family public housing developments throughout Boston that provide quality, public, and affordable housing for low- and moderate-income individuals and families from diverse racial/ethnic backgrounds. In 2009, 11% of Boston Public Housing Residents were White, 32% were Black, 47% were Hispanic, and 10% "other" racial/ethnic groups. The average household income for these residents is less than $14,000 per year.[26] Limited resources required the PHH-PRC Steering Committee to identify eight family housing developments to participate. Criteria for selection included high burden of chronic disease, size of development, racial/ethnic variability, and geographic variability.

The Clinical and Translational Sciences Institute at Boston University, BU BRIDGE, provided financial support for inclusion of seven of their 15 primary-affiliate federally qualified health centers in the assessment. These community-based, outpatient health, and multi-service centers located throughout Boston's neighborhoods provide comprehensive care to Boston's most vulnerable populations. In 2007, these centers provided care to nearly 200,000 individual patients (23% White, 35% Black, 19% Hispanic, 4% Asian/Pacific Islander) and nearly 80% living below 200% of the Federal Poverty Level.[27] We chose health centers in close proximity to housing developments to compare readiness of institutions working within the same geographic area, and thus serving similar populations. The main criterion for selection of the 7 health centers was geographic proximity to the housing developments (Figure 1). Together, the eight housing developments and seven health centers comprised the 15 communities included in this assessment.

Health Priority

Because readiness assessment is issue-specific and we wanted to ensure community engagement in the research process, the research team asked leadership from each of the 15 communities to choose one priority health topic for the assessment. Housing developments were represented collectively by the PHH-PRC partners who utilized data from their annual resident survey to identify multiple chronic diseases of concern, including obesity, diabetes, high cholesterol, hypertension, and smoking. PHH-PRC partners agreed to combine these chronic diseases into the broad category of cardiovascular disease or "heart health" for their assessments. Health center leadership, which included medical and administrative staff from each of the seven participating sites, was asked to identify the health priority for their individual health center. Priorities differed across health centers, though most also related to "heart health"; three chose obesity, one childhood obesity, one hypertension, one asthma, and one substance abuse.

Study Subjects

Readiness methodology requires four to six key respondent interviews per community. Key respondents were identified by leadership from their community, The Community Committee for Health Promotion for housing developments and medical directors or executive directors of the health center. Criteria for key respondents included adult community members knowledgeable about ongoing efforts around the chosen health priority and diversity across racial/ethnic groups representative of the larger community.

Interview Guide

A standardized, open-ended interview guide was adapted to measure the six dimensions of readiness: (1) Community efforts: To what extent are there efforts, programs, and policies

that address the issue? (2) Community knowledge of efforts: To what extent do community members know about local efforts and their effectiveness? Are the efforts accessible to all segments of the community? (3) Leadership: To what extent are appointed leaders and influential community members supportive of the issue? (4) Community climate: What is the prevailing attitude in the community toward the issue? (5) Community knowledge of the issue: To what extent do community members know about the causes of the problem, consequences, and how it impacts the community? and (6) Resources related to the issue: To what extent are local resources (people, time, money) available to support the efforts? PHH-PRC partners contributed to the modification of an existing interview guide to target the issues identified by each community, addressed language and literacy concerns, and added additional questions that targeted partnerships between housing developments and health centers. Self-reported socio-demographic variables including gender, age, race/ethnicity, and role in community were included along with 40 open-ended readiness questions. Interview guides were piloted in March 2010 with two housing development residents and one health center staff and modified accordingly. (For a copy of the interview guide see the on-line appendix http://muse.jhu.edu/journals/progress_in_community_health_partnerships_research_educaton_and_action/v006/6.3.battaglia02_supp01.pdf)

Data Collection

After obtaining written informed consent, four to six in-person interviews were conducted at each of the 15 communities by two authors (SM, SGB), each of whom completed in-person training by Tri-Ethnic Center staff. Each one-on-one interview lasted between 45 and 75 minutes, was audio-taped, and sent via a secure, password-protected website to the Tri Ethnic Center for transcription and primary analysis.

Community Readiness Score

Using a previously validated scoring system,[17,18] experienced Tri-Ethnic Center staff scored each community across six the dimensions of readiness on an anchored 9-point scale, with higher scores indicating higher levels of readiness. Interviews were reviewed and scored independently by two reviewers, who then met to discuss scores that did not match to reach consensus. Each question ties to certain dimensions, scores are given per dimension, not per question. Scores for each dimension are averaged to give each community an overall readiness score,[16] and by convention are rounded down to determine the stage of readiness. As shown in Table 1, scores range from 1 to 9 corresponding to each stage: (1) No Awareness, (2) Denial/Resistance, (3) Vague Awareness, (4) Preplanning, (5) Preparation, (6) Initiation, (7) Stabilization, (8) Confirmation/Expansion, and (9) High Level of Community Ownership.

Analyses

We used descriptive statistics to provide a summary of participant characteristics using SAS version 9.1 (SAS, Inc., Cary, NC). A community readiness score was calculated for each community and an independent *t* test was used to compare scores between communities. Three members of the research team (SM, TB, SGB) conducted a thematic analysis of the transcribed interviews to systematically organize observations in the data that were not represented in the readiness scale.[28] Investigators independently reviewed transcripts to identify reoccurring themes, and then discussed independent findings in a group forum. Reoccurring themes were then grouped into agreed upon broader thematic categories. As demonstrated by previous research utilizing this model, this additional qualitative analysis serves to enhance quantitative results by fostering a more thorough understanding of the unique factors that contribute to a community's level of readiness.[29]

RESULTS

We interviewed a total of 78 key respondents (43 housing development residents and 36 health center staff). More than half (73%) were female (Table 2). Key respondents from the health centers were majority White (67%), 17% Black, and 14% Asian/Pacific Islander. Conversely, housing development key respondents were largely (86%) racial/ethnic minorities: 58% Black, 28% Hispanic, and 9% American Indian/Alaska Native. Overall, health center key respondents were younger than housing development residents; however, all adult age groups were well-represented in both community settings. By study design, key respondents included management, leadership, lay, and outside members affiliated with the community.

Community Readiness Scores

Overall, community readiness scores were significantly higher for health centers than housing developments (mean,

5.8 vs. 3.33, respectively; $p < .0001$). Table 3 also demonstrates that there was little variability in scores across the 2 types of community settings, such that health center scores ranged from 4.98 to 7.48 (SD 0.91), while housing development scores ranged from 2.58 to 4.24 (SD 0.65). A score of 5 at the health centers indicates the Preparation Stage, meaning that active community leaders have begun planning in earnest, but the community itself (the health center) offers modest support of these efforts. According to the Community Readiness Model guide, to advance health promotion around the priority issue, the goal for these communities is to continue to gather pertinent information and work with key leaders and influential community members to introduce information about the issue and ongoing efforts to the target population (Table 1).[16] Examples of stage-specific strategies for health centers include conducting patient interviews or surveys to identify service gaps, improving existing services to address those gaps, and identifying key places to post information. For housing developments, an overall score of 3 indicates the Vague Awareness Stage, meaning that there is local concern but no immediate motivation to take action around heart health. The goal for efforts in these communities is to raise awareness that the community can do something about this issue. One recommended strategy for advancing heart health promotion for these communities is educating existing small groups within the developments about heart health.

Figure 2 depicts the mean readiness scores by dimension, comparing means for health centers with housing development communities. Despite the overall difference in stage of readiness between these two types of community settings, both health centers and housing developments scored highest in existing programs and policies to address their health priority (mean of 6.65 vs. 4.01) and in the resources available to address the issue (mean of 5.98 vs. 3.97). Health centers scored lowest in leadership (mean, 5.43) and community knowledge of efforts (mean, 5.57), whereas housing developments scored lowest in community knowledge of efforts and community knowledge of the issue (with means of 2.58 and 2.76, respectively).

* Percentages do not equal 100 because some participants selected multiple race/ethnicities.

Qualitative Findings

Several themes pertaining to programmatic planning were identified. In developments, two key themes emerged: (1) Barriers to heart health and (2) variability in site of care. In health centers, the major theme identified was a lack of targeted outreach efforts to housing developments.

Barriers to Heart Health. Housing development key respondents repeatedly report barriers to health that are attributable to basic life needs, including violence/safety, substance abuse, financial issues, insurance, and housing conditions. The following excerpts from two key respondents at different housing developments demonstrate this point:

Table 3. Summary of Overall Community Readiness Scores

Community	Mean Score	Range	Standard Deviation
Health Centers	5.88	4.98–7.48	0.91
Housing Developments	3.33	2.58–4.24	0.65

> The hallways are not clean. There's spit. There's vermin. There's all type of bad, disgusting things in there. . . . [Heart health] would be people's main concern because they want to be healthy, but come out and see that spit in front of your door; you might not think about jogging right after.
>
> It's a concern, but it's not at the front of people's minds. Gun violence is a big concern . . . you can see violence.

Site of Care. The second theme that emerged from the housing development key respondents was the tremendous variability noted in where residents reported receiving their care. Across the 43 housing development respondents, a total of 24 different sites of care were noted, and included both local community health centers and several academic medical centers. At one housing development, 13 different clinical sites were referenced as sites of care for community members.

Outreach to Developments. The final theme that emerged came from review of transcripts from health center key respondents. None of these key respondents felt that their current programming specifically targeted or reached out to their local housing development residents. While they did express an interest in working with these communities, they were largely unaware of any current initiatives, as these two excerpts demonstrate:

> We don't have any specific relationships [with local housing developments]. We just serve people that live in local housing projects, but we do not have any coordinated efforts that I'm aware of.
>
> We have patients who come in from . . . the housing projects, but there isn't a partnership.

DISCUSSION

This is the first study to use community readiness as a means to galvanize two unique community settings into action to address common health priorities among at-risk, underserved, urban populations. Our findings confirm a mismatch in health priorities as well as the level of readiness to address those health priorities between housing developments and community health centers. Although the community health centers report existing programs to address their priority health issues, community awareness of programs is limited in both settings. Further, housing developments demonstrate a local concern, but there is no immediate motivation to do anything about it, in part owing to perceived barriers to care. We found the readiness assessment to be a useful tool for engaging these communities in conversation and shared program planning by providing specific action-oriented guidance on stepwise program planning.

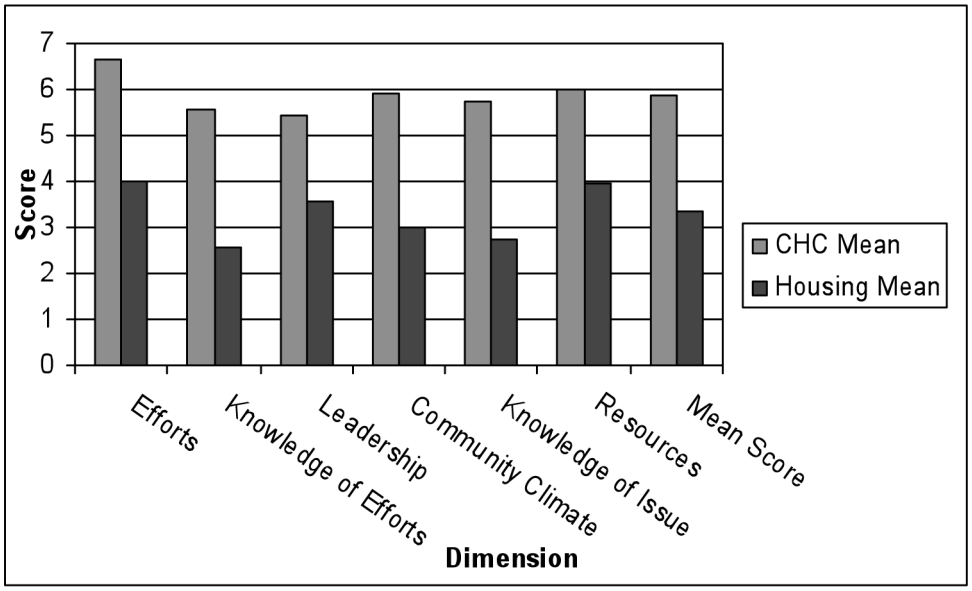

Figure 2. Mean Readiness Scores to Address Community-Identified Health Priorities by Dimension: Health Centers Versus Housing Developments

Each community was given the opportunity to identify its own health priority. Although there was much overlap in identified priorities, there was some disconnect between the two settings as reflected by one health center choosing asthma and another substance abuse; all others chose some issue related to cardiovascular disease. Understanding these differences is a critical first step in aligning priorities for future health promotion activities. As it stands, this information identifies those health centers that share a common health priority with the PHH-PRC and thus make logical partners for initial program planning efforts targeting heart health among these housing development residents.

Readiness scores for the identified health priorities indicate that only 2 of our 15 communities were ready for immediate program implementation (as indicated by a score of 6 or higher). Our assessments indicate that most communities are unprepared to take action despite awareness that there may be a health issue. This suggests that, for future prevention programs to be successful in these communities, there are a number of actions required first to raise awareness and to motivate community members to address the health issue. Information obtained across each community during the readiness assessments provides a rich platform to develop strategies that are specific to each community. For example, key respondents identified specific community members who are considered respected leaders and thus might serve as targets for awareness raising efforts. Immediate next steps in these communities would be meeting with these leaders to get recommendations on the best strategy to raise awareness across the respective community.

The mismatch identified between housing development and health center readiness is not surprising if one considers that health centers exist to address community health. Yet, one might expect that communities that are able to identify their own health priority might be further along the overall continuum of readiness. Given that this is the first application of this model to compare communities, there is no prior literature to draw from in synthesizing our findings. Despite this mismatch between housing development and health center communities, it is interesting that there is consistency across dimensions, even with the observed differences in overall phases of readiness. All communities scored highest in efforts but lowest in knowledge of efforts, suggesting that immediate next steps to program planning need to target education of community leaders and members. Yet the content of this education will differ between housing developments and health centers; according to the stage-specific strategies in the readiness model, targeted messages for housing developments should focus on the importance of heart health, and increasing knowledge of existing programs is needed for staff at health centers.

Analyses of these qualitative data suggest barriers across the housing development communities are largely related to social determinants of health, and confirm the notion that basic life needs preclude action and motivation to address chronic disease despite their high prevalence. These findings are consistent with the vast literature on barriers to accessing needed healthcare in urban, underserved populations.[7,30,31] Our findings also provide objective evidence for community leaders that targeting these barriers when planning prevention programs is essential to effectively impact health outcomes. Thus, our current work in program planning within these communities will address these barriers by adapting a patient navigation model,[32-35] which is designed to target such barriers to accessing health care services.

Our qualitative analyses also indicate that residents of Boston Public Housing Developments have a large variety of clinical care site options, which may contribute to the inertia to engage in care. Because there are so many choices, there is no single clinical setting for this "community" to seek care and knowledge, thus diluting the effect on any programmatic efforts at individual health centers. Although this finding may be unique to the Boston community given the large presence of health care training programs and the network of safety net community health centers, for this partnership it clearly suggests the need for more of a population-level approach for program planning targeting residents of Boston public housing. So, rather than matching developments and health centers on a one-to-one basis, we are planning for housing development navigator training to include comprehensive systems training with all local health centers as well as the common barriers reported by development respondents, and will thus be able to assist residents in accessing care anywhere in Boston.

We found the methods employed in the readiness assessment to be a useful tool for engaging these communities. First, the use of a validated measure to stage level of readiness

is helpful, as community partnership intervention teams often rely on limited impressions or subjective sources. In addition, having multiple respondents and common questions per community allowed for direct comparisons. As a result, the process generated mechanisms for feedback which will help communities make changes.

For example, the study group facilitated discussion of study findings that occurred in multiple community settings. Each community received a personalized report with action-oriented recommendations for their own use. As outlined, these specific findings guided the development of an active community-based patient navigation heart health intervention. In ensuring that all stakeholders were involved from the feasibility phase onward, we were able to avoid potential roadblocks and able to plan a more community appropriate intervention to address heart health within housing developments. In addition, having this platform for engagement served to introduce the research team to future partners and begin the process of building trust and buy-in. In fact, the Boston University Clinical Translational Sciences Institute is planning to use these findings to inform the local research community across both the institution and in the health centers about potential collaborators with common interests for future studies. Although our study has limited generalizability because it was conducted in a single urban setting, our approach utilized common methods and protocols and thus provides a generalizable tool for use in other settings.

CONCLUSIONS

The readiness assessment conducted here provides a foundation for both a dialogue between these two community settings as well as an action-oriented framework to guide collaborations. Eliciting perspectives of key stakeholders (residents of each housing development and staff of each corresponding health center) around a community-identified health priority helped to ensure community buy-in and support for program planning. Future collaborative efforts will be aligned with each community's level of readiness to address their priority health issue to ensure successful implementation. Given the validated methods employed, this approach to program planning may serve as a model for other community collaborations that seek to address a common preventable health issue in their target community.

ACKNOWLEDGMENTS

Our sincere appreciation to both the Boston University Partners in Health in Housing Prevention Research Center (PHH-PRC) and the Boston University Clinical Translational Sciences Institute (BU-BRIDGE) for their commitment to advancing the health of Boston, Massachusetts residents through community-based participatory research. This work would not be possible without the community members who volunteered to discuss the needs of their communities. The authors thank Linda Stanley, from the Tri-Ethnic Center for Prevention Research at Colorado State University, for providing training and guidance on our use of the Community Readiness Model. The findings and conclusions in this article are those of the Partners In Health and Housing Prevention Research Center at Boston University and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Abstract

Background: There is a need for controlled studies to assess the impact of patient navigation in vulnerable cancer populations.

Methods: Boston Patient Navigation Research Program conducted a quasi-experimental patient navigation intervention across six federally qualified inner-city community health centers, three assigned to a breast cancer navigation intervention and three assigned to a cervical cancer navigation intervention; each group then served as the control for the other. Eligible women had an abnormal breast or cervical cancer screening test conducted at one of the participating health centers during a baseline (2004–2005) or intervention period (2007–2008). Kaplan–Meier survival curves and proportional hazards regression examined the effect of patient navigation on time to definitive diagnosis, adjusting for covariates, clustering by clinic and differences between the baseline and intervention period.

Results: We enrolled 997 subjects in the baseline period and 3,041 subjects during the intervention period, of whom 1,497 were in the navigated arm, and 1,544 in the control arm. There was a significant decrease in time to diagnosis for subjects in the navigated group compared with controls among those with a cervical screening abnormality [aHR 1.46; 95% confidence interval (CI), 1.1–1.9]; and among those with a breast cancer screening abnormality that resolved after 60 days (aHR 1.40; 95% CI, 1.1–1.9), with no differences before 60 days.

Conclusions: This study documents a benefit of patient navigation on time to diagnosis among a racially/ethnically diverse inner city population.

Impact: Patient navigation may address cancer health disparities by reducing time to diagnosis following an abnormal cancer-screening event. *Cancer Epidemiol Biomarkers Prev; 21(10); 1645–54. ©2012 AACR.*

Introduction

There is widespread recognition that increasing complexity of cancer care contributes to outcome disparities (1, 2) as evidenced by the impact that lack of access to timely, quality cancer services has on outcomes among vulnerable populations defined by low income, inadequate insurance coverage, and minority race/ethnicity (3–7). To address this failure to equally deliver the spectrum of cancer services to all Americans, there is growing emphasis on patient navigation programs (8–10).

Patient navigation was designed to identify and eliminate barriers to accessing cancer services to achieve timely completion of care (11, 12). The goal of patient navigation is to facilitate timely care by meeting cultural needs and addressing barriers to accessing care at the individual level. Examples of navigation services include identifying patients at risk for delays, facilitating appointment scheduling, coordinating care among providers, organizing interpreter services, ensuring access to prior medical records, and providing logistic support for transportation, childcare, or linkage to community resources. Navigators are trained to help patients advocate for themselves in the health care system and provide emotional support during this stressful period.

Several demonstration projects and small clinical trials report the potential benefit of patient navigation at certain points in the cancer care continuum and in specific populations (10, 13–15) resulting in several organizations recommending patient navigation as standard care (16, 17). However, large-scale clinical trials across diverse

populations are still lacking. Implementation research is needed to assess the ability of navigation to be adopted in usual clinical practice, especially in safety net institutions that care for low-income patients (18). To provide controlled clinical trial data on the efficacy and effectiveness of patient navigation for follow-up of screening abnormalities, the Center to Reduce Cancer Health Disparities (CRCHD) and the American Cancer Society funded 10 intervention sites through 9 grants (11) to conduct a national Patient Navigation Research Program (PNRP). The Boston PNRP, one of the funded programs, was designed as an effectiveness study to assess the impact of patient navigation under usual clinical practice rather than the ideal circumstances of a randomized clinical trial.

Materials and Methods

Study design

We conducted a quasi-experimental intervention across 6 federally qualified inner-city community health centers targeting women with breast and cervical cancer screening abnormalities. The Boston program was designed as a clinical effectiveness study of patient navigation as a new standard of care, where all patients with screening abnormalities were included into the trial and thus the Boston University Institutional Review Board approved the study with a waiver of written informed consent. Using the community based participatory research process (19, 20) guided by a Community Advisory Panel, each health center partner agreed to collaborate in developing and evaluating the patient navigation program at their site. Each health center was assigned a navigation site for either abnormal breast or cervical cancer screening and a control for the other condition. To adjust for temporal trends and observe for contamination between the intervention and control conditions, we collected baseline data from the health centers on a random sample of all subjects with abnormal screening in 2004 to 2005, and collected data on all subjects with abnormal screening during the intervention period from January 2007 to December 2008. We followed all subjects for 365 days, censoring those who had not achieved diagnostic resolution by the end of the study.

Study sites

Because there were only 6 sites, each serving different racial/ethnic communities, rather than randomly assigning each to the navigation condition, the study team developed a strategic allocation protocol to reduce imbalance across the study by race/ethnicity.

Inclusion and exclusion criteria

We used electronic medical records to identify eligible women with an abnormal breast or cervical cancer screening test conducted at one of the participating health centers during the study periods. Breast abnormalities include abnormal mammograms, ultrasound or magnetic resonance imaging (MRI) of the breasts, coded as BI-RADS 0, 3, 4, or 5 using the Breast Imaging Reporting and Data System (21, 22), or abnormal clinical breast examinations with a mass or other lesion suspicious for cancer. Cervical cancer screening abnormalities included Pap test findings of low- and high-grade squamous intraepithelial lesions (LGSIL and HGSIL), atypical cells of unknown significance (ASCUS), when reflex testing for high risk human papilloma virus (HPV) was positive, or atypical glandular cells of unknown significance (AGUS). Women were excluded if they were pregnant at the time of the screening abnormality, as pregnancy may alter the evaluation protocol and its time course, or had a cognitive impairment that prevented their participation with a patient navigator. During the baseline period, we sampled all high-grade (BI-RADS 4, 5, and HGSIL) lesions and a random sample of all other mammographic and cytologic lesions with up to 100 subjects per health center (23). We included all women with abnormalities during the intervention period. When guidelines for management of ASCUS HPV–positive and LGSIL changed for women ages 18 to 21 years in 2007 (24), recommending annual Pap tests and not diagnostic colposcopy, we excluded, thereafter, those subjects where the clinician choose repeat Pap tests as the management, retaining any subjects if the clinician referred the patient for colposcopy.

Recruitment, training, and supervision of patient navigators

Patient navigators were hired as employees of the health centers, not part of the research staff. With personnel turnover, there were a total of 23 female navigators. They all had a high school education and some health care experience, such as medical assistant training. None had advanced training in social work or nursing. Each health center attempted to hire navigators who could address the language needs of their communities; five navigators spoke another language, including Spanish, Vietnamese, Albanian, and Portuguese Creole; all other navigators had access to robust interpreter services. They were integrated into the clinical team at the health center, receiving direct supervision from health center staff. All received standard training to ensure minimal competency. The research team conducted bi-monthly local training for all navigators and their supervisors throughout the study period. All navigators participated in annual face-to-face national PNRP trainings and several webinars to standardize the training across the national sites (25). A protocol was developed at each health center for identifying women with abnormal cancer screening. Navigators contacted patients by telephone to initiate navigation after a clinician had informed the patient of the test results. Navigators used the care management model (26) to identify barriers to recommended care, and developed strategies to address these barriers, with the focus on timely completion of the diagnostic evaluation. Follow-up occurred by telephone, mail, and in face-to-face meetings, usually at the health center. Navigators documented their activities in a structured template in the electronic medical

DOI:10.1158/1055-9965.EPI-12-0532

record, which allowed providers to view the activities in real time and allowed electronic capture of the navigator activities.

The research team conducted annual core competency assessments on all navigators, and provided feedback to the local supervisors. The research team also provided each site with a monthly spreadsheet of patients eligible for navigation at the health center and their progress in reaching diagnostic resolution.

Data collection

All data were captured through the electronic medical records at each of the health centers regardless of control or navigation status. Demographic information was captured from registration and billing systems. Electronic charts recorded all screening studies and their results, so we were able to capture abnormalities electronically. All subsequent information on the clinical diagnostic evaluation, including tests ordered, completed, and their results, were collected through manual abstraction by trained abstractors, with 10% of charts reviewed by a second abstractor for accuracy of abstraction with 3% errors identified.

Race/ethnicity was collected from registration data, as our prior work indicated a high correlation of this administrative data with patient self-report (27). We imputed the $n = 229$ (8%) missing race/ethnicity data from the following sources, in order of: providers' notes, country of origin (28), last name (29), or based on the majority race/ethnicity group of their community health center site. Missing language ($n = 174$, 6%) was imputed as other than English if there was documentation in the medical record of the primary language, of need for interpreter, or correspondence with the patient in another language.

Outcomes

The primary outcomes of interest in our study were whether and when diagnostic resolution of the screening abnormality was achieved, as defined by the Design and Analysis Committee for the National PNRP (11). Time to diagnostic resolution was defined as the time from the date of the initial screening abnormality to the date when the final definitive diagnostic test or evaluation was completed, a timepoint determined by the clinicians caring for the patient. For BI-RADS 4 and 5 lesions, it was usually biopsy. For BI-RADS 3 imaging, where serial 6 month imaging for up to 2 years is recommended, we observed only to confirm when the next imaging was completed after 6 months. We subtracted 180 days from the diagnostic evaluation time, which allowed us to compare all abnormalities in a similar timeframe. If the BI-RADS 3 was addressed in less than 180 days, we used 0.5 days for the time to diagnostic resolution. For BI-RADS 0 lesions, resolution was defined as either follow-up imaging designated BI-RADS 1 or 2, or completion of whatever diagnostic testing through biopsy had been recommended. For cervical abnormalities, diagnostic resolution was usually colposcopy.

Analysis

We followed our *a priori* analysis plan to conduct a difference in differences survival analysis, comparing the differences across the baseline and intervention time periods between the navigated and control study sites. We calculated separate Kaplan–Meier survival curves and proportional hazards regression models for breast and cervical subjects to examine the effect of patient navigation on time to definitive diagnosis for each clinical abnormality. Proportional hazards regression models examined the effect of patient navigation, controlling for differences between the baseline and intervention periods, grade of abnormality, and demographic covariates. We included as potential confounders the covariates of age (breast categories: 18–40, 41–64, >65 years and cervical categories: 18–20, 21–30, >30 years), high (BIRADS 4 and 5, HGSIL) versus lower (BIRADS 0 and 3, LGSIL) grade screening abnormality, race/ethnicity, primary language and insurance (private, public or no insurance), and percentage of zip code under federal poverty level as proxy for socioeconomic status. These models accounted for clustering by health center. We included interactions terms with the time to diagnostic resolution variable where proportional hazards assumptions were violated.

All analyses were conducted in SAS, and the proportional hazards regression procedure in SAS used a robust sandwich estimator for the covariance matrix in Wald tests for the global null hypothesis and individual parameters to account for clustering (30). The effect of patient navigation met assumptions of proportionality for the cervical cancer screening arm of the trial, but did not for the breast cancer screening arm. We noted that the survival curves for the baseline and intervention period for the breast navigated sites crossed at approximately 60 days, and therefore included an interaction term between intervention and time allowing differential effects of patient navigation over days 0 to 59 and days 60 to 365. All observations were censored at 365 days. A limitation of the sandwich estimator to account for clustering is that it is biased downward when there are few clusters (31). Therefore we conducted a secondary analysis using a shared gamma frailty model with a proportional hazards model fit through a penalized likelihood approach (using the frailtypack procedure in R; 32) as a second approach to account for clustering. This method does not allow one to account for the nonproportional hazards for navigation in the breast cancer screening arm in a single model. Therefore, we ran separate proportional hazards for diagnostic resolution within 59 days and for diagnostic resolution between 60 and 365 days in this secondary analysis.

Because we were specifically interested in knowing whether navigation had a greater impact on vulnerable groups of women, described here by race/ethnicity, primary language, and insurance coverage, we developed models including interaction terms for these variables with the navigation variable. Our primary analysis was conducted as an intention to treat analysis, including all women whether or not they received patient navigation.

DOI:10.1158/1055-9965.EPI-12-0532

We conducted a secondary analysis, excluding those navigated subjects where the navigator did not initiate patient navigation within 30 days for breast screening abnormalities and 60 days for cervical screening abnormalities.

Results

There were a total of 997 subjects in the baseline period and 3,041 subjects during the intervention period, of which 1,497 received navigation and 1,544 were controls. Tables 1 and 2 display demographics separately for breast and cervical subjects, looking at the overall group divided by both study period (baseline versus intervention) and by study site (navigation versus control sites). The majority of subjects were from racial or ethnic minority groups, including 30% from African American communities and 29% from Hispanic populations. The subjects spoke 18 primary languages, with Spanish (19%), Vietnamese (3.5%), Albanian (2%), and Portuguese (1%) being the most common. The differences in the proportion of women from each racial and ethnic group in the navigated versus control sites reflects the different communities served by each health center, and different sizes of the health centers. There are also differences in race/ethnicity over time within the health center populations. The proportion uninsured dropped from 40% to 29% overall between the baseline and intervention time periods, reflecting the impact of Massachusetts Health Insurance Reform, initiated in 2006 (33, 34).

Figure 1 represents the unadjusted proportion of subjects who ever reach a diagnostic resolution by 365 days, comparing differences across the 2 study periods (baseline and intervention) within navigation and control sites separated for breast and cervical cancer subjects. For the breast cancer screening arm, at baseline, the control sites had similar rates of diagnostic resolution compared with the navigated sites (89.6% vs. 89.7%). The control sites showed no improvement in the proportion of women reaching diagnostic resolution from the baseline to the intervention period (89.6% vs. 90.2%, $P = 0.7809$), whereas the percentage of women at navigated sites who resolved increased from 89.7% to 92.6% from the baseline to

[a]*P* value for test of homogeneity of proportions.
[b]Most common response was Asian (of which 53% were Vietnamese).
[c]Most common other languages included Vietnamese (20%), Albanian (8%), Portuguese, and Portuguese Creole (19%).
[d]Includes the following Pap test results: ASCUS/HPV+ (Atypical squamous cells of undetermined significance/positive for human papillomavirus) and LGSIL (low-grade squamous intraepithelial lesion).
[e]Includes the following Pap test results: AGUS, HGSIL, and carcinoma.

intervention period, although this difference did not reach statistical significance ($P = 0.12$). For the cervical cancer screening arm, the control sites had slightly higher rates of diagnostic resolution during the baseline period compared with the navigated sites (87.9% vs. 79.1%). The control sites again showed no change temporally at 365 days after abnormal screening (80.0% versus 78.6%, $P = 0.64$). However, the navigated sites showed significant improvement in diagnostic resolution comparing the baseline with the intervention period (79.1% vs. 87.9%; $P = 0.0008$).

Figures 2 and 3 display the Kaplan–Meier curves for time to diagnostic resolution (where the *y*-axis represents the proportion achieving diagnostic resolution) comparing the baseline and intervention periods across both the navigation and control sites. For breast cancer screening subjects in the navigation sites, there is a superimposition of the baseline and intervention period curves through about 60 days, when 73% of subjects in the baseline period have achieved resolution compared with 71% of subjects in the intervention period. Median days to resolution are also similar in the 2 periods, with median days to resolution of 29 days in the baseline period and 32 days in the intervention period. After 60 days, there is a consistently higher rate of resolution among subjects during the intervention than the baseline period. For patients without resolution by 60 days, median days to resolution decreased from 157 days to 70 days from the baseline to intervention period. The control sites had no change between the baseline and intervention time periods, also reflected at 60 days when 73% of subjects in the baseline period achieved resolution compared with 72% of subjects in the intervention period, and with median days to resolution of 27 days in the baseline period and 34 days in the intervention period. For cervical cancer screening subjects in the navigation sites, the intervention period showed more subjects achieved timely resolution almost immediately. For example, at 60 days, only 27% of subjects in the baseline period achieved diagnostic resolution compared with 39% of subjects in the intervention period,

DOI:10.1158/1055-9965.EPI-12-0532

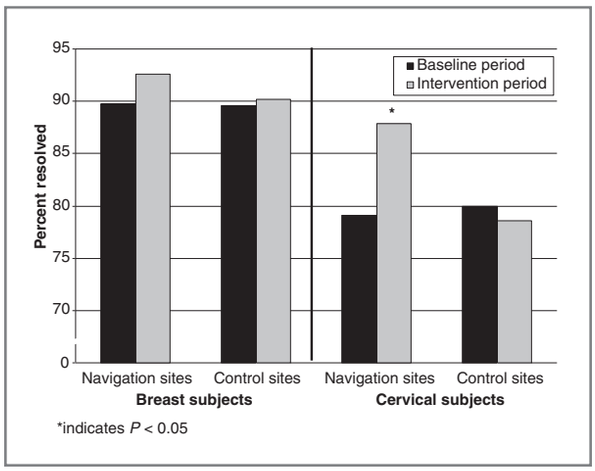

Figure 1. Percent of subjects in the Boston Patient Navigation Research Program who complete diagnostic resolution by 365 days by Study Period (baseline vs. intervention) within each Study Site Group (navigation vs. control sites), for both breast and cervical subjects.

and median days to resolution decreased from 110 in the baseline period to 76 in the intervention period. These improvements among intervention subjects in the cervical navigation sites persisted throughout the 365 day follow-up, compared with the baseline period, and compared with the control sites in either time period where the proportion of subjects achieving diagnostic resolution at 60 days was similar for baseline and intervention subjects (37% vs. 31%, respectively), and median time to resolution was also similar (84 days vs. 90 days).

Table 3 presents the adjusted HRs for the proportional hazards models, for breast and cervical cancer subjects, respectively. We found a significant benefit of patient navigation in reaching diagnostic resolution after adjusting for differences in differences between the navigation and control sites of the study and the intervention and baseline time periods. The model also adjusted for covariates and for clustering within each of the health centers. In the breast model, the adjusted HR for completing diagnostic evaluation in the first 59 days is 1.04 (95% CI, 0.83–1.30), indicating no difference between the navigated and control sites after adjustment. From days 60 through 365, there was a significant impact of patient navigation (aHR 1.40; 95% CI, 1.06–1.86), where HR more than 1.0 indicates that patient navigation is associated with more timely diagnostic resolution. For the cervical cancer screening subjects of the study, the adjusted HR was 1.46 (95% CI, 1.14–1.88), indicating a benefit of navigation over the control sites in reaching diagnostic resolution throughout the course of the study. Secondary analyses using a shared gamma frailty model to account for clustering gave similar effect size for breast cancer screening subjects, but were not significant in separate models for the first 59 days (aHR 1.03; 95% CI, 0.8–1.3) or for days 60–365 (aHR 1.5; 95% CI, 0.9–2.4), whereas significance remained among the cervical cancer screening subjects (aHR 1.4; 95% CI, 1.1–1.8).

In the breast model, several covariates were associated with delays in achieving diagnostic resolution. Compared with patients who had private insurance, those with public insurance (aHR 0.8; 95% CI, 0.8–0.9), but not uninsured (aHR 0.9; 95% CI, 0.8–1.0; $P = 0.07$), were less likely to have timely resolution. Patients with a primary language other than English or Spanish were also less likely to have timely resolution (aHR 0.8; 95% CI, 0.7–0.9). Index screening abnormalities of BI-RADS 3 (aHR 12.7; 95% CI, 8.7–18.6) or BI-RADS 4 or 5 (aHR 4.5; 95% CI, 2.0–10.0) were initially associated with more timely resolution, which decayed over time, compared with those with a

B, survival curve of time to diagnosis in cervical cancer screening control sites, before (baseline period, 2004–5) and during (intervention period, 2007–8) implementation of the navigation intervention.

BI-RADS 0 screening abnormality. Age, race/ethnicity, and percentage of zip code below federal poverty level were not predictors of timely resolution in the model.

In the cervical model, public insurance status and younger age were associated with delays in achieving diagnostic resolution. Compared with private insurance, publically insured (aHR 0.8; 95% CI, 0.7–0.9) but not uninsured women (aHR 1.0; 95% CI, 0.9–1.2) were less likely to have timely resolution. Women ages 18 to 40 (aHR 0.7; 95% CI, 0.6–0.9) were less likely to have timely resolution than older women. Race/ethnicity, language, screening abnormality, and socioeconomic status were not predictors of the outcome.

We were specifically interested in examining whether vulnerable populations defined by minority race/ethnicity, language other than English, or public or no insurance had a benefit from the intervention. None of the interaction terms of these variables by the navigation variable were significant in either the breast or cervical model, suggesting that there was no differential benefit of navigation for any specific group of women defined by these demographic variables.

Our data indicated that 124 (16.1%) women in the navigated arm did not receive navigation services within 30 days of the breast screening abnormality, and 103 (14.2%) of women did not receive navigation within 60 days of the cervical cancer screening abnormality. These findings varied by health center, and ranged from 4.0% to 29.6%. Removing women enrolled later into navigation did not change our findings (breast navigation effect $\geq$ 60 days: aHR, 1.4; 95% CI, 1.0–1.8; cervical navigation effect: aHR, 1.6; 95% CI, 1.3–2.1). Median time that a navigator spent per case varied by disease status; breast navigators spent a median of 60 minutes per subject with navigation activities [75% interquartile range (IQR), 30–127.5], with a median of 1 encounter per subject (range 0–15); whereas cervical navigators spent a median of 75 minutes (75% IQR, 30–120) in navigation activities, with a median of 2 encounters per subject (range 0–18).

Discussion

The Boston Patient Navigation Research Program showed a benefit of patient navigation for vulnerable communities of women with both breast and cervical cancer screening abnormalities with an adjusted HR between 1.4 and 1.5. Observing the navigated arm over 365 days, this translated into an additional 9% of patients with cervical abnormalities and 3% of women with breast screening abnormalities completing diagnostic resolution to determine whether or not they have a premalignant or invasive cancer. By including all individuals with a screening abnormality, this study represents an assessment of the effectiveness of the patient navigation intervention for an entire population cared for in a safety net system of care, leading to greater external validity. Individual randomized clinical trial methodologies are often unable to randomize the most difficult to reach patients who may be in greatest need of navigation (14), and thus limits their external validity. Our effectiveness design includes this difficult to reach group of women while ensuring identical methods in the navigated and control arms of the study, and thus provides an estimate of the effect of navigation when applied to an entire practice population. Our data provide scientifically rigorous evidence of how navigation can be implemented.

The generalizability of our findings extends to a diverse group of women from multiple communities and cultures: more than 55% of our sample were from minority communities, and more than 60% were either publicly insured or uninsured. Each community health center that

[a]Cox proportional analysis adjusted for age, race/ethnicity, language, insurance, index abnormality, and socioeconomic status, and for clustering with community health center.

participated in the trial provided care to unique immigrant and minority communities in the greater Boston area. Our work shows that navigation is broadly beneficial to all groups. We did not find that our navigation intervention preferentially supported any group of subjects, defined by race/ethnicity, language, or insurance status. The increased rates of insurance seen in our intervention period of 2007 to 08 compared with the baseline 2004 to 05 periods reflect the impact of Massachusetts Health Insurance reform. The persistent uninsured rates of 8% to 47% by health center, all higher than the overall 5% uninsured in the state in 2008 (35), reflect that women who are uninsured despite insurance reform disproportionately seek their care at community health centers. Our finding that publically insured subjects had less timely care compared with uninsured subjects is consistent with other studies and suggests that insurance status may be a marker for other social determinants of health (36, 37).

The benefit of patient navigation does not seem to be only from shifting the diagnostic completion curve to an earlier time for all, but also in increasing the proportion completing diagnostic resolution. Our data in the breast cancer screening abnormalities suggests that navigation does not show an immediate benefit, but may be of greatest benefit for those with initial delays. This may be because many patients who complete in a timely manner will do so without the help of a navigator. This has implications for institutions with limited resources that wish to develop navigation programs with the most effective impact. Several navigation programs addressing annual mammography screening, for example, began at 18 months, providing patients a 6-month window to complete screening on their own before activating navigation (38).

The main limitation of our trial is the lack of randomization of subjects into the intervention and control groups. This could have resulted in potential imbalance of both measured and unmeasured differences between the groups. We attempted to address this design limitation by collecting baseline data from all sites. This allowed us to adjust for secular trends and baseline differences in the health centers. The lack of any differences over time in the control groups suggest that there was no secular trend to account for our findings. It also suggests that there was little contamination of the navigation intervention into the control arms. A related limitation is that our study was conducted at 6 urban, East Coast community health centers. While our analyses do account for clustering of patients within health centers, available methods of accounting for clustering in the context of proportional hazards regression for time-to-event data do not perform well with a small numbers of clusters. Our results may not generalize to less urban settings, or other regions of the country, and we acknowledge that our data collection methods did not account for care received outside of the affiliated health care system, though our previous work has shown that the majority of this population have documented longevity within this safety-net health system (39, 40).

To successfully disseminate patient navigation programs, there are several components critical to ensure success. Safety-net institutions, including community health centers and hospital ambulatory centers, will require an initial and ongoing training program to ensure the competence of navigators. Care sites will require the ability to track patients with screening abnormalities, and link this tracking to the work of the navigators. The methods developed for the health centers in this project fulfill these components while also meeting many of the principles of the Patient Centered Medical Home, including criteria for care coordination, registry/tracking, and meaningful use of electronic medical records (41). Because this study was not powered to provide clarity on all aspects of navigation, including its impact among specific sub-populations or on patient-reported outcomes or cost-effectiveness, it lays the groundwork for the future studies necessary to inform best practices.

This study highlights the benefits of a community based participatory research process (20) where the design of the research protocol as a quality improvement effectiveness research project was developed with leadership of the health centers and under the guidance of an active Community Advisory Panel. The findings provide controlled clinical trial data on the effectiveness of patient navigation to promote equal access to timely diagnostic cancer care for a racial/ethnically diverse low-income population. Perhaps the strongest indicator of the success of this intervention is the fact that the health centers continued to implement the intervention with internal funds following completion of the trial and saw this as a key

DOI:10.1158/1055-9965.EPI-12-0532

component of their Patient Centered Medical Home implementation.

Disclosure of Potential Conflicts of Interest

Prevention of Fatal Opioid Overdose

Leo Beletsky, JD, MPH
Josiah D. Rich, MD, MPH
Alexander Y. Walley, MD, MSc

OPIOID OVERDOSE IS A BURGEONING PUBLIC HEALTH crisis, accounting for at least 16 000 deaths annually in the United States.[1] Opioid overdose occurs across sex, ethnic, age, and geographic strata and involves both medical and nonmedical opioid use. To date, federal government response has focused primarily on monitoring and securing the drug supply.[1] This Viewpoint suggests various steps necessary to support a more comprehensive approach.

During the time it typically takes some overdoses to turn fatal, it is possible to reverse the respiratory depression and other effects of opioids with the antagonist naloxone. Community-based organizations, health care institutions, and local and state agencies have begun to train and equip potential nonmedical bystanders to recognize and reverse overdose events using first aid techniques and emergency supplies of naloxone.[2,3] As the number of such initiatives has increased, the 53 000 program trainees have tracked more than 10 000 reports of overdose rescues in the United States.[2] These efforts have targeted drug users (syringe access programs, drug treatment centers, correctional facilities),[1] physicians (to "coprescribe" naloxone along with opioids),[4] and first responders (ie, fire and police).[3] The concept has also gained traction among policy makers, including the Office of the National Drug Control Policy and professional organizations.[5]

Despite the mounting supportive evidence, the number of these programs remains limited in many communities with elevated rates of fatal overdose.[2] Multiple barriers limit the diffusion of this innovation: the price of naloxone has skyrocketed in the context of a severe shortage; few prescribers are aware of and are willing to facilitate overdose prevention education and naloxone access; funding for program activities and evaluation research remains sparse; and the Food and Drug Administration (FDA)–approved formulation of naloxone is suboptimal for out-of-hospital use.

In April 2012, an interagency hearing on naloxone access was convened by the FDA and brought together practitioners, regulators, researchers, and people personally affected by overdose. Although the meeting underscored numerous regulatory hurdles, decisive action is necessary to advance overdose prevention programs beyond the proof-of-concept phase (TABLE).

The FDA must ensure that adequate supplies of naloxone are available to meet the increasing demand. Like many sterile injectable products, naloxone is in chronic shortage. Most naloxone programs experience challenges in obtaining naloxone because of cost increases or suppliers' inability to fill orders.[1] As existing programs scale up and more jurisdictions adopt these measures, federal action can help expand naloxone supply, such as by fast-tracking importation licenses.

Health care practitioners are optimally positioned to facilitate opioid overdose prevention. Equipping clinicians and providing incentive for them to screen patients for overdose risk and to educate patients, their families, and caregivers about recognizing and responding to overdoses is an important step, alongside community-based education about opioid overdose and naloxone distribution. Explicitly integrating overdose prevention, including naloxone coprescription, into the FDA-industry cooperative strategy for evaluation and mitigation of opioid risk also could be helpful.[4]

Clinicians may be unclear about legal risks associated with prescribing naloxone[6] and may be concerned about the possibility of facilitating risky drug use[6]; yet there is no evidence of such disinhibition.[7] Prescribing naloxone to manage opioid overdose is consistent with its FDA-approved indication, precipitating no increased liability as long as prescribers adhere to general rules of professional conduct.[7] Some states have passed laws indemnifying clinicians from risk of malpractice lawsuits perceived to arise from prescription of naloxone. Others have introduced Good Samaritan laws shielding lay bystanders and persons experiencing overdose from possible civil liability (flowing from providing first aid) and criminal drug charges when 911 is called.[7] Using evidence-based model legislation, federal coordination can help disseminate these legal protections to encourage clinician engagement, lay responder rescue, and help-seeking.

In out-of-hospital settings, the administration of injectable drugs carries the risk of needle-stick injury and presents logistical barriers, such as the absence of a sterile syringe and delay in preparation.[3] FDA action is needed to fast-track approval of naloxone delivery systems that are safe and user-friendly for nonmedical responders. Administration of intranasal naloxone via aftermarket nasal atomizers is an "off-label" system increasingly used by out-of-hospital emergency medical personnel and by community-based programs.[3] The lack of FDA approval limits the implementation of intranasal formulations and devices: nasal atomizers are difficult to stock and seldom covered by insurance. FDA approval of intranasal naloxone is predicated on research demonstrating such a formulation to be "substantially

Table. Potential Federal Action to Improve Prevention of Fatal Overdose

Barrier/Limiting Factor	Remedial Federal Action	Agency in Charge
Naloxone shortage and high cost	Allow temporary importation from qualifying foreign manufacturers	FDA
	Monitor supply and demand	FDA
	Provide funding for dissemination of overdose prevention and management education, including naloxone distribution to potential bystanders through community-based and addiction treatment programs	SAMHSA, CDC
Lack of health care training to screen for and address problematic opioid use, opioid overdose risk, and underutilization of out-of-hospital naloxone	Require Opioid REMS programs to cover overdose prevention and the role of naloxone	FDA
	Create and disseminate existing practitioner training and toolkits (such as the materials available at http://prescribetoprevent.org/) to facilitate opioid overdose prevention Materials should be tailored to priority settings and populations, including chronic pain therapy, drug treatment facilities, and emergency departments	SAMHSA, AHRQ, national professional associations
Lack of prescriber incentives to deliver overdose prevention and management education	Reimburse overdose prevention education interventions and cover naloxone prescription and delivery devices	CMS
Prescriber concern about legal risks to self and patients from naloxone prescription; bystander reluctance to call 911	Formulate and disseminate model legislation providing legal immunity to naloxone prescribers and lay responders to change police behaviors and encourage witnesses to call 911	DOJ, Bureau of Justice Assistance
Lack of public awareness about risk factors, signs and symptoms, and appropriate response to overdose	Conduct public awareness campaigns about risk factors, signs and symptoms, and response to overdose	FDA, CDC, ONDCP
Research	Evaluate community-based naloxone access initiatives, Good Samaritan laws, and interventions targeting drug users and possible bystanders on overdose risk behaviors	NIH, CDC, DOJ
	Evaluate the effects of education, brief interventions, laws and regulations, and other interventions on clinician practice and patient overdose morbidity and mortality outcomes	NIH, CDC, DOJ
	Provide funding for program evaluation and clinical research on intranasal and autoinjector devices	NIH, CDC, SAMHS
Explore alternative models of naloxone access	Such models may include a new "over-the-counter-plus" class of drugs and pharmacist naloxone prescription	FDA, national professional associations

Abbreviations: AHRQ, Agency for Healthcare Research and Quality; CDC, Centers for Disease Control and Prevention; CMS, Centers for Medicare & Medicaid Services; DOJ, Department of Justice; FDA, Food and Drug Administration; NIH, National Institutes of Health; ONDCP, Office of the National Drug Control Policy; SAMHSA, Substance Abuse and Mental Health Services Administration.

equivalent" to the current formulation. Federal funding is needed to clear this hurdle because naloxone is an off-patent, generic medication not widely considered to be a promising investment by major pharmaceutical companies. Use of an autoinjector—a safe and effective method for delivery of epinephrine—represents another alternative that would require FDA approval.

Federal agencies are uniquely situated to address national public health crises through increasing awareness, funding, and coordinated action. Community-based organizations, state and local health departments, and professional societies have taken the lead in developing, implementing, and publicizing overdose education and naloxone distribution as a component in a comprehensive response to this veritable epidemic.[5] The federal government should actively support research and programmatic action on overdose education and naloxone access.

Team Improvement and Patient Safety Conferences

Culture Change and Slowing the Revolving Door Between Skilled Nursing Facility and the Hospital

Randi E. Berkowitz, MD; Robert Schreiber, MD; Michael K. Paasche-Orlow, MD, MA, MPH

To improve the safety culture of a skilled nursing facility, we conducted multidisciplinary "Team Improvement for Patient and Safety" (TIPS) case conferences biweekly to identify causes of transfers to acute care hospitals and improvement opportunities. Staff perceptions of organizational patient safety culture were assessed with the Nursing Home Survey on Patient Safety Culture. Over the course of the year, we held 22 TIPS conferences. Mean item scores increased during the study, indicating improved staff perceptions of patient safety culture ($P < .005$). **Key words:** *multidisciplinary conferences*, *nursing home*, *patient safety*, *quality improvement*, *safety culture*, *team conferences*

NURSING HOME PATIENTS are frequently admitted to hospitals.[1-3] This is costly and contributes to poor patient outcomes. In addition, a proportion of these events are avoidable, as has been demonstrated by several recentlypublished interventions.[1,4] Of 1.8 million skilled nursing facility (SNF) admissions in the United States during 2006, 23.5% resulted in readmission to an acute care hospital within 30 days at a cost of $4.3 billion.[3] Unplanned transfers from SNFs for acute patient problems are often associated with adverse events or medication errors and are burdensome to the patient and family.[1] Known causes of acute care hospital transfers from the SNF include lack of on-site medical staff, unavailability of rapid laboratory testing services or immediate intravenous fluids and medications, inadequate assessment to identify clinical deterioration, communication gaps, and lack of clarity regarding advance directives.[4,5]

Several interventions have been shown to successfully decrease 30-day rehospitalization rates in the acute care setting. Some projects have involved various approaches for activating patients, families, and providers to improve patient safety during care transitions. For example, Coleman et al[6] showed that care transition coaches decrease rehospitalizations even up to 180 days after hospital discharge. Similarly, Naylor et al[7] showed that advanced practice nurses can lower hospital

readmissions in patients with congestive heart failure. Jack et al[8] used inpatient nurses with a checklist and personalized patient education materials along with a postdischarge pharmacist telephone call, which resulted in a one-third decrease in the rate patients returned to the hospital within 30 days.

Few interventions, however, have focused on transitions from the SNF to the hospital.[9,10] Ouslander et al[1] using a comprehensive rehospitalization reduction program called INTERACT and the Evercare demonstration project[11] have decreased hospital transfers from nursing facilities. More recently, Berkowitz et al[12] described a successful intervention to improve transitions of care in an SNF. This 3-pronged intervention included (1) an admission checklist for physicians to encourage discussion of repeat hospitalizations before worsening of symptoms, (2) automatic palliative care consultations for patients with more than 3 rehospitalizations, and (3) Team Improvement for Patient and Safety (TIPS) conferences, recurring multidisciplinary team meetings to analyze root causes of failures in care.

The TIPS conferences were designed to increase the organizational commitment to patient safety and transitions of care among frontline staff. This was motivated, in part, by studies that have shown that a higher degree of organizational commitment to patient safety, as reflected by the Nursing Home Survey on Patient Safety Culture, is linked to improved patient outcomes in SNFs.[13,14] In this article, we describe in detail the design and implementation of a successful TIPS program that was part of the larger intervention resulting in a 20% reduction in transfer rates on our skilled nursing unit.[12] Staff attitudes on patient safety culture before and during the intervention are discussed, based on biannual responses to the benchmarked Nursing Home Survey on Patient Safety Culture designed specifically for nursing home providers and staff; the survey evaluates opinions regarding the culture of patient safety in a nursing home.[15]

METHODS

Nursing facility

The project was implemented on a 50-bed subacute rehabilitation unit admitting approximately 1000 patients per year. The medical staff members were all salaried employees consisting of 1.5 full-time equivalent of a nurse practitioner and 1.5 full-time equivalent of physician time. The unit is housed in a 600-unit long-term care, religious-affiliated, not-for-profit organization in Boston, Massachusetts. In addition to standard rehabilitation care, on-site services include radiology, electrocardiograph (ECG) technician, mobile laboratory, blood transfusion, psychiatry, geriatric psychiatry, and a palliative care team composed of a chaplain, a nurse, a physician, and a social worker.

Planning process

The project was approved by the Hebrew SeniorLife institutional review board as a quality improvement project. A multidisciplinary team was convened to understand the scope of the problem, determine objectives for the project, develop concrete steps to address the problem of avoidable acute care hospital transfers, and reassess outcomes. The team was composed of the medical director, the director of nursing, the administrator, staff nurses and aides, therapists, a rabbi from the palliative care team, a daughter whose mother had experienced multiple rehospitalizations, a statistician, and representatives from a local acute care hospital and a home health agency. This group met twice before the project began to determine the format of TIPS conferences, approach to root-cause analyses of care transitions, outcome measures, and how to involve the palliative care team.

Measures

To measure fidelity to the project and give credit to those who participated, attendance of core staff was recorded at TIPS meetings. Core staff included nurses, physicians, nurse practitioners, administrators, nursing administrators, a member of the quality

improvement committee, therapists, social workers, and palliative care team members.

Staff attitudes on the organizational patient safety culture were monitored at baseline and biannually with the Nursing Home Survey on Patient Safety Culture.[15] The surveys were distributed to the core target audience for the TIPS meeting. Surveys were sent by e-mail, and a paper version also was available. The Nursing Home Survey on Patient Safety Culture includes 42 survey items measuring 12 dimensions and an additional overall resident safety question. The dimensions are as follows: teamwork (4 items), staffing (4 items), compliance with procedures (3 items), training and skills (3 items), nonpunitive response to mistakes (4 items), handoffs (4 items), feedback and communication about incidents (4 items), communication openness (3 items), supervisor expectations and actions promoting resident safety (3 items), overall perceptions of resident safety (3 items), management support for resident safety (3 items), and organizational learning (4 items.) Answers to all Likert scale questions were coded 1 to 5, ranging from "strongly disagree" to "strongly agree." In addition, an overall rating of patient safety in the facility was included as the 43rd item.

Mean composite dimensions scores for the perception of organizational patient safety culture were calculated by summing the scores for individual questions (with appropriate inversion of reverse-coded items) and dividing by the number of questions answered. Respondents who answered "does not apply/don't know" were treated in the same way as those who did not answer the item (missing). In addition, following Agency for Healthcare Research and Quality methods, the mean percentage of positive responses was derived by scoring each question answered "strongly agree" or "agree" as a positive response. The mean percentage of positive responses overall was calculated by adding the number of respondents who reported "agree" or "strongly agree" divided by the number of respondents for that item. The percentage of positive responses was calculated both for the entire survey and for 7 specific dimensions (teamwork, nonpunitive response to mistakes, feedback and communication about incidents, supervisor expectation and actions promoting resident safety, organizational learning, and communication openness) of the survey identified by the project team to be most relevant to the TIPS program.

Statistical analysis

Single-factor analyses of variance were calculated to compare the (1) mean overall composite scores, (2) mean scores for the 7 specified dimensions thought to be most relevant to the intervention, (3) mean percentage of positive responses, and (4) mean percentage of positive responses for composite dimensions—across the 3 time points of survey administration (ie, preinitiation of TIPS conferences, 6 months, and 12 months). Data were analyzed with Microsoft Excel 2003.

Intervention

TIPS conferences were conducted every 2 weeks during the 1-year study period. All direct care staff members were invited and were told that attendance would be taken. Other staff as well as patients and their families were invited (eg, ECG technicians, maintenance, security, information technology, home care agency staff, an outpatient pharmacist, family members, and patients) on a case-by-case basis. Cases of potentially avoidable acute care hospital transfers or adverse events that might have ended in an acute care hospital transfer were identified by the medical director, hospital nursing liaisons, the nursing quality improvement specialist, members of the palliative care team, patients, families, and staff, as well as providers at acute care hospitals and home care agencies, They were all asked to report such information to the medical director (Table). Potential cases were preliminarily reviewed by the medical director and scheduled for a TIPS conference session within 1 to 2 weeks of the event at a time key participants could attend. The TIPS conference sessions were designed to last 30 minutes. In

Table. Examples of New Procedures to Reduce Rehospitalization and Improve Patient Care Developed From TIPS Conferences

1. Standardized discharge checklist (includes patient and family education and sending discharge summary to outpatient pharmacy, home care agency, and primary care provider)
2. Protocols to reduce risk of medication errors
   a. Anticoagulation protocol checklist with pharmacy, nursing, and provider daily review
   b. Sign on medication carts, "Medication pass in progress," to minimize interruptions/distractions of nurses during medication administration
   c. Medication list at patient bedside to involve patient and family in detecting potential errors
   d. Medication reconciliation process with patient, family, pharmacy, nursing, and providers
3. Procedures for working with disruptive families
   a. Behavioral plans initiated within 1 d of admission and set expectations for respect shown to staff
   b. Early plan of care for daily patient needs
   c. Call to hospital and outside providers to ensure message similar to families among all providers
4. Procedures for telephone communication with families
   a. Single number at facility for family to call for issues
   b. Care manager staffing this call-in line responsible to correct problem or find appropriate team members to answer concerns
   c. Call-in line for patients who are in the facility or after discharge
5. Procedures related to customer service
   a. Development of plan for patients at appointments to get their next meal
   b. Call light response rate program initiated with hourly rounds
6. Universal transfer form development with our state Department of Public Health

Abbreviation: TIPS, Team Improvement and Patient Safety.

the first 5 minutes, the case was presented. After this, the medical director facilitated a 15-minute group discussion, in which an explicit expectation was set for all attendees to participate. The final 10 minutes of the session was dedicated to the development of action steps. If a patient or family member presented the case, the presenter was excused after the presentation to allow for open staff discussion. The medical director led the majority of the conferences.

Mechanics of the conferences

To encourage development of actionable steps, the leader used a white board to record problems and help the group identify concrete solutions. The leader also made an effort to engage all the staff members in the discussion. Staff members were called on if they were not speaking during the conferences.

To ensure participation by nursing aides and direct care staff, meetings were conducted on the unit to minimize the time staff members were unable to answer call lights and dispense medications. A rotating nurse and aide covered call lights during each conference. In addition, meeting times were varied to allow night and evening shift staff members to attend.

To ensure that the lessons learned from the conferences were broadcast widely to staff both within and outside our organization, an e-mail listserve was created and short "tips from TIPS" were e-mailed on the same day of the conference. This enabled staff members from all shifts who might not have attended a particular conference to learn from the cases as well. The evening supervisor used these e-mails to review the cases with staff on weekends and nights. We invited multiple patients and family members to come back and give

their perspective on outcomes that had not been ideal.

RESULTS

Over the course of the year, we held 22 TIPS conferences. The cases discussed in the TIPS conferences were all held within 2 weeks of the sentinel events. TIPS conference attendance by core unit staff was 81%. TIPS conference discussions led directly to multiple procedural changes to improve patient safety and decrease readmission risk (Table). Baseline, 6-month, and 1-year Nursing Home Survey on Patient Safety Culture response rates were 12.5%, 56.9%, and 49.4%, respectively. Mean scores increased during the study, indicating improved patient safety culture (pre-TIPS, mean [M] = 3.3, n = 10; 6-month, M = 3.5, n = 41; 1-year, M = 3.9, n = 40; analysis of variance, $F_{2,88} = 5.66$, $P < .005$). Percentage of positive response rates for the overall survey and the 7 selected dimensions showed increasing trends during the course of the study (Figure).

DISCUSSION

The TIPS conference initiative improved the staff perception of the patient safety culture of the unit. This likely contributed to the observed 20% decrease in the acute care hospital transfer rates that we have previously reported.[12] Several key aspects that were important to the success of this program were institutional support and program leadership. We had intended to hold TIPS conferences every 2 weeks throughout the course of the year. While we did not meet that goal, holding 22 of 26 (85%) conferences with high attendance represents a high degree of fidelity to the program. The support of the institution's senior management was critical to help build a culture of accountability that was not focused on blame. It also was critical to have a committed program leader to choose appropriate cases, encourage attendance, and ensure implementation of the solutions identified. For example, the SNF had a medication error in which a patient did not receive some doses of medicine. There was an immediate apology to the patient that was publicized broadly within our institution, and the patient presented her experience after this event at a TIPS conference. Pharmacy, nursing, and medical procedures were changed to review the list of all orders for medications that were expiring that day. The chief executive officer of our organization publicly congratulated the team and its efforts. We had several conferences after this in which nurses who themselves had been involved in medication errors requested TIPS conferences to address these events.

Culture change

When the conferences first began, staff nurses did not want to attend the conferences, as they feared that they alone would be blamed. In addition, there was fear that if more acutely ill patients were kept on the unit instead of being sent to the hospital, then the nursing workload would increase, which would adversely impact the care being given to other patients.

To encourage open conversation, the first cases chosen were ones in which the medical director bore the major responsibility for the outcome. Open conversations by the leader about ways in which she might have prevented a transfer helped to foster a nonblaming atmosphere. Thought leaders among direct nursing staff were identified. Once they engaged productively with the TIPS program, they encouraged participation by their peers. If the conversation did shift to blaming, the discussion was redirected by the leader. Aides in particular were reticent to speak in the first conferences, but over time, they began to feel more comfortable voicing concerns.

We anticipated that keeping potentially more acutely ill patients would present challenges for direct care staff. For example, we reviewed the case of a dying woman whose family had decided against a transfer to the hospital and the patient died on our unit on comfort measures. However, the woman required a significant amount of both nursing and aide time to ensure her comfort. In

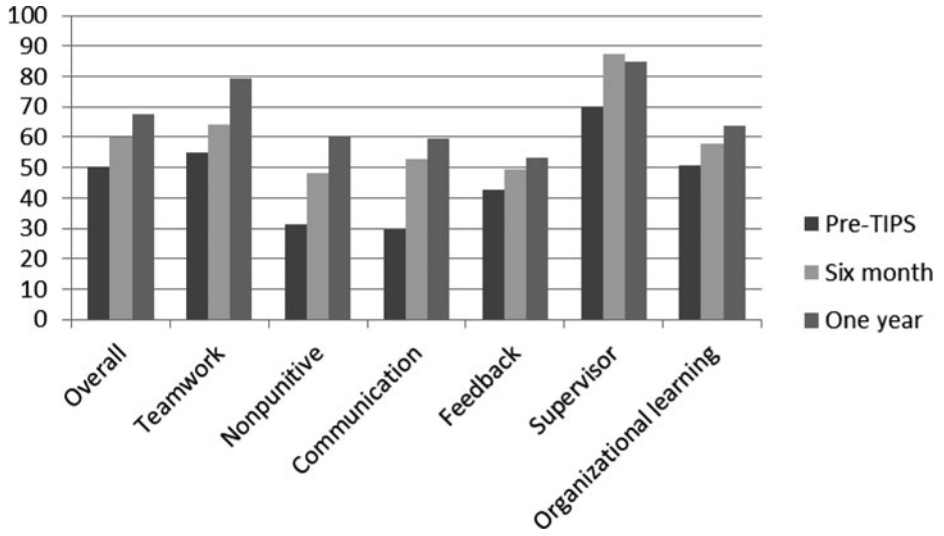

Figure. Percentage of staff reporting "agree" or "strongly agree" from the Nursing Home Survey on Patient Safety Culture to questions on dimensions of patient safety. TIPS indicates Team Improvement and Patient Safety.

response to this case, we brought senior nursing leadership into the TIPS meeting to discuss staffing concerns associated with very ill patients and developed a plan for future cases to use other staff resources in the building such as a nursing supervisor whom staff had been hesitant to call.

Involvement of the entire team

Early on we recognized that many of the issues involved team members both within and outside our core team. In one case, the husband of a dying patient would walk up and down the hallway in the evenings intimidating direct care staff and threatening to sue them. This issue was identified, and through TIPS, a behavioral management plan was implemented. In another case, a woman went out to the hospital with atrial fibrillation because the ECG printout was lost. The ECG technician explained that the machine stored information and could easily have reprinted a hardcopy. She and the secretarial staff developed a process to ensure that the ECG would reliably reach the clinicians. Another TIPS case involved a patient who had gained 20 lb on the unit without this being recognized by the staff. Information technology staff members were brought in to demonstrate how biometric data such as weight could be recorded on our electronic medical record to more effectively track weight changes.

We also involved participants from outside our institution. We reviewed the case of a male patient discharged home from the unit who soon ended up back in the hospital because of a lack of ostomy bags. We had nurses from a home care agency present the case and the downstream effects of not sending bags home with the patient. Outpatient pharmacists were brought in to TIPS conferences as we identified issues of patients who had incorrect medications from outdated medication lists delivered to their homes.

Another benefit of implementing TIPS was the rapid review and discussion of the sentinel event, generally within a week. This increased staff ability to remember details of the events and quickly give a sense of closure around difficult situations. The conferences helped staff to see problems looming early on in a patient's stay. Staff members were frequently heard saying, "We'd better address this before it becomes a TIPS case."

The staff survey results were reviewed, and a subcommittee composed of frontline aides, nurses, therapists, our administrator, and the director of nursing was formed to tackle issues noted in the survey. Some of the presentations at the conferences by patients and families were very moving and helped focus staff members on the patient perspective. Lessons learned were in multiple areas of care delivery: time-out for high-risk discharges, standardized handoff to next team, shift-to-shift communication, easy access for patients and families after discharge, patient and family understanding of illness and prognosis, optimizing delivery of bad news, addressing disruptive families within a day of admission, communication with outside providers for ensuring unified messages to families and review of care, and identifying community resources. Care processes on the SNF unit that were addressed included infection control, medication errors, and customer service.

The project described in this article was 1 element of a 3-pronged approach to improve discharge that also included standardized physician admission assessments and automatic palliative care consultations for high-risk patients. It is not possible to determine which changes in our care processes produced the reduction in hospital admissions or improvement in our patient safety culture. The study was limited by small sample size. Because of this, we were not able to stratify our results by provider class. In addition, the baseline survey included a smaller proportion of participants than would have been ideal. We believe that this was possibly due to staff feeling fearful of completing the survey or skeptical of the anonymous nature of the data collection. While it is difficult to judge how this may have affected our results, it seems likely that this phenomenon would either be nondifferential or bias our findings to be an underestimation of the impact of TIPS, as nonparticipants would most likely hold more negative perceptions than those who chose to participate.

While research has focused on how interdisciplinary teams function in relation to clinical outcomes, additional work is needed to understand how to translate quality improvement efforts to sustained culture change for patient safety.[16] As health care reform is implemented over the coming decade with pay for performance and encouragement of collaboration across the continuum of care, it will be critical to have effective SNF teams partnering with hospitals, primary care medical homes, and home care agencies to manage transitions in care and avoid unnecessary hospitalizations. The results of this study suggest that a program such as the one described in this article could contribute to improved patient care by focusing the attention of SNF staff on improving quality and patient safety.

Without concerted effort, the current explosion in health information technology will further widen the digital health divide for individuals with inadequate health literacy. However, with focused investment of time and energy, technology has the potential for reducing disparities through intelligent, usable, and accessible systems that tailor information, advice, counseling, and behavioral support to an individual's need at a given time and place.

The development of information technology (IT) for patient and consumer health applications has been exploding in the past decade, with thousands of websites, hundreds of mobile applications, and dozens of special-purpose devices targeted at the health care market. However, this growth in technology is actually likely to increase health disparities for those with limited health, computer, and reading literacy, unless effort is devoted to the development of IT specifically designed for these disadvantaged groups, and issues of technology access are addressed. The design of technology for low-literacy individuals needs to be primarily focused on improved interface design, but all aspects of usability of health information systems must be addressed, including which health messages are delivered at a given time. There is now ample evidence that individuals with low health literacy have difficulty accessing and using state-of-the-art digital health communication media, such as websites (Jensen, King, Davis, & Guntzviller, 2010; Neter & Brainin, 2012; Neuhauser & Kreps, 2008; Sarkar et al., 2010). Barriers to health IT access, including cost, high-speed Internet access, access to consumer and patient medical devices, and rural-urban and regional variability in access, are often ignored by researchers developing new health technologies, but their resolution is crucial to ensure the ultimate success of their efforts.

Address correspondence to Timothy W. Bickmore, Northeastern University, Computer Science, WVH202, 360 Huntington Avenue, Boston, MA 02115, USA. E-mail: bickmore@ccs.neu.edu

If these issues of usability and access are addressed, IT has the potential to reduce health literacy-based disparities through the use of intelligent but easy-to-use systems that can inform, teach, persuade, and counsel, using messages that are perfectly tailored for an individual to understand and act upon in a given situation. There is now a growing body of research into the development and evaluation of computational artifacts designed specifically for populations with low health literacy that demonstrates the potential of IT to level the playing field by providing information at the place and time it is needed and in a format that is more understandable and actionable than traditional print media. Several of these artifacts have even been shown to be preferred over oral communication with health providers because they have the potential to provide a low-pressure context in which patients—especially those with low health literacy—do not feel talked down to and are open to asking questions (Bickmore, Pfeifer, & Jack, 2009).

In the rest of this article, we briefly survey the state of the art in using technology to help individuals with inadequate health literacy: automated assessment of individual health literacy level and document readability, and automated interventions for providing health information and/or counseling to individuals with inadequate health literacy. We close with some thoughts on future opportunities for the use of technology to assist individuals with low health literacy.

Information Technology in Health Literacy Assessment of Individuals

Several researchers have developed IT systems for automatically assessing the health literacy of individuals. Lobach and colleagues (Lobach, Arbanas, Mishra, Campbell, & Wildemuth, 2004; Lobach, Hasselblad, & Wildemuth, 2003) developed a computer-administered questionnaire to automatically assess users' reading and computer literacy levels, then used this assessment to automatically tailor the user interface to these factors. Yost and colleagues (2009) also developed a talking touchscreen system that assessed health literacy in English and Spanish, with the objective of completing assessments more efficiently and more accurately than the standard Test of Functional Health Literacy in Adults. To date, these efforts have been designed as research tools. In the near future, computer-adaptive testing will shorten the duration of these assessments and make them even easier to use. This could potentially lead to clinical use if and when a given patient's health literacy status needs to be identified in order to trigger specific interventions, although this has not yet occurred as of the time of writing.

Information Technology in Readability Assessment

Other researchers have developed automated approaches to assessing the readability levels of printed documents and websites. Although the Flesch-Kincaid readability calculator is the most well known given that it is a feature in Microsoft products, Dale-Chall, Gunning-Fog, SMOG, and other algorithms for automatically assessing the readability of documents are available in most modern word processors (Ley & Florio, 1996). These standard measures are easy to compute and use but are not reliable, as demonstrated by several recent studies (e.g., Feng, Jansche, Huenerfauth, & Elhadad, 2010). To date, they have been good tools to identify blocks of text that are likely to be inadequate. However, a transformation may be taking place as more sophisticated algorithms, on the basis of techniques from computational

linguistics have yielded more accurate results (Feng et al., 2010). Preliminary research has also been conducted into automatically mapping lay ("consumer") health care terms to standardized medical nomenclature (Zeng & Tse, 2006). This work lays the groundwork for systems that can eventually be developed to automatically translate between technical language and language that people can better understand.

Information Technology–Based Interventions

Several computerized health interventions have now been developed and evaluated specifically for individuals with low health literacy, such as multimedia touch screen computers that administer standard diagnostic questionnaires (Bryant et al., 2009; Wofford, Currin, Michielutte, & Wofford, 2001), and health education systems that are designed to accommodate a wide range of health, computer, and reading literacy levels (Gerber et al., 2005; Kandula et al., 2009). These systems commonly provide information using audio, video or graphical displays along with text to minimize the literacy level required of users, and often use touch screen input so that users do not need to have mouse and keyboard proficiency (Gerber et al., 2005; Kandula et al., 2009). For example, the Multimedia Diabetes Education Program uses images, 2D animation, and spoken audio (narrator) along with text. In a study of 190 patients (21% with low health literacy), it was found that all patients had significant increases in diabetes knowledge after interacting with the program, although the program did not fully compensate for low health literacy.

Interactive voice response (or phone-based) systems represent another modality that may be particularly well-suited to deliver interventions to low-literacy individuals because these systems (a) deliver information in speech instead of text and (b) use the ubiquitous communication channel of the telephone so that participants neither need computer literacy nor computer access (Piette, 2000). Schillinger and colleagues (2008) compared a multilingual interactive voice response system for diabetes self-management support with monthly group medical visits, and demonstrated that the interactive voice response system resulted in greater engagement, especially among participants with limited literacy. Shea and colleagues (2008) performed a direct comparison of a health satisfaction survey (Consumer Assessment of Healthcare Providers and Systems) delivered either in its original 63-item text format, the text format augmented with images, or a bilingual interactive voice response–based implementation, and demonstrated that significantly more individuals with inadequate health literacy completed the survey, and completed it is less time and with fewer errors, when delivered through interactive voice response compared with the other two modes.

Our own research in this area involves the use of embodied conversational agents that appear on the computer as animated characters that simulate the conversational nonverbal behavior that accompanies human face-to-face dialogue, such as hand gestures, facial displays, and gaze (Figure 1). We have found that patients learn more with embodied conversational agents compared to other modalities (e.g., human instructors), regardless of health literacy, and that individuals with inadequate health literacy generally report higher levels of satisfaction with embodied conversational agents and ask more questions with embodied conversational agents compared to individuals with adequate health literacy (Bickmore and Paasche-Orlow, 2011). However, as with the Multimedia Diabetes Education Program, embodied conversational agents did not fully compensate for low health literacy (Bickmore, Pfeifer, & Paasche-Orlow, 2009; Bickmore et al., 2010).

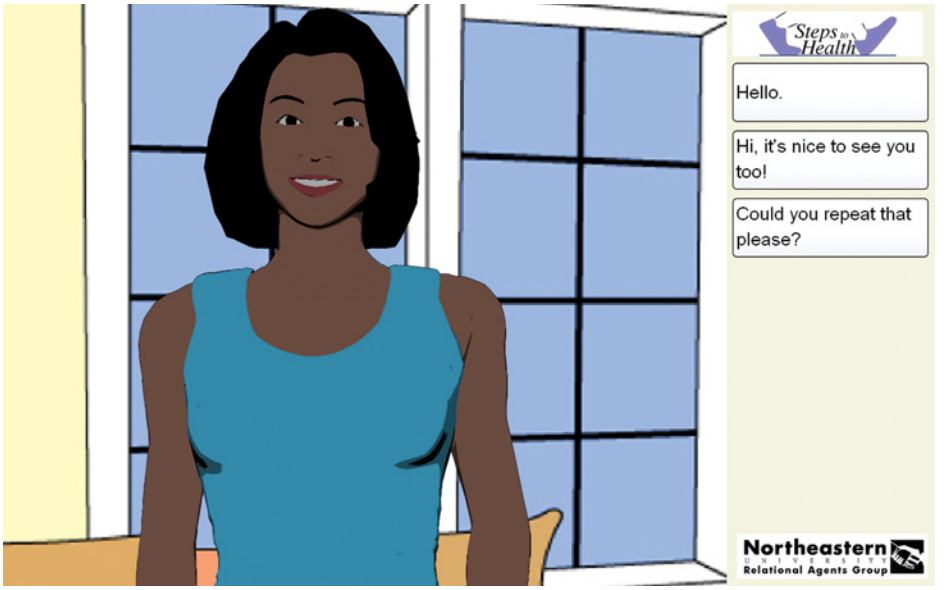

Figure 1. Example of embodied conversational agent used in walking promotion intervention for older adults (Bickmore et al., 2010). (Color figure available online.)

Future Directions for Information Technology in Health Literacy

There are a great many promising directions of research into how technology can improve the health of individuals with inadequate health literacy. As described earlier, most of the work to date in this area has been on the development of technologies designed to improve an individual's knowledge about specific areas of health and self-care, such as diabetes. Even in this area, there is a tremendous opportunity for new research into improved pedagogical methods that can be borrowed from the field of Intelligent Tutoring Systems and applied in specific health domains (Nkambou, Bourdeau, & Mizoguchi, 2010). In addition to improving knowledge, intelligent systems can be used to improve skill deficits in health care (e.g., inhaler technique) as well as underlying deficits in basic literacy skills. For example, automated reading tutors that listen to learners read out loud and provide coaching (Mostow et al., 2003) and math tutors that provide adaptive, personalized instruction to improve numeracy skills have both been developed and tested (Melis & Siekmann, 2004). IT systems can also play a role in providing access to health care and other services. For example, intelligent online directories have been designed to help connect urban, low income populations with community services including health care, housing, food security, and income security services (Fleegler, Lieu, Wise, & Muret-Wagstaff, 2007). Extending this kind of matchmaking service to add educational support for people who are struggling with their care is an important research direction.

Intelligent counseling systems can go beyond the provision of knowledge and literacy skills to impact a wide range of other psychological constructs associated with health literacy. Just as a good human counselor can work with an individual to improve self-efficacy and motivation to change a health behavior, automated

counseling agents can use techniques from health behavior change to improve health behaviors over time, and the messages and techniques used could be tailored to the individual's literacy (Bickmore & Giorgino, 2006; Bickmore, Schulman, & Sidner, 2011). Counseling agents could also be used to change norms by modeling or demonstrating ideal health behavior (e.g., medication adherence, walking, weight loss), and help prevent the discounting of future effects of current health decisions by reminding individuals of the long-term ramifications of their actions. Agents could also help address the fatalism about health outcomes many individuals with inadequate health literacy embrace by making individuals aware of the choices they have in their care and changing their expectations about the future.

Information systems could be used to significantly improve patient–provider communication for individuals with low health literacy. Interventions to promote patient activation are particularly important for low-literacy patients because they tend to ask fewer questions in comparison with individuals with adequate literacy (Katz, Jacobson, Veledar, & Kripalani, 2007; Schillinger et al., 2003). Mobile systems that maintain lists of questions and issues for patients and promote their resolution during medical encounters represent one of many ways that IT systems could become automated advocates for those who lack family or friends who can perform this role. Automated coaches could also give patients practice interacting with virtual health providers to build self-efficacy for interactions with the actual health care system. Automated systems could also be used to help facilitate and mediate patient–provider interactions by, for example, negotiating the agenda of problems to address with providers and by facilitating shared decision making. Automated systems could also be used to change the behavior and attitudes of providers themselves when interacting with low-literacy patients by, for example, prompting them to evaluate comprehension and other best practice interventions.

Last, IT systems can be used to significantly enhance the social support networks for individuals with low health literacy. Existing websites such as PatientsLikeMe.com and the many condition-specific support websites are wonderful resources for those who are connected into the digital world, but these resources are largely out of reach for those with low computer literacy and limited resources. In addition, the members of these online communities tend be well educated and highly health literate, which may represent a barrier for low-literacy individuals to fully participate. Parallel resources need to be established for those who lack this digital and health fluency and lack access to IT systems to connect them both to expert health advice and peers who can provide emotional, informational, and instrumental support.

Conclusion

Imagine a future in which an individual can carry a mobile device (perhaps their smartphone) that not only provides health information, but senses and interprets the environment and makes proactive recommendations about actions that might affect their health. The device could also translate health-related text into actionable messages, tailored not only to the individual's health literacy level, but their educational and cultural background, values, and even emotional state, providing information and recommendations at the time and location, and in the format, that will have the most effect. Such a digital health conscience would need a detailed cognitive model of its wearer, going beyond canonical models of health literacy and culture—which can simply reinforce stereotypes—to a detailed representation of a

user's unique desires, beliefs, and behavior patterns, and how these have changed over time. Elements of such systems already exist, and limited versions are certainly in our near future. However, the market for health IT products will not take care of our most vulnerable populations on its own; we need continued, focused, evidence-based research to continue developing technologies that specifically address disparities for individuals with low health literacy in order to realize this potential.

Non-linear mixed models in the analysis of mediated longitudinal data with binary outcomes

Emily A Blood[1,2*] and Debbie M Cheng[1]

Abstract

Background: Structural equation models (SEMs) provide a general framework for analyzing mediated longitudinal data. However when interest is in the total effect (i.e. direct plus indirect) of a predictor on the binary outcome, alternative statistical techniques such as non-linear mixed models (NLMM) may be preferable, particularly if specific causal pathways are not hypothesized or specialized SEM software is not readily available. The purpose of this paper is to evaluate the performance of the NLMM in a setting where the SEM is presumed optimal.

Methods: We performed a simulation study to assess the performance of NLMMs relative to SEMs with respect to bias, coverage probability, and power in the analysis of mediated binary longitudinal outcomes. Both logistic and probit models were evaluated. Models were also applied to data from a longitudinal study assessing the impact of alcohol consumption on HIV disease progression.

Results: For the logistic model, the NLMM adequately estimated the total effect of a repeated predictor on the repeated binary outcome and were similar to the SEM across a variety of scenarios evaluating sample size, effect size, and distributions of direct vs. indirect effects. For the probit model, the NLMM adequately estimated the total effect of the repeated predictor, however, the probit SEM overestimated effects.

Conclusions: Both logistic and probit NLMMs performed well relative to corresponding SEMs with respect to bias, coverage probability and power. In addition, in the probit setting, the NLMM may produce better estimates of the total effect than the probit SEM, which appeared to overestimate effects.

Background

SEMs are a general modeling framework often used in the social sciences to analyze complex relationships between variables, such as mediated relationships between variables. A mediator is a variable in the causal pathway between a predictor and the outcome of interest. SEMs are becoming more common in the clinical research setting and can be used to model hypothesized causal pathways between variables of interest. Extensions of SEMs have been developed to allow for more general types of dependent variables, including binary outcomes [1]. Common statistical techniques for non-mediated longitudinal binary data include non-linear mixed models (NLMM) [2] and generalized estimating equations (GEE) [3]. When interest is primarily in the total effect of a predictor on an outcome, even if mediation may be present, these commonly used techniques may be preferred over SEMs as they specify straightforward predictor-outcome variable relationships and do not require specialized software, as the SEM often does. It is therefore of interest to determine, in a setting conducive to using SEMs, whether a method such as NLMMs adequately models the total effect of a predictor on binary outcomes without directly modeling mediation. We focus on NLMM rather than GEE in this paper as it is more similar to the non-linear SEMs for longitudinal data available in SEM software-both are conditional rather than marginal models.

Comparisons have been made between SEM and other statistical models in different contexts [4-13]. Mixed effect models have been evaluated against SEMs with continuous data [14,15], and found to adequately model mediated predictor-outcome relationships. MacKinnon et al. [16] examined the calculation of mediated effects in cross-sectional binary data with non-SEM techniques using two different methods (difference of coefficients

Full list of author information is available at the end of the article

and product of coefficients). While, Palta and Lin [17] compared structural equation models to various marginal models in longitudinal binary data without mediation. To our knowledge, evaluation of NLMMs relative to SEMs has not yet been performed in the context of mediated longitudinal binary data.

Linear and non-linear mixed models differ both in terms of the distributional assumptions and the estimation techniques used for inference. In addition, the parameter estimates in non-linear mixed models using a logit or probit link are inherently scaled to the predictors (and mediators) included in the model. Therefore, comparisons of parameter estimates between NLMMs with different sets of predictors must first be re-scaled in order to make them comparable [16].

In this paper, we evaluate the performance of NLMMs relative to SEMs for the modeling of mediated, binary longitudinal data in a setting where the SEM is presumed to be optimal. The purpose is to assess whether there is an impact of direct modeling of causal pathways in terms of bias, power, and coverage probability when the goal is to determine the total effect of the main independent variable. A simulation study is performed to assess these two classes of models across a variety of settings. We also describe, in an appendix, two different approaches for rescaling estimates when analyzing real world data in order to allow direct comparisons between NLMMs and SEMs or to compute mediated effects via NLMMs only.

Methods

In the current study, we consider a longitudinal data setting with binary outcomes, a repeated binary predictor, a repeated continuous mediator, and a continuous covariate measured at baseline. An example of such a clinical setting would be a prospective cohort study evaluating the impact of heavy alcohol consumption on HIV disease progression, defined as low CD4 cell count (e.g. <350 cells/μL). Heavy alcohol consumption may influence progression of HIV, while also influencing adherence to anti-retroviral therapy (ART). Level of adherence to ART is also a predictor of HIV disease progression. In this setting there is a repeated binary independent variable of primary interest, heavy alcohol consumption (z_j), and a longitudinal binary outcome, low CD4 cell count (Y_j) signifying HIV progression. In addition, ART adherence (M_j), a continuous mediating variable, is measured repeatedly, and age (w) is a continuous covariate assessed at baseline. ART adherence is said to be a mediator because the primary independent variable, heavy alcohol use, may affect CD4 count directly as well as indirectly through ART adherence. We arbitrarily assume six timepoints at which the predictor, outcome and mediator are measured. Time is represented by t_j with j = 1, 2,..., 6. In this setting, we considered measurement times to be equally spaced and the same for all individuals. We generated data with a mediated non-linear relationship between the predictor (heavy alcohol consumption) and outcome (low CD4 cell count), i.e. we allowed the mediator (ART adherence) to be directly affected by the predictor and the outcome to be directly affected by both the predictor and mediator. Both the probit and logit links were assessed. We also describe the application of these models to data from a prospective cohort study evaluating the impact of heavy alcohol use on HIV disease progression.

As described by Fitzmaurice, Laird, and Ware [18] and others, binary outcome models can be described equivalently in two ways. The first approach would be to define a linear function of an underlying latent continuous variable (Y^*) that when dichotomized represents the observed binary outcome (Y). For example, we could define a continuous latent (unobserved) variable Y^* such that observed Y is 1 if $Y^* > 0$ and 0 otherwise and write:

$$Y^* = \beta_0 + \beta_1 x + \varepsilon \quad (1)$$

A second approach would be to define a non-linear model of the probability of a binary response. If we consider $\epsilon \sim N(0,1)$, the model in Equation 1 defines a univariate probit model that can be equivalently represented using the following non-linear link format:

$$P(Y = 1) = \Phi(\beta_0 + \beta_1 x).$$

Likewise, if we could consider the errors in Equation 1 to have standard logistic distribution (mean of 0 and variance of $\frac{\pi^2}{3}$) the model defines a univariate logistic model that can be represented as:

$$P(Y = 1) = \frac{\exp(\beta_0 + \beta_1 x)}{1 + \exp(\beta_0 + \beta_1 x)}.$$

In more complex situations, such as the longitudinal data we are studying, the same equivalence between model descriptions exist and we use both model formulations for the NLMMs and SEMs that follow. The convention for binary or categorical outcomes in SEMs has been to describe binary regression models with the latent variable format while the NLMMs are often defined using the non-linear link format.

SEM

To evaluate the performance of NLMMs in a setting conducive to the use of SEMs, we generated mediated longitudinal binary outcomes using a non-linear SEM. We then fit the data with a NLMM as well as the non-

linear SEM to evaluate the performance of the NLMM relative to the SEM. The non-linear SEM used to generate the data and subsequently fit to the generated data is described below.

Following the notation from above, x_j is the independent variable of primary interest, M_j is the continuous mediating variable, w is a continuous time-invariant covariate, and t_j represents time-point. Using the latent variable notation, we define a continuous unobserved outcome Y_{ij}^* that takes a value of 1 only if $Y_{ij}^* > 0$ for j = 1 to 6. This model can be expressed as follows (dropping the subject index i for simplicity), where:

Measurement model

$$Y_j^* = U_1 + t_j U_2 + \lambda M_j + \kappa z_j + \varepsilon_j \quad (2)$$

Just as in the simpler models above, if we assume $\epsilon_j \sim$ N(0,1) this defines a probit model and if we assume $\epsilon_j \sim$ Logistic $(0, \frac{\pi^2}{3})$ this defines a logit model.

Structural model

$$U_1 = \alpha_1 + \gamma_2 w + \varsigma_1 \quad (3)$$

$$U_2 = \alpha_2 + \varsigma_2 \quad (4)$$

For j = 1 to 6,

$$M_j = \alpha_3 + \gamma_1 z_j + \varsigma_{2+j}, \quad (5)$$

where U_{i1} represents a latent intercept, U_{i2} represents a latent slope, z_{ij} represents the repeated binary predictor and M_{ij} represents the repeated continuous mediator. The errors in the structural model are normally distributed with cov(ζ_1, ζ_2) = Ψ, cov($\zeta_3 : \zeta_8$) = Θ and $\zeta_{(2+j)} \sim$ N(0, θ). This model can be represented in a path diagram (Figure 1), a visual display of the interrelationships between variables typically presented along with SEMs.

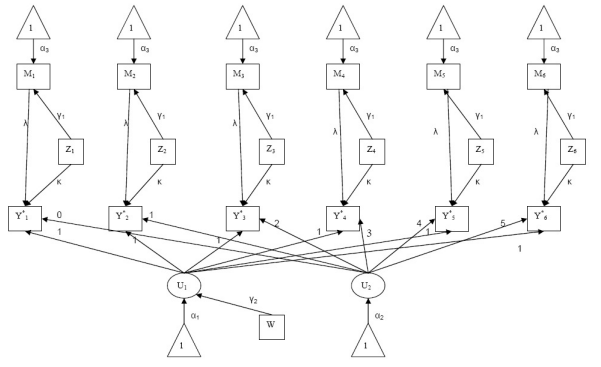

Figure 1 Path diagram. The non-linear structural equation model defined in Equations 2 to 5.

The parameters of the SEM defined in Equations 2 - 5 include: λ, which represents the effect of the repeated mediator on the repeated outcome; γ_1, which represents the effect the repeated primary independent variables on the repeated mediator; γ_2, which represents the effect of the continuous covariate on the repeated outcomes; and κ, which represents the effect of the repeated independent variable on the repeated outcome.

In this simulation study we focused on the total effect of the repeated binary predictor and the repeated binary outcome, which is represented by $\lambda\gamma_1 + \kappa$. The interpretation of the parameters of this model is subject-specific since it represents the effect of a predictor on the outcome when the individual intercept, individual slope and mediator value are held constant.

When the structural model Equations (3-5) are substituted into the measurement model Equation 2, the full model can be rewritten as:

$$Y_j^* = \omega_j + \varsigma_1 + t_j \varsigma_2 + \lambda \varsigma_{2+j} + \varepsilon_j$$

where $\omega_j = (\alpha_1 + \lambda\ \alpha_3) + \gamma_2 w + \alpha_2\ t_j + (\kappa + \lambda\gamma_1)\ z_j$. The following presents the non-linear link formats for the probit and logit SEMs where the structural equations have been substituted into the measurement equation (the subject index i has again been dropped for simplicity):

Probit SEM

$$\mathrm{E}(\mathrm{Y}_1|\varsigma_1, \varsigma_2, \varsigma_{2+j}) = \Phi(\omega_j + \varsigma_1 + t_j \varsigma_2 + \lambda \varsigma_{2+j}) \quad (6)$$

Logit SEM

$$E(Y_j|\varsigma_1, \varsigma_2, \varsigma_{2+j}) = \frac{\exp(\omega_j + \varsigma_1 + \mathrm{t_j}\varsigma_2 + \lambda\varsigma_{2+j})}{1 + \exp(\omega_j + \varsigma_1 + \mathrm{t_j}\varsigma_2 + \lambda\varsigma_{2+j})} \quad (7)$$

To fit these models, Mplus uses maximum likelihood estimation when a logit link is used and weighted least squares estimation with a robust estimation of standard errors (WLSMV) when a probit link is used [19].

Non-linear mixed effects model

The following NLMM was evaluated in comparison to the SEM:

$$Y_j^* = \beta_0 + \beta_1 w + \beta_2 t_j + \beta_3 z_j + b_1 + b_2 t_j + e_j. \quad (8)$$

where b_1 is a random individual intercept and b_2 is a random individual slope. Since the objective is to evaluate the total effect of the main independent variable, the mediator is excluded from this model [20]. The regression coefficient associated with the primary predictor

(β_3) therefore represents its total (i.e. direct plus indirect) effect on the outcome [14].

Probit NLMM

The probit model assumes that $e_j \sim N(0,1)$ and can be written as:

$$E(Y|b_1, b_2) = \Phi(\nu_j + b_1 + b_2 t_j) \quad (9)$$

where $\nu_j = \beta_0 + \beta_1 w + \beta_2 t_j + \beta_3 z_j$.

Logit NLMM

the logit model assumes that $e_j \sim$ Logistic $(0, \sqrt{\frac{\pi^2}{3}})$ and can be written as:

$$E(Y|b_1, b_2) = \frac{\exp(\nu_j + b_1 + b_2 t_j}{1 + \exp(\nu_j + b_1 + b_2 t_j)} \quad (10)$$

These models can be fit with SAS PROC NLMIXED which estimates parameters via maximum likelihood [21]. We note that the regression coefficients of the NLMM are interpreted conditional on the random individual intercept and random individual slope, but marginal on the residual error of the mediator (since the mediator is not included in the model).

Comparing NLMMs to SEMs

As noted previously, the SEM and NLMM condition differently on the mediating variable. Specifically, the SEM conditions on the random intercept and slope as well as on the residual variance of the mediating variable, while the NLMM conditions only on the random intercept and random individual slope. Thus estimates from the two types of models are not directly incomparable. Instead, to compare parameters from the NLMM to that of the SEM, we must first re-scale the regression coefficient from the NLMM so that it represents the effect of the primary predictor variable z_j conditional on the mediator. To determine the scaling factor, we rewrite the SEM (for both the probit and logistic models) conditional only on the variance of the random intercept and slope to mimic the conditioning in the NLMM.

Comparing probit models

For the probit SEM, we generated the data according to the model described in Equations 6 and 7. Conditioning only on the variances of the random intercept and slope (ζ_1 and ζ_2), but not on the variance of the mediator (ζ_{2+j}), it can be shown that:

$$\begin{aligned} E(Y|\varsigma_1, \varsigma_2) &= P(Y^* > 0|\varsigma_1, \varsigma_2) \\ &= P(\varepsilon_j + \lambda\varsigma_{2+j} > -(\omega_j + \varsigma_1 + t_j\varsigma_2)|\varsigma_1, \varsigma_2). \end{aligned} \quad (11)$$

The sum of terms on the left-hand side of the inequality do not have a standard normal distribution since $\lambda\zeta_{2+j}$ is added to ϵ_j which itself has a standard normal distribution. In order to express the probability in Equation 11 using the standard normal cumulative probability function, we re-scale the terms on either side of the inequality by the standard deviation of $\epsilon_j + \lambda\zeta_{2+j}$ to create a standard normal random variable:

$$\begin{aligned} &= P\left(\frac{\varepsilon_j + \lambda\varsigma_{2+j}}{\sqrt{1+\lambda^2\theta}} > \frac{-(\omega_j + \varsigma_1 + t_j\varsigma_2)}{\sqrt{1+\lambda^2\theta}} \,|\varsigma_1, \varsigma_2\right) \\ &= \Phi\left(\frac{(\omega_j + \varsigma_1 + \varsigma_2 t_j}{\sqrt{1+\lambda^2\theta}}\right) \end{aligned}$$

Conditioning on only the variance of the random individual intercept and slope, all regression coefficients are divided by the factor $\sqrt{1+\lambda^2\theta}$. For example, the regression coefficient associated with z_j, which was $\kappa + \lambda\ \gamma_1$, is now $\frac{\kappa + \lambda\gamma_1}{\sqrt{1+\lambda^2\theta}}$. Thus, the model parameters from the SEM are scaled to the variance of $\epsilon_j + \lambda\zeta_{2+j}$ which is $1 + \lambda^2\ \theta$ and the model parameters from the NLMM are scaled to the variance of ϵ_j which is 1, resulting in a scaling factor of $\sqrt{\frac{1+\lambda^2\theta}{1}}$ Parameter estimates from the SEM and NLMM must be on the same scale before making direct comparisons. For example, the total effect of the main independent variable from the probit NLMM, β_3, which is also conditioned only on the random individual intercept and slope (Equation 9) should be multiplied by a factor of $\sqrt{1+\lambda^2\theta}$ before it is compared to the total effect from the probit SEM, $\kappa + \lambda\gamma_{71}$. Direct comparisons of parameter estimates from the NLMM to those from the SEM without first re-scaling would underestimate effects by a factor of $\sqrt{1+\lambda^2\theta}$. In the current study we present the conditional total effect estimates from the SEM and compare them to scaled and unscaled NLMM estimates. Note that in the analysis of real (i.e. non-simulated) data, true parameter values are unknown and therefore must be estimated. We describe in the appendix two approaches for rescaling estimates in practice to allow direct comparisons between NLMMs and SEMs or to compute mediated effects via NLMMs only.

Comparing logistic models

Unlike the probit model, when the logit SEM is conditioned on only the random intercept and slope, the true relationship between the predictor and the outcome no longer follows a logistic model. That is, the distribution of the terms on the left-hand side of Equation 11 in a logit SEM does not follow a logistic distribution since the sum of a normal random variable (ϵ_j) and logistic random variable (ζ_{2+j}) does not follow a logistic distribution. The result of this is that the scaled coefficients from the logit NLMM only approximate the mediated relationship described in a logit SEM. A similar situation occurs, for example, when comparing a non-linear

mixed model to a non-linear generalized estimating equation as noted by Fitzmaurice, Laird, and Ware [18].

The scale factor for the logit model is created in the same was as it was for the probit model. The regression coefficient representing the total effect of the main independent variable (β_3) from the logit NLMM, can be multiplied by the standard deviation of $\epsilon_j + \lambda\zeta_{2+j}$ and divided by the standard deviation of ϵ_j. The scaling factor for the logit model is therefore: $\left[\left(\frac{\pi^2}{3} + \lambda^2\theta\right)/\frac{\pi^2}{3}\right]^{\frac{1}{2}}$.

Simulation plan

Data generation and model fitting

Because the goal of this study was to evaluate the performance of NLMM relative to SEMs in the setting where the SEM is presumed to be optimal, the SEM framework was used to generate the mediated binary data for the simulation studies. Data were generated according to Equations 2-5. For the probit model, errors in Equation 2 were assumed to be independent standard normal random variates. For the logistic model, the errors in Equation 2 were assumed to be independent standard logistic random variates. Data generation was repeated to create 1000 datasets. NLMM were fit with SAS (Version 9.2) PROC NLMIXED and SEM were fit with Mplus (Version 5.2).

Simulated data scenarios

We evaluated the performance of NLMM against SEM across several scenarios by examining the following:

- Sample size: ranging from 100 to 1000. The range of sample sizes was chosen to evaluate sample sizes that achieved adequate power with a moderate effect size.
- Effect size: ranging from 0.2 to 0.5. The range of effect sizes represent small to moderate effect sizes as defined by Cohen [22].
- Distribution of effects: three cases were evaluated: equally distributed direct and indirect effects, primarily direct effects of the main independent variable, and primarily indirect effects of the main independent variable. The total effect sizes (0.3 for probit models and 0.4 for logit models) were chosen such that adequate power was obtained when direct and indirect effects were equally distributed.

Model performance was assessed based on the following: 1) Bias- the difference between the true parameter value and the mean observed parameter value divided by the true parameter value; 2) Coverage probability- the percentage of the 1000 95% confidence intervals that contained the true parameter value; 3) Power - the percentage of the 1000 datasets in which the null hypothesis that the total effect of the main independent variable is equal to zero was statistically significant.

Results

Logistic link

The results evaluating the conditional total effect from simulations evaluating sample size are displayed in Table 1. For the logistic model, a sample size of 700 was required to obtain adequate (83%) power to detect a moderate effect size (0.3) for both the SEM and NLMM. Across all sample sizes, the estimates of power for the scaled NLMM were comparable to the SEM. As expected, for the unscaled NLMM, effects were underestimated in all cases. For example with a sample size of 600, the bias of the SEM was -0.6% while the bias for the unscaled NLMM was -3.8% and the bias of the scaled NLMM was -1.6%. Once the scale factor was applied to the NLMM, however, the estimated bias decreased and the power and coverage probability estimates were similar to that of the SEM. The results for the unscaled NLMM are therefore not described in subsequent tables as they are not directly comparable to the SEM results.

The results of the simulations in which the effect size (Table 2) and effect distribution (Table 3) were varied also demonstrated that the appropriately scaled NLMM produced comparable estimates of the total effect of the exposure relative to the SEM. The scaled NLMM results were similar to the comparison SEM with low bias at all effect sizes (ranging from -2.0% to 0.4%) and effect distributions (ranging from -1.4% to -1.0%). As expected, the models showed increasing power with increasing effect sizes (e.g., from 37% power for an effect size of 0.2 to 98% power for an effect size of 0.5) and power was highest (91%) when the effect distribution was primarily direct.

Probit models

For the probit model, the SEM showed consistent positive bias (i.e., no simulation scenario with the probit model resulted in a negative bias for the probit SEM). For example, the estimated bias for a sample size of 100 was 51.5% and decreased to 7.5% with a sample size of 1000. In comparison, the scaled NLMM had bias ranging from 2.7% to -2.1%. Notably, the estimated power for the NLMM was consistently higher than that of the comparison SEM. In the effect size simulation scenarios, bias in the SEM appeared to increase with effect size (effect sizes of 0.2, 0.3, and 0.5 resulted in biases of 7.6%, 8.8%, and 11.7%, respectively). In contrast, the

probit NLMM showed relatively small bias (-0.7% to 1.7%) for all effect sizes. For the probit model, the scaled NLMM generally performed better than the SEM, across a range of sample sizes, effect sizes, and effect distributions, with higher estimated power and lower bias.

Positive bias in probit models

We explored possible explanations of the unexpected positive bias observed for the probit SEM models. We repeated simulations by first eliminating mediation from the simulated scenarios to evaluate whether the positive bias in the SEM persisted in unmediated settings. In addition, we assessed different estimation methods, including WLSMV (implemented in MPlus software) and also maximum likelihood using iteratively reweighted least squares (implemented in Splus and SAS). We found that the mean regression coefficient estimates using WLSMV had larger bias in nearly all cases compared to estimates using maximum likelihood and iteratively reweighted least squares (Table 4). The positive bias for the WLSMV method was avoided only with a sample size of 5000. Our results suggest that the WLSMV, which is used by Mplus, may produce positively biased results. This bias was also present, however to a smaller degree, in the NLMM fit with maximum likelihood.

Real data example: alcohol and HIV disease progression

To demonstrate the application of both the logit and probit NLMMs and SEMs evaluated in the simulation study, we analyzed data from a prospective cohort study evaluating the effect of alcohol use on HIV disease progression. Samet et al. have previously reported the analyses from this longitudinal cohort study [23]. The original analyses combined data from two cohorts (the HIV-ALC and HIV-LIVE cohorts), however, to illustrate the models evaluated in this paper, we have used data from the HIV-LIVE study only. For clarity of presentation, we limited the analyses to subjects who reported any ART use during follow-up, had complete data on the first four time-points (as Mplus and SAS have different methods for handling missing data in these models), and examined only the following key variables: heavy alcohol consumption (yes vs. no), the main independent variable; ART adherence (percentage of pills taken in the last three days), the mediator; age, a potential confounder; and low CD4 cell count (dichotomized at <350 cells/μL), the primary outcome. Each variable was assessed every six months for up to four years, however for the current example only the first four time-points were analyzed in order to maximize the number of subjects with complete data. The resulting dataset was composed of 98 individuals contributing 392 observations. The total effect of heavy alcohol consumption on low CD4 cell count was not significant for any of the SEMs or NLMMs fit to the data. For the logit SEM, the total effect estimate (SE) was 0.554(1.246) with an associated p-value of 0.66. The scaled result from the logit NLMM was similar: estimated total effect (SE) = 0.5107(0.701), p = 0.47. However for the probit link, the estimated total effects (SE) from the SEM and NLMM appeared to differ substantially (probit SEM: 6.287(52.661),p = 0.91; scaled probit NLMM: 0.303(0.391), p = 0.44). Thus consistent with the results from the simulation study, the logit SEM and NLMM produced similar estimates in the real data example, whereas the probit SEM produced estimated effects that appeared much larger in magnitude in comparison to the probit NLMM.

Simulated univariate probit model with a single predictor and single binary outcome. Simulation results fit using weighted least squares with robust standard errors (WLSMV) in Mplus and maximum likelihood via iteratively re-weighted least squares (ML-IRLS) in Splus, and SAS.

Discussion

The purpose of this study was to evaluate the performance of NLMMs relative to SEMs in the analysis of mediated longitudinal binary outcomes in a setting where the SEM is presumed to be optimal. We found model performance differed based on the link function that was used in the non-linear portion of the models. Based on simulations performed across a variety of settings, the logistic NLMM performed well with respect to bias, coverage probability and power relative to the logistic SEM. The results were similar for the SEM and scaled NLMM in the logistic model setting, with both accurately estimating the effect of the time-dependent

predictor on the longitudinal binary outcome. Application of these techniques to a real-date example from a prospective cohort assessing the effect of heavy alcohol consumption on low CD4 cell count also illustrate the similarity of results from the logit SEM and NLMM.

For the probit model, however, the SEM consistently overestimated the total effects of the predictor and generally had larger bias and lower power compared to the NLMM in both mediated and non-mediated data. The larger bias may be due to the weighted least squares estimation method used for the probit SEMs (fit with Mplus), which differs from the maximum likelihood estimation method used for the NLMM (fit with SAS) and for the logistic SEM (fit with Mplus). In contrast to the SEM, the scaled probit NLMM had good performance (low bias and high power and coverage probability) with adequate sample sizes. Similar results were observed in the real data example where estimates from the probit SEM appeared larger than those from the probit NLMM.

The results showing similar estimated effects for the SEM and NLMM in the logistic model setting are similar to results seen in the non-mediated case where SEM was compared to the generalized estimating equations (a non-SEM) technique. Palta and Lin [17] compared probit models for SEM and generalized estimating equations in the analysis of data from a cohort study and found that when appropriately scaled, the two models yielded similar results. They noted, however, that the SEM allowed for more flexible specification of variance structure and therefore allowed coefficients to be scaled to provide marginal or cluster-specific interpretation.

To obtain scaled NLMM estimates in practice, it may be preferable to model the mediation by fitting separate equations, one for each pathway, using maximum likelihood rather than weighted least squares (the only estimation method currently available for probit link models in MPlus). The potential burden of fitting multiple equations separately rather than simultaneously using SEMs may be outweighed by the benefit of using maximum likelihood estimation which, in the probit model simulations, appeared to produce less biased results. In addition, estimating scale parameters and using the product of coefficients method appears to produce acceptable estimates of the total effect of the exposure. Our study demonstrated that results using this approach were similar to those obtained when NLMM results were scaled using true parameter values. If indirect effects are of interest and the NLMM is used to analyze the mediated longitudinal binary data, scaling will also be necessary. Unlike the case with linear models for continuous outcome data, the product of coefficients method is not equivalent to the "difference of coefficients" method of determining the indirect or mediated effect [24] in the case of binary outcomes. Using the difference of coefficients approach in linear models, the total effect is obtained by fitting a model that excludes the mediating variable and the direct effect is obtained by fitting a model including the mediating variable. The indirect effect is then determined by taking the difference between the total effect and direct effect. However, in the binary case, the scale of the direct effect obtained from a model that includes the mediating variable is different from the scale of the total effect obtained from a model that excludes the mediating variable [16]. As demonstrated by MacKinnon et al., to obtain comparable estimates of the indirect effect in binary outcome models, the total effect must be appropriately scaled before the difference is taken.

This study presents results based on simulated data from a single-mediator model. Conclusions from these results may not be generalizable to scenarios with different data characteristics. For example, in scenarios with multiple mediators and pathways, the advantages and disadvantages of NLMMs relative to SEMs may differ. The performance of NLMMs and SEMs in other scenarios, such as the analysis of nominal and ordinal outcomes as well as the case of multiple mediators, should be evaluated in future studies.

Conclusions

Overall, we found the NLMM performed sufficiently well in the analysis of mediated longitudinal binary outcomes with respect to bias, coverage probability, and power. Under the logistic model, both the NLMM and SEM had acceptable performance and the results for the two types of models were similar. The NLMM requires scaling of the regression parameters and this scaling requires fitting additional models to separately estimate direct effects of the predictor, and effects of the primary predictor on the mediator. An advantage of the SEM is that it can fit all of the linear and non-linear models simultaneously, avoiding the burden of fitting multiple models. For the probit model, however, the SEM estimated using weighted least squares may overestimate effects. In contrast, the NLMM appears to perform adequately across a range of settings and therefore is preferred over the SEM for probit models.

Appendix

Estimating the Scaling Factor for Total Effect Estimates

Scaling effect estimates is necessary to obtain total effect estimates that represent the total effect of the predictor on the outcome, conditional on the mediation. This is the case when one wishes to compare estimates from SEMs to estimates from NLMMs, but also necessary if one wishes to compute indirect (i.e. mediated) effects using results from NLMMs only. The difference in scale

for models with differing sets of predictors is due to the variance of the residual error term being fixed. This is not an issue in linear models where this variance is estimated rather than fixed [16-18]. In practice, the unknown parameters necessary for scaling, i.e. θ (the variance of ϵ_j and λ (the effect of the mediator on the outcome), can be estimated by fitting the following additional models:

$$M_j = \alpha_0 + \alpha_1 z_j + \varepsilon_j \quad (12)$$

$$\Phi^{-1}(Y_j) = \beta_0 + \beta_1 w + \beta_2 t_j + \beta_3 z_j + \beta_4 M_j + b_1 + b_2 t_j \quad (13)$$

The first model (Equation 12) is similar to part of the structural model in the SEM (Equation 5), but instead is fit as a general linear model for longitudinal data with M_j as the outcome and z_j as the predictor that allows correlation between the repeated observations. Using data from the alcohol and HIV example described earlier, this would be a model with longitudinal ART adherence measures as the outcome and measures of heavy alcohol consumption as time-varying predictors. The second model is an NLMM modeling Y_j as a function of a random intercept and slope, and fixed effects for the continuous covariate (w), time (t_j), the repeated binary predictor (z_j), and the repeated mediator (M_j). For the HIV example, this would be a model with low CD4 count as the outcome and include both heavy alcohol consumption and ART adherence as predictors.

Using Equations 12 and 13, the estimated variance of ϵ_j provides an estimate of θ and the estimated coefficient β_4 associated with M_j provides an estimate of λ. The original, unscaled NLMM estimate of the total effect of the primary predictor, β_3 from Equation 8), can then be rescaled by multiplying by the factor: $\sqrt{1 + \hat{\lambda}^2\hat{\theta}}$ for a probit model (or $\left[\left(\frac{\pi^2}{3} + \hat{\lambda}^2\hat{\theta}\right)/\frac{\pi^2}{3}\right]^{\frac{1}{2}}$ for a logit model).

An alternative approach to using scaled regression coefficients would be to model indirect and direct pathways separately and obtain the total effect by summing the indirect and direct effects. That is, estimates of the coefficients β_3 and β_4 associated with z_j and M_j, respectively (from Equation 13) can be used along with estimates of the coefficient α_1 associated with z_j (from Equation 12) to obtain the estimated total effect of the main independent variable $\hat{\beta}_3 + \hat{\alpha}_1\hat{\beta}_4$.

In the current simulation study, we calculated the total effects of the main independent variable using both of the approaches described above. For the probit model, both methods yielded results comparable to those where the true parameters were known. The rescaled NLMM resulted in a parameter estimate (standard error) of 0.407 (0.105) which is a bias of 1.7%. The product of coefficients method yielded an estimate of 0.400 (0.102), which is a bias of 1.7%. Both estimates were very similar to those obtained using true values for the scaling factor, parameter estimate of 0.407 (0.096) and bias of 1.7%.

BACKGROUND: Uncontrolled hypertension remains a significant problem for many patients. Few interventions to improve patients' hypertension self-management have had lasting effects. Previous work has focused largely on patients' beliefs as predictors of behavior, but little is understood about beliefs as they are embedded in patients' social contexts.

OBJECTIVE: This study aims to explore how patients' "explanatory models" of hypertension (understandings of the causes, mechanisms or pathophysiology, course of illness, symptoms and effects of treatment) and social context relate to their reported daily hypertension self-management behaviors.

DESIGN: Semi-structured qualitative interviews with a diverse group of patients at two large urban Veterans Administration Medical centers.

PARTICIPANTS (OR PATIENTS OR SUBJECTS): African-American, white and Latino Veterans Affairs (VA) primary care patients with uncontrolled blood pressure.

APPROACH: We conducted thematic analysis using tools of grounded theory to identify key themes surrounding patients' explanatory models, social context and hypertension management behaviors.

RESULTS: Patients' perceptions of the cause and course of hypertension, experiences of hypertension symptoms, and beliefs about the effectiveness of treatment were related to different hypertension self-management behaviors. Moreover, patients' daily-lived experiences, such as an isolated lifestyle, serious competing health problems, a lack of habits and routines, barriers to exercise and prioritizing lifestyle choices, also interfered with optimal hypertension self-management.

CONCLUSIONS: Designing interventions to improve patients' hypertension self-management requires consideration of patients' explanatory models and their daily-lived experience. We propose a new conceptual model — the dynamic model of hypertension self-management behavior — which incorporates these key elements of patients' experiences.

INTRODUCTION

Hypertension continues to be a major US health problem; it is underdiagnosed, undertreated, and even when treated, often poorly controlled; over one-third of patients on antihypertensive medications have uncontrolled disease.[1] Poor hypertension control has been attributed to provider factors, such as clinical inertia in prescribing adequate medications[2,3] and patient factors, including poor adherence to medications and lifestyle management.[4–6] Few interventions to improve hypertension control have had resounding, sustained effects.[7]. Thus, finding ways to improve hypertension self-management remains a significant challenge.

Prior interventions have included educating patients about hypertension, improving BP self-monitoring at home, and nurse or pharmacist-led care. A recent Cochrane review found that purely educational interventions improved patient knowledge but were largely ineffective in improving hypertension control. Patient self-monitoring and nurse or pharmacist-led interventions held greater promise, although results were heterogeneous.[7]

One reason for the failure of purely educational interventions may be that they lack a patient-centered focus, thereby failing to address patients' unique barriers to hypertension

self-management. A patient-centered approach would incorporate how patients understand hypertension, attempt to manage hypertension, and prioritize its management in their lives. Many interventions are built upon theories that beliefs or illness perceptions drive patients' illness self-management.[8,9] Kleinman[10] reframes beliefs as integrated "explanatory models (EMs)" — patients' understanding of the causes, pathophysiology, course of illness, symptoms, and effects of treatment. EMs of an illness like hypertension are situated within social contexts; they are formed and persist in the context of the communities in which patients live. Thus, in order to influence health-related self-management behaviors, one must understand both patients' beliefs about an illness and their social context.

Further understanding hypertension self-management experiences would foster a patient-centered approach to hypertension control. Previous studies have examined patients' 'lay' models of hypertension,[11–13] but not how EMs relate to social context, or how they impact various hypertension self-management behaviors. In this qualitative study, we extend prior work by examining patients' EMs, social contexts, and hypertension self-management behaviors. We explore these aspects of patients' hypertension experiences and propose a new conceptual model of patients' illness self-management.

METHODS

Participants and Recruitment

We recruited a purposive sample of African-American, white and Latino patients with uncontrolled hypertension from primary care clinics at two large US Veterans Affairs (VA) Medical Centers serving diverse populations located in the Northeast and Southwest, respectively. In a 1-year period, we sought to recruit 20 patients from each racial/ethnic group to obtain a wide range of responses, with the expectation that we would reach thematic saturation for a diverse population. Each site's institutional review board approved the study.

Patients were eligible to participate if they had a diagnosis of hypertension and uncontrolled blood pressure (BP) (≥140/90 mmHg) documented at least once in the previous 6 months in the VA's electronic medical record, and a BP>140/90 mmHg at their primary care visit. A research assistant (RA) called patients prior to their appointment to invite participation. At the visit, the RA administered eligibility screening, collected demographic information, took BP readings and obtained written informed consent. The data were collected between February 2007 and June 2008.

Data Collection

A trained RA conducted semi-structured 1.5 hour interviews with patients. A $20.00 gift card was given for participation. Patients were asked to describe their family, a typical day, experiences living with hypertension, knowledge about hypertension, what they thought caused hypertension, the severity of their hypertension, their concerns about hypertension, communication with their provider, and medications and strategies they used to manage their hypertension.

Data Analysis

Interviews were audio-recorded, professionally transcribed verbatim, and reviewed for accuracy. We used qualitative analytic techniques informed by grounded theory.[14,15] We started by exploring how EMs affected hypertension self-management. Consistent with a grounded theory approach, we sought to identify other aspects of patient experience emergent in the data. Five team members began by open coding five transcripts together, identifying themes grounded in participants' language, and generating a coding dictionary that was refined with coding of subsequent interviews. We collapsed codes into broader categories, informed by the data and EM categories of "cause," "course," "pathophysiology," "symptoms," and "treatment," and by aspects of social context. We identified participants' hypertension self-management behaviors — reports of what they did to control their hypertension — and developed summary templates describing each participant's EMs, social context, hypertension self-management behaviors, perceptions of clinical encounters, and primary barrier to hypertension self-management. Investigators paired up to analyze subsequent interviews and complete templates, which were reviewed by the entire team, and cases were contrasted using constant comparison analysis. Throughout the analytic process, we iteratively refined conceptual links between constructs to develop a conceptual model.

RESULTS

We interviewed 48 patients (19 African-American, 20 white, and 9 Hispanic). We failed to recruit the target number of Hispanic patients, due to the relatively low Hispanic prevalence at our sites and greater participation refusal. The average age was 60; 92 % were men; 88 % had at least a high school degree, and yet income was low (see Table 1). The average BP at the clinic visit was 160/93 mmHg. We identified two major domains affecting patients' hypertension self-management behaviors: 1) four different aspects of EMs, including beliefs regarding the cause of hypertension, hypertension symptoms, the illness course (including whether they thought hypertension was chronic or intermittent), and treatment value and effects; and 2) aspects of patients' social context, routines, habits, and

competing health problems, which we termed "daily-lived experience" (DLE).

Patients described a wide range of EMs and DLEs that adversely affected their hypertension self-management behaviors and BP control (Tables 2 and 3). We first treat EM and DLE as separate and provide exemplary quotes demonstrating how EMs and DLEs were related to patients' reported hypertension self-management behaviors. We then show how EMs and DLEs may relate to one another in shaping self-management, and describe the resulting conceptual model. For 47 of the 48 patients we interviewed, we identified at least one EM or DLE that adversely affected their hypertension self-management behavior. We did not identify any unique racial/ethnic differences in EMs or DLE.

Explanatory Models (EMs)

One aspect of EMs was notably absent from patients' interviews: pathophysiology, or a biomedical conceptualization of the condition. Few patients described their understanding of the pathophysiology of hypertension, and when they did, these understandings were not linked to hypertension self-management behaviors. In contrast, perceptions of cause, illness course, symptoms, and treatment were related to self-management in several ways.

Cause. When asked what caused their high BP, patients' responses corresponded to notions of both the chronic disease of hypertension and to a temporary increase in BP associated with daily activities. Patients did not distinguish these two 'illnesses,' and often engaged in behaviors to avoid the latter, rather than behaviors that addressed biomedically attributed causes of hypertension . Patients noted causes including: 1) heredity, 2) general life stress, 3) poor diet (especially salt intake), and 4) lack of exercise.

Table 2. Explanatory Models and Corresponding Hypertension Self-Management Behaviors. These Represent the Range of Explanatory Models Described by Patients in Qualitative Interviews as Affecting Hypertension Self-Management Behaviors

Explanatory Model	Hypertension Self-Management Behavior
Cause	
Stress as primary cause	Stays calm, avoids stressful situations; takes antidepressant as treatment
Exercise causes increased BP	Avoids exercise to keep BP low
Pain causes increased BP	Managing pain, taking pain medications will control hypertension
Course of Illness	
Hypertension comes and goes	Takes medications when BP goes up
BP cannot be controlled	Won't exercise and forgets medications
Little concern about hypertension – does not affect my life	Avoids going to the doctor; Forgets medications
Own definition of what is considered 'high'	Only take medication when BP is >190/100 mmHg
Symptoms	
I can tell when my BP is high; I get headaches, dizziness when my BP is high	Takes medications only when symptoms occur
I have no symptoms of high blood pressure; therefore it is not a problem	Doesn't take medications
Eating bacon doesn't make me feel bad, so it doesn't affect my BP.	Eats bacon as desired
Treatment	
Only exercise can help me control my HBP	Exercises and therefore allows himself to smoke, drink and not take medication.
Garlic and vinegar can help me control my HBP.	Focuses on these remedies, while not taking medications or altering diet or sodium intake

Patients also described causes typically associated with temporary rises in BP: 1) increased situational stress, 2) pain, and 3) exercising. Hypertension self-management behaviors were related to both types of perceived causes. For example, one woman who responded that stress was the cause of her hypertension went on to say:

Table 3. Daily-Lived Experience and Corresponding Reported Behaviors that Interfere With Hypertension Self-Management. These Represent the Range of DLEs Described by Patients in Qualitative Interviews as Affecting Behaviors that Might Interfere with Hypertension Self-Management

Daily-Lived Experience	Behaviors Interfering with Hypertension Self-Management
Lonely, isolated lifestyle	Eats out at restaurants for social interaction, which limits ability to control salt intake.
Serious competing chronic illnesses	Disregards hypertension in favor of managing these illnesses. Unable to engage in exercise.
Lack of routines and an unstructured lifestyle	Forgets to take medications; misses doctor appointments.
Experiences medication side effects, such as impotence	Decides not to take medications.
Frequent alcohol use	Avoids medications while drinking, doubles up on medications when not drinking.

> "I think that my main reason for moving upstate is to find tranquility and maybe calm myself. And I keep saying, if I move upstate, I won't have hypertension, I probably will not need medication, the lifestyle's going to be different, it'll be more relaxed." (#1– Latino woman, age 51)

This woman had described a complex, stressful city life, including work and family stressors. Her EM that stress was the cause of her hypertension, reflected in her statement that if she moved she would no longer have hypertension, led her to consider altering her living situation. This view could perhaps contribute to poorer medication adherence.

Course of Illness. The course of illness refers to patients' perceptions of the path, controllability and severity of the illness. Some patients viewed hypertension as an intermittent problem that comes and goes. They were not concerned with hypertension as a chronic problem that needed constant management; rather, they focused on it when they knew their BP was high. For example, one woman stated:

> "If my blood pressure is anywhere between, let's say, 190 over 100, then I'm okay. As far as I'm concerned, I feel fine….right now that's what it's running about. And I'm still taking my medicine, though I'm not up to the max dose that I was up to before. So in my eyes, I'm fine. … if after a point … it starts creeping up to 220 over 120, then I have to do something at that point. It's getting too high. I know that. But if it's in the low 90, 180 range, to me, that's not considered high for me. Because I feel I'm still feeling fine. I can function." (#2 – African American woman, age 53)

This woman expressed an EM of hypertension as intermittent; moreover, 'normal BP' for her is incongruent with the biomedical view of poor hypertension control. Subsequently, she altered her self-management behavior depending on her EM of 'high' blood pressure. She hinted that how she feels and functions, rather than an objective measurement, changes her behavior.

Symptoms. Patients discussed symptoms of hypertension in two ways: 1) "There are no symptoms of hypertension," or 2) "I can feel when my blood pressure is high" (see the previous quote). In the first view, patients stated that since they did not have any symptoms associated with their hypertension, there was no need to adhere to hypertension management recommendations. One man who didn't have symptoms stated:

> "[Hypertension] doesn't affect me. If it would just hit me, "boom!" and it would like put me to a point where I was … I'm getting dizzy from eating bacon or whatever, then I would change that, I wouldn't do that. But it hasn't." (#3 – African American man, age 73)

He expressed an EM in which the presence of symptoms indicated a need for concern, incongruous with the view of hypertension as the silent killer. Subsequently, he continued to eat bacon, despite recommendations to the contrary.

Other patients described hypertension symptoms including headaches, "pressure on your chest," feeling "queasy or uneasy," neck aches, backaches, or racing pulse. One man described having a headache and feeling "the blood [rush] to your head." Many of these patients altered their hypertension self-management behaviors depending on their symptoms. One man stated:

> "I can almost tell when it's a little bit getting higher, I start feeling a little different in my head, you know, it's like a headache or something, like a little pressure. So I back off on eating (inaudible) and whatnot, or I take an extra pill on that day. I mean, I usually take two, and I would do that and it sort of levels it again. Or I really stop eating everything that has salt and sodium … and that seems to work." (#4 – Latino man, age 63)

The EM that high blood pressure produces symptoms led him to alter his medication and diet depending upon his symptoms. This behavior, in turn, may contribute to poorly controlled BP.

Treatment. Beliefs about treatment effectiveness shaped hypertension self-management, and were linked to patients' perceptions of causes and symptoms. Some endorsed taking medications, altering diet and engaging in exercise as effective treatment. Others, such as the following man, expressed concerns about taking medications for BP control, and altered treatment accordingly.

> "Higher dosages concern me. I felt that my pressure was higher than…. I must have done something and it started getting higher, and I came to your walk-in clinic. And I was given a higher dosage. And I didn't take it, I just went home and I relaxed. I think I might have taken one actually, or one-half." (#5 – Latino man, age 63)

This man's EM that high medication doses may be harmful led him to rely more on relaxation than taking medications to control his hypertension. Note this behavior also reflects an EM that relaxation is an effective treatment.

Another man stated that he didn't like taking medication, liked to drink and smoke, and that only exercising would control his hypertension:

> "So, like I run. I run, until I, you know, I'm tired and can't run any more. I stop. I sit. I collect myself and then I go again. … I smoke, so I work on my lungs as much as I can. And the thing is I'm trying to clear them so I can breathe better and basically have more wind… But now, I'm on—they got me on—blood pressure pills. I'm taking medication for high blood pressure."
> *INTERVIEWER:"Right. And how many are you on for blood pressure?"*
> "Just—I take one a day. You know, sometimes I do. Sometimes I miss it, you know. But my doctor, my primary care doctor, she wants me to take these every day. I don't like medication too much. I like natural things." (#6 – African American man, age 64)

His EM was that taking medication was unnatural, and therefore concerning. Despite his acknowledgement that smoking is bad for him, he expressed an EM that getting exercise can overcome negative effects from smoking. He subsequently relied solely on exercise to control his BP.

Daily-Lived Experience (DLE)

Patients were asked to tell the interviewer about their lives and describe a typical day. The ways patients managed their hypertension were often embedded in descriptions of their daily activities. We identified five aspects of patients' DLE that were related to hypertension self-management behaviors: 1) isolated lifestyle, 2) serious competing health problems, 3) lack of habits and routines, 4) barriers to exercise, and 5) prioritizing lifestyle choices (Table 3). Below we provide some exemplars, noting also how patients' EMs intersected with DLE.

Lonely and Isolated Lifestyle. Many patients lived alone, were retired, unemployed, or on disability. Subsequently, they had little regular daily social interaction. One exception was venturing out to a local diner for daily meals, through which they attained the social interaction necessary to sustain their mental health. This practice, however, meant that they had little control over the amount of salt in their food. One man stated:

> "I live alone, you know? So I don't like cooking for one person. So I always go someplace to get lunches or dinners or whatever, or I go out and eat. Even eggs, you know, you can have a pinch of sodium in eggs, they already have it; they have sodium already. So everything that I eat might have sodium, and that little bit could bring it way up". (#7 – Latino man, age 61)

This man's EM was that sodium was bad for his hypertension. However, his DLE included eating at restaurants for social engagement, interfering with his ability to control his sodium intake.

Serious Competing Health Problems. Most participants had multiple co-occurring illnesses that competed with their hypertension self-management. Some confused hypertension treatment regimens with regimens for other conditions. Problems such as having arthritis or pain interfered with following exercise recommendations. For others, controlling hypertension was not considered important relative to other conditions. For example, when asked about how concerned he was about hypertension, one man who was HIV positive and had diabetes responded:

> "I'm not at all concerned about it, because I got the HIV and I got the diabetes. And high blood pressure is just another one."
> *INTERVIEWER: "How has it affected your overall health, if in any way?"*
> "I think I keep saying, to the best of my knowledge, I don't feel it anywhere." (#8 – African American man, age 67)

The DLE of having other competing health problems to manage interfered with this man's hypertension self-management. His EM of hypertension as symptomless further rendered it unimportant relative to his other health problems.

Lack of habits and routines. Some patients described highly unstructured lifestyles with few routines, and forgetting to take medications. When asked by the interviewer what made it difficult for him to lower his BP, one man replied:

> "Some very simple things. First of all, sometimes I scrap my morning routine. Sometimes I get up in the morning. By the time I realize, 'Oh, I didn't take my medicine yet,' it's one or two in the afternoon, okay." (#9 – white man, age 54)

This man's DLE included disrupted routines, which subsequently resulted in not taking his medication as prescribed. This disruption, rather than any EM about his medications, interfered with medication adherence and hypertension control.

Others had unpredictable daily lives. One man described working on a boat at sea, during which time he often forgot

to bring enough medication, was unable to obtain refills, and sometimes forgot to take it. He also described difficulty controlling his diet, as the ship's cook prepared very salty food. Thus, despite having medication and limiting salt as part of his EM for controlling BP, his daily life presented barriers to doing so.

Barriers to Exercise. Many participants expressed an EM that exercise was important to managing their hypertension, but they experienced barriers to exercising. One barrier was other health conditions, such as arthritis, that prevented them from engaging in exercise. Another was an unsafe environment. One man explained:

> "I do the exercise. Sometimes I go out and I walk up and down the steps. …'You do that for 30 minutes,' I said, 'It is almost equivalent to walking a mile' … because in my neighborhood, it is not real safe to be walking around, up and down the street."
> *INTERVIEWER: "They got loose dogs everywhere, huh?"*
> "Not only the dogs, gangsters." (#10 – white man, age 64)

This man's DLE of living in an unsafe neighborhood challenged his ability to get his desired exercise, despite the fact that he endorsed an EM in which exercise helps control BP.

Prioritizing Lifestyle Choices. Patients described lifestyle choices that affected their hypertension self-management. For example, one man stated that he "liked to drink."

> "Sometimes I wouldn't take [BP medication] for two or three days because I'm drinking. And when I continue, I'll take two for a couple days, and that's it. You know, if I feel my pressure is too high so I just double-dose, you get it? Only for a couple days, and then I go back to the regular dose." (#11 – African American man, age 57)

Drinking alcohol was part of his DLE. He understood the potential problems of drinking while taking his medication, so he altered his medication use. He also expressed an EM of the effects of treatment: the total amount of medication taken in a week is important, rather than daily adherence.

EMs and DLE Together

Patients' narratives about their hypertension reveal the intertwined nature of EMs and DLEs. In some instances, the EM might drive DLE and behavior. For example, in quote #5, the gentleman's EM is that he doesn't wish to take medications because they aren't natural. This subsequently drives his behavior around exercising, which is something that he *can* do in his daily life.

In other cases, DLE might drive the EM. In quote #1, the woman described a DLE in which stress was prevalent in the inner city context in which she lived. She attributed her high BP to this stressful life context, and in turn, believed that moving to a more peaceful setting would control her BP. If she moved, and her BP did not improve, this could alter her EM about the cause of her hypertension.

Conversely, there are instances where patients' DLE interfered with their abilities to act on their EM. This is especially salient in the case of sodium intake. Many patients reported that lowering their salt intake was important for controlling their BP, but as noted in quote #7, eating out and eating prepared foods limited patients' abilities to control their salt intake. This in turn may reinforce an EM that excess salt causes hypertension.

Conceptual links between these constructs resulted in the development of the Dynamic Model of Chronic Disease Self-Management (see Fig. 1). In this model, EMs and DLE continually shape one another in relationship to behavior, and may change over the course of a patient's illness, as has been noted in our childhood asthma work.[16] When discussing EMs and DLEs, patients suggested that communication with providers was also important to their self-management. Research supports the importance of this dimension on patient adherence.[17] Thus, we also include patient-provider communication in the model.

DISCUSSION

Patients' reports of their EMs and DLEs demonstrate that hypertension self-management does not occur primarily in the doctor's office. Rather, patients self-manage their hypertension in complex social contexts, in which they develop hypertension EMs while engaging in daily activities. Our findings show different ways in which EMs and DLEs can affect patients' hypertension self-management, including adherence to medications and recommended healthy behaviors.

Previous studies have demonstrated how differences in EMs affect patients' illness management behaviors[13,18] and confirm our finding that patients' EMs lead patients toward particular hypertension self-management behaviors that may interfere with hypertension control.[19] 12. Huertin-Roberts[12] found that African American women differentiated between "high blood pressure," thought to be responsive to diet and medication changes, and "high-pertension," a disease of the nerves caused by stress and factors that elicit emotional upset, and responsive to stress

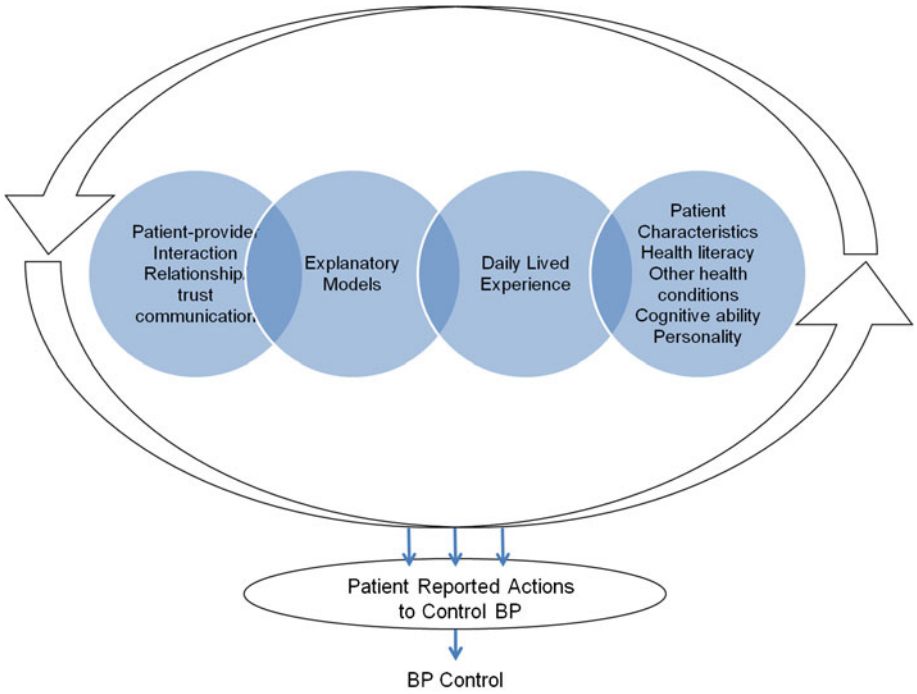

Figure 1. Dynamic model of hypertension self-management behavior.

relief rather than antihypertensives. Others have found that medication beliefs contribute to medication adherence.[9,20] These studies are consistent with theories of health behavior that account for behavior in terms of patients' internal cognitive assessments and motivations for engaging in healthy behaviors.[21–24]

Our findings demonstrate, however, that patients' self-management is based on more than their EMs or beliefs. Patients' DLE, including their social context, routines and management of competing health demands, may conflict with their EMs, and interfere with good self-management. Previous work in understanding chronic disease self-management has similarly found an important role of routines in disease self-management.[16,25]

The intervention challenge is that patients with uncontrolled hypertension have complex constellations of EMs, DLEs, other illnesses and competing priorities that converge to influence self-management behaviors. As shown in the conceptual model, DLEs and EMs are inextricably intertwined to shape behavior. If one were to imagine that an individuals' hypertension self-management experience were a strand of yarn, each fiber may constitute an EM or DLE; but if one were to pull on one strand, all the others would follow, altering the yarn altogether.

Limitations. Our findings are limited by three factors. Because this study was conducted in the VA, findings may not generalize to non-veteran populations or women, since most participants were men. Additionally, we did not observe the behaviors described; patients' reported behaviors may differ from actual behavior. Finally, although we reached saturation with our white and African American samples, we were unable to enroll as many Latino patients as intended; therefore, we may have missed some additional novel EMs or DLEs.

Interestingly, participants' infrequently stated understanding of hypertension pathophysiology was not related to self-management behaviors, suggesting that focusing on explaining how hypertension works in the body may not be an effective approach to improving hypertension control. Hypertension discussion in clinical encounters has often been restricted to adherence assessment (although even this may not occur[26]), with limited time spent counseling patients about hypertension self-management and lifestyle.[27]

While prior interventions have been tailored to particular patients' needs,[7,8,28] these interventions remain focused on providing information or education to patients to encourage them to improve their hypertension self-management behaviors, with little focus on patients' EMs in the daily life context in which they manage their illness. Many participants were able to state what they *should* do to control hypertension, but persisted in not doing so. Thus, these results suggest that improving patients' hypertension self-management requires an approach beyond assessment and education.

Encouraging patients to discuss their EMs and DLEs can enhance clinician understanding of patients' lived experience

of hypertension and subsequent self-management behaviors.[29] Some participants expressed EMs that are inconsistent with biomedical knowledge leading to poor self-management. In these instances, providers should acknowledge these differences and tailor their intervention to accommodate those beliefs.[29,30] For example, a provider may acknowledge that while reducing stress may be helpful for health, hypertension control requires additional lifestyle and medication management. Simply reminding patients to take medications and engage in healthy behavior is unlikely to be effective without addressing aspects of the patients' context. Techniques such as motivational interviewing may be effective in focusing on these aspects of hypertension management.[31] Cooper's suggestion[28] that providers need to 'get to know the patient as a person,' would likely lead providers to a better understanding of patients' DLE. These steps might lead to a decrease in contextual errors in treating hypertension: treatment errors based on a misunderstanding of the patients' context of disease management.[32]

Our findings underscore the importance of finding novel approaches in health care delivery systems to address the complex social and behavioral aspects of chronic disease self-management. While providers may address patients' EMs and DLEs during routine clinical encounters, short clinic visits often preclude such in-depth conversations, although Haidet convincingly argues that such conversations need not necessarily take more time.[33] Approaches using team based care,[28] including health coaches[34] in the context of a patient-centered medical home, may be ideal for addressing these key aspects of patient hypertension self-management.

Performance Improvement

Is Development of Postoperative Venous Thromboembolism Related to Thromboprophylaxis Use? A Case-Control Study in the Veterans Health Administration

Ann M. Borzecki, MD, MPH; Andrew J. Cowan, MD; Marisa Cevasco, MD, MPH; Marlena H. Shin, JD, MPH; Michael Shwartz, PhD; Kamal Itani, MD; Amy K. Rosen, PhD

Postoperative pulmonary embolism/deep vein thrombosis (pPE/DVT) is a common, costly, and potentially life-threatening complication.[1] Without thromboprophylaxis, DVT occurs in 15% to 60% and PE in 0.5% to 5% of major surgery patients, with the highest risk following orthopedic procedures, particularly total hip replacement[1]; pPE/DVT is associated with an excess of $21,000 in hospital charges, 5.4 hospital days, and fourfold 30-day mortality.[2,3]

Multiple randomized trials and meta-analyses have shown that prophylaxis, particularly pharmacoprophylaxis, can significantly reduce this risk, with reductions of almost 70% among general surgical patients.[1,4,5] Despite this, and the long-standing existence of national evidence-based PE/DVT prevention guidelines,[1,6] observational studies continue to report prophylaxis underuse.[7–9]

In recognition of these gaps in care, The Joint Commission and the Surgical Care Improvement Project (SCIP) have developed chart-based process measures addressing appropriate thromboprophylaxis use.[10] The Agency for Healthcare Research and Quality (AHRQ) has also included pPE/DVT as a Patient Safety Indicator (PSI). PSIs are outcome measures that use administrative data to identify potentially preventable adverse events.[11] The Centers for Medicare & Medicaid Services (CMS) has subsequently added the SCIP Venous Thromboembolism (VTE) measures and the pPE/DVT PSI to their hospital pay-for-reporting program.[12,13] In addition, CMS no longer reimburses for PE/DVTs following total hip or knee replacements.[14]

Given the adverse clinical consequences, as well as associated institutional penalties for pPE/DVT occurrences, we need to understand the extent to which these events are related to prophylaxis-related process-of-care failures and therefore potentially preventable through improved care. Although several recent case series have examined guideline-adherent thromboprophylaxis rates in either at-risk patients or those experiencing pPE/DVT events, data are limited, and somewhat conflicted, on whether thromboprophylaxis use differs between patients who do and

Article-at-a-Glance

Background: Observational studies continue to report thromboprophylaxis underuse for postoperative pulmonary embolism/deep vein thrombosis (pPE/DVT) despite the long-standing existence of prevention guidelines. However, data are limited on whether thromboprophylaxis use differs between patients developing pPE/DVT versus those who do not or on why prophylaxis is withheld.

Methods: Administrative data (2002–2007) from 28 Veterans Health Administration hospitals were screened for discharges with (1) pPE/DVT as flagged by the Agency for Healthcare Research and Quality (AHRQ) Patient Safety Indicator software and (2) pharmacoprophylaxis-recommended procedures, and the medical records were reviewed to ascertain true pPE/DVT cases. Controls were selected by matching cases by hospital, age, sex, diagnosis-related group, and predicted probability for developing pPE/DVT, and who underwent a pharmacoprophylaxis-recommended procedure. Records were assessed for "appropriate pharmacoprophylaxis use," defined primarily per American College of Chest Physicians (ACCP) guidelines, and reasons for anticoagulant nonuse.

Results: The 116 case-control pairs were similar in terms of demographics, surgery type, ACCP risk category, and appropriate pharmacoprophylaxis rates overall. Of the highest-risk patients, respective pharmacoprophylaxis rates among cases and controls were 88% versus 92% among hip/knee replacements and 31% versus 48% among cancer patients. Of the cases and controls who did not receive appropriate pharmacoprophylaxis, only about 25% had documented contraindications. Reviewers identified contraindications in 14% of cases and 9% of controls.

Conclusions: Similarities in preventive pPE/DVT practice between cases and controls suggest that pPE/DVTs occur despite implementation of guideline-adherent practices.

those who do not develop pPE/DVT.[7–9] Physician implicit review of chart-confirmed pPE/DVT cases (*N* = 28), using 1994 data, revealed a potential process failure in 61% versus only 2% of controls.[15] However, a subsequent case-control study, using 1995–2004 chart data, reported similar prophylaxis adherence in cases and controls (*N* = 172).[16] In addition, relatively few recent studies have reported on thromboprophylaxis use among high-risk patients,[9,16,17] or on the reasons for or appropriateness of withholding thromboprophylaxis.[18] Further, despite the Veterans Health Administration (VHA)'s strong commitment to development and implementation of quality improvement initiatives, little is known about VTE practices in the VHA.[19]

We therefore undertook this study to better understand the relationship between adherence with guideline-related processes of care and pPE/DVT development and to explore VTE prevention practices in the VHA.

Methods

Study Design and Data Sources

As part of a larger VHA study examining the validity of selected PSIs, from May 2009 through July 2010 we conducted a retrospective case-control study using data from October 1, 2002, through September 30, 2007. We obtained acute care hospital administrative discharge data from the VHA National Patient Care Database Patient Treatment File (PTF),[20,21] and electronic medical record (EMR) data using VistAWeb, a program enabling centralized access to VHA-wide facility data.[22]

Hospital Sampling

Our hospital sampling method is described in detail elsewhere.[23] Briefly, we applied the AHRQ PSI software (v.3.1a) to the PTF–derived database to obtain individual PSI counts and composite scores (a combined measure of 11 PSIs). We selected a geographically diverse sample of 28 of 158 VHA acute care hospitals using a stratified sampling method based on observed and expected PSI counts and composite scores. The final hospital sample included hospitals from 19 of 21 VHA regional health care networks (otherwise known as Veterans Integrated Service Networks), and 20 states representing a mix of rural (for example, Togus, Maine) and more urban areas (for example, Los Angeles). (All the US Census Bureau–designated regions and divisions of the 48 contiguous states and the District of Columbia were represented.)

Pulmonary Embolism/Deep Vein Thrombosis Case and Control Identification

Case and control identification required several steps (Figure 1, page 350). First, as part of a previous study examining the positive predictive value of the PSI pPE/DVT,[23] we randomly selected 112 PSI software–flagged pPE/DVT cases (4 per sample hospital); two trained nurse-abstractors reviewed these EMRs to identify true pPE/DVTs (*N* = 48).[23,24] Second, we excluded cases with ineligible procedures (that is, those not appropriate for prophylaxis [*N* = 25]; *see* below for eligibility); and third, we confirmed there were no upper-extremity DVT cases. This left 23 cases for matching. We then screened additional flagged cases in batches of 112, repeating Step 2 (screening for eligible procedures), then Steps 1 and 3 (nurse-abstractor confirmation of PE/lower-extremity DVT) until we obtained approximately 100 cases. This target sample size was based on power calculations that assumed a pharmacoprophylaxis use difference of 20% between cases and controls and a rate of approximately 50% among cases.[25]

We used the SCIP–recommended procedures for thromboprophylaxis as initial reference to determine surgeries for inclusion.[26] Additional selection was based on study clinician opinion [A.M.B., A.J.C.] with expert surgical input [K.I.]; only major surgeries were included. We excluded neurosurgical procedures since they often do not receive pharmacologic prophylaxis, and included lower-extremity orthopedic procedures associated with fractures (excluding below knee) and lower-extremity amputations lasting beyond one hour.

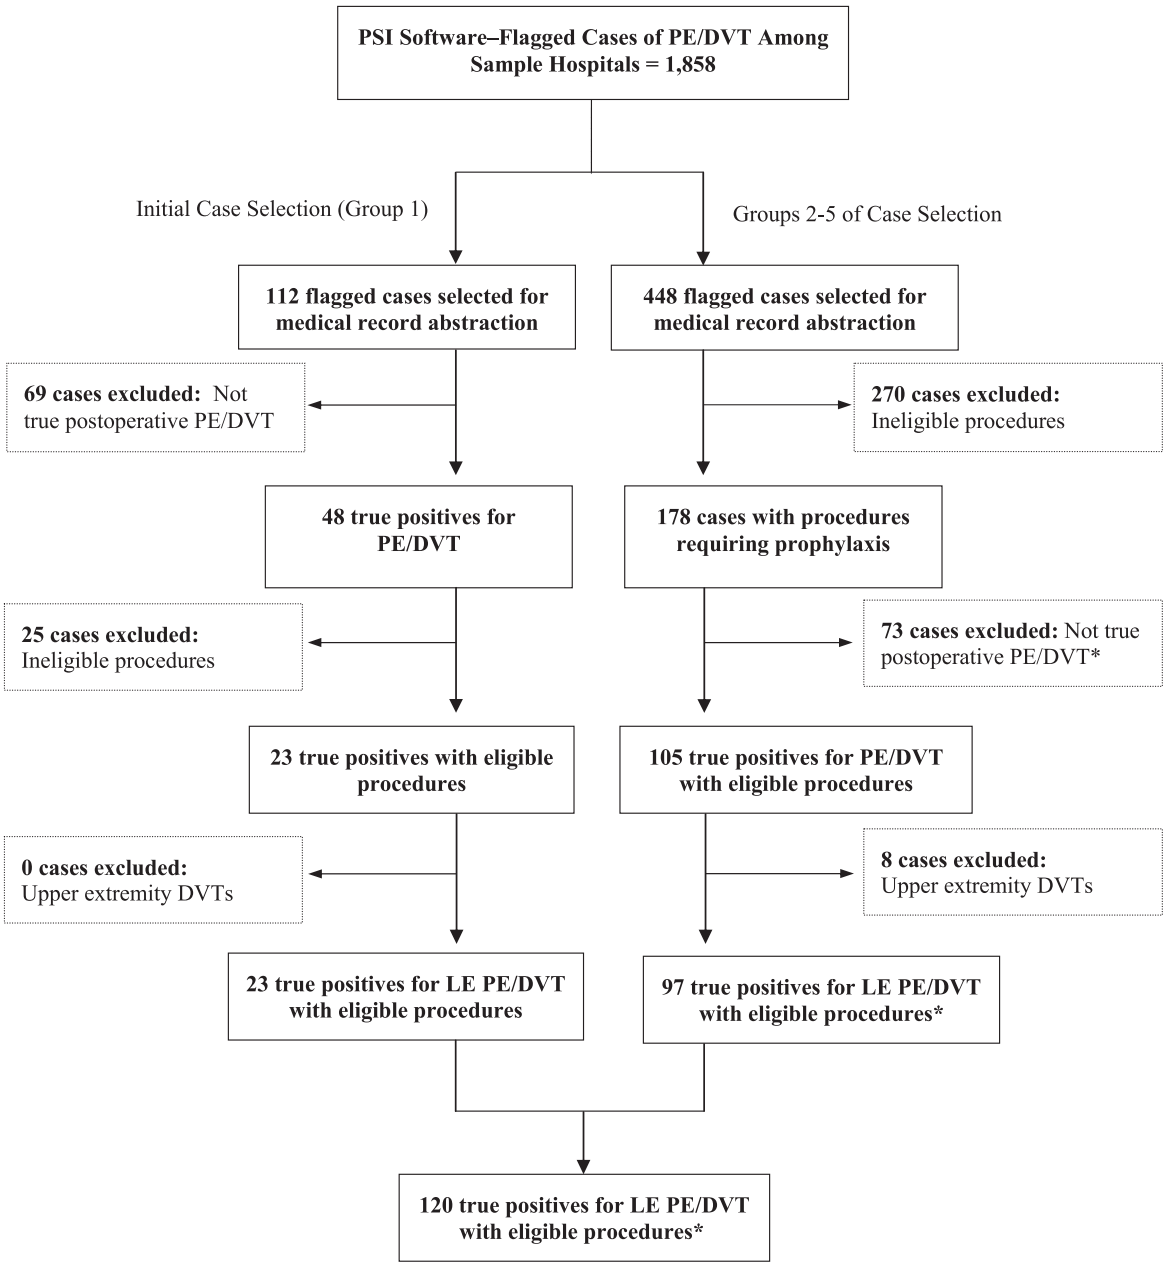
In total, we screened 560 PSI software–flagged cases (five groups of 112, including the initial 112) (Figure 1); among those with eligible procedures, 128 were confirmed as true pPE/DVTs. We excluded 8 upper-extremity DVTs, plus 3 cases occurring more than 30 days after surgery.

Using the PTF, we then matched true pPE/DVT cases one-to-one with controls (that is, patients not experiencing a pPE/DVT), based on hospital, age (within 5 years), sex, and diagnosis-related group ([DRG], which accounts for procedure type). Within strata defined by these variables, we selected the control with the closest predicted probability of developing pPE/DVT based on a logistic regression model that included age, sex, DRG, and discharge comorbidities.[27] We similarly screened out controls on the basis of procedure eligibility as described for cases. We lacked an appropriate match for 1 case; our final sample consisted of 116 matched cases and controls. Our cases came from 27 of the 28 sample hospitals. The average number of cases per site was 4.1 (standard deviation [SD], 2.7) or median 3.5 (range, 0–10).

Electronic Medical Record Abstraction

Starting with preliminary tools and guidelines from AHRQ,[28]

Selection of Pulmonary Embolism (PE)/Deep Venous Thrombosis (DVT) Cases



* From groups 2–5; 3 additional cases were excluded for PE/DVT occurring > 30 days postoperatively, and 1 case was excluded because of no control match, yielding a final sample of 116.

Figure 1. *Case and control identification required several steps, as shown. LE, lower extremity.*

we developed separate but comparable abstraction instruments for cases and controls. Specific to cases, the instrument included questions about case ascertainment per the PSI definition.[24] There had to be documentation in the discharge summary, radiology reports, or physician progress notes that the patient experienced a VTE postoperatively. All but 2 cases had radiographic confirmation; these 2 cases were reviewed by study clinicians [A.M.B., A.J.C.] and retained as true events. (See Kaafarani et al. for further EMR abstraction details.[23])

For both cases and controls, the instrument contained iden-

† $p < .05$; significant difference between cases and controls.

‡ Median time from admission to venous thromboembolism (VTE) diagnosis was 6.5 days (25th and 75th percentiles: 3.0, 12.0); median time from diagnosis to discharge was 10.0 days (25th and 75th percentiles: 5.0, 19.0).

§ Includes known neoplasms present on admission and masses present on admission that were diagnosed as malignancies.

‖ BMI based on admission height and weight.

Includes congenital and acquired states other than malignancy; 1 case and 1 control had a known Factor V Leiden mutation (and a prior VTE).

** Based on procedure (hip or knee replacement or hip fracture surgery) and/or age > 40 years and having a prior VTE/molecular hypercoagulability or current neoplasm. (Geerts WH, et al. Prevention of venous thromboembolism. *Chest.* 2001;119(1 Suppl):132S–175S [reference 31]; Geerts WH, et al. Prevention of venous thromboembolism: The Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. *Chest.* 2004;126(3 Suppl):338S-400S. [reference 32].) Major trauma and acute spinal cord injury patients are also at the highest risk. Only 1 control fit these latter criteria.

tical questions about demographics, patient- and procedure-related risk factors, and perioperative thromboprophylaxis use, plus contraindications to pharmacoprophylaxis, including a history of recent (within four weeks) or active intracerebral, gastrointestinal, respiratory, or urinary tract bleeding, a known bleeding disorder (inherited or acquired, such as severe liver disease), or platelet count < 75,000.[29,30] The two nurse-abstractors were also encouraged to write-in additional documented reasons for lack of pharmacoprophylaxis use. For controls, records were also examined out to 90 days following discharge to look for late VTE events. (We initially tested interrater reliability on approximately 10% of cases; average agreement across records was 92%. Further abstraction details are described elsewhere.[23])

Analyses

We compared cases and controls on several variables, including demographics, patient-related risk factors, surgery type, American College of Chest Physicians (ACCP) risk category (Table 1, above),[31,32] and thromboprophylaxis use. We conducted similar analyses comparing prophylaxis use between and within surgical specialties, with subcategorization of orthopedic procedures, and compared risk factors within surgery type.

Thromboprophylaxis Use. We categorized thromboprophylaxis use into mutually exclusive groups: "appropriate pharmacoprophylaxis," "mechanical prophylaxis only," and "no prophylaxis." We used the SCIP VTE measures specifications (v.2.6b), derived from the seventh version of the ACCP guidelines (ACCP 7), to define appropriateness.[27,32] Appropriate pharmacoprophylaxis required both proper timing of administration (within 24 hours of the procedure) and use of recommended anticoagulants; the "mechanical prophylaxis only" group similarly required use of appropriately timed and recommended forms of mechanical prophylaxis (Appendix 1, available in online article). For procedures not represented in the SCIP measures (for example, lower-extremity amputations), we referred directly to ACCP 7 for recommended anticoagulants.[32] Of note, the SCIP specifications differ from ACCP guidelines in being more explicit with respect to appropriate timing of prophylaxis administration, outlining appropriate prophylaxis options for a specific set of major surgeries, and not accounting for patient VTE risk factors (for example, SCIP considers mechanical prophylaxis as appropriate in all urologic patients, even high-risk ones).[26,32] Because ACCP guidelines recommend that mechanical prophylaxis be used as an adjunct to anticoagulants, particularly in high-risk patients, we

also calculated the percentage on both appropriate pharmacologic and mechanical prophylaxis.[32]

Reasons for Lack of Pharmacoprophylaxis. Study clinicians [A.M.B., A.J.C] reviewed EMRs of all patients who did not receive appropriate pharmacoprophylaxis and in whom nurse-abstractors did not identify a potential contraindication (including records with delayed prophylaxis; that is, initiated > 24 hours postoperatively). They looked for other potential reasons for lack of pharmacoprophylaxis use, such as significant perioperative bleeding (for example, bleeding-associated systolic blood pressure drop to < 90 mm Hg, or hematocrit drop to < 25% immediately postoperatively, or requiring ≥ four units of blood), significant renal impairment (estimated glomerular filtration rate < 30ml/min or end-stage renal disease on dialysis), or epidural anesthesia/analgesia use. This last item was included because the SCIP specifications consider withholding of pharmacoprophylaxis in patients undergoing epidural anesthesia or with an epidural catheter in situ as appropriate, provided mechanical prophylaxis is used, contrary to ACCP guidelines.[1,32]

We compared groups using parametric (chi-squares and *t*-tests) and nonparametric tests (Wilcoxon rank-sum) as appropriate. We also calculated effect size (ES) for selected results to characterize the clinical significance of findings.[33] (Effect sizes of 0.2, 0.5, and 0.8 are considered small, medium, and large respectively.[33]) SAS version 9.1 (SAS Institute Inc., Cary, North Carolina) was used for all analyses.

Results

Patient Sample Characteristics

Table 1 shows baseline characteristics of sample patients. Cases and controls were similar with respect to sex, race/ethnicity, and age; all patients were at least 40 years old. The most common preadmission risk factors overall were current neoplasm and obesity (that is, body mass index [BMI] ≥ 30). Individual risk factors were similar between cases and controls, except for more prior VTEs in cases (16% versus 5%; $p = .01$) and more obesity in controls (36% versus 22%; $p = .03$). Cases and controls were comparable with respect to major surgery type; orthopedic surgery was the most common category (> 54% of cases and controls) followed by general surgery (> 29% of cases and > 26% of controls; Table 2, page 353). Eighty-two percent of cases and 77% of controls were in the ACCP highest risk category ($p = .42$); all were at least high risk.

There were few significant differences in risk factors between cases and controls by surgery type, other than higher prior VTE rates among orthopedic cases and impaired mobility among lower-extremity amputation cases (data not presented; available from authors.) Notably, current neoplasm was particularly common among patients undergoing thoracic (100% of cases, 88% of controls), urologic (88% of cases, 71% of controls), and general surgery (44% of cases, 52% of controls). We found no late VTE events among controls.

Overall Thromboprophylaxis Rates

As shown in Table 2, more controls than cases received appropriate pharmacoprophylaxis (72% versus 62%), although the difference was not statistically significant ($p = .13$; ES = .16). Mechanical prophylaxis alone was used in 32% of cases and 22% of controls ($p = .11$); 6% of both cases and controls did not receive any prophylaxis. Fifty-three percent of cases and 58% of controls received both appropriate pharmacologic and mechanical prophylaxis ($p = .60$).

Surgical Specialty-Specific Thromboprophylaxis Rates

Orthopedic patients were significantly more likely to receive appropriate pharmacoprophylaxis compared with other surgical groups ($p < .01$), with similar rates among cases and controls (> 87%). Urologic patients had the lowest rates (0% and 29% for cases and controls, respectively). There was a nonsignificant trend toward higher prophylaxis rates among controls versus cases for the nonorthopedic surgical groups.

We saw opposite results with respect to mechanical prophylaxis only use. Nonorthopedic surgical patients (other than lower-extremity amputations and thoracic patients) had significantly higher mechanical prophylaxis rates compared with orthopedic patients ($p < .001$); urologic patients had the highest rates (88% of cases and 71% of controls).

Rates of no prophylaxis were comparable between cases and controls by specialty group, ranging from 0% to 50% for cases undergoing orthopedic procedures versus lower-extremity amputations. With respect to use of both pharmacologic and mechanical prophylaxis, trends were similar to those seen with appropriate pharmacoprophylaxis.

ACCP Highest-Risk Groups

Eighty-one percent of both cases and controls undergoing orthopedic procedures represented hip or knee replacements. Among these joint replacement patients, 88% of cases and 92% of controls received appropriate pharmacoprophylaxis ($p = .65$); all received some form of prophylaxis; approximately three quarters of both groups received a combination of appropriate pharmacologic and mechanical prophylaxis (Table 2.)

While 83% of patients with a prior VTE in both groups

§ Open reduction internal fixations of fractures, including proximal femoral fractures, are not included in the SCIP measure (QualityNet. Specifications Manual, Version 2.6b: Discharges 04/01/2009 to 09/30/2009. Accessed Jun 27, 2012. http://www.qualitynet.org/dcs/ContentServer?c=Page&pagename=QnetPublic%2FPage%2FQnetTier4&cid=1221491528970. Appendix A - ICD-9 Code Tables, revised Nov 19, 2008 [Tables 5.19, 5.21, 5.22, 5.23, and 5.24] [reference 26]).

‖ Not included in the SCIP VTE measure. Removing these patients produces similar "all procedure" rates (for example, pharmacoprophylaxis rates would be 64% in cases and 72% in controls).

received pharmacoprophylaxis, only 31% of cases and 48% of controls with a neoplasm received appropriate pharmacoprophylaxis (p = .19; ES = 0.33). Of those in the highest ACCP risk category based on either procedure or patient risk factors, 68% of cases and 75% of controls received pharmacoprophylaxis (p = .33); 56% of cases and 62% of controls received both pharmacologic and mechanical prophylaxis (p = .46).

Reasons for Lack of Pharmacoprophylaxis

Nurses identified contraindications in only approximately 25% of both cases and controls who did not receive appropriate pharmacoprophylaxis. Table 3 (page 354) shows results after clinician EMR review. Clinicians identified bleeding contraindications in 12% of all cases (N = 14) and 9% of controls (N = 10). Of these, 57% of cases (N = 8) and 60% of controls (N = 6) had these reasons explicitly documented, and 57% (N = 8) and 70% (N = 7), respectively, represented patients with cancer. Another 2 cases had documentation of not receiving pharmacoprophylaxis because of fall risk. Among patients with contraindications, all but 1 case, a patient with peripheral vascular disease, received appropriate mechanical prophylaxis. Two additional cases developed VTEs within 24 hours postoperatively. We felt that we could not conclude that they lacked a contraindication to pharmacoprophylaxis. Given the relatively short time frame between the procedure and the VTE event, postoperative documentation of the acute complication would likely have taken precedence over documentation of contraindications. (Had we excluded these patients from the original sample, our results would not have appreciably changed.)

Thus, accounting for contraindications and early VTE occurrence, a total of 78% of cases and 80% of controls were appropriately managed (p = .75). This represented 56% of cases and 72% of controls with malignancy (p = .19; ES = .32). Accounting for contraindications, assessments of appropriate management increased for all surgical groups except thoracic cases and lower extremity amputation controls (Figure 2, page 355.)

Of the remaining patients, either no reason was given or identified in the record as to why they did not receive appropriate pharmacoprophylaxis (16% of both cases and controls), or potential reasons for withholding prophylaxis were not consistent with accepted contraindications (that is, the presence of an epidural catheter or use of aspirin as prophylaxis instead of anticoagulants; 6% of cases and 4% of controls). No identifiable cause for lack of pharmacoprophylaxis use was found proportionately most often in lower-extremity amputation patients. Of note, among patients with "delayed" prophylaxis (that is, started

* There were no significant differences between cases and controls overall. Row percentages are shown. LE, lower extremity.

† Including a history of bleeding on admission, intraoperatively, or postoperatively, or a bleeding history with anticoagulation (1 case and 1 control), or at bleeding risk because of thrombocytopenia (platelets < 75, 1 case) or end-stage renal disease (1 case).

‡ These were epidural catheters that stayed in place for ≥ 1 day postoperatively for analgesia; 1 case had this explicitly noted by a clinician as a reason for withholding anticoagulation. An additional 3 cases (2 orthopedic and 1 LE amputation) and 5 controls (3 orthopedic, 1 general surgery, and 1 LE amputation) had an epidural as anesthesia for surgery only.

§ One case and 1 control, each of whom underwent elective knee replacements, received aspirin as prophylaxis.

‖ Includes 2 cases with a pulmonary embolism within 1 day postoperatively who did not receive or have any pharmacoprophylaxis ordered before the event, and 2 cases—including 1 patient undergoing a hip open reduction internal fixation—who were deemed to be at too high fall risk.

in hospital but > 24 hours postoperatively; 2 cases and 8 controls) we did not find documentation of resolution of a contraindication (accepted or otherwise), except for 2 controls in whom it was started after an epidural catheter was removed.

Discussion

This study is one of the few investigations of VHA surgical patients to examine thromboprophylaxis use and the first VHA study to our knowledge to evaluate the association of process failures with outcomes. Among this high-risk group of veterans undergoing major operative procedures, we did not find a significant difference in pharmacoprophylaxis use between cases and controls. Overall, appropriate pharmacoprophylaxis rates were modest, although rates of appropriate management were high when accounting for contraindications; 62% of cases and 72% of controls received guideline-recommended PE/DVT pharmacoprophylaxis, with a further 16% of cases and 8% of controls appropriately managed given contraindications. Had we approximated SCIP criteria by considering mechanical prophylaxis use as appropriate in all urologic patients or patients receiving epidural anesthesia[26,32] and by excluding non-SCIP-eligible procedures (that is, lower-extremity amputations and fractures), 83% of our cases and 90% of controls would have received appropriate prophylaxis (not accounting for SCIP exclusion criteria).[21,27]

Pharmacoprophylaxis rates varied widely by surgery type, with the highest rates among orthopedic patients; general surgery, thoracic, and urologic patients had comparatively lower rates. Among the highest ACCP risk groups, very high pharmacoprophylaxis rates were seen among joint replacement patients and those with a VTE history (> 80%), with much lower rates among cancer patients (39% overall). These lower rates persisted even after accounting for contraindications. (Although the clinical significance—that is, effect size—of case-control differences was slightly larger among cancer patients, both groups were relatively undertreated.)

Clinical trial results strongly support the process-outcome link between perioperative PE/DVT pharmacoprophylaxis use and decreased occurrence of DVT, PE, and death, with much weaker evidence supporting mechanical prophylaxis and only with respect to DVT risk reduction.[1] Thus, the ACCP guidelines generally recommend mechanical prophylaxis alone only when the bleeding risk is unacceptably high.[1] Although we did find a trend toward lower pharmacoprophylaxis use (and conversely higher mechanical prophylaxis use) in cases compared to controls (both overall and within each nonorthopedic surgical group), these differences were not statistically significant. Interestingly, when we performed a post hoc analysis among the nonorthopedic patients, we found borderline significant differences in pharmacoprophylaxis rates (32% in cases versus 53% in controls; $p = .049$, ES = 0.39). However, after we accounted for contraindications, differences in appropriate prophylaxis use disappeared (64% versus 66%; $p = 1.0$, ES = .03). Thus, although

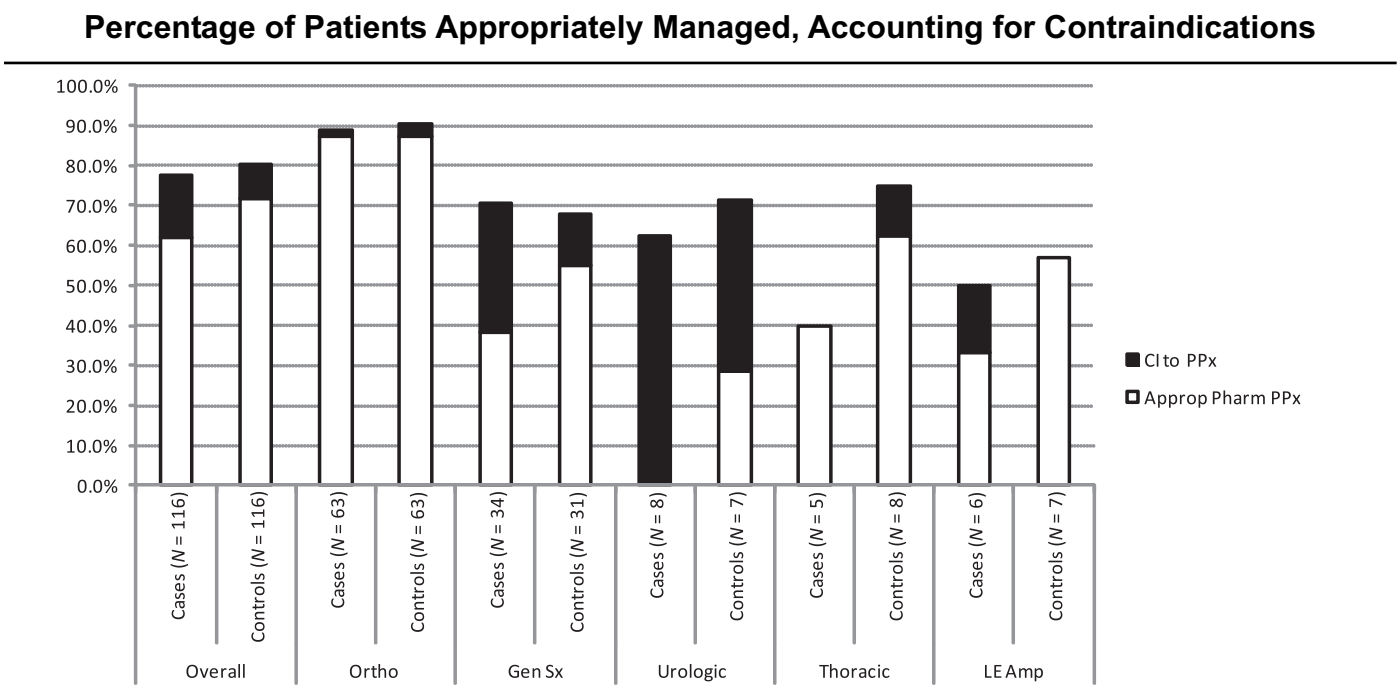

Figure 2. *Accounting for contraindications to pharmacoprophylaxis, assessments of appropriate prophylaxis increased overall and for all surgical groups, except thoracic cases and lower-extremity amputation controls. For example, overall, 62% of cases received appropriate pharmacoprophylaxis; an additional 16% either had accepted contraindications to this but received appropriate mechanical prophylaxis or had early occurrence of venous thromboembolism. If this subgroup is considered as appropriately managed, then the percentage of cases appropriately managed increased from 62% to 78%. CI to PPx, contraindication to prophylaxis; Approp Pharm PPx , appropriate pharmacologic prophylaxis; Ortho, orthopedic; Gen Sx, general surgery; LE Amp, lower-extremity amputation.*

more cases did not receive pharmacoprophylaxis, which may have contributed to at least some events, several of these were appropriately treated and therefore not clearly preventable. Moreover, these findings remain consistent with existing observational studies, both case-control and case series, that show that many pPE/DVT events occur despite the apparent use of best practices.[18,25,34]

A similar disconnect between observational study and clinical trial results with respect to process-outcome links has been noted for various conditions.[35–37] Clinical trials occur in a structured setting with a relatively homogeneous population; few interventions are as effective in actual practice. Further, as hypothesized by Shackford et al., guideline-recommended measures may simply be "insufficient to prevent VTE in some high-risk patients."[16(p. 9)] However, we are not advocating for a decrease in prophylaxis use. Rather, our findings suggest opportunities for improvements in preventive care, particularly among cancer patients and those undergoing nonorthopedic procedures. Although each surgical specialty has its own guidelines, the ACCP VTE prophylaxis guidelines are considered the standard of care in the United States. Clinicians during our study period (2002–2007) would have been influenced by both the sixth (released in 2001) and seventh (released in 2004) versions of these guidelines, which contained very similar recommendations.[31,32] Orthopedic procedures have the highest procedure-associated VTE risk, the strongest evidence base for prevention, and, therefore, the strongest recommendations for pharmacoprophylaxis. However, ACCP 6 and 7 also strongly recommend pharmacoprophylaxis for patients undergoing major general and thoracic procedures, particularly if they are older than 40 years of age or have other VTE risk factors; patients older than 40 years of age with a prior VTE or cancer are considered at highest risk, similar to orthopedic patients.[31,32] For major urologic or vascular procedures, the guidelines recommend anticoagulant use if patients have VTE risk factors. Thus, several of our high- and highest-risk cases and controls did not receive guideline-recommended care (even accounting for contraindications). Of note, our findings would be similar even accounting for the recommendations of the recently published ACCP 9, other than one notable exception; aspirin is now considered an acceptable anticoagulant alternative in patients undergoing major orthopedic surgery.[38] Among patients undergoing knee arthroplasty, we had one case and one control who received only aspirin.

Nevertheless, our rates of appropriate pharmacoprophylaxis

are generally higher than those reported in recent case series of surgical patients.[7,9,16,18,39,40] A multinational trial using chart review (the ENDORSE study) and two large studies in the United States that used administrative data from similar time periods reported overall appropriate pharmacoprophylaxis rates between 18% and 55%.[7,9,39,40] Rates also varied by specialty, with the highest rates among orthopedic patients (38% to 74%), and the lowest rates tending to be among urologic patients (26% to 32%).[7,9,40] The ENDORSE study also found that patients with prior VTE had a higher likelihood of receiving recommended prophylaxis than cancer patients.[9] Among studies of surgical patients experiencing VTE, two single site studies, one using 2009 data (N = 89), and the other, the previously noted case-control study, found that 63% and 40%, respectively, received appropriate pharmacoprophylaxis; an additional 25% and 23%, respectively were appropriately managed given contraindications.[18]

There are several possible explanations for the discrepant rates, particularly with the larger case series, including slightly different appropriateness definitions (all were based on ACCP 6 or 7 guidelines),[31,32] data sources used, patient characteristics, and included procedure types. Our population's higher VTE risk likely led to higher prophylaxis rates. For example, in the ENDORSE study, rates of prior VTE, active cancer, and orthopedic procedures were only 3%, 17%, and 13%, respectively.[9]

Other important findings of our study were that relatively few of the patients who did not receive pharmacoprophylaxis had documented contraindications and that approximately half of these cases and controls had no identifiable reason for lack of use even after careful clinician review. Few previous studies have investigated this aspect of prophylaxis, other than reporting bleeding risk.[9,39] In a setting with an established VTE prophylaxis protocol, including an order sheet with check boxes to indicate contraindications, Weigelt et al. found that only 1% of cases were missing documentation of contraindications.[18] However, Shackford et al. found up to 37% of VTE cases had no contraindications documented or identified.[16]

Our study design is unique compared to related recent studies in surgical patients in that we used a well-established administrative data–based indicator, the AHRQ PE/DVT PSI, to flag PE/DVT cases.[16,18,34] However, given the PSI's recognized relatively high rate of misidentification of events (and underdetection of events), we then confirmed cases through chart review.[23,41,42]

Limitations

Our study had a few limitations. First, our sample size may have been too small to show statistical significance. However, the calculated effect size for the level of difference observed for the whole sample was relatively small at 0.16.[33] Effect size is independent of the sample size. Thus, even if we had found a statistically significant result by including twice as many cases and controls, this difference is too small to be clinically meaningful. In addition, as noted, other studies support this lack of difference in management of cases and controls.[16] Second, although we matched cases and controls on VTE risk using administrative data, chart-abstracted data demonstrated some individual risk factor differences between groups, notably with respect to prior VTE and obesity. However, by chart data all patients were in the high or highest ACCP VTE risk categories, with similar distributions by group. Third, despite using very accurate medication data (obtained from bar-coded medication administration logs), we may be overestimating appropriate pharmacoprophylaxis rates, given that we assessed prophylaxis use up to three days postoperatively but not beyond this. Further, although standard prophylaxis dosing for unfractionated and low molecular weight heparin had to be adhered to, target International Normalized Ratios (INRs) were frequently not documented. Because we could not determine warfarin-dosing appropriateness, we deemed any regular warfarin use as appropriate. Nevertheless, our rates are still higher than those in the ENDORSE study, which did not consider dosage and only examined prophylaxis use at a single time-point. In addition, our methods of assessing appropriateness are similar to those of other recent chart-review studies.[16,18,39] Finally, it is possible that some controls may have had subclinical VTE. However, our findings are consistent with related studies that included only symptomatic VTEs.[16,18] Although we focused on in-hospital outcomes, related studies used 30-day outcomes.[16,18] More recent data have also raised concern about events occurring up to 90 days following surgery, particularly hip replacements.[43] We therefore examined EMRs of all controls up to 90 days postdischarge and found no VTE events; all had evidence of ongoing VHA use after discharge to at least 90 days, unless they died in-hospital or prior to day 90. (None of the deaths were attributed to a VTE.)

Implications and Next Steps

Our findings and those of others suggest that even with 100% compliance with current SCIP VTE measures or even with modifications to increase use of pharmacoprophylaxis, pPE/DVTs will still occur. It may be important to incorporate other factors such as VTE risk or anticoagulant dosage and duration into VTE process measures to realize the full potential of such measures in improving patient safety. Moreover, penalizing providers for pPE/DVT events, such as events that follow joint replacements,

may be inappropriate because the vast majority of pPE/DVT events occur despite appropriate pharmacoprophylaxis. In addition, our finding that clinicians often failed to document reasons for lack of pharmacoprophylaxis is concerning from a medicolegal standpoint. We expect that such documentation will improve over time as provider awareness of performance monitoring and public reporting increases because this information is necessary to satisfy the SCIP VTE measures for certain surgery types.

Further work is needed to understand why these pPE/DVT events are happening. This may occur at the local level by means of observational studies, including local quality improvement activities that carefully assess process factors, using prospective data collection to determine whether important strategies such as early mobilization are actually being implemented. Clinical trials are also necessary to examine additional strategies to reduce VTE events.

Conclusion

Similarities in pPE/DVT preventive practices between cases and controls suggest that pPE/DVT events occur even with implementation of evidence-based practices. However, despite high overall rates of guideline-adherent care, certain high-risk patient groups were relatively undertreated, and documentation of prophylaxis contraindications was frequently absent. While these deficiencies should be addressed through VHA quality improvement efforts, further research is necessary to uncover additional methods to prevent pPE/DVT. J

Funding was provided by the US Department of Veterans Affairs Health Services Research and Development Service grant number SDR 07-002. The authors extend special thanks for their assistance to Kathleen Hickson, RN, PhD, and Sally MacDonald, RN, for abstraction of electronic medical records and modification of the abstraction instrument; Haytham Kaafarani, MD, MPH, for development of the abstraction instrument and case review; Amresh Hanchate, PhD, for development and analysis of predicted probability scores and matching methods; Elaine Hickey, RN, for assessment of interrater reliability; Hillary Mull, MPP, and Qi Chen, MD, MPH, for development of the electronic abstraction form; Susan Loveland, MAT, for programming expertise and identification of the hospital sample, flagged cases, and matched controls; Qi Chen and William O'Brien, MS, for programming; and Elaine Hylek, MD, MPH, for manuscript review and comments.

Performance Measure Name: Surgery Patient with Recommended Venous Thromboembolism Prophylaxis Ordered.

Description: Surgery patients with recommended venous thromboembolism (VTE) prophylaxis ordered anytime from hospital arrival to 24 hours after surgery end time.

SCIP VTE-2

Performance measure name: Surgery Patients Who Received Appropriate Venous Thromboembolism Prophylaxis Within 24 Hours Prior to Surgery to 24 Hours After Surgery

Description: Surgery patients who received appropriate venous thromboembolism (VTE) prophylaxis within 24 hours prior to Surgical Incision Time to 24 hours after surgery end time.

SCIP–Recommended VTE Prophylaxis Selection for Surgery

Surgery Type	Recommended Prophylaxis Options
General Surgery (Table 5.19)*	Any of the following: • Low-dose unfractionated heparin (LDUH) • Low molecular weight heparin (LMWH) • Factor Xa Inhibitor (Fondaparinux) • LDUH or LMWH or Factor Xa Inhibitor combined with IPC or GCS
General Surgery with High Risk for Bleeding† (Table 5.19)*	Any of the following: • Intermittent pneumatic compression (IPC) devices • Graduated compression stockings (GCS)
Urologic Surgery (Table 5.21)*	Any of the following: • Low-dose unfractionated heparin (LDUH) • Low molecular weight heparin (LMWH) • Factor Xa Inhibitor (Fondaparinux) • Intermittent pneumatic compression (IPC) devices • Graduated compression stockings (GCS) • LDUH or LMWH combined with IPC or GCS
Elective Total Hip Replacement (Table 5.22)*	Any of the following started within 24 hours of surgery: • Low molecular weight heparin (LMWH) • Factor Xa Inhibitor (Fondaparinux) • Warfarin
Elective Total Knee Replacement (Table 5.23)*	Any of the following: • Low molecular weight heparin (LMWH) • Factor Xa Inhibitor (Fondaparinux) • Warfarin • Intermittent pneumatic compression (IPC) devices • Venous foot pump

Correlates of Antiretroviral and Antidepressant Adherence Among Depressed HIV-Infected Patients

Kathryn A. Bottonari, Ph.D.,[1] Shanti P. Tripathi, M.S.,[2,3] John C. Fortney, Ph.D.,[2,3] Geoff Curran, Ph.D.,[2,3] David Rimland, M.D.,[4] Maria Rodriguez-Barradas, M.D.,[5] Allen L. Gifford, M.D.,[6,7] and Jeffrey M. Pyne, M.D.[2,3]

Abstract

Although crucial for efficacy of pharmacotherapy, adherence to prescribed medication regimens for both antiretrovirals and antidepressants is often suboptimal. As many depressed HIV-infected individuals are prescribed both antiretrovirals and antidepressants, it is important to know whether correlates of nonadherence are similar or different across type of regimen. The HIV Translating Initiatives for Depression into Effective Solutions (HI-TIDES) study was a single-blinded, longitudinal, randomized controlled effectiveness trial comparing collaborative care to usual depression care at three Veterans Affairs HIV clinics. The current investigation utilized self-report baseline interview and chart-abstracted data. Participants were 225 depressed HIV-infected patients who were prescribed an antidepressant ($n=146$), an antiretroviral ($n=192$), or both ($n=113$). Treatment adherence over the last 4 days was dichotomized as "less than 90% adherence" or "90% or greater adherence." After identifying potential correlates of nonadherence, we used a seemingly unrelated regression (SUR) bivariate probit model, in which the probability of adherence to HIV medications and the probability of adherence to antidepressant medications are modeled jointly. Results indicated that 75.5% ($n=146$) of those prescribed antiretrovirals reported 90%-plus adherence to their antiretroviral prescription and 76.7% ($n=112$) of those prescribed antidepressants reported 90%-plus adherence to their antidepressant prescription, while 67% of those prescribed both ($n=113$) reported more than 90% adherence to both regimens. SUR results indicated that education, age, and HIV symptom severity were significant correlates of antiretroviral medication adherence while gender and generalized anxiety disorder diagnosis were significant correlates of adherence to antidepressant medications. In addition, antiretroviral adherence did not predict antidepressant adherence ($\beta=1.62$, $p=0.17$), however, antidepressant adherence did predict antiretroviral adherence ($\beta=2.30$, $p<0.05$).

Introduction

Despite ongoing advances in pharmacotherapy in the treatments of depression and HIV, many depressed HIV-infected individuals experience only partial response due to nonadherence to prescribed regimens. Indeed, depressive symptoms have been repeatedly identified as a consistent, yet mutable, barrier to medical treatment adherence.[1,2] Moreover, depression has been identified as a common barrier to HIV treatment adherence.[3] Yet, despite advances in antidepressant treatment, there is evidence that depressed patients (both HIV-infected and non-HIV–infected) have trouble adhering to prescribed antidepressant regimens.[4,5] Although past research has explored demographic, behavioral, and health-related barriers to adherence to depression and HIV treatment separately, limited research has examined whether common or distinct factors are barriers for individuals being prescribed both types of medications.

Examination of such variables will likely add to providers' knowledge of treating the "whole" patient, i.e., examination of psychosocial and medical factors that exist for HIV-infected individuals.[6] The present investigation focuses on barriers to adherence for both antidepressant and antiretroviral medications among depressed HIV-infected individuals prior to their enrollment in an intervention trial aimed at improving depression treatment and outcomes among treatment-seeking HIV-infected individuals.

To date, the literature has examined barriers of adherence to antiretrovirals and antidepressants separately. Extensive research has been conducted on identifying barriers to HIV treatment adherence given the virologic consequences of non-adherence (i.e., virologic failure and development of resistance). The most common factors found to impact HIV treatment adherence include complexity of treatment regimens, side effect profiles, excessive substance use, psychopathology (e.g., depression and anxiety), beliefs about medication, self-efficacy, social support, coping style, and memory lapse.[7] In contrast to HIV treatment adherence, research on antidepressant adherence is relatively sparse. Identified barriers to antidepressant adherence have included younger age, female gender, first episode versus recurrent depression, low self-efficacy, lower levels of formal education, severity of symptoms, side effect profiles, beliefs about medication-taking behavior, regimen characteristics, and forgetting.[8–12] Finally, given evidence that many individuals require maintenance treatment beyond remission of depressive symptoms,[13] it is of concern that several investigators have identified premature discontinuation of treatment as a more severe form of nonadherence. One retrospective chart review indicated that only 44% of their sample completed 6 months of treatment, suggesting that the majority of patients do not receive the full benefit of the antidepressants.[14] Given the illness profiles of both depression and HIV, research is needed to identify barriers to adherence for both antidepressant and antiretroviral medications.

More recently, research has begun to emerge examining adherence patterns among depressed HIV-infected patients. Several investigations have demonstrated improved HIV treatment adherence outcomes with use of antidepressant treatment. First, there was preliminary data from a retrospective chart review suggesting that adherence to antiretrovirals was positively correlated with antidepressants adherence ($r = 0.31$; $p < 0.02$) and of improved virologic responses given evidence of adherence to antidepressants (>80%).[15] Second, several investigations have provided evidence of improved adherence to antiretrovirals among depressed individuals taking antidepressants.[5,16,17] Walkup and colleagues[17] reported that prescription of an antidepressant in a prior month increased the odds of adherence to antiretroviral in the subsequent month. Furthermore, Horzberg and colleagues[5] attempted to unpack the relationship between depression, adherence to antiretrovirals, and HIV treatment adherence. They reported that depressed HIV-infected individuals who were highly adherent (>90%) to their antidepressants had similar antiretroviral adherence profiles to nondepressed individuals and that both of these groups had significantly better antiretroviral adherence than those who were both depressed and nonadherent to their antidepressants. Finally, there is evidence that antidepressant treatment also helps improve adherence to complex antiretroviral regimens.[18] However, given evidence that antidepressant and antiretroviral adherence are related, it would be of interest to identify factors that predict adherence to both types of medication.

This investigation is part of the larger, three-site, two-arm, single-blinded, randomized controlled effectiveness trial, HIV Translating Initiatives for Depression into Effective Solutions (HI-TIDES).[19] The goal of the HI-TIDES trial was to compare a collaborative care intervention[20] to treatment as usual (TAU) in the treatment of depression for depressed HIV clinic patients. The larger trial involved an intervention utilizing an offsite HIV depression care team (registered nurse depression care manager, pharmacist, and psychiatrist) who delivered up to 12 months of collaborative depression care supported by a Web-based decision support system. However, given that medication was the primary mode of depression treatment within the trial, adherence to prescribed regimens was essential. Therefore, the aim of the current investigation was to isolate demographic, mental health, and physical health related factors that were associated with preintervention adherence patterns. Identification of these factors will be helpful for future efforts to improve provision of physical and mental health interventions for HIV-infected veterans.

Methods

Participants

Eligible participants were HIV-seropositive males and females (aged 18 and over), who were being treated for HIV at one of three Veterans Administration Medical Centers (VAMC) HIV clinics and were identified as having clinically significant symptoms of depression during the screening session (i.e., Patient Health Questionnaire [PHQ-9][21] depression score ≥ 10). Exclusion criteria were: no access to a telephone, current acute suicidal ideation, significant cognitive impairment as indicated by a score greater than 10 on the Blessed Orientation-Memory-Concentration (BOMC),[22] self-report history of bipolar disorder or manic depression, and medical record diagnosis of schizophrenia. After completing the informed consent process, participants completed the baseline assessment and were randomly assigned to intervention or usual care. Two hundred seventy-six individuals were randomized at the baseline research session and 225 are included in these analyses as they had a baseline prescription for either antiretroviral treatment ($n = 192$), antidepressant treatment ($n = 146$), or both ($n = 113$). All participants signed informed consents approved by their VAMC's Institutional Review Board (IRB) prior to the initiation of any research procedures.

Measures

Demographics The baseline interview included questions about the veteran's demographics characteristics. Data utilized in these analyses included gender, age, race, marital/partner status, and level of formal education.

Patient Health Questionnaire—9 items (PHQ-9)[21] The PHQ-9 is a 9-item self-report measure that was used to screen for the presence of symptoms of depression. A PHQ-9 score of

greater than 10 has strong psychometric properties in primary care settings (e.g., 99+% sensitivity and a 91% specificity).

Symptom Checklist—20 items (SLC-20).[23] Depression symptom severity over the 2 weeks before the baseline interview was measured using the Hopkins Symptom Checklist SCL-20. The SCL-20 includes the 13-item depression scale plus 7 depression-related items from the Hopkins Symptom Checklist-90–Revised. The items are scored from 0 to 4 and averaged to provide a mean depression severity score from 0 to 4.

Mental health diagnoses. The Mini International Neuropsychiatric Interview (MINI)[24] is a brief structured interview for the major Axis I psychiatric disorders, shown to be valid and reliable when compared to the Structured Clinical Interview for DSM-III-R and the CIDI.[25] The MINI was used to assess for the presence of clinically significant depression (i.e., major depression) and also for comorbid mental health conditions (i.e., generalized anxiety disorder, panic disorder, posttraumatic stress disorder, alcohol use disorder, any alcohol use over the last year and number of drinks in week before interview).

Physical comorbidity. Chronic physical health conditions (other than HIV) were measured using the 21-item Physical Comorbidity scale from the Depression Outcomes Module.[26,27]

HIV-related symptomatology. HIV symptom severity was measured using the 20-item Symptoms Distress Module,[28] which summarizes the degree to which each symptom bothered the participant in the past 4 weeks on a scale from 0 = I do not have this symptom to 4 = this symptom bothers me a lot. We also created a count variable to address the number of self-reported symptoms.

Quality of life. Health status was measured using the physical and mental health component summary scores from the Medical Outcomes Study SF-12V.[29] Health-related quality of life was measured using the Quality of Well-Being self-administered scale (QWB-SA).[30,31] The QWB-SA score is derived from general population preference weights and ranges from death (0.0) to perfect health (1.0).

Self-reported medication adherence. Antidepressant and HIV medication adherence were measured separately using the AIDS Clinical Trial Group assessment,[32] which asks participants to report the number of pills per day they are supposed to take and the number of pills they skipped taking for each medication for each of the past 4 days. Percent adherence was calculated as follows. First, for each of the last 4 days, the number of pills prescribed minus number of pills taken divided by the total number prescribed for each medication was calculated. Then, add the percentage adherence for each of the last 4 days and divide by 4; this algorithm allowed us to take into account the number of pills and to better account for the "weight" of a missed pill (e.g., missing 1 pill of a 2-pill regimen likely has a bigger influence on efficacy than missing 1 pill of a 6-pill regimen). However, the distributions for both antidepressant and antiretroviral adherence were skewed as approximately 75% of the sample reported 100% adherence. The distributions were not amenable to transformation and as such, we decided to dichotomize the data in "less than 90%" and "90% or greater." This cut-point was chosen as our recent work demonstrated that 90% adherence was the most sensitive cut-point for antidepressant adherence.[33] Although 95% adherence is a long accepted benchmark among HIV treatment adherence research,[34] more recent research indicates that level of adherence varies by regimen and resistance profile.[35,36] We chose 90% for both types of medication for consistency in analyses.

Patient knowledge of regimen. As the adherence data were based on self-report, we did a chart review for medications prescribed to examine patient knowledge of regimen. Previous research has identified that poor knowledge of one's regimen can be associated with nonadherence to HIV medications.[37] As such, we included this in our examination of possible correlates of adherence to both types of medication; however, due to limitations in our data, we were only able to compare knowledge of names of medications. We measured knowledge in two ways. First, we measured if they knew the correct number of antidepressant and antiretroviral medications that they were prescribed. Second, we coded the names of the medications so that we could compare patient's knowledge of both the number and names of their prescribed antidepressant and antiretroviral medications to the ones reflected in their chart (chart was assumed to be gold standard). We calculated a percentage by dividing the number of correctly identified medications by the number that were prescribed to them as noted in their chart (e.g., chart review said they were prescribed Med A, Med B, and Med C; Veteran reported Med A and Med C but NOT Med B; their knowledge percentage would be 66.7%.)

Procedure

Veterans were screened for depressive symptoms by clinic staff during routine clinical care visits with their HIV provider. Veterans who fulfilled the screening criteria were referred to research to learn about the larger HI-TIDES trial. If interested, they completed the informed consent procedure at that visit and were called by research staff, on average, 7 days later, completed their baseline interview. The baseline interview contained questions about demographics, physical and mental health symptoms, treatment history, treatment preferences, and self-reported treatment adherence for both antiretrovirals and antidepressants. This interview was completed before the veteran was informed about which arm they were randomized to (intervention versus TAU). Following completion of the baseline interview, research staff conducted a chart review of the participant's electronic medical record at the VA to gather information about their current prescriptions and comorbid health conditions.

Data analytic strategy

Analyses were conducted using SAS 9.2[38] (SAS Inc., Cary, NC) and Stata 9.0 (StataCorp, College Station, TX).[39] There were three steps in the analyses to identify predictors, run the seemingly unrelated bivariate probit (SUR) model, and finally, to add adherence as an explanatory variable. Preliminary analyses to examine the relationship between participant characteristics and adherence (separate analyses for antidepressant and antiretroviral adherence) were conducted using appropriate tests based on the distribution of the item.

Independent variables that were significant at the bivariate level $p < 0.20$ with either antidepressant or antiretroviral adherence were included as variables in the final models. To examine correlates of adherence, we used an SUR model, where the probability of adherence to HIV medications and the probability of adherence to antidepressant medications are modeled jointly. The SUR model specifically accounts for the possibility that the unmeasured factors affecting adherence to HIV medications also affect adherence to antidepressant medications, which leads to correlated error terms across the two probit regression equations. These unmeasured factors include omitted variables impacting adherence to antidepressant and HIV medications, and the measurement error common to assessing adherence to antidepressant medication and adherence to HIV medications. The SUR model assumes this correlation follows a bivariate normal distribution (with covariance ρ) and calculates whether the error terms are significantly correlated and the direction of the correlation.[40,41] The significance of the correlation coefficient ρ is tested using a likelihood ratio test that compares the log likelihood of the model where ρ is restricted to 0 to the log likelihood of the model where ρ is unrestricted. If the correlation is not statistically significant (e.g., $\rho = 0$), it implies that unmeasured factors influencing adherence to HIV medications and the unmeasured factors influencing adherence to antidepressant medications are different, and therefore that the two decisions are likely made independent of one another. In this case, the most appropriate statistical analysis involves estimating the parameters of two separate probit regressions. On the other hand, if the correlation is positive and significant, it implies that unmeasured factors affect the adherence to antiretroviral and antidepressant medications in the same way. Conversely, if the correlation is negative and significant, it suggests that the unmeasured factors affect adherence to HIV medications and antidepressant medications in opposite directions. In either case (significantly positive or negative correlated error terms), a significant correlation suggests that the decision to take HIV and antidepressant medications as prescribed are interdependent and should be modeled jointly using the seemingly unrelated bivariate probit model. Once the proper model specification (two independent probit models or seemingly unrelated bivariate probit model) was determined, significant correlates of nonadherence were examined based on the significance of the parameter estimates of the independent variables. The direction and magnitude of the correlate effects was determined by calculating standard marginal effects.[42] Finally, two additional models were run to examine the impact of each type of adherence on the other. When adherence for one type of medication is included as an explanatory variable in the SUR equation predicting adherence for the other type of medication, it is referred to as the bivariate probit with endogenous dummy model[41] or the recursive model for dichotomous choice.[43] For the model predicting antidepressant adherence to be fully identified, the probit equation includes one exogenous independent variable (depression severity) that is not included as independent variables in the probit equation predicting antiretroviral adherence. Likewise, for the model predicting antiretroviral adherence, to be fully identified, the probit equation includes one exogenous independent variable (HIV severity) that is not included as independent variables in the probit equation predicting antidepressant adherence (Fig. 1).

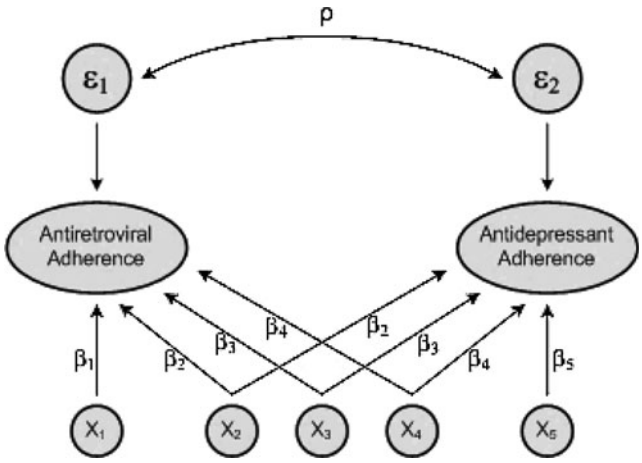

FIG. 1. Seeming unrelated regression (SUR) model. β, parameter estimates; ρ, correlation between the error terms; X, independent variables; ε, error terms.

Results

Sample characteristics

The sample consisted of 225 depressed HIV-infected veterans. Overall, the majority of the sample was male (97%), middle-aged (50 ± 10 years), and had a high school diploma (93%). Approximately 60% of the sample was African American, which is similar to the U.S. HIV population.[44] Over three fourths of the participants met criteria for major depressive disorder based on the MINI. Moreover, 75% of the sample also met criteria for at least 1 other comorbid mental health disorder. The participants reported a range of comorbid physical health conditions. The sample self-reported high rates of adherence to both their antidepressants and their antiretrovirals. Results indicated that 75.5% of those prescribed antiretrovirals ($n = 192$) reported 90% or greater adherence to their antiretroviral prescription while 76.7% of those prescribed antidepressants ($n = 146$) reported 90% or greater adherence to their antidepressant prescription (Table 1).

Among the subset of participants with both prescriptions ($n = 113$), adherence rates were as follows: both prescriptions less than 90%: $n = 11$ (9.73%); antiretroviral adherence less than 90% and antidepressant adherence 90% or greater: $n = 16$ (14.16%); antiretroviral adherence 90% or greater and antidepressant adherence less than 90%: $n = 10$ (8.85%); and both prescriptions 90% or greater : n = 76 (67.26%; see Table 2).

Table 3 provides descriptive characteristics and bivariate relationships between correlates and treatment adherence.

Bivariate relationships between correlates and treatment adherence

Separate analyses were conducted to examine bivariate relationships between demographic correlates, mental health diagnostic status, alcohol use measures, markers of physical health including HIV symptoms (both number and severity), measures of physical comorbidity, quality of life, medical knowledge, study-related factors (i.e., site), and treatment adherence (Table 3). Age ($p < 0.05$), race, education,

Table 1. Overview of Treatment Adherence and Medications Prescribed

	Antiretroviral medication (n = *192*) *Mean ± SD; range*	*Antidepressant medication* (n = *146*) *Mean ± SD; range*
Treatment adherence		
Antiretroviral adherence (%)	87.7 ± 25.7; range = 0–100	
Antidepressant adherence (%)		84.3 ± 32.3; range = 0–100
No. of medications prescribed		
Antiretrovirals—self-report	2.4 ± 1.1; range = 0–6	
Antiretrovirals—chart review	2.1 ± 1.3; range = 0–6	
Antidepressants—self-report		1.1 ± 0.4; range = 0–3
Antidepressants—chart review		0.9 ± 0.6; range = 0–3

SD, standard deviation.

depression severity, self-reported number ($p < 0.05$) and severity of HIV symptoms ($p < 0.05$), physical comorbidity, and quality of well-being ($p < 0.05$) were associated with antiretroviral adherence at $p < 0.20$ in bivariate analyses. Given the high correlation between the "number of HIV symptoms" variable and the "severity of HIV symptoms" variable, only the severity measure was used in subsequent analyses. In contrast, antidepressant adherence was associated with the following correlates at $p < 0.20$: gender, age ($p < 0.05$), marital status, generalized anxiety disorder diagnosis ($p < 0.05$), comorbid mental health disorder ($p < 0.05$), and any alcohol use in the past year. Given that the 'comorbid mental health condition' variable was highly correlated with "generalized anxiety disorder" variable, only the "generalized anxiety disorder" variable was used in subsequent analyses.

Final prediction model

A seemingly unrelated bivariate probit model was estimated and the positive correlation between the two errors terms was significant ($\rho = 0.64$, Wald test of ρ: $\chi^2(1) = 9.84$, $p = 0.002$). Therefore, correlates of adherence to antiretrovirals and antidepressants were estimated jointly. Education, age, and HIV symptom severity were significant correlates of antiretroviral medication adherence while gender and generalized anxiety disorder were significant correlates of adherence to antidepressant medications (see Table 4 for full results). The results from the bivariate probit with endogenous dummy models (available from first author upon request) indicate that antiretroviral adherence does not predict antidepressant adherence ($\beta = 1.62$, $p = 0.17$) but antidepressant adherence does predict antiretroviral adherence ($\beta = 2.30$, $p = 0.036$).

Table 2. Adherence Rates Among Those Prescribed Both Antidepressant and Antiretroviral Medications

	Antiretroviral medication	
Antidepressant medication	< 90% adherence	≥ 90% adherence
< 90% adherence	9.73%	8.85
≥ 90% adherence	14.16%	67.26%

Discussion

The present study attempted to isolate demographic, mental health, and/or physical health factors that were associated with preintervention adherence patterns among depressed HIV-infected patients. While antiretroviral adherence did not predict antidepressant adherence, antidepressant adherence predicted antiretroviral adherence. Antidepressant adherence predicting antiretroviral adherence is consistent with previous research.[5,16–18] Certain demographic factors (i.e., age and level of education), physical health (i.e., HIV severity), and mental health (i.e., generalized anxiety disorder diagnosis) were associated with adherence but there were relatively few significant correlates indicating the presence of omitted variables. We did note that older adults and those with comorbid generalized anxiety disorder were more adherent, suggesting that there may be additional attention to adherence with increasing age and also among those with a tendency to worry. The finding that a higher level of education was predictive of poorer adherence in the SUR equation predicting antiretroviral adherence was surprising. In a recent review of results from developed and developing nations, education was not identified as a predictor of antiretroviral adherence.[7] However, in our sample there was a relatively small number of subjects who did not have a high school diploma, therefore, this finding should not be over-interpreted. The negative relationship between adherence and HIV symptom severity suggests to us that those who are feeling better may be motivated to maintain this status via adherence to their regimens. Overall, our findings were modest, suggesting the variables we measured were of limited utility in predicting nonadherence behaviors.

The clinical implications of our findings may be helpful for clinical providers. Results suggested that antidepressant adherence affected adherence to antiretrovirals but not vice versa. Given that the subjects enrolled in this investigation are active patients in HIV clinics and were suffering from depression, this suggests that clinical providers' efforts to improve antidepressant adherence may also improve antiretroviral adherence, which is especially important given the virologic impact of inconsistent antiretroviral adherence. Our findings mirrors several other investigations that have also provided evidence of improved adherence to antiretrovirals among depressed individuals taking antidepressants.[5,16–18] However, we also simultaneously found that antiretroviral adherence did not impact antidepressant adherence. Even so, more research is needed to examine potential moderators

[a] $p < 0.05$; The correlation between the two errors terms of the seemingly unrelated bivariate probit model was significant ($\rho = 0.64$, Wald test of ρ: $\chi^2(1) = 9.84$, $p < 0.01$).

SUR, seemingly unrelated regression; CI, confidence interval.

of the relationship between antidepressant and antiretroviral adherence.

The present investigation has a number of strengths as well as noteworthy limitations. First, a major strength of the present investigation is the use of real-world patients, i.e., depressed HIV-infected veterans who were patients seeking care in three VA HIV clinics. The eligibility criteria for this investigation were minimal so as to facilitate generalizability of these finding and the overall trial to HIV-infected veterans seeking care in the VA more generally. Moreover, the racial makeup of our sample (60% African American) is similar to the U.S. HIV population,[44] which further improves generalizability. Second, we were able to examine correlates for both antiretroviral and antidepressant adherence simultaneously using the SUR modeling techniques. Limitations of the present investigation include reliance on self-reported treatment adherence (which involves considerable measurement error), limited variables available due to limitations in data collection, restriction of sample to veterans, use of cross-sectional data, few women in the sample, and modest sample size in the SUR model. Although there are benefits and drawbacks to self-reported HIV treatment adherence, it can be used to effectively estimate adherence.[45] Even so, future trials may want to build on our results using more objective methods of measurement such as MEMS caps, pill count, or pharmacy record review and utilize a window of measurement that is longer than 4 days.[46] Additionally, we believe that limitations in the variable "patient's knowledge of regimen" may be responsible for the nonassociation between the knowledge and adherence variables. Furthermore, though the Veterans Affairs network of health care (VAMCs) is the largest provider of HIV care in the United States, the veteran population does not mirror the overall HIV-infected population in the United States. Indeed, veterans in care for HIV infection are more likely to be male and older than the average U.S. HIV-infected adult. Although the percentage of female veterans receiving care at VAMCs is increasing, women are underrepresented in comparison to the percentage of HIV-infected women in the general U.S. population. We were limited in the interpretation of gender-related and possibly education-related findings given the limited variability of these factors in our sample. Finally, although we had 225 participants with either an antidepressant or antiretroviral prescription in our baseline sample, our sample size was much smaller ($N = 113$) when we restricted the sample to those with both prescriptions.

In conclusion, among our clinically depressed, treatment-seeking HIV-infected participants, demographic factors (i.e., age and level of education), physical health (i.e., HIV severity), and mental health (i.e., generalized anxiety disorder diagnosis) were correlates of self-reported adherence. We found limited support for additional mental and/or physical health factors as correlates of adherence to these regimens. Our findings also demonstrated that antidepressant adherence was associated with antiretroviral adherence in the SUR model but not vice versa. Future research is needed to identify and test additional factors and interventions that jointly impact antiretroviral and antidepressant adherence among treatment-seeking HIV-infected patients.

Prevalence, Distribution, and Risk Factor Correlates of High Thoracic Periaortic Fat in the Framingham Heart Study

Kathryn A. Britton, MD, MPH; Alison Pedley, PhD; Joseph M. Massaro, PhD; Erin M. Corsini, BS; Joanne M. Murabito, MD, ScM; Udo Hoffmann, MD, MPH; Caroline S. Fox, MD, MPH

***Background*—**Thoracic periaortic adipose tissue (TAT) is associated with atherosclerosis and cardiovascular disease (CVD) risk factors and may play a role in obesity-mediated vascular disease. We sought to determine the prevalence, distribution, and risk factor correlates of high TAT.

***Methods and Results*—**Participants from the Framingham Heart Study (n=3246, 48% women, mean age 51.1 years) underwent multidetector computed tomography; high TAT and visceral adipose tissue (VAT) were defined on the basis of sex-specific 90th percentiles in a healthy referent sample. The prevalence of high TAT was 38.1% in women and 35.7% in men. Among individuals without high VAT, 10.1% had high TAT. After adjustment for age and VAT, both women and men with high TAT in the absence of high VAT were older and had a higher prevalence of CVD ($P<0.0001$) compared with those without high TAT. In addition, men in this group were more likely to be smokers ($P=0.02$), whereas women were more likely to have low high-density lipoprotein cholesterol ($P=0.005$).

***Conclusions*—**Individuals in our community-based sample with high TAT in the absence of high VAT were characterized by an adverse cardiometabolic profile. This adipose tissue phenotype may identify a subset of individuals with distinct metabolic characteristics. **(*J Am Heart Assoc.* 2012;0:e004200 doi: 10.1161/JAHA.112.004200)**

Key Words: body fat distribution • obesity • perivascular adipose tissue • risk factors • visceral adipose tissue

Obesity is associated with cardiovascular morbidity and mortality.[1] The mechanisms by which obesity might contribute to vascular disease remain incompletely understood. Body fat distribution may be a cardiovascular risk factor even after accounting for generalized adiposity.[2] One component of abnormal body fat deposition involves the deposition of adipose tissue, so-called ectopic fat, around organs and the vasculature.[3] Perivascular fat is one such ectopic fat depot that has been postulated to have a local pathogenic effect on blood vessels.[4–8] Thoracic periaortic fat is a subtype of perivascular fat that can be quantified using multidetector computed tomography (MDCT).[9]

Thoracic periaortic fat (TAT) may be a novel risk marker for cardiovascular disease.[10,11] We have previously shown that TAT is associated with certain metabolic risk factors after adjustment for body mass index (BMI) as well as abdominal aortic and coronary calcium after adjustment for either BMI or visceral adipose tissue (VAT).[11] However, the prevalence and age distribution of TAT in a community-based sample has not been described. In addition, given the known correlation between TAT and VAT[11] and the known association of VAT with cardiometabolic risk,[12] we sought to examine the relative association of high TAT versus high VAT with cardiometabolic risk by examining different patterns of thoracic periaortic and visceral fat deposition in a cohort of middle-aged individuals enrolled in the Framingham Heart Study.

Methods

In 1971, children of those in the original Framingham Heart Study cohort and their spouses were enrolled in the

Offspring cohort. In 2002, individuals with at least 1 parent in the Offspring cohort were enrolled in the Third-Generation cohort. The study designs have been described previously.[13,14] The present study included participants from the Offspring and Third-Generation cohorts who participated in the MDCT substudy between 2002 and 2005 as previously described.[12] Of the 3529 participants in the MDCT substudy, 3246 had interpretable values for TAT. Of the individuals with interpretable TAT, 3228 had interpretable values for VAT. For individual regressions, any individuals with data missing the covariate of interest were excluded. The study protocol was approved by the institutional review boards of the Boston University Medical Center and Massachusetts General Hospital. All subjects provided written informed consent.

MDCT Scan Protocol and Adipose Tissue Measurements

Participants underwent radiographic assessment of their thorax and abdomen in the supine position using an 8-slice MDCT scanner (LightSpeed Ultra, General Electric, Milwaukee, WI) as previously described.[9] The thoracic scan was performed during an inspiratory breath hold with prospective ECG triggering (with the center of acquisition window at 70% of the R-R cycle to minimize cardiac motion). The average scan time was 18 seconds (tube voltage of 120 kVp, tube current of 320 mA (<220 lbs) or 400 mA (>220 lbs) with a gantry rotation time of 500 ms and a temporal resolution of 330 ms. Thoracic and abdominal MDCT images were reconstructed as 2.5- and 5-mm nonoverlapping slices, respectively.

TAT and VAT were assessed using a dedicated workstation (Aquarius 3D, TeraRecon, San Mateo, CA). Fat volumes were measured by a semiautomatic segmentation technique requiring manual definition of tissue borders. Fat within an area of interest was defined by pixels with characteristic Hounsfield units (HU; window width −195 to −45 HU; window center −120 HU). The area of interest for TAT was defined anteriorly by the area immediately surrounding the thoracic aorta (defined by a line drawn horizontally through the esophagus, which connected to the left costovertebral joint) and posteriorly by the right lateral border of the vertebral body and the anterior edge of the vertebral body.[9] This resulted in a 6.75-cm column of fat (27 slices) surrounding the thoracic aorta. VAT was quantified on abdominal scans as previously described.[12] Briefly, the reader defined the area of interest by tracing the abdominal muscular wall and separating the subcutaneous from the visceral abdominal fat depot. These areas of interest were summed over the 25 abdominal slices. Intrareader and interreader (assessed between 2 readers) reproducibility was excellent for both TAT and VAT, with intraclass and interclass correlations >0.98.[9,15] A visual representation of the methodology for measuring TAT is presented in Figure 1.

Covariate Assessment

Covariates were measured at the seventh Framingham Offspring examination (1998–2001) and the first Third-Generation examination (2002–2005). BMI was defined as weight (in kilograms) divided by the square of the height (in meters). Waist circumference (WC) was measured at the level of the umbilicus. Current smoking was defined as smoking ≥1 cigarette per day in the past year. Alcohol use was assessed by physician-administered questionnaires, and dichotomized on the basis of consumption of ≥14 drinks per week (in men) or ≥7 drinks per week (in women). A physical activity index (PAI) score was calculated by summing the reported numbers for each level of activity, weighted by their estimated metabolic expenditure, as described previously.[16] The PAI ranges from a minimum score of 24, indicating 24 hours of

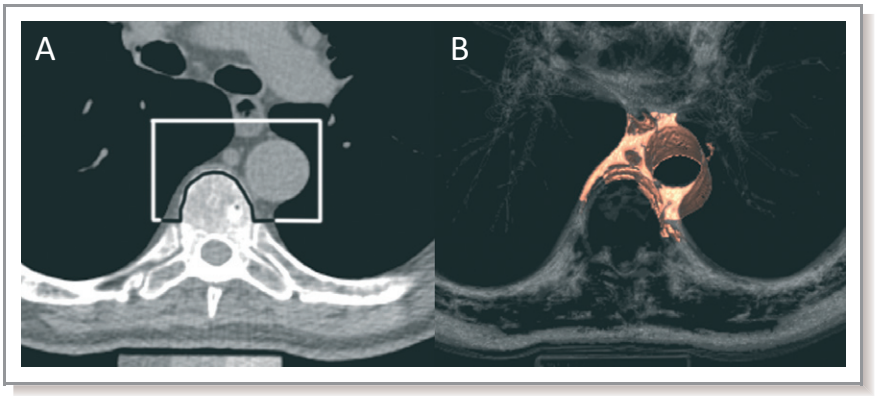

Figure 1. A, The region of interest drawn around the aorta using anatomic landmarks. Adipose tissue within this region of interest, defined as pixels with Hounsfield units between −195 and −45, is considered periaortic fat. B, 3D reconstruction. Reproduced from Fox et al (10) with permission from the publisher.[10]

sleeping, to a maximum score of 120, indicating 24 hours of heavy physical activity. Serum triglycerides, total and high-density lipoprotein cholesterol, and fasting plasma glucose were measured on fasting morning samples. Fasting plasma glucose ≥126 mg/dL or treatment with a hypoglycemic agent or insulin was used to define diabetes mellitus. Hypertension was defined as a systolic blood pressure ≥140 mm Hg, diastolic blood pressure ≥90 mm Hg or treatment with an antihypertensive agent. Metabolic syndrome was defined from the modified Adult Treatment Panel criteria.[17] If periods had stopped for >1 year, women were considered postmenopausal. Cardiovascular disease included coronary heart disease, stroke, intermittent claudication, and congestive heart failure.

Statistical Analysis

To determine the prevalence of high TAT, a healthy referent sample was created by hierarchical exclusion of participants with the following covariates: BMI≥30 kg/m^2 (n=874), presence of hypertension (or use of antihypertensive medications; n=562), triglycerides ≥150 mg/dL or lipid-lowering medication (n=424), low high-density lipoprotein (HDL) cholesterol (<40 mg/dL in men and <50 mg/dL in women; n=193), impaired fasting glucose, diabetes or use of hypoglycemic medications (n=215); prevalent cardiovascular disease (CVD; n=9); current tobacco smoking (n=118); BMI<18.5 kg/m^2 (n=12), and missing covariates (n=24), resulting in 499 women and 316 men. We defined high TAT as a sex-specific fat volume ≥90th percentile from the healthy referent sample. Sex-specific TAT volumes <90th percentile from the healthy referent sample were classified as normal. The 90th percentile was chosen to ensure adequate sample size in the healthy referent sample to provide statistically robust estimates for the fat volume cutoff values. This method used to determine the volume for high TAT was the same as that used for other fat depots in the Framingham Heart Study.[18,19] High TAT, by this definition, corresponded with volumes ≥10.2 cm^3 in women and ≥19.0 cm^3 in men. Prevalence estimates of high TAT were then determined in the overall sample (including those individuals who had been excluded from the healthy referent sample) and stratified by sex and the following age categories: 35 to 44, 45 to 54, 55 to 64, 65 to 74, and 75 to 84 years.

To establish the risk factor profiles associated with different patterns of TAT and VAT, we stratified our sample into 4 mutually exclusive categories on the basis of TAT and VAT volumes: (A) normal TAT and normal VAT, (B) high TAT but normal VAT, (C) high VAT and normal TAT, and (D) high TAT and high VAT. High VAT has been previously defined as ≥1359 cm^3 in women and ≥2323 cm^3 in men. Given the known correlation between TAT and VAT,[10] we examined differences in risk factor levels between the discordant categories (groups B versus C) using sex-specific age-adjusted analyses of covariance (ANCOVAs) and logistic regressions. Given that high VAT is already recognized as associated with an adverse cardiometabolic risk factor profile, we also examined differences in risk factors among individuals with normal VAT that were discordant for high TAT (groups A versus B). For these analyses, we used sex-specific ANCOVAs and logistic regressions adjusted for age as well as the volume of VAT. We also adjusted for VAT given that individuals with high TAT and normal VAT tended to have higher absolute volumes of VAT compared with those with normal TAT and normal VAT. We did not adjust for height given the lack of documented association between height and TAT (r=0.05, P=0.25 in women; r=0.01, P=0.75 in men)[11] We tested for an age interaction across the 4 different categories of TAT/VAT. When age interactions were significant, we performed additional analyses stratified by median age. Finally, we performed a sensitivity analysis restricting our sample to the Third-Generation cohort in whom risk factor assessment and MDCT scans were performed during the same period.

SAS version 9.1 was used to perform all computations. Two-sided P values <0.05 were considered significant. Because of the exploratory nature of this study, no adjustments were made for multiple comparisons.

Results

Overall, 1558 women and 1688 men for a total sample of 3246 individuals were included in this analysis. For the overall sample, the mean values for TAT in women and men were 9.9 and 17.5 cm^3, respectively. The characteristics of the sample population are described in Table 1.

Distribution of Thoracic Periaortic Fat in the Community

Sex- and age-specific TAT volumes are represented in Table 2. TAT volumes increased with age into the eighth decade for women and into the seventh decade for men for all percentiles of fat.

Prevalence of High Thoracic Periaortic Fat

The overall and age-stratified prevalence of high TAT, defined as ≥90th percentile in the healthy referent sample, is reported in Table 3. The overall prevalence for high TAT was 38.1% in women and 35.7% in men and increased with age (P value for linear trend <0.0001). As expected, the prevalence of high TAT increased with increasing BMI and waist circumference categories (Table 4).

§Defined as ≥14 drinks weekly for men and ≥7 drinks weekly for women.
‖Defined as fasting plasma glucose 100 to 125 mg/dL and not currently taking diabetes medication.

Cardiometabolic Risk Factor Profiles by Patterns of Thoracic Periaortic Fat and Visceral Adipose Tissue

Given the known high correlation between TAT and VAT (r=0.75, P<0.001),[11] we divided individuals into 4 categories on the basis of the presence or absence of high TAT and the presence or absence of high VAT to better evaluate the unique correlates of each fat depot. We then compared cardiometabolic risk factors between individuals with high TAT and normal VAT versus high VAT and normal TAT. In addition, among individuals with normal VAT, we compared cardiometabolic risk factors among individuals discordant for high TAT.

In the overall sample, 16.4% of women and 18.8% of men were discordant for high TAT and high VAT. Comparing discordant groups, women with high TAT and normal VAT compared with high VAT and normal TAT were older but tended to have lower measures of clinical adiposity and better cardiometabolic risk factor profiles after adjusting for age (Table 5). In contrast, men with high TAT and normal VAT compared with high VAT and normal TAT were older and had a lower waist circumference, but otherwise the cardiometabolic profiles were not significantly different (Table 5).

Among individuals with normal VAT, high TAT compared with normal TAT was associated with a more adverse cardiometabolic profile. Specifically, these individuals were older and had a higher prevalence of the majority of cardiometabolic risk factors, including a higher prevalence of metabolic syndrome (Table 5). Findings were similar when we also adjusted for BMI (data not shown). However, individuals with high TAT and normal VAT also had a higher absolute volume of VAT compared with individuals with normal TAT and normal VAT. Given this difference in VAT volumes, our findings presented in Figure 2 reflect additional adjustment of these models for the absolute volume of VAT. In these models, the presence of high TAT was associated with prevalent CVD in both sexes (age- and VAT-adjusted P=0.01 in women, Figure 2A; and P=0.004 in men, Figure 2B). In addition, among women with normal VAT, high TAT was associated with significantly lower HDL levels (P=0.005) (Figure 2A). In men with high TAT and normal VAT, there was a higher prevalence of smoking (age-VAT-adjusted P=0.02) and higher BMI (P=0.004) compared with individuals with normal VAT and normal TAT. After adjustment for the volume of VAT, the difference in the prevalence of metabolic syndrome was no longer different between those with high TAT versus normal TAT. When we reexamined the association of high TAT versus normal TAT with CVD prevalence after adjustment for low HDL and current smoking (in addition to adjustment for age and volume of VAT), there remained a significant association in both women (P=0.02) and men (P=0.01).

There were multiple significant age interactions across the 4 categories of TAT/VAT categories. Thus, we performed analysis stratified by median age. The results were generally similar to the overall findings (data not shown). Finally, in our sensitivity analysis limited to the Third Generation cohort, who underwent risk factor and MDCT assessment during the same time period, findings were overall similar (Table 6).

TAT indicates thoracic periaortic fat.
*Excess TAT defined as ≥90 percentile of the sex-specific cut points (≥10.2 and ≥19.0 cm^3 in women and men, respectively) in a healthy referent sample.
†Fifteen women and 54 men from the total sample were either <35 years of age or missing information on age and therefore were excluded from this analysis.

Discussion

In our community-based sample, more than a third of individuals had high TAT. In the absence of high VAT, excess TAT identified a subset of individuals with a higher prevalence of adverse cardiometabolic characteristics compared with individuals without high TAT even after adjustment for total volume of VAT. This included a higher prevalence of CVD in both women and men, lower HDL levels in women, and a higher prevalence of current smoking in men. These findings provide a better understanding of the risk factor correlates of TAT, a specific subtype of perivascular fat. Further experimental studies are required to elucidate whether TAT is pathogenic.

Multiple basic science and small clinical studies have suggested a local effect of perivascular fat that changes with the development of obesity.[5,6,8] Previous work in the

Table 4. Sex-Specific Prevalence (Standard Error) of High TAT* by BMI and Waist Circumference Category

BMI Category	Women (n=1544)	Men (n=1674)	Waist Circumference Category	Women (n=1539)	Men (n=1671)

VAT indicates visceral adipose tissue; TAT, thoracic periaortic fat; BMI, body mass index; HDL, high-density lipoprotein; CVD, cardiovascular disease.

*TAT and VAT categories are defined as high if ≥90th percentile sex-specific cut points in healthy referent sample. High TAT corresponded to volumes ≥10.2 and ≥19.0 cm^3 in women and men, respectively. High VAT has been previously defined as ≥1359 cm^3 in women and ≥2323 cm^3 in men.

†Sample sizes vary from row to row, as available data were used for a given characteristic.

‡Defined as fasting plasma glucose 100 to 125 mg/dL and not currently taking diabetes medication.

§Defined as ≥150 mg/dL or lipid treatment.

‖Defined as <40 mg/dL (men) and <50 mg/dL (women).

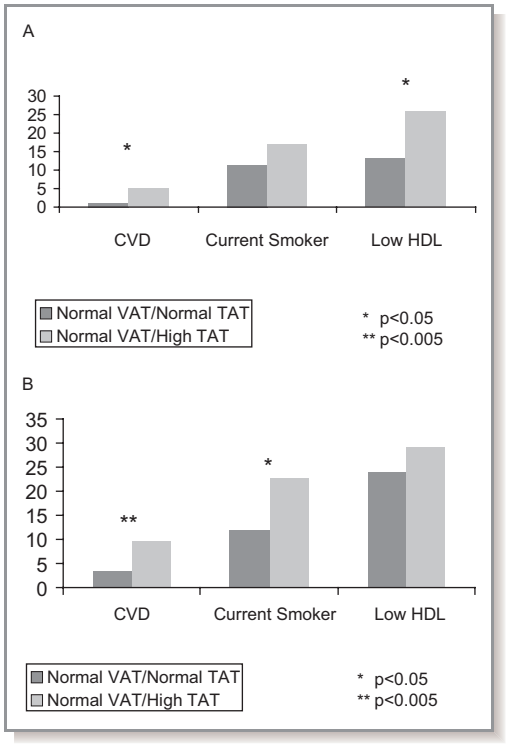

Figure 2. Differences in cardiometabolic features among (A) women (n=873) and (B) men (n=977) with normal VAT/normal TAT vs normal VAT/high TAT. Prevalence rates and *P* values are adjusted for age and volume of VAT. CVD indicates cardiovascular disease; HDL, high-density lipoprotein; TAT, thoracic periaortic adipose tissue; VAT, visceral adipose tissue.

Framingham Heart Study has demonstrated a novel and reliable method of quantifying thoracic periaortic fat by MDCT.[9] We now present a comprehensive age- and sex-specific description of TAT distribution in a community-based sample and report differences in cardiometabolic features among subcategories of TAT and VAT.

Our findings that more than one third of individuals in the community had high TAT is similar to our previous reports of fat depots, including VAT, pericardial, and intrathoracic fat.[18,19] Despite this similar prevalence among various fat depots, our findings suggest that a high volume of TAT is associated with adverse cardiometabolic features among the subset of individuals with normal VAT. Prior work has highlighted the existence of "metabolically obese normal weight individuals" who exhibit glucose intolerance and hyperinsulinemia despite a normal BMI.[20] Differences in visceral adiposity have been postulated to contribute to this phenotype.[21] Our findings suggest that high thoracic periaortic fat may also identify a "metabolically obese" group among individuals who do not meet criteria for excess VAT. Some of these differences, such as the higher prevalence of CVD, are present in both sexes. However, others are sex specific, with a prevalence of low HDL higher in women than men. This finding is consistent with prior literature suggesting stronger associations of ectopic fat and metabolic risk factors in women compared with men. However, the prevalence of current smoking was higher in men than in women with high TAT/normal VAT compared with normal TAT/normal VAT.

TAT is directly wrapped around the aorta, and this distinct anatomic location may explain the specific association between high TAT and CVD among individuals with normal VAT. TAT may serve as a marker of perivascular fat throughout the body including smaller blood vessels, and perivascular fat has been postulated to have adverse effects on the vasculature.[4,5] Supporting this, prior work in the Framingham Heart Study has demonstrated an association between TAT and both abdominal aortic calcium and coronary artery calcium among individuals without known cardiovascular disease. These associations persisted after adjustment for VAT and standard cardiovascular risk factors.[10] Alternatively, our findings that high TAT was associated with CVD among individuals with normal VAT may reflect that these individuals were more likely to have a higher prevalence of certain CVD risk factors, including low HDL in women and smoking in men.

Our findings of a difference in the prevalence of smoking among men with normal VAT but discordant for TAT deserves specific comment. Smokers tend to have a lower body weight but are known to have a higher risk of cardiovascular disease. Ectopic fat distribution, specifically higher volumes of VAT, is already known to differ between smokers and nonsmokers.[22] We have extended these findings among individuals with normal VAT by demonstrating a higher prevalence of male smokers among individuals with high versus normal TAT. These findings are noteworthy given the potential modulating role of nicotine on perivascular fat previously demonstrated in animal models.[23] Specifically, exposure of rats to nicotine prenatally and during lactation led to an increase in total adiposity as well as perivascular fat in the offspring compared with controls. Furthermore, the normal anticontractile effect of perivascular fat on blood vessels was no longer present in nicotine-exposed offspring, but was restored with the transfer of the medium surrounding normal fat. Thus, nicotine was associated with higher volumes as well as dysfunction of perivascular fat. These findings are consistent with prior work suggesting that excess perivascular adipose tissue disrupts the normal contribution of perivascular fat to vascular tone[24] and further suggest that nicotine may contribute to this process. Other studies also support a potential role of nicotine on adipose tissue.[25,26] For example, differences in adipose tissue lipoprotein lipase activity have been found between smokers and nonsmokers.[25] Thus, elucidation of the full expression profile of perivascular fat in response to nicotine may help to extend our observational findings.

VAT indicates visceral adipose tissue; TAT, thoracic periaortic fat; BMI indicates body mass index; CVD, cardiovascular disease; HDL, high-density lipoprotein.

*TAT and VAT categories are defined as high if ≥90th percentile sex-specific cut points in healthy referent sample. In the Third Generation, high TAT corresponded to volumes ≥8.79 and 15.72 cm^3 in women and men, respectively. High VAT has been previously defined as ≥1359 cm^3 in women and ≥2323 cm^3 in men.

†Sample sizes vary from row to row, as available data were used for a given characteristic.

‡Defined as fasting plasma glucose 100 to 125 mg/dL and not currently taking diabetes medication.

§Defined as ≥150 mg/dL or lipid treatment.

‖Defined as <40 mg/dL (men) and <50 mg/dL (women).

Strengths and Limitations

The major strength of our study is the relatively large sample size and community-based nature of the cohort. This allowed exploration of differences within subgroups of TAT and VAT and limited referral bias. We assessed TAT and VAT using a highly reproducible CT volumetric assessment. Certain limitations warrant discussion. The cross-sectional and observational design of the analysis prevents inferences of causality or temporality. The Framingham Heart Study is predominantly white, and results cannot be generalized to other ethnic groups. We did not have information on the severity of CVD. Our analyses were exploratory, and we did not account for multiple testing. Replication of our findings in independent cohorts is warranted. There were temporal differences between the MDCT scans and the risk factor assessments among the Offspring cohort. However, our sensitivity analysis limited to the Third-Generation cohort (in which MDCT scans and risk factor assessment occurred during the same period) demonstrated overall similar findings. Finally, our findings do not suggest that TAT quantification should be used as a clinical tool.

Conclusions

Elevated TAT is prevalent in the community and is associated with adverse cardiometabolic features, including CVD, smoking, and low HDL among individuals with normal VAT. Further work to better understand the biology of TAT and its association with metabolic and cardiovascular disease may provide insight into a potentially unique pathogenic role of periaortic fat.

ABSTRACT

We evaluated the validity of questions designed to identify lifetime and active epilepsy, medication use, and seizure occurrence on population-based surveys. Subjects were interviewed by telephone, and responses were compared with information in their medical records. Prevalence, sensitivity, specificity, and positive predictive value (PPV) were calculated. The prevalence of ever having been diagnosed with epilepsy was 3.1% by self-report and 2.7% by medical record review. Sensitivity was 84.2%, specificity was 99.2%, and PPV was 73.5% for self-reported lifetime epilepsy, and values were similar for active epilepsy. By comparison, sensitivity was higher and specificity was lower for epilepsy medication use and seizure occurrence. The PPV for seizure occurrence was substantially higher for a recall period of 12 months than for 3 months. These results compare favorably with results for other chronic conditions, such as diabetes and arthritis, and indicate that questionnaires can be used to identify epilepsy at a population level.

1. Introduction

Epilepsy is one of the most common neurological disorders in the United States [1,2]. Depending on the region and methods of measurement, recent prevalence estimates range from 0.6 to 2.0% for lifetime epilepsy and from 0.5 to 1.0% for active epilepsy [3-8].

Epilepsy has important effects on physical activities and emotional health and can lead to diminished social functioning and decrements in health-related quality of life [5,9,10]. Persons with epilepsy are more likely to report fair or poor health status and more unhealthy days than persons without epilepsy [5,10], and persons with active epilepsy report worse health than those with inactive epilepsy. Adults with epilepsy are also more likely to report being depressed than those without epilepsy, and are significantly more likely to smoke, not exercise, and be obese than people without epilepsy [3,11]. Given the significance of this condition, it is important to conduct population-based surveillance of epilepsy to measure its prevalence and monitor changes over time, identify variability in population subgroups, and provide information for purposes of planning and targeting interventions for those with epilepsy.

Various methods have been used to identify patients with epilepsy in prevalence studies. Hauser et al. used a database with detailed medical information from their large epidemiological study of Rochester, MN, USA, to identify patients with epilepsy [12]. Others have used individual practices' medical records to identify epilepsy cases [13]. Although both of these methods provide accurate epilepsy identification, they are not feasible for assessing epilepsy in larger community-wide populations, nor are they feasible for continuous monitoring.

Measurement of epilepsy prevalence in a community population can be accomplished through the use of surveys. The Epilepsy Group at the Centers for Disease Control and Prevention (CDC) developed a set of five questions (Table 1) to assess the prevalence and impact of epilepsy. Prevalence of epilepsy is determined by the first three questions in the set. Although these questions have been used in numerous surveys, including the Behavioral Risk Factor Surveillance Survey (BRFSS), the California Health Interview Survey (CHIS), and the Healthstyles Survey [3,5-8,10,11,14], they have not previously been subject to validation. The present study sought to validate the questions used to estimate epilepsy prevalence by comparing patients' responses with documentation in their medical records.

Table 1
Epilepsy screening questions.

1. Have you ever been told by a doctor that you have a seizure disorder or epilepsy?
2. Are you currently taking any medicine to control your seizure disorder or epilepsy?
3. How many seizures of any type have you had in the last 3 months?
4. In the past year, have you seen a neurologist or epilepsy specialist for your epilepsy or seizure disorder?
5. During the past month, to what extent has epilepsy or its treatment interfered with your normal activities like working, school, or socializing with family or friends?

2. Methods

2.1. Study population

The study was conducted among a sample of patients at Boston Medical Center (BMC) in Boston, MA, USA, who were ≥18 years old, able to speak English, and cognitively able to participate in a telephone interview. BMC is an urban multispecialty teaching hospital that provides primary and specialty care and is also a major source of care for low-income residents and immigrants. The study was approved by the Boston University Medical Center Institutional Review Board.

Because a simple random sample of patients would yield few cases of epilepsy, we sampled patients after stratifying according to probability of having an epilepsy diagnosis. To identify putative epilepsy cases, we searched the electronic administrative/billing and medical record system, which covers visits back to 2000, for all patients with an ICD-9 code of either 345.XX[1] or 780.39 or a listing of the terms "epilepsy" or "seizure disorder" in the medical record problem list. Similar methodology has been used by others to identify epilepsy cases using ICD-9 codes [15-18]. For putative noncases, we started with a list of all patients who had a doctor in the primary care clinic and who met the general study eligibility criteria, and removed persons who met the criteria for putative cases.

We narrowed the sampling frame for both putative cases and noncases to patients who had made either: (1) two or more visits to the primary care or neurology clinics within the past 2 years, or (2) one visit to the primary care clinic or neurology clinic and at least one nonemergency inpatient visit within the past 2 years. This criterion was imposed to increase the likelihood that there would be a current telephone number for contacting subjects as well as sufficient information in the medical record to establish the validity of their survey responses. Because of these concerns, subjects whose only contact with BMC was through the emergency department were excluded. Although the emergency department is a potentially important point of care for persons with epilepsy, a preliminary review of medical records found that information documented in the record of an emergency department visit was insufficient to identify a case of epilepsy unless there were also other visits to BMC. A random sample of eligible putative cases and noncases were then selected to be contacted for a phone interview.

2.2. Data collection

Patient information was obtained from different sources; those used in this analysis include the administrative/billing database, telephone interviews, and medical chart reviews. The administrative/billing database provided basic demographics: sex, age, race/ethnicity, marital status, zip code of residence (which together with 2000 Census data was used to assign the median neighborhood income to each subject), medical insurance information, and health care utilization data.

2.3. Patient recruitment and telephone interviews

Interviews were conducted over a 10-month period from December 2006 to October 2007. After receiving permission from their neurologist or primary care physician, we used telephone numbers from the administrative record to contact potential respondents. Trained interviewers made a minimum of nine attempts to reach each patient at different days and times, including evenings and weekends. For patients we were unable to contact and who had made a subsequent visit to BMC, we consulted the administrative record for an updated telephone number. On reaching a potential respondent, we described the study in a general manner that did not reveal its purpose or its focus on epilepsy. Persons who agreed to participate were consented by phone and administered the questionnaire; no proxy respondents were permitted. All interviews were conducted in English. The average length of the interview was 15 minutes.

The telephone interview questionnaire (see Appendix for entire survey instrument) contained the five Behavioral Risk Factor Surveillance System (BRFSS) screening questions regarding epilepsy (Table 1), as well as the VR-12 Health Survey instrument, BRFSS Healthy Days questions, and demographic items. We also added several supplementary epilepsy and seizure-related questions designed to provide more detail and help interpret answers to the screening questions. Questions included age at first diagnosis, causes of seizures if not epilepsy, number of seizures (lifetime and past 12 months), and site of medical care for ongoing epilepsy treatment and for most recent seizure. All five screening questions were asked of all study participants regardless of their responses to a previous item. To assess reliability of responses, we called back 50 putative cases within 4–6 weeks of their initial interview and readministered the screening questions and selected additional items.

2.4. Medical chart reviews

Data collection from the medical charts of telephone questionnaire respondents was performed by specially trained research staff with a clinical background. The chart review instrument comprised clinical variables capable of validating the screening questions and was developed based on the input of study epileptologists and neurologists. The form and protocols for the chart reviews were developed and tested in an iterative fashion to accommodate the variability in chart documentation as practiced in different settings and by different physicians. The chart review forms are available from the corresponding author (L.E.K.).

The reviewers abstracted data related to epilepsy, including its assessment, treatment, side effects, and complications, using clinician notes for primary care and specific medical subspecialty visits, as well as documented data on emergency department and inpatient visits. Chart reviews covered the period that a patient began receiving care at BMC beginning as far back as 2000, when the electronic medical record system first became operational, through the date of the phone interview. The note from each visit was reviewed and

[1] 345 is a nonspecific code for epilepsy; epilepsy diagnosis is usually documented with 345 and single- or double-digit index entries: 345.xx. 780.39 is a nonspecific code for seizures.

information on diagnoses, seizure history, referrals, and changes in medications contained in the note was entered onto the data abstraction instrument. Abstractions were aided by a glossary of medical terms, which also contained the names of all medications used in the treatment of epilepsy and described each respective class of drugs.

Specific data elements captured fell into three general categories: demographics and utilization of services, seizure history and diagnosis, and treatment and medications. The seizure history and diagnosis section included the occurrence, frequency, and recurrence of seizures and diagnoses of epilepsy or "seizure disorder." The treatment and medications section covered dosage and frequency and whether a recent change had been made in the medication. Diagnoses of other medical conditions were also collected from the chart and used to construct indices of physical and mental comorbidities [19].

A sample of records were reviewed a second time by a second abstractor to determine interrater reliability. A higher percentage of charts were tested during the first 2 months of data abstraction to identify and correct any areas of particularly high disagreement among the abstractors.

2.5. Validation of epilepsy test items

We used information collected from patient medical records at BMC as the standard against which to compare self-report data from the telephone questionnaire for screening questions Q1–Q3 (Table 1). A diagnosis of epilepsy (Q1) was confirmed based on documentation in the patients' medical record. Medical records documented the clinical histories of epilepsy, as well as EEG and other neuroimaging test results, blood work, and referrals with varying degrees of detail. Thus, we accepted physician diagnoses as evidence of epilepsy when these were documented in the medical record without ambiguity or inconsistency. However, when ambiguities were noted, an epileptologist G.M. who was an internal consultant to the study and familiar with the study protocols reviewed the record, considering all available clinical information in the charts, including test results, to make the case determination.

The criterion for a diagnosis of epilepsy was explicit mention of "epilepsy" or "seizure disorder" in either a clinician note or the patient's problem list. Current medication use (Q2) was confirmed based on prescriptions noted in the medical record at the time of the telephone interview. Occurrence of seizures in the past 3 months (Q3) was validated based on mention of a seizure at any visit to BMC during that time frame as calculated from the date of interview. We were also interested in the validity of 12-month recall of seizures and so included this item in the telephone questionnaire, which was validated as described above but for a 12-month period.

2.6. Statistical analysis

All data from administrative records, questionnaires, and chart reviews were entered into a relational database and linked by a common study ID number. We first calculated the adjusted response rate as the number of completed interviews divided by the total sample excluding those determined to be ineligible and those expected to be ineligible among those who were not contacted based on the proportion ineligible among those contacted [20,21]. We also calculated the cooperation rate (completed interviews as proportion of potential respondents reached and determined to be eligible). Response rates are reported separately for putative epilepsy cases and noncases and stratified by the demographic, utilization, and clinical factors listed in Tables 2A and 2B.

The primary measures used to assess the accuracy of Q1–Q3 were sensitivity, specificity, positive predictive value, and the difference in the estimate of prevalence based on self-report versus chart-based data. Because the sample had been constructed to oversample persons likely to have epilepsy, we weighted three strata, as identified hierarchically in the electronic billing system [putative cases based on (1) ICD-9 345.1 or (2) ICD-9 780.39 or problem list mention, and (3) putative noncases], so that their distribution would be more representative of a sample randomly drawn from a community-based population. We weighted the data to the distribution of the three strata in the electronic billing system for patients who attended the Primary Care Center at BMC, which we took as the closest approximation to a community-based sample among the BMC patient population. The distribution of the three strata was 1.76% for 345.1 putative cases, 2.44% for 780.39 putative cases, and 95.8% for putative noncases. We weighted each stratum so that it summed to its proportion of the total sample size. Weights were equal to 0.064, 0.131, and 4.46 for the three strata, respectively.

Using the weighted data, we first calculated measures of validity for reported lifetime and active epilepsy. We defined reported lifetime epilepsy as an affirmative answer to the first screening question: "Have you ever been told by a doctor that you have a seizure disorder or epilepsy?" We defined active epilepsy as a report of lifetime epilepsy along with (1) currently being on medication for epilepsy and/or (2) having had a seizure in the past 3 months [5-8]. We also tested an alternative definition in which the period of last seizure was extended to 12 months. We excluded seven participants who could not be categorized as self-reporting lifetime or active epilepsy because they responded "don't know" or "refused" to the relevant questions.

We also assessed validity of lifetime and active epilepsy stratified by demographic (sex, age, race, median income of zip code of

residence), utilization (most recent visit before initial phone contact, total number of neurology and primary care visits in past 2 years), and clinical (physical health comorbidities, mental health comorbidities) variables. We summed the current physical and mental health comorbidities based on ICD-9 codes listed in the administrative/billing database from 30 physical health and 6 mental health conditions that constitute the Selim Comorbidity Index, a previously validated measure [19]. However, we excluded seizures, which is one of the conditions in the original index.

One analytical complication in the stratified analysis arose from the presence of a single false-positive report of epilepsy among the 215 subjects in the putative noncase stratum, all of whom were determined not to have epilepsy by chart review. Because subjects in this stratum had such large weights relative to the two putative case strata, the demographic or clinical category that happened to contain this individual always had lower accuracy than other strata. Because of its distorting effect on the results, we excluded this one observation from the analysis of stratum-specific measures.

We used the same accuracy measures to evaluate the performance of Q2 and Q3. We restricted analyses to respondents with self-reported lifetime epilepsy, regardless of confirmation by chart review, as this represented the performance of the questions as they would function in an actual survey setting where all respondents who answered affirmatively to the first question would be asked the remaining questions. We again excluded the single putative noncase with a false-positive report of lifetime epilepsy. This individual constituted the only observation in this stratum and greatly inflated the standard error while providing essentially no information about the true distribution of responses. Therefore, the analysis included only the two putative case strata, which together accounted for 86% of the weighted value of all participants with self-reported epilepsy.

For all of the above analyses, we used the SVYSET procedure in STATA 10.1, accounting for different weights and the stratified sampling scheme [22]. Because the standard symmetric confidence intervals based on the normal approximation to the binomial are increasingly inaccurate at proportions very close to 0 or 1, we calculated asymmetric 95% confidence intervals based directly on the binomial distribution [23].

3. Results

We sampled a total of 1727 putative epilepsy cases (1033 ICD-9 345.xx, 694 ICD-9 780.39) and 1100 putative noncases. Compared with the latter, putative cases were more likely to be white (38% vs 19%), have made fewer visits to BMC in the past 2 years (one to three visits: 43% vs 30%), and have fewer physical health comorbidities (none or one comorbidity: 41% vs 22%). Among the putative epilepsy cases, 332 were ineligible, 580 could not be reached, 348 refused to be interviewed, and 467 completed the telephone interview. The corresponding figures among putative noncases were 209 ineligible, 387 unable to be reached, 288 refused, and 216 completed.

Response rates were 38% among putative cases and 28% among putative noncases, whereas the cooperation rates were 57 and 43%, respectively (Table 2A). Response and cooperation rates were higher for putative cases than noncases in virtually all demographic, utilization, and clinical categories. Factors associated with higher response rates among both putative cases and noncases included more recent visit to BMC, greater number of visits in past 2 years, and more physical health comorbidities. Among putative noncases, response rates were also higher among persons with a larger number of mental health comorbidities. Differences in response rates between putative cases and noncases were particularly large among those who were residents of the lowest income tertile of zip codes (39% vs 23%), had not been to BMC for >1 year (25% vs 7%), and had made 1–3 (34% vs 18%) or ≥10 (47% vs. 32%) visits to BMC in the past 2 years.

3.1. Lifetime and active epilepsy

The results for the validation of lifetime and active epilepsy are summarized in Table 3. The prevalence of lifetime epilepsy in this sample was 3.1% by self-report and 2.7% by chart review. Sensitivity and specificity of self-reported lifetime epilepsy were 84.2 and 99.2%, respectively, and the positive predictive value (PPV) was 73.5%. Approximately 85% of subjects with lifetime epilepsy had active epilepsy by both chart review and self-report. Of the 302 patients with active epilepsy based on chart review, only one was

Sensitivity	84.2 (79.3–88.1)	81.1 (75.8–85.5)
Specificity	99.2 (97.5–99.7)	99.3 (97.5–99.8)
Predictive value		
Positive	73.5 (48.1–89.2)	73.9 (43.3–91.3)
Negative	99.6 (99.4–99.7)	99.5 (99.4–99.7)

[a] Lifetime epilepsy: reported ever being told by a doctor that had epilepsy or a seizure disorder.
[b] Active epilepsy: lifetime epilepsy plus reported currently taking medicine for epilepsy or a seizure disorder OR reported having a seizure within the past 3 months.

not taking medication but had had a seizure in the 3 months prior to the interview. Sensitivity, specificity, predictive value, and the difference in active epilepsy prevalence between self-report and chart review were almost the same as for lifetime epilepsy. Extending the time since last seizure to 12 months had almost no impact on the prevalence or accuracy of active epilepsy, because the great majority of respondents qualified on the basis of taking medication.

Table 4 outlines the results of a stratified analysis of the accuracy of active epilepsy based on demographic and clinical variables. Prevalence measured by self-report was generally lower than that measured by chart review, but differences were generally small (range: 0.1–0.8%). Measures of specificity also varied within a small range (99.5–100%). There were no significant differences in sensitivity, but rates were lower for older adults and those who had not visited BMC for ≥6 months. Persons with mental comorbidities had a significantly lower PPV than those without any comorbidities.

We also used logistic regression analysis to simultaneously adjust for all the characteristics in Table 4 to identify the primary predictors of a false (positive or negative) response for active epilepsy. The odds of a false response were higher among subjects who were male, had more physical or mental comorbidities, and had not visited BMC for ≥6 months (data not shown).

We also conducted a supplementary analysis to explore reasons for the false-positive responses for lifetime epilepsy. Because Q1 asks "Have you ever been told by a doctor that you have a *seizure disorder* or *epilepsy*," we hypothesized that false-positive responses were more likely to occur among subjects who had experienced a seizure which had not been diagnosed with epilepsy. A subsequent question in the telephone interview asked whether patients were specifically diagnosed as having epilepsy or another seizure disorder, and 62% of false-positive responses named some sort of seizure disorder but not explicitly epilepsy, compared with 41% of true-positive responses.

The medical history of the single false-positive case from the putative noncase stratum illustrates the potential for this problem. In addition to responding affirmatively to the question about lifetime epilepsy, the subject also reported currently using medication for epilepsy or seizure disorder. In response to follow-up questions, the subject could not say whether the diagnosis was epilepsy or something else. Review of the medical record revealed that the subject had suffered serious head trauma several years ago. The subject was started on an antiseizure medication (phenytoin), which appears to have been discontinued. The subject reports never having any seizures in two separate sections of the questionnaire, and there is no evidence of seizures in the medical record. On the basis of these facts, we suggest that the subject likely was told of the risk of seizure following the head trauma and therefore interpreted the term *seizure disorder* in the questionnaire as applicable. The subject continues to be followed for chronic headaches, which are likely linked in the subject's mind to the underlying "seizure disorder" resulting from the head trauma and, therefore, may explain the affirmative answer to current use of medication for a seizure disorder.

3.2. Medication use and seizure occurrence

The prevalence of current medication use among those who self-reported having epilepsy was similar by self-report and chart review (78.3% vs 81.8%) (Table 5). Sensitivity was 90% and specificity 74%. As expected given the high prevalence, the PPV (93.9%) was higher than the negative predictive value (62.1%). The sensitivity

[a] Excludes single false-positive putative non-case (see Methods).

and specificity of report of seizure occurrence in the past 3 months were very similar to those for medication use. However, there was a substantial difference in seizure prevalence between self-report and chart review (35.1% vs 19.3%). The PPV was 49.5%. When seizure occurrence in the past 12 months was substituted for the 3-month recall period, the prevalence of both self-reported and chart-verified seizure increased substantially to 51.9 and 39.2%, respectively, although there was little change in the extent of the difference between the two measures (15.8% at 3 months and 12.7% at 12 months). Other measures of validity were also similar with the exception of the PPV, which increased from 49.5% for 3-month to 69.4% for 12-month recall.

It is possible that the low PPV and substantial disparity between self-reported and chart-based prevalence of seizure were due not to a problem with the question or subjects' memory, but rather to the fact that we only had access to BMC medical records. If an individual had a seizure that was not treated or was treated elsewhere and not documented in the BMC medical record, the response would have been classified as a false positive. Subjects who were classified as making true-positive responses were more likely than those classified as making false-positive responses to report having come to BMC for treatment of their last seizure (66% vs 35%). To better understand the possible impact of treatment location, we reanalyzed the data for 3-month recall based on the assumption that the ratio of true to false positives among those who did not go to BMC for care of their last seizure would have been the same as for those who did get care at BMC. The difference between self-reported and chart-based prevalence decreased from 15.8 to 10.4%, whereas sensitivity increased by 2.9%, specificity by 8.7%, and the PPV by 17.4%.

Among the 50 subjects who were interviewed a second time to assess test–retest reliability, κ values were 0.64 for lifetime epilepsy, 0.88 for medication use, and 0.65 for seizure occurrence.

4. Discussion

Well-validated epilepsy screening assessments are important for purposes of monitoring both the burden of epilepsy and the needs of people with epilepsy at a community level. Tools for surveillance systems are important for planning health care delivery systems, designing appropriate clinical care services, and designing and implementing preventive services for policy makers interested in future resource allocations. The results of this study indicate that the questions developed by the CDC Epilepsy Group are valid for the identification of epilepsy. Sensitivity and specificity exceeded 80 and 99%, respectively, for both lifetime and active epilepsy. In addition, prevalence as measured by self-report was within 0.4% of the estimate based on chart review prevalence for lifetime and active epilepsy. The absolute estimates of self-report prevalence, specificity, and PPV were higher in the stratified results than in the overall analysis, which was due to the exclusion of the single false-positive putative noncase who had a highly disproportionate effect on the estimates. However, the focus in the stratified analysis should be on the relative variation in estimates between strata rather than the absolute level. Few meaningful differences were seen for any measure by stratum of demographic, clinical, or medical care utilization characteristics. However, being male, having more physical or mental comorbidities, and not having visited BMC for $\geq$6 months were associated with inaccurate responses.

The study used a stratified sampling design which greatly overrepresented people with epilepsy. Had we used a simple random sample, it would have been necessary to interview more than 10,000 subjects to identify the same number of people who reported having epilepsy. We weighted our data to reflect the prevalence of putative epilepsy among primary care patients as a proxy for a community-based sample. It was important to weight the sample in this manner because the PPV of self-reported epilepsy is affected by the prevalence in the population in addition to the accuracy of the test. Had the data not been weighted, the estimate of the PPV would have been artificially high. Even so, probably because the sample was drawn from a medical setting, the prevalence of epilepsy—both self-report and chart-based—was somewhat higher in our study than in community-based estimates, particularly for active epilepsy.

In our study, we asked all the screening questions of each subject regardless of how they responded to the first question concerning whether they had ever been told they had epilepsy or a seizure disorder. In a typical setting, however, only persons responding affirmatively to this question would proceed to the subsequent questions. The PPV provides information regarding the universe of people being asked the remaining questions and the proportion who actually have epilepsy. Both lifetime and active epilepsy had a PPV of 74%, although the estimate was somewhat imprecise (as reflected by the wide confidence intervals) owing to the influence of the false-positive putative noncase. Based on this estimate, it appears that approximately one of four people answering the remaining questions does not actually have epilepsy.

The levels of sensitivity and specificity in this study are similar or higher than have been reported in studies that assessed the validity of self-report compared with medical records for other chronic conditions. For example, a study of 599 HMO subscribers in Colorado compared telephone self-report for diabetes with medical records and found 73% sensitivity and 99.3% specificity [24]. A similar study among $\geq$45-year-old residents of Olmsted County, MN, USA, that used self-administered questionnaires showed 66% sensitivity and 99.7% specificity for diabetes [25]. A study that compared telephone self-report of arthritis with rheumatologist examination found a sensitivity of 70.8% and specificity of 70.3% [26]. Diabetes and arthritis exhibit similarities to epilepsy in that all three conditions are long-lasting and share similar impacts on quality of life including physical, psychological, and social functioning.

There are also some limitations to this study. Despite multiple efforts to contact and enroll subjects, the response and cooperation rates were low, as might be expected among a disproportionately low-income and transient population. Despite the fact that we did not mention that the study concerned epilepsy, the rates were higher for persons with putative diagnoses of epilepsy. To the extent that subjects in the study differed in the accuracy of their responses compared with those who did not participate, our results could have been affected. However, as previously noted the results of this study are comparable to those reported in other studies assessing the validity of self-report compared with medical records. The biggest differences between responders and nonresponders was that those who responded were more likely to have more contact, and more recent contact, with BMC and were also more likely to have more physical and mental comorbidities. More recent contact was also associated with greater accuracy, which would suggest that the

observed measures of sensitivity and specificity may be somewhat overstated. However, this effect appears to be modest because only 13% of subjects had not had recent contact.

There are also limitations to using chart review as the validation standard. For patients whose main source of epilepsy care is elsewhere, there may not be sufficient documentation in the BMC record to validate the screening questions and the occurrence of seizures, as suggested by the the fact that subjects categorized as false positive were more likely to have reported receiving care for the most recent seizure elsewhere or not at all. Additionally, the independence of charts from patient self-report may be overestimated. The source of documentation of a seizure occurrence in a chart may be the patient's self-report to the physician, which can make seizures particularly problematic to validate using medical records, unlike other conditions such as hypertension and hypercholesterolemia that can be measured using objective tests in a clinical setting. Even the presence of lifetime epilepsy in the medical record may rely on the patient's self-report, particularly if he or she is an inactive case with no current seizures or medication use.

Finally, our sampling frame in general may not be generalizable to a community sample or sample with different sociodemographic characteristics. We worked with a population receiving care in an urban tertiary care setting and, in particular, one of the only safety-net hospitals in the area that provides free care. Therefore, subjects included in this study are likely sicker and more disabled, as well as poorer and less likely to have health insurance, than a general community-based sample. Thus, it would be useful to replicate this study in other populations to assess the generalizability of these findings.

In summary, for population surveillance of epilepsy prevalence, as well as medication use and seizure occurrence, future population-based assessments using these items can provide important information regarding the prevalence and characteristics of epilepsy in the US population.

Abstract

Background—Optimizing post-discharge medication adherence is a target for avoiding adverse events. Nevertheless, few studies have focused on predictors of post-discharge medication adherence.

Methods—The Pharmacist Intervention for Low Literacy in Cardiovascular Disease (PILL-CVD) study used counseling and follow-up to improve post-discharge medication safety. In this secondary data analysis, we analyzed predictors of self-reported medication adherence after discharge. Based on an interview at 30 days post-discharge, an adherence score was calculated as the mean adherence in the previous week of all regularly scheduled medications. Multivariable linear regression was used to determine the independent predictors of post-discharge adherence.

Results—The mean age of the 646 included patients was 61.2 years, and they were prescribed an average of 8 daily medications. The mean post-discharge adherence score was 95% (SD = 10.2%). For every 10 year increase in age, there was a 1% absolute increase in post-discharge adherence (95% CI 0.4% −2.0%). Compared to patients with private insurance, patients with Medicaid were 4.5% less adherent (95% CI −7.6% to −1.4%). For every 1-point increase in baseline medication adherence score, as measured by the 4-item Morisky score, there was a 1.6% absolute increase in post-discharge medication adherence (95% CI 0.8% to 2.4%). Surprisingly, health literacy was not an independent predictor of post-discharge adherence.

Conclusions—In patients hospitalized for cardiovascular disease, predictors of lower medication adherence post-discharge included younger age, Medicaid insurance, and baseline non-adherence. These factors can help predict patients who may benefit from further interventions.

Background

In the outpatient setting, medication adherence (defined as percentage of prescribed medication doses taken by a patient during a specific time period) ranges between 40 and 80 percent for chronic conditions. [1] During acute care hospitalization, changes are often made to patients' medication regimens, which can be confusing and contribute to non-adherence, medication errors, and harmful adverse events. [2] Indeed it is estimated that almost half of patients encounter a medication error after discharge, and approximately 12–17% experience an adverse drug event after returning home. [3–6] It is likely that some of these adverse events may be the result of medication non-adherence. [7] Improved patient-provider communication, systems to reconcile pre- and post-hospitalization medications, as well as development of mechanisms to enhance adherence may prevent many of these errors and have become new targets for quality improvement. [4, 8] Although post-discharge medication adherence is a crucial target for avoiding adverse events and re-hospitalization, few studies have focused on understanding its incidence and predictors, in particular patient demographic factors such as age and insurance status. [9–11]

In addition, few studies have looked at general and post-hospital adherence in a population where health literacy is measured, an important area because medication changes during hospitalization may be particularly confusing for patients with low health literacy. [11, 12] Health literacy is defined as "the degree to which an individual has the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions."[13] Prior outpatient research shows that low health literacy is associated with poor patient understanding of the medication regimen and instructions for medication use, which may contribute to post-discharge medication non-adherence.[14, 15] Understanding the factors associated with post-discharge medication adherence could help refine interventions that are oriented toward improving transitions in care, patient safety, and reducing unnecessary re-hospitalization.

We report here on factors associated with post-discharge medication adherence using data from the Pharmacist Intervention for Low Literacy in Cardiovascular Disease (PILL-CVD) study. [16]

Methods

Study and Participants

PILL-CVD was a federally-funded, two-site randomized controlled trial using pharmacist-assisted medication reconciliation, inpatient pharmacist counseling, low-literacy adherence aids, and telephone follow-up that aimed to decrease rates of serious medication errors after hospital discharge. [16] The study targeted patients with cardiovascular disease (hospitalized on cardiology or general medical or geriatric services for acute coronary syndromes [ACS] or acute decompensated heart failure [ADHF]) at two large academic hospitals, Brigham and Women's Hospital (BWH) and Vanderbilt University Hospital (VUH).

Subjects were eligible for enrollment if they met criteria for ACS or ADHF, were likely to be discharged to home as determined by the primary medical team at the time of study enrollment, and took primary responsibility for administering their medications prior to admission (caregivers could be involved in medication management after discharge).

Exclusion criteria included severe visual or hearing impairment, inability to communicate in English or Spanish, active psychiatric illness, dementia, delirium, illness too severe to participate, lack of a home phone number, being in police custody, or participation in another intensive medication adherence program (e.g., due to renal transplant).

Out of 6416 patients originally screened for possible enrollment, 862 were randomly assigned to receive usual care or usual care plus the intervention, and 851 remained in the study.[16] Both the main study and this secondary data analysis were approved by the Institutional Review Boards of each site.

Baseline measures

Following informed consent and study enrollment, a variety of baseline data were collected on study participants from medical records and patient interview, including primary language, demographic information (age, race, insurance status, income, and education level), cognition (through administration of the 0–5 point MiniCog scale) [17] and level of health literacy (through use of the 0–36 point short form of the Test of Functional Health Literacy in Adults, s-TOFHLA scale). [18] Baseline information was also collected on medication use, including number of preadmission medications, measurement of self-reported adherence prior to admission (using the Morisky scale, a validated 0–4 point questionnaire shown to correlate with disease control and indicative of general patterns of adherence), [19] and a medication understanding score, adapted from other instruments, which quantifies understanding of the indication, dose, and frequency of up to 5 randomly selected preadmission medications on a 0–3 point scale. [16,20, 21]

Outcome measures

Outcomes were collected 30 days post-discharge through a structured questionnaire, administered by telephone. Only patients who completed this call are included in the present analysis. Post-discharge medication adherence was assessed by asking patients to report the number of days out of the previous week they had taken each medication from their post-discharge regimen exactly as prescribed.[22] A score was calculated for each medication as the proportion of adherent days (e.g., if a patient reported missing 2 days of a medication in the previous week, then adherence would be 5/7 or 71%). A global post-discharge adherence score was then derived for each patient by averaging the adherence score for all regularly-scheduled medications. This quantitative measure focused on adherence to medications patients knew they should be taking and did not measure medication discrepancies (sometimes termed “unintentional non-adherence”).

Analysis

Patient characteristics were summarized and reported using simple descriptive statistics. Candidate predictors of post-discharge medication adherence were chosen *a priori* from patient characteristics assessed during hospital admission. These included patient age, gender, race, ethnicity, marital status, insurance, years of education, presence of PCP, study site, number of preadmission medications, medication understanding, baseline adherence, cognition, and health literacy. Unadjusted results were calculated using univariable linear regression with each patient’s adherence score as the dependent variable and each predictor as the independent variable. Adjusted results were then derived using multivariable linear regression with all the candidate predictors in the model.

Lastly, because of missing data for some predictors, in particular baseline adherence and medication understanding, multiple imputation techniques were used to impute missing data and increase statistical power. [23] We used the Markov Chain Monte Carlo (MCMC) method for multiple imputation, which generally assumes that the data came from a normal

distribution and that the missing data are missing at random. Because of the essentially normal distribution of the data, and because the amount of missing data was so small (<1% for almost all variables, 5% for baseline adherence, and 8% for medication understanding), we expected little bias and present the complete case analysis, which maximized statistical power.

Two-sided p values < 0.05 were considered significant, and SAS version 9.2 (Cary, NC) was used for all analyses.

Results

Table 1 shows descriptive baseline patient characteristics of study sample (responders) as well as non-responders at 30 days. For the responders, the mean age of the 646 patients was 61.2 years, 94.7% were insured, and 19.3% had inadequate or marginal health literacy. Patients were prescribed an average of 8 preadmission medications. Most patients (92.3%) had a regular primary care physician prior to admission. Non-responders had non-significant trends towards having lower health literacy, medication understanding, and baseline medication adherence.

The average post-discharge adherence score was 95% (SD = 10.2%), and less than 10% of patients had an adherence score of less than 85%; overall the distribution was left-skewed. Table 2 illustrates crude and adjusted parameter estimates for variables in the model. Table 3 shows significant findings in the fully adjusted model, which used multiple imputation techniques to account for missing data.

Intervention arm was of borderline statistical significance in predicting post-discharge adherence (p=0.052), and so was removed from the final model. Study site, age, insurance, and baseline adherence were the only significant independent predictors of post-discharge adherence in the fully adjusted model (Table 3). For example, for every 10 year increase in age, patients had, on average, an adjusted 1% absolute increase in their adherence score (95% CI 0.4% to 2.0%). For every 1-point increase in baseline medication adherence (based on the Morisky scale), there was a 1.6% absolute increase in medication adherence (95% CI 0.8% to 2.4%). In unadjusted analyses, patients with Medicaid were less adherent with medications after discharge than were patients with private insurance. This difference became non-significant in adjusted analyses, but when analyses were repeated using multiple imputation techniques, the results again became statistically significant – Medicaid insurance was associated with a 4.5% absolute decrease in post-discharge adherence compared with private insurance (95% CI −7.6% to −1.4%). Study site (specifically, Brigham and Women's Hospital) was also a significant predictor of greater post-discharge medication adherence. Years of education was a significant predictor of adherence in unadjusted analyses but was not an independent predictor when adjusted for other factors. When baseline adherence was removed from the multiple imputation model, there were no changes in which factors were significant predictors of adherence.

Discussion

In this study, we found that low baseline adherence, younger age, Medicaid insurance, and study site were significant predictors of lower 30-day medication adherence. Of particular interest is our finding regarding baseline adherence, a simple measure to obtain on hospitalized patients. It is notable that in our study, education was not an independent significant predictor of post-discharge adherence, even when baseline adherence was removed from the model. The same is true for medication understanding, cognitive function, and health literacy.

Older patients appeared more adherent with medications in the month after hospital discharge, perhaps reflecting increased interaction with the healthcare system (appointments, number of physician interactions), a greater belief in the importance of chronic medication management, or a higher level of experience with managing medications. A similar relationship between age and adherence has been shown in outpatient studies of patients with hypertension, diabetes, and other chronic diseases. [24–27]

Medicaid patients may be less likely to remain adherent because of the plan's limited coverage of medications relative to patients' ability to pay. For example, Medicaid in Tennessee covers the first 5 generic medications at no cost to the patient but has copayments for additional medications and for brand name drugs. Medicaid in Massachusetts has copayments of $1 to $3 for each medication. Alternatively, Medicaid insurance may be a marker for other patient characteristics associated with low adherence for which we were not fully able to adjust.

Site differences were also notable in this study; these differences could have been due to differences in insurance coverage in Tennessee vs. Massachusetts (which has near-universal coverage), differences in types of insurance (e.g., fewer patients at Brigham and Women's Hospital had Medicaid than at Vanderbilt), cultural and geographic differences between the two locations, or other differences in transitional care between the two sites.

This study corroborates previous literature on medication adherence (specifically unintentional non-adherence) in the outpatient setting, [4, 8–11] for example on the association of younger age with low adherence in certain populations. On the other hand, it may contrast with previous literature which has sometimes shown a relationship between patient education or health literacy and medication adherence. [14, 15, 28–35] However, previous studies have not focused on the transition from inpatient to outpatient settings. Perhaps intensive medication education in the hospital, even under usual care, mitigates the effects of these factors on post-discharge adherence. Finally, baseline adherence seems to correlate with post-discharge adherence, a finding which makes intuitive sense and has been previously reported for specific medications.[36]

There are several limitations to this study. Although large, the study was performed at only two clinical sites where most patients were white and fairly well-educated, perhaps because patients admitted to a tertiary care center with ACS or ADHF are more affluent than general medical inpatients as a whole; this may limit generalizability. Post-discharge medication adherence might have been higher than in other patient populations given the nature of the population, possible loss-to-follow-up bias, and the fact that half of the subjects received an intervention designed to improve medication management after discharge; such low rates of non-adherence in our study may have reduced our ability to detect important predictors in our models. In addition, the period of follow-up was 30 days, thus limiting our findings to short-term post-discharge medication adherence. Post-discharge medication adherence was based on patient self-report, which not only assumed that the patient was still managing his/her own medications after discharge, but may also be susceptible to both recall and social acceptability bias, which might overestimate our adherence scores, again limiting our ability to detect important predictors of non-adherence. However, other studies have shown a good correlation between self-reported medication adherence and other more objective measures [37, 38] and recall was only for 7 days, a measure used previously in the literature[39, 40] and one designed to reduce recall bias. Systematic under-reporting in certain patient populations is less likely but possible.

In the future, research should focus on targeting patients who have low baseline adherence to evaluate the effects of various interventions on post-discharge medication outcomes.

Repeating the study in a population with a high prevalence of low health literacy might be illuminating given that previous studies have shown that patients with low health literacy have less ability to identify their medications and have less refill adherence. [29, 30]

In conclusion, in patients hospitalized with cardiovascular disease, predictors of lower post-discharge adherence include younger age, Medicaid insurance, and low baseline adherence. It may be prudent to assess baseline adherence and insurance type in hospitalized patients in order to identify those who may benefit from additional assistance to improve medication adherence and medication safety during transitions in care.

A Doctor's Response to Torture

Stepping off the plane in an unfamiliar country, jet-lagged, and unable to speak a word of the native language, I was a little disoriented. I met my patient—whom I will call Rashid—at the hotel in less than an hour of my arrival. He was apprehensive. We spent the evening in a relaxed, informal atmosphere with a group of attorneys. Despite the fact that I was a white, non-Muslim, American woman, we were able to make a connection. Rashid took us to a beautiful beach, peppered with traditional wooden fishing boats, and he gave local children a few coins to pick some baobab fruit for us to sample from a very unusual looking tree. The attorneys, Rashid, and I listened to his music and teased him about his taste in Western hip-hop.

As a physician evaluator for Physicians for Human Rights, I had been asked to interview Rashid. There was no clinical space in which to perform this evaluation, so we used my hotel room. I quickly learned the extent of Rashid's profound suffering. He described himself as a ghost wandering around the town in isolation, unable to eat or sleep. He repeatedly asked me if he was "crazy," because that is how he perceived himself. He detailed the horrors of his arrest, during which he was beaten so badly that he was admitted to a hospital with multiple fractures and internal injuries. He described how he was kidnapped from his hospital bed and survived a 5-year ordeal in U.S. custody in multiple detention sites, including Afghanistan. In the stifling, humid hotel room, he detailed the methods of his torture: severe beatings, prolonged painful stress positions, prolonged solitary confinement, forced nakedness and humiliation, sleep deprivation, withholding of food, sexual assault (anal rape and sodomy), forced intravenous medication during interrogations that he thought might be a "truth serum," and painful shackling. At times, he was denied medical and psychiatric care.

As the hours wore on, Rashid's story became almost unbearable. There were times when we both broke down in tears. Rashid described being forced to lie on a wet mat, naked and handcuffed, having cold water poured on him while being kicked and beaten, and then rolled up in the wet mat "like a corpse"—cold, wet, and shivering. In the "water room," men attempted to insert the spout of a water jug into his anus. He reported that his arms were chained to an overhead pipe while he was in a standing position for what he estimates was 4 days. His heels could not touch the floor and he developed severe back and shoulder pain. He was not allowed to use the toilet, and loud music blared the entire time. ("It is just death.") He went on to describe being locked naked in a "coffin"; he could not move and it was difficult to breathe. At one point during his detention, his flesh started rotting under a cast that was left unattended for too long. His request for medical care was ignored until he protested by going on a hunger strike for 6 days.

Rashid's prominent symptoms included extreme sleep disturbance, sadness, loss of appetite with substantial weight loss, and difficulty interacting with other people, (including family and friends), resulting in profound isolation. He has not been able to work as a result of his debilitating psychological symptoms and has no means to support himself. The lack of self-sufficiency has caused further depression, feelings of inadequacy, and shame and humiliation when he has to rely on his family for basic needs. Rashid told me he wakes up at 2 a.m. and takes walks. ("My head feels empty, like an empty box.") His life has unraveled since his return from U.S. custody, and he is unable to return to his former level of functioning and reintegrate back into his family and community. He meets diagnostic criteria for posttraumatic stress disorder and major depression, but those Western-based diagnoses do not adequately characterize his palpable suffering.

In the evening, Rashid borrowed a car and we decompressed on a drive to the beautiful bush and beaches. I had to abandon the Western doctor–patient boundaries. I learned about local life and customs and tasted the local food. I photographed the old colonial buildings and monkeys and camels. I then met his mother and sister, at his request. We sat on the floor of a simple but welcoming cement structure, were served sweets and coffee, and were treated as warmly as if we were family or close friends. I explained to Rashid's family that he wasn't "crazy" and that there was hope for recovery. Neither Rashid nor his family knew of posttraumatic stress disorder, or understood the link between the torture and his symptoms. Their gratitude for my simple explanation was humbling. We conducted our final interviews on the beach at Rashid's request. After his 5 years in confinement, this vast expanse of beauty was a place of solace and comfort for him. He would stop every so often and illustrate a point by drawing in the sand, such as when he drew a rough reproduction of a cage in which he had been confined. It was difficult to leave Rashid after having uncovered such desperate need and having no available resources to alleviate his suffering. My fears were intensified by the fact that Rashid's suffering was not the aftermath of a natural disaster, but one deliberately inflicted by other humans. After departure, I received a text message from Rashid. "Thank u my Dr. U help me very much and my brain it gonna be OK."

This unique and complicated situation demanded creative and unorthodox measures. The combined collaboration of Physicians for Human Rights and a local organization made initial treatment for this man a reality. After I left, the United Nations Voluntary Fund for Victims of Torture agreed to fund treatment and rehabilitation services, and a psychologist traveled from a neighboring coun-

try to provide mental health treatment. An antidepressant was sent by post, and I initially gave instructions and monitored Rashid's progress by cell phone. I continue to have regular phone contact with him to provide support and to monitor symptoms while trying to organize more regular treatment. I have seen improvement in his self-esteem because he is better able to understand the root cause of his symptoms. I have detected something new in our communication—hope. Rashid is now hopeful about his recovery and future. And I am hopeful that it is possible to repair the wounds my country has inflicted.

Rashid was given a document upon his release that confirmed his confinement as well as his innocence. On the basis of my evaluation, I have a high degree of medical certainty that he was tortured while in U.S. custody. Nonetheless, neither he nor I know the identity of the perpetrators.

The Impact of a 25-Cent-Per-Drink Alcohol Tax Increase

James I. Daley, MPH, Mandy A. Stahre, MPH, Frank J. Chaloupka, PhD, Timothy S. Naimi, MD, MPH

Background: Excessive alcohol consumption causes 79,000 deaths annually in the U.S., shortening the lives of those who die from it by approximately 30 years. Although alcohol taxation is an effective measure to reduce excessive consumption and related harm, some argue that increasing alcohol taxes places an unfair economic burden on "responsible" drinkers and socially disadvantaged people.

Purpose: To examine the impact of a hypothetic tax increase based on alcohol consumption and sociodemographic characteristics of current drinkers, individually and in aggregate.

Methods: Data from the 2008 Behavioral Risk Factor Surveillance System survey were analyzed from 2010 to 2011 to determine the net financial impact of a hypothetic 25-cent-per-drink tax increase on current drinkers in the U.S. Higher-risk drinkers were defined as those whose past-30-day consumption included binge drinking, heavy drinking, drinking in excess of the U.S. Dietary Guidelines, and alcohol-impaired driving.

Results: Of U.S. adults who consumed alcohol in the past 30 days, 50.4% (or approximately 25% of the total U.S. population) were classified as higher-risk drinkers. The tax increase would result in a 9.2% reduction in alcohol consumption, including an 11.4% reduction in heavy drinking. Compared with lower-risk drinkers, higher-risk drinkers would pay 4.7 times more in net increased annual per capita taxes, and 82.7% of the net increased annual aggregate taxes. Lower-risk drinkers would pay less than $30 in net increased taxes annually. In aggregate, groups who paid the most in net tax increases included those who were white, male, aged 21–50 years, earning ≥$50,000 per year, employed, and had a college degree.

Conclusions: A 25-cent-per-drink alcohol tax increase would reduce excessive drinking, and higher-risk drinkers would pay the substantial majority of the net tax increase.
(Am J Prev Med 2012;42(4):382–389)

Background

Excessive alcohol consumption is a leading cause of preventable death[1] attributed to approximately 79,000 deaths annually in the U.S., shortening the lives of those who die of it by an average of 30 years.[2] Drinking is also a major risk factor for a variety of adverse health outcomes, such as unintentional injuries, violence, unintended pregnancy, and cardiovascular disease.[3–7] Alcohol is also a major cause of social problems (e.g., child neglect, divorce); legal and criminal justice problems; and economic costs.[4]

Increasing the price of alcohol through alcohol excise taxes is an effective means of reducing excessive drinking, and it is considered the most important public health intervention to reduce alcohol-related harm.[8–10] A meta-analysis of 50 publications found that doubling the alcohol excise tax would reduce alcohol-related mortality by an average of 35%, traffic crash deaths by 11%, sexually transmitted disease by 6%, violence by 2%, and crime by 1.4%.[10] Further, a comprehensive review found an inverse relationship between alcohol price and consumption, and determined that a 10% increase in alcohol prices would result in a 3%–10% decrease in overall consumption.[9]

Despite strong evidence of public health benefit, there have been few recent alcohol tax increases, and many initiatives to raise them have been defeated on the basis of arguments about the economic fairness of alcohol taxes. One argument against raising alcohol taxes is that such

increases will place a large and unfair financial burden on "responsible" (i.e., lower-risk) drinkers. Also, there is concern about how much those with lower socioeconomic status (i.e., racial and ethnic minorities, those with lower incomes, less education) would have to pay compared with other groups. To explore these issues further, data from the Behavioral Risk Factor Surveillance System (BRFSS) survey were analyzed to examine the effect of a hypothetic 25-cent-per-drink tax increase on U.S. adults who drink alcohol. The purpose of the present study was to assess the net financial impact, both individually and in aggregate, of a hypothetic tax increase on the basis of alcohol consumption characteristics and socioeconomic factors among current drinkers in the U.S.

Methods

Survey

Data for the current study came from the 2008 BRFSS. A detailed overview of the BRFSS including survey methods and information on data weighting is available at www.cdc.gov/brfss/ and www.cdc.gov/brfss/technical_infodata/quality.htm. In brief, the BRFSS is a state-based random-digit-dial telephone survey of people aged ≥18 years that is overseen by the CDC and conducted monthly in all states, the District of Columbia, and some territories. Analysis was limited to the 50 U.S. states. The 2008 BRFSS had a response rate of 53.3%. A total of 411,736 respondents, including 200,587 reporting alcohol consumption in the previous 30 days, constituted the study population. BRFSS data were weighted on the basis of age, gender, and race/ethnicity to be representative of the U.S. population aged ≥18 years.

Measures

The BRFSS "core" (i.e., questions asked of all drinkers in all states) alcohol questions were used to assess drinking frequency and the average number of drinks consumed during drinking days during the past 30 days among current drinking U.S. adults aged ≥18 years. The core BRFSS also collects information on the frequency of binge drinking (i.e., consuming five or more drinks for men or four or more drinks for women per occasion in the past 30 days),[11] the greatest number of drinks consumed in the past 30 days, and alcohol-impaired driving (i.e., the number of times a person drove after having "perhaps too much to drink").

To determine average daily alcohol consumption by an individual, a participant's frequency of drinking days in the past 30 days was multiplied by their usual number of drinks consumed per drinking day and divided by 30. For binge drinkers, their average daily alcohol consumption was adjusted to account for self-reported estimates of binge drinking, using the indexing method originally described by Armor and Polich[12] and applied to the BRFSS data.[13] For the current study, men reporting a maximum drink value of five or more and women reporting a maximum drink value of four or more were classified as binge drinkers.[11] Heavy drinking was defined as an average daily consumption of more than two drinks for men or an average daily consumption of more than one drink for women.[2]

"Higher-risk" drinkers were defined as those with any of the following: drinking above U.S. Dietary Guidelines (defined as consumption during drinking days of three or more drinks for men or two or more drinks for women)[14]; binge drinking; alcohol-impaired driving; or heavy drinking. "Lower-risk" drinkers were defined as those not meeting any of the four higher-risk criteria defined above.

Increasing the price of alcohol through a tax would decrease its consumption based on the price elasticity of demand for alcohol. The price elasticity of demand (−0.51) was obtained from a recent meta-analysis.[15] To determine the average price of a standard drink in the U.S., a weighted average of on- and off-premises prices for beer, wine, and spirits was calculated[16] based on beverage-specific per capita consumption in the U.S. in 2007 (the most recent year for which data were available: 52.1% beer, 31.5% liquor, 16.4% wine[17]) and assuming that 75% of alcohol is purchased from off-premises establishments.[18,19] Assuming a 100% pass-through of the tax to the price paid by consumers, 25 cents constituted 18.1% of the average weighted price per drink ($1.38), yielding a 9.2% reduction in consumption. After factoring in the impact of the price increase on average daily consumption, annual alcohol consumption was calculated on a per capita and aggregate basis by multiplying the average number of drinks per day by 365.

The net tax increase was calculated by first determining the current amount of annual federal alcohol taxes already being paid by drinkers (10 cents per drink[7,20]). Total annual taxes paid after a hypothetic 25-cent-per-drink increase were then calculated by multiplying an individual's price elasticity–adjusted annual consumption by 35 cents per drink (10 cents per drink in current taxes plus a hypothetic 25-cent-per-drink increase). The net increase in expenditures was then calculated by subtracting current annual tax expenditures from the total annual tax expenditures after the tax increase (i.e., after adjusting consumption to account for the impact of the higher price). Per capita and aggregate net tax increase–associated revenues were then assessed among a variety of subgroups based on their alcohol consumption characteristics and sociodemographic factors such as age, gender, race/ethnicity, education, income, and employment status. Analyses were performed from May 2010 through August 2011, using SAS, version 9.2.

Results

After weighting, 50.5% of U.S. adults who reported current drinking in the past 30 days constituted the study population (Appendix A, available online at www.ajpmonline.org). Among current drinkers, 50.4% were classified as higher-risk drinkers, and 49.6% were classified as lower-risk drinkers. Among higher-risk drinkers, 58.8% usually consumed three or more drinks per drinking day; 63.0% reported binge drinking, including 25.3% with three or more binge episodes; and 7.5% reported alcohol-impaired driving. A majority (75.2%) of lower-risk drinkers reported usually consuming one drink per drinking day and 80.2% of lower-risk drinkers reported between 1 and 10 drinking days in the past 30 days. Men drank more than women for all consumption measures. Among male higher-risk drinkers, 78.3% usually consumed three or more drinks per drinking day, 20.2% drank a maximum of ten or more drinks on one occasion in the previous 30 days, 77.5%

reported binge drinking, and 10.4% reported impaired driving.

Higher-risk drinkers were further characterized on the basis of the risk criteria that were used to define them as such (Appendix B, available online at www.ajpmonline.org). The most common risk factor reported was exceeding the U.S. Dietary Guidelines (82.9%), followed by binge drinking (63.0%); heavy drinking (26.4%); and impaired driving (7.5%). Overall, higher-risk drinkers reported a mean of 1.8 of the four risk criteria. The mean number of fulfilled risk criteria based on strata of socioeconomic factors including race/ethnicity, education, income, and employment status was similar overall, ranging from 1.7 to 1.9.

As a result of the tax increase, current drinkers would reduce their annual consumption from 319.1 to 289.7 drinks per year (absolute reduction 29.4 drinks annually, relative reduction 9.2%, data not shown). Compared with lower-risk drinkers, higher-risk drinkers would have larger absolute reductions in the number of drinks consumed (48.4 fewer drinks vs 10.2 fewer drinks). Among heavy drinkers (the subset of higher-risk drinkers defined on the basis of average consumption), the tax increase would reduce annual consumption by 58.6 drinks annually, and result in an 11.4% relative reduction in heavy drinking (from 14.0% to 12.4%, or 1.8 million people).

Table 1 provides per capita data regarding total drink consumption and the net additional cost of a hypothetic alcohol tax increase of 25 cents per drink, analyzed by various socioeconomic characteristics. On a per capita basis, higher-risk drinkers would pay 4.7 times as much in net additional taxes compared with lower-risk drinkers. Those exceeding four risk criteria would pay approximately 10 times more than those exceeding only one risk criteria, and approximately 16 times more than those exceeding none (i.e., lower-risk drinkers). Among various strata of lower-risk drinkers, none would pay more than $35.04 per year in net increased taxes. Higher-risk drinkers who would pay the most in additional taxes include men, those with less education, those of lower income, and retired people. Lower-risk drinkers who would pay the most in additional taxes include men, those of white race, college graduates, and those with incomes exceeding $50,000.

Table 2 presents similar data but on an aggregate, rather than per capita, basis. Additional net tax revenue was approximately $7.9 billion annually, and 82.7% ($6.5 billion) of this was to be paid by higher-risk drinkers. Among all drinkers and among higher-risk drinkers, those aged 21–50 years, men, those of white race, college graduates, those earning $50,000 or more per year, and employed people paid the most in terms of aggregate tax increases. Those exceeding three alcohol-related risk criteria (11.5% of all drinkers) paid approximately 48% of tax revenues.

Discussion

Raising the price of alcohol through taxation is a highly effective strategy by which to reduce excessive drinking and related harm. A 25-cent-per-drink tax increase would result in more than a 10% reduction in heavy drinking, which would yield a substantial public health benefit for a behavior that currently leads to approximately 79,000 deaths annually in the U.S.[2] However, it is likely that the morbidity and mortality benefits would exceed those suggested by the change in consumption, because absolute consumption would decrease most among those who drink the most and who incur most alcohol-attributable consequences.[10,21]

In addition, because the risk of alcohol-attributable harm increases exponentially with increasing levels of consumption,[22] even moderate reductions in consumption among those drinking the most leads to relatively large reductions in alcohol-attributable harm. Finally, youth drinkers may experience greater-than-average reductions in alcohol consumption from a tax increase because they tend to be high-risk drinkers and because their price elasticity of demand is typically high. This effect was not modeled, because of a lack of an available meta-analysis of the price elasticity of demand for this group.[10,21]

Higher-risk drinkers (including those who reported binge drinking, consumption during drinking days that exceeded U.S. Dietary Guidelines limits, heavy drinking, or alcohol-impaired driving) would pay approximately five times as much individually and in aggregate compared with lower-risk drinkers, whereas the typical lower-risk drinker would pay less than $30 in net additional taxes annually. This result demonstrates that even though alcohol taxes are applied to all drinks (i.e., alcohol taxes cannot selectively be applied based on who is purchasing the alcohol), they cost higher-risk drinkers considerably more than lower-risk drinkers because of how skewed alcohol consumption is in the U.S.: A relatively small percentage of drinkers consume most of the alcohol, and most lower-risk drinkers do not drink regularly or consume much alcohol. Having higher-risk drinkers pay far more than lower-risk drinkers not only is desirable from a fairness perspective but results in larger absolute reductions in consumption among higher-risk drinkers, which is desirable from a public health perspective.

There is also interest about who pays the most in alcohol taxes based on socioeconomic factors, particularly among lower-risk drinkers who are unlikely to be detrimental to public health and safety. Among lower-risk

Note: Data are for lower- and higher-risk U.S. adult drinkers, by selected characteristics, BRFSS survey, 2008. Data have been modeled to include a decrease in consumption as a result of the increased price of a drink due to a hypothetic 25-cent-per-drink tax, based on the price elasticity of alcohol. BRFSS data were weighted to be representative for U.S. adults aged ≥18 years on the basis of age, gender, and race/ethnicity.

[a]Higher-risk drinkers were defined as anyone reporting one or more of the following risk factors: binge drinking, heavy drinking, drinking in excess of Dietary Guidelines limits, or alcohol-impaired driving. Lower-risk drinkers were defined as not reporting any of the preceding risk factors. Binge drinking was defined as one or more occasions of consuming four or more drinks for women or five or more drinks for men. Heavy drinking was defined as consuming an average of more than two drinks per day for men or more than one drink per day for women. Drinking above Dietary Guidelines was defined as consumption of three or more drinks for men and two or more drinks for women during drinking days. Impaired driving was defined as nonzero response to the question *During the past 30 days, how many times have you driven when you've had perhaps too much to drink?*

[b]The number of the risk criteria exceeded refers to the sum of any of the four alcohol-related risk criteria used to define higher-risk drinking.

BRFSS, Behavioral Risk Factor Surveillance System

drinkers, both in aggregate and on a per capita basis, groups who paid the most for an alcohol tax increase were male, white, relatively affluent and educated, and employed. Therefore, assuming that alcohol tax revenues were used for offsets across the board to other tax obligations, lower-risk drinkers from relatively disadvantaged socioeconomic groups would realize a net economic gain from an alcohol tax increase.

Among higher-risk drinkers, however, those who were relatively poor, less educated, and not employed paid more in per capita tax increases than other groups. Also, it should be noted that any tax increase on those with less income will take a larger proportion of their income than would the same tax on someone earning more, and could thus be potentially regressive in nature. In this case, however, that larger financial impact might lead to greater reductions in drinking and a larger public health benefit for those same individuals.

It is important to acknowledge that the distribution of taxes paid by higher-risk and lower-risk drinkers is dependent on the classification criteria for the two groups. Of the 57.4 million higher-risk drinkers, 17.8 million were considered higher risk solely because their consumption exceeded the U.S. Dietary Guidelines but exceeded no other risk thresholds. This subset of higher-risk drinkers consumed less alcohol overall (and hence paid less in taxes) than other higher-risk drinkers.

Their net per capita taxes paid would increase by $31.30 annually, and in aggregate they would pay an additional $556 million, or 8.5% of the amount that would be paid by the higher-risk group (data not shown). Had they been classified as lower-risk drinkers instead, the remaining higher-risk drinkers would have paid 6.1 times more than lower-risk drinkers in per capita taxes, and accounted for 75% of total tax paid (compared with paying 4.7 times more than lower-risk drinkers and 83% of all additional taxes paid when only those drinking above U.S. Dietary Guidelines are included in the higher-risk group).

Imposing alternative assumptions would have changed the current findings. Had a different tax increase been used, consumption and revenue increases would have changed accordingly (e.g., higher taxes would cause larger decreases in consumption but higher revenue). The overall price elasticity of demand for the current study was based on a recent meta-analysis[15]; however, had meta-analyses of price elasticities for subgroups (e.g., based on income, age, drinking quantity) been available, the observed distribution of tax revenues would have been somewhat different.

For example, assuming a larger price elasticity of demand for those of younger ages or lower income would have resulted in relatively larger reductions in their drinking and a reduced tax burden for them. Although a full pass-through of the tax was modeled (i.e., assuming that 100% of the tax was passed on as a price increase), modeling either a smaller or larger relative pass-through would have resulted in a smaller or larger change in price, which would have affected consumption and tax impacts accordingly.

Characteristics of surveys generally, including BRFSS, also make it likely that the financial impact of the tax increase would differ from our estimates.[23] Specifically, BRFSS estimates of consumption account for less than one third of consumption based on sales tax data,[24,25] suggesting that actual additional revenue from a 25-cent-

Note: Data are for higher- and lower-risk U.S. adult drinkers, by selected characteristics, BRFSS survey, 2008. Data have been modeled to include a decrease in consumption as a result of the increased price of a drink due to a hypothetic 25-cent-per-drink tax, based on the price elasticity of alcohol. BRFSS data were weighted to be representative for U.S. adults aged ≥18 years on the basis of age, gender, and race/ethnicity.

[a]Higher-risk drinkers were defined as anyone reporting one or more of the following risk factors: binge drinking, heavy drinking, drinking in excess of Dietary Guidelines limits, or alcohol-impaired driving. Lower-risk drinkers were defined as not reporting any of the preceding risk factors. Binge drinking was defined as one or more occasions of consuming four or more drinks for women or five or more drinks for men. Heavy drinking was defined as consuming an average of more than two drinks per day for men or more than one drink per day for women. Drinking above Dietary Guidelines was defined as consumption of three or more drinks for men and two or more drinks for women during drinking days. Impaired driving was defined as a nonzero response to the question *During the past 30 days, how many times have you driven when you've had perhaps too much to drink?*

[b]The number of risk criteria exceeded refers to the sum of any of the four alcohol-related risk criteria used to define higher-risk drinking.

BRFSS, Behavioral Risk Factor Surveillance System

per-drink tax would be approximately $29 billion. In addition, survey respondents are less likely to include those who consume high amounts of alcohol compared with those who consume lower amounts.[26–29] This implies that in the current study, the proportion of alcohol consumption and tax expenditures accounted for by higher-risk drinkers are underestimates relative to consumption and expenditures by lower-risk drinkers.

Despite the lack of any randomized study of low-dose alcohol and any morbidity or mortality outcome, and despite the fact that observational studies of established moderate drinkers are limited by confounding and selection bias, much attention has been paid to possible health benefits of low-level (sometimes termed "moderate") alcohol consumption.[30–33] However, to the extent that there are health benefits associated with moderate drinking, reducing higher-risk alcohol consumption to more moderate levels by means of a tax increase would have the salutary side effect of increasing the number of people to whom such benefit might accrue. Moreover, the reductions in higher-risk drinking following a tax increase would lead to sharp reductions in overall alcohol-related mortality.

A strong theoretic justification for taxes generally, and for alcohol excise taxes in particular, is to recoup the social and economic costs incurred from the sale of alcohol that are not borne by its producers, sellers, or consumers (i.e., the "external" costs of alcohol consumption).[22] These external costs are considerable, and include health-related effects; social problems (e.g., child abuse and neglect, marital problems, alcohol-related crimes); and economic costs (e.g., healthcare costs, legal and criminal justice system costs, lost economic productivity, and higher car insurance premiums).[2,34–37] Currently, the net external costs (external costs minus tax revenues) for alcohol in the U.S. are approximately $1 per drink; remedying this disparity would require raising alcohol taxes by an order of magnitude from present levels.[38–40]

The gap between the societal costs of alcohol sales and its corresponding excise tax rates continues to widen.[41] This is because most alcohol excise taxes at the federal and state levels are based on volume and have not been increased regularly or in large enough increments over time,[42] resulting in an erosion of the value of these taxes in inflation-adjusted terms.[42,43] For example, the federal beer tax has remained unchanged since it was last raised in 1991, and its inflation-adjusted value has eroded by approximately 40% in the interim.[43,44]

Raising alcohol taxes provides multiple benefits in terms of public health and economic fairness.[44] It would reduce harm from the third-leading preventable cause of death in the U.S.,[1] reduce costs to responsible drinkers by lowering tax obligations in other areas, begin to recoup alcohol-related costs to society associated with alcohol sales by moving taxes more closely in line with historical standards, and provide badly needed revenue to cash-strapped state and federal governments at a time when there is extreme reluctance to increase income or property taxes.

Disparities in safe sex counseling & behavior among individuals with substance dependence: a cross-sectional study

Meredith M D'Amore[1*], Debbie M Cheng[2,3], Donald Allensworth-Davies[4], Jeffrey H Samet[2,5] and Richard Saitz[2,6]

Abstract

Background: Despite the vast literature examining disparities in medical care, little is known about racial/ethnic and mental health disparities in sexual health care. The objective of this study was to assess disparities in safe sex counseling and resultant behavior among a patient population at risk of negative sexual health outcomes.

Methods: We conducted a cross-sectional analysis among a sample of substance dependent men and women in a metropolitan area in the United States. Multiple logistic regression models were used to explore the relationship between race/ethnicity (non-Hispanic black; Hispanic; non-Hispanic white) and three indicators of mental illness (moderately severe to severe depression; any manic episodes; ≥3 psychotic symptoms) with two self-reported outcomes: receipt of safe sex counseling from a primary care physician and having practiced safer sex because of counseling.

Results: Among 275 substance-dependent adults, approximately 71% (195/275) reported ever being counseled by their regular doctor about safe sex. Among these 195 subjects, 76% (149/195) reported practicing safer sex because of this advice. Blacks (adjusted odds ratio (AOR): 2.71; 95% confidence interval (CI): 1.36,5.42) and those reporting manic episodes (AOR: 2.41; 95% CI: 1.26,4.60) had higher odds of safe sex counseling. Neither race/ethnicity nor any indicator of mental illness was significantly associated with practicing safer sex because of counseling.

Conclusions: Those with past manic episodes reported more safe sex counseling, which is appropriate given that hypersexuality is a known symptom of mania. Black patients reported more safe sex counseling than white patients, despite controlling for sexual risk. One potential explanation is that counseling was conducted based on assumptions about sexual risk behaviors and patient race. There were no significant disparities in self-reported safer sex practices because of counseling, suggesting that increased counseling did not differentially affect safe sex behavior for black patients and those with manic episodes. Exploring the basis of how patient characteristics can influence counseling and resultant behavior merits further exploration to help reduce disparities in safe sex counseling and outcomes.

Background

Sexually transmitted infections (STIs) and unintended pregnancy are prevalent among racial/ethnic minorities and individuals with mental illness, and associated with a host of negative health outcomes and costs [1-7]. Unintended pregnancy is costly on many levels, including direct medical costs of births, abortions and fetal losses, indirect costs of wages lost from not working and psychological costs associated with the challenges posed by unintended pregnancy [8-10]. Unintended pregnancies were recently estimated to cost taxpayers $11 billion each year [11,12]. Unintended pregnancies affect the parents (who may endure financial hardship and limitations to their educational attainment) [9,10] and children, in terms of birth outcomes and worse cognitive, emotional and behavioral development [9,10,13-15]. Sexually transmitted infections, including chlamydia, gonorrhea, human papiloma virus (HPV) and the human immunodeficiency virus (HIV), are highly prevalent, preventable infections that can lead to serious health consequences including chronic pain, infertility and mortality [1]. The costs associated with the treatment of STIs are substantial, with an estimated $6.5 billion expended in 2000, for 15-24 year olds alone [16].

In 2001, the rate of unintended pregnancy was highest for black and Hispanic women (98 and 78 per 1,000, respectively), compared with that for whites (35 per 1,000) [3]. More recent data from 2006-2010 report the following percentages of unintended pregnancies resulting in births: 20% non-Hispanic white, 35% Hispanic and 45% black women [17]. Disparities also exist in rates of STIs. For example, black men and women are most affected by chlamydia and gonorrhea, having 9-19 times higher rates than whites [1]. Patients with mental illness have worse health outcomes and a higher medical burden compared to the general population [18-20], including high rates of unintended pregnancy and abortion [5,21,22]. Individuals with mental illness are at higher risk for acquiring STIs and having unintended pregnancies due to increased rates of unprotected intercourse as a result of having less knowledge about contraception, lower capacity to plan ahead, inability to navigate contraceptive resources and being at higher risk for sexual coercion [4-6,23-32].

Substance use, the consumption of alcohol and/or use of illicit drugs, is also associated with sexual risk behaviors [7,33]. The precise link between substance use and engagement in sexual risk behaviors has not been fully established in the literature, but studies suggest that this relationship is primarily a function of less consistent condom use and having multiple sex partners [7,34,35]. Thus, individuals with substance dependence are another vulnerable population at increased risk for unprotected sex, unintended pregnancy and STIs [2].

Identifying barriers to contraceptive usage and safe sexual behaviors is vital in order to prevent STIs and unintended pregnancy. Clinicians can play a pivotal role in educating patients about safe sex and helping to increase their knowledge and use of contraception [36-39]. Although many factors outside of the medical encounter can influence patient sexual behavior and contraception use, clinicians have an opportunity to counsel populations at risk of negative sexual health outcomes, with the potential of affecting patient behavior. This counseling has the potential to reduce risky sexual behaviors and related negative health outcomes [36-41]. Contraceptive counseling in primary care, where there is a preventive focus and a longitudinal relationship with patients, can impact patient contraceptive use and method choice [42].

Despite a higher prevalence of sexual risk behaviors among people with substance dependence than in the general population [7], little is known about disparities in sexual health care among these individuals. Communication problems in the patient-clinician exchange may occur differentially across race/ethnicities and among patients with mental illness, thereby contributing to the disparities in contraceptive use and, subsequently, STIs and unintended pregnancy [37,43]. Primary care clinicians in particular may feel discomfort in discussing these issues because of their sensitive nature and lack of training [44-46]. Despite the vast literature about racial disparities in medical care, little is known about disparities specific to sexual health care [47]. One recent study of low income women found that blacks were more likely to report being pressured by their clinician to use contraceptives, compared to whites [47]. A series of studies found that many African Americans who received family planning care felt discriminated against and held conspiracy beliefs about birth control (such as "birth control is a form of Black genocide") [48].

There is also a dearth of literature assessing disparities in clinician safe sex counseling for people with mental illness [49]. Clinicians may unknowingly make assumptions about the sexual risks of patients with mental illness or their ability to comply with birth control regimens, which may affect clinicians' decisions to provide appropriate counseling and discuss contraceptive options. Sexual health counseling for patients with mental illness is complex and challenging. Clinicians have the challenge of assessing the patient's autonomy in decision-making and risk of unintended pregnancy and STIs. They also need to use judgment to consider how capable the patient is of using contraceptives consistently and effectively [29]. They need to ensure patients fully understand contraceptive options, risks, and benefits [29]. Guidelines to help clinicians assess patient autonomy may be subverted by subconscious bias in decision-making. The role clinicians can play in addressing the sexual health needs of individuals with mental illness warrants further study [50].

Further investigation into the role of clinicians is essential to improving disparities in patients' safe sex behaviors, including the usage of and adherence to contraception. The objectives of this study are therefore to examine whether race/ethnicity and indicators of mental illness are associated with two separate outcomes: patient report of primary clinician's safe sex counseling and practicing safe sex due to counseling among individuals with substance dependence. We hypothesized that minority patients and those with serious mental illness symptoms may receive less safe sex counseling, but anticipate that these disparities will be attenuated after controlling for other patient sociodemographic characteristics, sexual risk behavior and the quality of clinician-patient relationship.

Methods

This was a secondary analysis of cross-sectional data collected for a randomized controlled trial (Addiction Health Evaluation and Disease management (AHEAD) Study) conducted in Boston, Massachusetts from September 2006 to September 2008. This study was approved by the Boston University Medical Campus Institutional Review Board (H-23464). All subjects provided informed consent, and procedures were followed in accordance with the Helsinki Declaration of 1975. A certificate of confidentiality was obtained from the National Institute on Alcohol Abuse and Alcoholism to further protect participants' privacy. The AHEAD study is a randomized clinical trial evaluating chronic disease management for substance dependence in primary care. All subjects had current alcohol and/or drug dependence, by DSM IV criteria [51] (assessed using the Composite International Diagnostic Interview Short Form) [52], were willing to establish or continue primary care at the study location and had engaged in recent heavy drinking or recent drug use. If they had primary care elsewhere but wanted to change to Boston Medical Center (BMC), they were considered eligible. If they had no primary care clinician, they had to be willing to be referred to one at BMC. These subjects were primarily recruited from a residential detoxification unit, but also from a large urban safety-net primary care clinic and through recruitment advertisements on public transportation. Subjects were at least 18 years of age, spoke English or Spanish, and were without indication of cognitive impairment at screening (assessed by a Mini Mental State Examination score greater than 20) [53]. Half of the enrolled subjects were randomized to the AHEAD clinic intervention, which included a team comprised of a nurse care manager, social worker, psychiatrist and internist. All study subjects were reimbursed $35 for completing all baseline visit procedures and $50 at the three month follow-up visit.

The inclusion criteria for our analysis included: completing the 3-month follow-up visit, reported having one particular doctor that they considered to be their regular primary care doctor and being self-reported non-Hispanic black, non-Hispanic white or Hispanic. The question about having a regular doctor asked: "Is there one particular doctor (or primary care provider, e.g. Nurse Practitioner or Physician's Assistant) that you consider to be your regular personal primary care doctor?" Because this survey then continued to use the term "doctor" to encompass all of the primary care clinicians listed above, we continue to use the term "doctor" in reporting the results.

Independent variables

The key independent variables in this study are race/ethnicity and three indicators of serious mental illness. Race/ethnicity was self-reported and categorized as: non-Hispanic white, non-Hispanic black, and Hispanic at the initial study visit. The number of subjects in other racial categories was small (n=20) and therefore were excluded from analyses. The three mental illness variables in this analysis include: moderately severe to severe depression; any past manic episodes; and ≥3 psychotic symptoms, all assessed at the three month study visit. (Mental illness was captured at baseline, but because most participants were starting a detoxification program the 3 month visit provided more accurate data.) Depression was assessed using the Patient Health Questionnaire short form (PHQ-9) which is comprised of nine items about respondents feelings in the last two weeks, such as "feeling down, depressed or hopeless", with responses ranging on a four point scale from "not at all" to "nearly every day" (scores 0-3 points) [54]. We considered someone to be depressed if s/he had a PHQ-9 score of 15 or more, indicating moderately severe to severe depression [54,55]. Past manic or hypomanic episodes were assessed using the Mini International Neuropsychiatric Interview (MINI) [56]. Symptoms of mania include hypersexuality and impulsivity, and thus create the potential for increased sexual risk behavior [57]. This measure used a series of items to assess hypo/mania, asking about the frequency, duration and characteristics of manic episodes, with dichotomous responses of "Yes" or "No". The MINI has been validated as a diagnostic tool in accordance with criteria from to the DSM-IV [56]. Psychotic symptoms were measured using four items from the Behavior and Symptom Identification Scale (BASIS) [58]. These items included: thinking you had special powers, hearing voices or seeing things, thinking people were watching you and thinking people were against you. Subjects were asked about their experience of these symptoms during the past week and asked to rate the frequency of these experiences on a scale ranging from "never" to "always". We considered an individual to have substantial current psychotic symptoms if s/he responded "sometimes", "often", or

"always" on three out of the four items. The complete BASIS measure is comprised of 24 items and using three out of four items not considered diagnostic, but an indication of psychosis.

Dependent variables

The key dependent variables were two items about safe sex counseling and self-attributed resultant patient safe sex behavior, assessed during the three month study interview. The first item, having ever talked about safe sex with your regular doctor, was taken from the Primary Care Assessment Survey (PCAS) [59,60]. The PCAS is a patient reported instrument created to assess several domains that constitute quality primary care [59]. The specific question asked was "Which of the following has your regular doctor ever talked to you about:. . ..safe sex?" (response: yes/no). The second dependent variable, having ever practiced safer sex because of your doctor's advice, was taken from a survey used to examine the relationship between patient income and physician counseling about health risk behaviors [61]. The specific question asked was "Which of the following have you ever done because of your doctor's advice?. . .Practiced safer sex" (response: yes/no). We included all patients who responded to these questions in our analysis. For the second dependent variable, having practiced safer sex because of a doctor's advice, the sample was restricted to only those who had reported ever receiving safe sex counseling.

Covariates

The covariates included in the analyses were self-reported age, gender, education (less than high school; high school; more than high school) and which randomized group the subject was assigned to, taken from the initial study visit. We also included whether the subject had multiple (i.e., >1) male and/or female sex partners in the last three months, as an indication of sexual risk behavior. These data were taken from the audio computer assisted self-interviewing (ACASI) portion of the three month follow-up interview. We included these covariates given their potential effect on receipt of safe sex counseling and behavior [62-64]. We also included quality of the patient-doctor relationship, specifically assessing trust and communication from the PCAS, to evaluate if these variables attenuated any observed relationships between race/ethnicity, mental illness, and the outcomes of interest. The PCAS trust scale was scored based on a series of eight items and the communication scale was based on seven items [59]. These scales were scored as continuous variables and transformed to a scale of 0-100 for multivariable analyses [59].

Statistical analysis

First, descriptive statistics were obtained for all variables stratified by each dependent variable (ever received safe sex counseling and ever practiced safer sex because of this advice). Bivariable tests were also performed for descriptive purposes. Next, we performed a series of multiple logistic regression models to test associations between indicators of mental illness and race/ethnicity with each outcome. For the outcome, having practiced safer sex because of a doctor's advice, the analysis was restricted to the subset who reported ever receiving safe sex counseling. Spearman correlations were used to evaluate potential collinearity between independent variables and covariates. No pair of variables included in the same regression model was highly correlated ($r>0.40$). The following four models were fit for each of the two dependent variables. Model 1 was a preliminary, minimally adjusted model that included the main independent variables race/ethnicity and indicators of mental illness (depression, having had any manic episodes and psychotic symptoms), and two potential confounders: randomization group and multiple sex partners in the last three months. Model 2 additionally controlled for key sociodemographic characteristics: age, education, and gender. Model 3 added the trust scale from the PCAS as a continuous variable. Model 4, the final model representing the primary analyses, included the communication scale from PCAS as a continuous variable, and removed the trust scale. We did not include trust and communication scores in the same model due to their high correlation ($r=0.67$). The findings reported in the Results section are taken from the final model (Model 4) with communication score, unless otherwise specified. Adjusted odds ratios (AOR) and 95% confidence intervals (CI) are reported. All analyses were conducted using two-sided tests and a significance level of 0.05. Due to the exploratory nature of the analyses, adjustments were not made for multiple comparisons. Statistical analyses were performed by the Boston University School of Public Health's Data Coordinating Center using SAS software (version 9.1; SAS Institute, Cary, NC).

Results

Of the 563 individuals enrolled in the AHEAD study, 500 were followed up at 3 months. Of those, 299 reported that they had a regular doctor and 295 of those answered the two questions about safe sex counseling and behavior. After excluding the 20 subjects who were not black, white or Hispanic, our final sample for the analysis of ever received safe sex counseling included 275 individuals. The study sample was comprised of 44% white, 45% black and 11% Hispanic women and men (Table 1), with a mean age of 40 (range 18-61) and median age of 42 (not shown). Moderately severe to severe depression was common, reported among 58% of subjects. Forty percent reported a previous manic episode and 16% had at least three psychotic symptoms. Approximately 71% (195/275) of the sample reported having a doctor ever talk to them about safe sex. These 195

subjects comprised the sample for the analysis of ever practiced safer sex because of your doctor's advice. Among the subset who received counseling, 76% (149/195) reported practicing safe sex because of their doctor's advice. In the adjusted models, higher trust (AOR=1.03, 95% CI: 1.01, 1.04; Model 3) and better communication (AOR=1.02, 95% CI: 1.01, 1.04) were associated with higher odds of receipt of safe sex counseling (per 1 point increase on a scale of 0-100; Table 2). Having multiple sex partners in the last three months (AOR=0.44, 95% CI: 0.21, 0.94) was associated with lower odds of practicing safer sex because of this advice, compared to those with 0-1 sex partners (Table 3).

Results by race/ethnicity

In bivariable analyses, whites had the lowest observed proportion of their doctor ever talking to them about safe sex (p=0.007; Table 1), compared to blacks or Hispanics. There were no significant findings by race/ethnicity for practicing safer sex because of a doctor's advice. In the multivariable models, after adjustment for covariates, black subjects had significantly higher odds of a doctor having ever talked with them about safe sex (AOR=2.71, 95% CI: 1.36, 5.42; Table 2) compared to whites. No racial/ethnic group was associated with significantly higher odds of reporting ever practicing safe sex because of a doctor's advice compared to whites (Table 3). Results were similar across all adjusted models.

Results by indicators of mental illness

In bivariable analyses, those who reported a manic episode (p=0.007) or three or more psychotic symptoms (p=0.04) had higher odds of reporting that their doctor had ever talked to them about safe sex (Table 1), compared to those who had not had an episode or had less than three psychotic symptoms, respectively. None of

the mental illness variables were significantly related to practicing safer sex because of a doctor's advice. In fully adjusted models, having a manic episode remained significantly associated with higher odds of a doctor having ever talked to them about safe sex (AOR=2.41, 95% CI: 1.26, 4.60; Table 2). The association was statistically significant across all adjusted models. None of the mental health variables were significantly associated with practicing safer sex because of their doctor's advice in adjusted models (Table 3).

Discussion

The majority of adults with substance dependence in our sample reported being counseled about safe sex from their primary care doctor. Of those who were counseled, about three quarters reported that they practiced safer sex because of this advice. Our results suggest that improvements in safe sex counseling are needed for all individuals with substance dependence, particularly whites. This is consistent with prior literature that suggests general deficiencies in safe sex counseling and the need to integrate this into regular health care visits [41,61,65]. Lack of counseling may be a result of primary care clinicians feeling it is not their responsibility to counsel patients in sexual health behaviors [44]. Clinicians may also be uncomfortable in sexual health counseling and need more training related to sexual health [46]. Time constraints and lack of support staff have been cited as potential reasons for lack of sexual health counseling [44,45,66]. The expanded role of nurses or case managers may be a potential solution in improving quality sexual health care [45]. Of note, patient trust and communication with their doctor were the only covariates associated with receipt of safe sex counseling. This suggests that improving patient-doctor trust and communication may increase safe sex counseling for patients with substance dependence.

Our findings suggest that safe sex counseling can have a positive impact on patient behaviors. Understanding

the discourse between patients and clinicians and effective methods for delivering contraceptive information is critical in developing practice guidelines and guidance for clinicians [67]. Future research should focus on understanding how clinicians can affect patient behavior, in an effort to reduce disparities in sexual health and outcomes.

Blacks and those with manic episodes reported being counseled by their doctors significantly more about safe sex. Although most who received counseling reported practicing safe sex because of their doctor's advice, this was not more likely to translate into safer sex practices for one racial/ethnic group or individuals with indicators of mental illness. Interestingly, the covariates included in both sets of analyses largely did not affect the significant associations between race/ethnicity or mental illness with our outcomes. Although the findings that blacks are counseled more about safe sex are in contrast to our hypotheses, there is literature to support the finding of increased counseling for minorities [62]. Previous disparities research suggests that clinician behavior may be influenced by population based studies that affect their decision making in counseling patients [68,69]. Thus, if clinicians know from the literature that racial/ethnic minorities are more likely to have negative sexual health outcomes, they may counsel these patients more about safe sex practices. Clinicians may also have implicit, sub-conscious biases related to race that are not fully apparent but could affect patient counseling [70,71]. Counseling based on assumptions about sexual risk behaviors because of patient race can be considered stereotyping, that leads to disparities in counseling black patients more about safe sex. Instead, patient-centered counseling, based on individual risk factors, tailored to that individual's needs, is ideal.

Patients with manic episodes may have been counseled more, given that hypersexuality is associated with these episodes [57]. It is difficult to disentangle the meaning of this finding, given that the subject was asked about current psychotic symptoms and depression, but *any* prior history of manic episodes. It is not clear if the manifestation of symptoms or diagnosis of mental illness came before or after safe sex counseling and thus we cannot determine if increased counseling among this group is in fact related to their mental illness. We also cannot verify that the clinician knew of the patient's mental illness.

Although many interventions for increasing safe sex practices can be found in the literature [72], particularly for young and poor, minority women, there is not a major focus on individuals with substance dependence. Most of the interventions targeting substance users focus solely on reducing HIV infection [62,73], instead of prevention of general STIs and unintended pregnancy. Interventions should focus on the interaction of factors, such as substance use, race/ethnicity and mental illness, that may lead to disparities in sexual health outcomes [63]. Ultimately, reducing negative sexual health outcomes will require a multipronged intervention targeted at the patient, clinician and system level to help influence patient behavior and enhance the patient-clinician interaction [37].

Our findings should be interpreted within the limitations of our study. Although our analysis examined three racial/ethnic groups, we did not test for within group differences (i.e., by type of Hispanic origin) or interactions by gender, because of potential sample size issues [74]. The findings that black patients and those with manic episodes had significantly higher odds of reporting being counseled could also be due to differential response bias or incomplete statistical adjustment (i.e., history of sexually transmitted infections). This study is based entirely on patient self-report, which may be subject to recall or social desirability bias. However, understanding if safe sex counseling occurred and how it affected behavior from patient's perspective is ideal because they can most accurately report if/how counseling influenced their practices. Our sample was enrolled within one metropolitan area and the majority of subjects was of low socioeconomic status and thus may not be generalizable to all other substance dependent populations. We were unable to determine if patients received safe sex counseling from another type of clinician (other than their primary care doctor) or practiced safer sex because of advice from another clinician. There may also be temporal issues, in asking about lifetime safe sex counseling versus symptoms of mental illnesses, which may have manifested after counseling occurred (as described above).

We did not have data to account for the U.S. Preventive Services Task Force recommendations of counseling if patients had an STI within the last year, which may have affected safe sex counseling. Instead, we used number of sex partners in the last three months as an indicator of sexual risk behavior. We also used only partial diagnostic instruments as indicators of mental illness, particularly for psychotic symptoms. Despite these limitations, this study is among the first to examine racial/ethnic and mental health disparities in safe sex counseling and practices among individuals with substance dependence. This paper is one of many that will answer the call for studies to test hypotheses about how clinician behaviors affect disparities in health care [68]. Beyond merely documenting that counseling occurred, research needs to focus on enhancing our understanding of how counseling can have an impact on patient risk behavior.

Conclusions

Black patients and those with a history of manic episodes were found to be counseled more about safe sex than white patients and those without manic episodes, respectively, despite controlling for sexual risk. Exploring the basis of

how patient characteristics can influence counseling and resultant behavior merits further exploration to help reduce disparities in safe sex counseling and outcomes.

Effectiveness of a Risk Screener in Identifying Hepatitis C Virus in a Primary Care Setting

Mari-Lynn Drainoni, PhD, Alain H. Litwin, MD, Bryce D. Smith, PhD, Elisa A. Koppelman, MSW, M. Diane McKee, MD, Cindy L. Christiansen, PhD, Allen L. Gifford, MD, Cindy M. Weinbaum, MD, and William N. Southern, MD

Objectives. We evaluated an intervention designed to identify patients at risk for hepatitis C virus (HCV) through a risk screener used by primary care providers.

Methods. A clinical reminder sticker prompted physicians at 3 urban clinics to screen patients for 12 risk factors and order HCV testing if any risks were present. Risk factor data were collected from the sticker; demographic and testing data were extracted from electronic medical records. We used the *t* test, χ^2 test, and rank-sum test to compare patients who had and had not been screened and developed an analytic model to identify the incremental value of each element of the screener.

Results. Among screened patients, 27.8% (n = 902) were identified as having at least 1 risk factor. Of screened patients with risk factors, 55.4% (n = 500) were tested for HCV. Our analysis showed that 7 elements (injection drug use, intranasal drug use, elevated alanine aminotransferase, transfusions before 1992, ≥ 20 lifetime sex partners, maternal HCV, existing liver disease) accounted for all HCV infections identified.

Conclusions. A brief risk screener with a paper-based clinical reminder was effective in increasing HCV testing in a primary care setting. (*Am J Public Health.* 2012;102:e115–e121. doi:10.2105/AJPH.2012.300659)

Hepatitis C virus (HCV) is a significant public health problem. With 3.2 million Americans chronically infected,[1] HCV is the leading cause of liver-related deaths,[2] accounting for 15 000 deaths in 2007.[3] Although earlier treatments were moderately effective in reducing the HCV disease burden,[4] new treatments with greater promise have become available.[5] Because treatment cannot be offered without diagnosis and 45% to 85% of patients with HCV are unaware of their infection,[6,7] interventions designed to increase the number of HCV cases diagnosed are urgently needed.

Guidelines for HCV screening vary. The Centers for Disease Control and Prevention (CDC) recommends that patients who have injected drugs, who have long-term hemodialysis histories or persistently abnormal alanine aminotransferase (ALT) levels, who had blood transfusions or organ transplants before July 1992 (when HCV was eradicated from the nation's blood supply), who have been exposed to HCV (e.g., their mothers were HCV positive or they have been exposed at their workplace), or who are HIV positive[8] be assessed for HCV risk. Other authorities have expanded recommendations to include current sexual partners of individuals with HCV,[9,10] people who have had multiple sex partners, intranasal cocaine users, people with tattoos or repeated body piercings, people with high levels of daily alcohol use over time, Vietnam-era veterans,[11] and immigrants from countries with high HCV prevalence rates.[12]

In addition, with respect to research on HCV risk, various studies have shown that homelessness, incarceration,[13] tattoos,[14] barbershop shaving,[15] body piercing,[16] ear piercing among men,[17] use of intranasal drugs and crack cocaine,[18] and mental illness[19] are associated with higher risk. Although not explicitly recommending testing, this literature suggests that these are potential HCV risk factors for which screening may be appropriate.

Multiple approaches can be used in HCV testing programs. Universal screening of people with identified risks appears to best meet CDC's recommendations and to be the most efficient strategy, given that individuals with identified risk factors have been shown to have a much higher prevalence of HCV than the general population.[1] As the front-line health care providers for most Americans, primary care settings offer an important opportunity to incorporate HCV risk assessments, although examination of this model has been limited.

In 2 studies conducted in primary care settings, patient self-administered questionnaires have been used to assess HCV risk screening. In one of these studies, set in an urban clinic, patients completed a 27-item risk assessment[20]; the other study, set in a Veterans Health Administration facility, involved a retrospective analysis of HCV testing among veterans who had reported HCV risk factors on a self-administered questionnaire.[21] To date, no HCV screening tools have been validated, and no studies comparing different types of interventions have been conducted, including comparisons of patient-completed screening instruments and screeners implemented by primary care providers (PCPs).

We implemented a PCP-based risk screening intervention that successfully increased rates of HCV testing among patients at risk.[22] Because existing guidelines do not concur on what factors should trigger HCV testing, we included a moderately large number of risk factors (12) in assessing the intervention. However, it was unknown which factors of the screening intervention were responsible for the screener's success and whether an abbreviated set of risk factors would be equally successful. To inform both the development of a parsimonious screening intervention and the revision of risk-based HCV testing guidelines, we examined which factors were the strongest independent predictors of testing and diagnosis of HCV.

The Hepatitis C Assessment and Testing project (HepCAT), a prospective cross-sectional

evaluation conducted in 3 urban primary care clinics, was designed to inform CDC's revision of its HCV testing recommendations. HepCAT's major goal was to evaluate an intervention designed to identify patients at risk for HCV with a PCP-implemented risk screener and test those identified as at risk. Another objective was to parse out a limited number of factors to include in a simple and effective screener. We hypothesized that using the risk screener would increase testing rates and that a brief screener incorporating fewer risk factors would perform as well as the full screener. We examined the performance of the screener overall as well as the extent to which each specific risk factor predicted HCV.

METHODS

The HepCAT project was funded by the CDC through the Agency for Healthcare Research and Quality's Accelerating Change and Transformation in Organizations and Networks (ACTION) program. ACTION promotes "field-based research designed to promote innovation in health care delivery by accelerating the diffusion of research into practice"[23] rather than funding only traditional research studies involving comparison and control groups.

The ACTION network includes 15 partnerships, each with a lead organization that serves as the prime contractor for projects. Boston University is the prime contractor for one partnership that includes the Montefiore Medical Center in the Bronx, New York, and HepCAT, a collaborative effort between these 2 organizations, was conducted in 3 clinics affiliated with the center. The 3 clinics provide approximately 150 000 primary care visits annually to more than 54 000 adults; the clinics are located in economically depressed areas of the Bronx and serve patients with high rates of poverty, substance use, and sexually transmitted diseases. The estimated prevalence of HCV infection in the adult population seen in the 3 clinics is 7.7%.[24]

Intervention

The risk-based screening intervention involved prompting physicians with a clinical reminder sticker to ask whether a patient had any of 12 specific HCV-related risks and to order HCV tests according to the presence of those risks. The sticker (Figure 1) incorporated a double-layer "carbon copy" design; once completed, the top copy of the sticker could be removed and placed in a secured box in the examination room for research purposes while the other copy remained affixed to the medical chart.

In addition to the sticker, intervention training included the following: on-site educational sessions including a standardized presentation for all PCPs and clinic staff delivered prior to and once during the intervention period, regular communication between the research team and clinical leadership, electronic provision of a weekly scientific article on HCV to all PCPs, and environmental reminders (HepCAT buttons, pocket cards, and posters). Also, project staff visited each clinic twice per week to place stickers on all progress notes, encourage adherence to screening protocols, and elicit feedback from PCPs and other clinic staff. Furthermore, each clinic had a "physician champion," a member of the research team who regularly visited the clinic to maintain PCPs' engagement in the intervention. All PCPs were supplied with a script (in English and Spanish) to standardize and normalize the introduction of the screener.

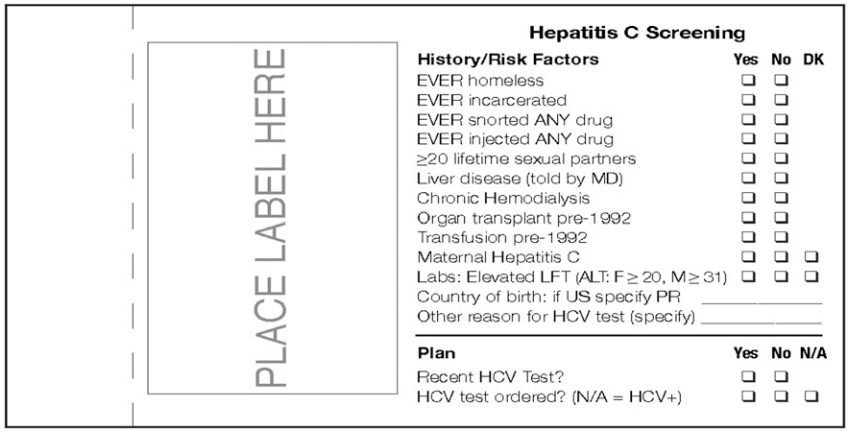
Each PCP was asked to complete the sticker at every visit for patients who had not been tested for HCV in the preceding 12 months and to order an HCV antibody test if any risk factor was identified. The risk-based screening intervention was conducted over a 15-week period from November 2008 to March 2009.

Data Collection

Given the expectation that all adults seen in the clinics would be screened, demographic and HCV testing information on each adult (18 years old or older) seen during the intervention period was extracted from the electronic medical record. Risk factor data were collected from the risk screener sticker. These data sets were merged into a single database. We compared patients who had been screened with those who had not been screened. Among screened patients, we examined risk factors, HCV testing, and HCV positivity rates.

Measures

The main outcomes in our analysis were HCV testing and HCV positivity. A patient was considered to have been tested if an anti-HCV antibody test was performed within 90 days of the clinic visit date. HCV antibody positivity was defined as a positive anti-HCV test within the same time period. To determine the effects of the screener on HCV testing and positivity, we analyzed patients who had and had not been screened separately. A patient was considered screened if a sticker was submitted with any information about HCV risk factors recorded. A patient was considered not screened if no sticker was submitted or if the submitted sticker was blank. After examining the main



Note. ALT = alanine aminotransferase; DK = don't know; HCV = hepatitis C virus; LFT = liver function test; N/A = not applicable; PR = Puerto Rico.

FIGURE 1—Clinical reminder sticker used in the risk screening intervention.

outcomes, we examined the incremental value of each element of the screener to assess its performance with respect to promoting HCV testing and identifying cases of anti-HCV positivity; analyses focused on proportions of patients tested and results for patients with each risk factor.

Data Analysis

We used Stata software in conducting our analyses.[25] We initially conducted the *t* test, the χ^2 test, the rank sum test to compare screened and nonscreened patients with respect to demographic characteristics. Among screened patients, we examined the proportions with any risk identified (vs no risk identified), the proportions who had (vs had not) been tested, and rates of HCV positivity. We then investigated the rates of testing and HCV positivity associated with each risk factor.

We identified the incremental value of each screener element through an iterative process as follows. Initially we determined which risk factor was most strongly associated with positivity and counted the number of positive cases identified by asking about that risk factor. Next, we removed the HCV-positive cases identified by the first risk factor and determined which of the other risk factors identified the most remaining positive cases. Then the HCV-positive cases identified by the second risk factor were removed and a third risk factor that identified the most remaining cases was sought. The process was repeated until the remaining risk factors did not identify any new HCV positive cases.

RESULTS

Of the 13 371 patients with at least 1 primary care visit during the intervention period, 4339 had previously been tested and 51 were missing critical data; as a result, 8981 patients were included in our analysis. Table 1 shows comparisons of patients screened and not screened during the intervention period.

The mean age of the 8981 patients was 47.8 years, and one fourth were male. More than half were Latino, about 30% were Black, and fewer than 5% were White. About half were insured via Medicaid, just under a quarter had commercial insurance, about 14% were uninsured, and 12% had Medicare. A screener was completed for 3250 (36.2%) of the patients seen. Male and White patients were more likely to be screened, and Black patients were less likely to be screened; there were no differences in screening rates according to age or insurance status.

Table 2 presents proportions of testing and yield (rate) of anti-HCV positivity among those screened and not screened and among those with and without identified risks. During the intervention, 13.1% of all patients seen in the clinics were tested for HCV. However, this level of testing was driven primarily by screening: 25.3% of screened patients were tested, as opposed to only 6.2% of unscreened patients. The yields of anti-HCV positivity were 5.9% among those with no screening documentation and 5.0% among the screened population.

Of the 3250 patients screened, 27.8% (n = 902) had at least 1 HCV risk factor. Of these patients, 55.4% (n = 500) were tested for HCV; 13.7% of tested patients had no identified risk. The yield of anti-HCV positivity among tested patients was higher for those with a risk factor (6.8%) than for those without a risk factor (2.2%).

TABLE 1—Characteristics of Patients Seen During the Intervention Period: Bronx, NY, 2008–2009

Characteristic	Total (n = 8981), No. (%)	Screened (n = 3250), No. (%)	Not Screened (n = 5731), No. (%)	*P*
Gender				.002[a]
Male	2330 (25.9)	906 (27.9)	1424 (24.8)

[a]Significant difference between groups at $P < .05$.

Identification of Risk Factors

Table 3 provides details on the 902 screened patients identified as having at least 1 HCV risk factor. The most commonly identified risk factors, documented among more than 20% of screened patients, were history of multiple sex partners, intranasal drug use, elevated ALT, homelessness, and incarceration. Histories of liver disease and blood transfusions before 1992 were reported by 10% to 15% of those screened. A smaller percentage (6.2%) of patients reported injection drug use; just over 2% reported maternal HCV. Very few patients (< 1%) reported chronic hemodialysis or organ transplants before 1992.

Testing Rates for Each Risk Factor

All prevalent risk factors predicted testing relatively well, at close to or above 50% of the time. Testing was most often conducted (> 60% of the time) among those who reported histories of multiple sex partners, transfusions, and maternal hepatitis. In addition, more than half of those with histories of incarceration, intranasal drug use, and elevated ALT were tested, as were almost half of those with histories of homelessness, injection drug use, and liver disease.

Yield of Patients Tested

Overall, the yields of HCV testing were high. Sixty-three percent of patients with a history of injection drug use had positive anti-HCV test

TABLE 2—Hepatitis C Virus (HCV) Screening, Testing, and Yield During the Intervention Period: Bronx, NY, 2008–2009

	Tested for HCV, No. (%)	Yield (Anti-HCV Positivity), No. (%)
Total seen (n = 8981)	1179 (13.1)	62 (5.3)
Not screened (n = 5731)	357 (6.2)	21 (5.9)
Screened (n = 3250)	822 (25.3)	41 (5.0)
No risk (n = 2348)	322 (13.7)	7 (2.2)
Any risk (n = 902)	500 (55.4)	34 (6.8)

results. Positivity was also high among those reporting liver disease (26.8%), maternal HCV (16.7%), intranasal drug use (15.7%), incarceration (10.9%), homelessness (9.0%), multiple sex partners (8.4%), elevated ALT (7.3%), and transfusions (6.9%).

Incremental Value of Screener Elements

Table 4 illustrates the incremental predictive value of each risk factor starting with the factor with the highest yield: injection drug use. Injection drug use was the strongest predictor of anti-HCV positivity; sole inclusion of the "ever injected drugs" variable would have predicted 41.5% of identified cases. Intranasal drug use was the second strongest predictor; the incremental benefit of adding "ever snorted drugs" as a second factor would have led to the additional identification of 14.6% of cases, for a total yield from a 2-question screener of 56.1% of the identified cases of anti-HCV positivity. Ultimately, we determined that a 7-element screener that comprised injection drug use, intranasal drug use, elevated ALT, transfusions before 1992, maternal HCV, 20 or more lifetime sex partners, and existing liver disease would have accounted for all anti-HCV cases identified.

DISCUSSION

We found that anti-HCV testing increased in a primary care setting when a 12-item risk screener was implemented and that 10 elements identified patients at risk. However, 6 of the elements would have identified the same number of cases of anti-HCV positivity, suggesting that a briefer screening instrument would be equally effective.

Our findings demonstrate the utility of risk-based testing in identifying individuals positive for anti-HCV, confirming the findings of previous studies.[20,21] Earlier research showed that the 3 study clinics had already tested 39.7% of their patient populations and had estimated that 59.7% of these patients were anti-HCV positive before the risk screening intervention.[24] Although it could be argued that the individuals identified before the intervention would have presented with the most obvious risks, the risk screener still identified an additional 13.1% for screening in the previously untested group, and of these patients 62 were anti-HCV positive. This increase in testing was primarily because of the screened population; 25.3% of screened patients were subsequently tested for HCV, whereas the testing rate among unscreened patients was 6.2%. More than half of patients who had at least 1 risk factor identified on the screener were tested. Thus, the intervention was effective in increasing testing rates both overall and, particularly, among patients with identified risk factors.

It is notable that the testing rate among patients identified as having HCV risk factors was not closer to 100%, particularly in the case of risk factors such as injection drug use that are widely known to be associated with HCV. There may be several reasons for this finding, including the steps required by both patient and PCP to complete the anti-HCV testing process. For patients, testing required going to a separate area in the clinic and waiting to have blood drawn; for PCPs, ordering tests required completing a lab slip. These may be important barriers to be mindful of in attempts to increase testing in primary care settings,

TABLE 3—Risk Factor Identification, Hepatitis C Virus (HCV) Testing, and Yield: Bronx, NY, 2008–2009

Factor	Risk Factor Identified, No. (%)	Tested for HCV, No. (%)	Yield (Anti-HCV Positivity), No. (%)
Ever homeless	234 (25.9)	111 (47.2)	10 (9.0)
Ever incarcerated	214 (23.7)	119 (55.6)	13 (10.9)
Ever snorted drugs	252 (27.9)	134 (53.2)	21 (15.7)
Ever injected drugs	56 (6.2)	27 (48.2)	17 (63.0)
≥ 20 lifetime sex partners	270 (29.9)	167 (61.9)	14 (8.4)
Liver disease (physician diagnosis)	115 (12.7)	56 (48.7)	15 (26.8)
Chronic hemodialysis	9 (1.0)	2 (22.2)	0 (0.0)
Transplant before 1992	5 (0.5)	2 (40.0)	0 (0.0)
Transfusion before 1992	108 (12.0)	72 (66.7)	5 (6.9)
Maternal hepatitis C	19 (2.1)	12 (63.2)	2 (16.7)
Elevated alanine aminotransferase (documented in electronic medical record)	242 (26.8)	137 (56.6)	10 (7.3)

Note. Totals sum to more than 902 because patients often had multiple factors identified. The sample size was n = 902.

TABLE 4—Incremental Value of Hepatitis C Virus (HCV) Screening Items: Bronx, NY, 2008–2009

Factor	No. of Patients With Identified HCV Risk	No. of Patients With Positive Test Results (% of Positive Cases Overall)	Cumulative %
Ever injected drugs	56	17 (41.5)	41.5
Ever snorted drugs	200	6 (14.6)	56.1
Elevated alanine aminotransferase (documented in electronic medical record)	185	4 (9.8)	65.9
Transfusion before 1992	59	3 (8.0)	73.1
≥ 20 lifetime sex partners	115	2 (4.9)	78.0
Maternal hepatitis C	10	1 (2.4)	80.5
Liver disease (physician diagnosis)	23	1 (2.4)	82.9
Ever homeless	66	0 (0.0)	82.9
Ever incarcerated	67	0 (0.0)	82.9
Chronic hemodialysis	0	0 (0.0)	82.9
Transplant before 1992	0	0 (0.0)	82.9
Total		34/41	82.9

Note. The cumulative percentage does not reach 100% because 7 of the 41 patients with positive anti-HCV results had no risk factors identified on the risk screener.

particularly given the myriad screening and preventive care activities that are already recommended.

In addition, there was no requirement in the HepCAT protocol for patients to be tested at the visit when the sticker was placed in the chart, and the PCP may have planned to test the patient at a later visit. Only the Veterans Health Administration, via a federal mandate and real-time electronic clinical reminders, has developed a mechanism to fully implement risk-based HCV screening and testing in primary care settings[23]; an electronic reminder to screen might be the only method to achieve full implementation.

A key question in the development and implementation of the HepCAT intervention was which items to include in the screener. Although screened patients reported high rates of intranasal and injection drug use, as well as multiple sex partners, homelessness, incarceration, liver disease, and transfusions, our analysis illustrated that a screener with fewer risk factors could be as effective as the 12-item screener. Our results showed that two thirds of patients with positive anti-HCV test results were identified with a screener that included just 3 factors (injection drug use, intranasal drug use, elevated ALT); 4 additional factors (transfusions, maternal hepatitis C, 20 or more lifetime sex partners, liver disease) identified an additional 17% of cases.

It appears that some factors, such as incarceration and homelessness, may actually be proxies for the other risk factors and will not produce additional benefits in terms of identifying cases of anti-HCV positivity. However, because 17% of the patients with positive anti-HCV test results had no risk factors identified on the screener, it will be important to understand the characteristics of patients without risk factors who were tested and the reasons they were tested, including assessing how demographic differences may or may not relate to other risk factor differences. For example, it is important to examine reasons why male patients were more likely to be screened than were female patients and White patients were more likely to be screened than were Black patients.

Our findings mirror recent work showing that a parsimonious screener can be effective[1,21] and practical in the context of routine care. Consistent with our results, Zuniga et al.,[21] using retrospective data on veterans, found that screening only for injection drug use would have identified 41% of cases of anti-HCV positivity in that population; in addition, they found that a risk screener including only 5 factors (injection drug use, blood transfusion before 1992, service during the Vietnam era, tattoos, and history of abnormal liver function tests) and a risk screener incorporating the 5 factors independently associated with anti-HCV positivity would have identified 97% of cases with 20% fewer individuals being tested. Our results also are consistent with an analysis of National Health and Nutrition Examination Study data conducted by Armstrong et al.,[1] who found that injection drug use, elevated ALT, and transfusions before 1992 identified 85% of cases of anti-HCV positivity.

An important difference between our work and previous studies is our inclusion of intranasal drug use as a screening item. We found that although intranasal drug use was not independently associated with anti-HCV positivity (probably as a result of sample size limitations), it identified almost 15% of cases of positivity. Given our findings and the possibility that patients will be more likely to acknowledge intranasal than injection drug use owing to the stigma often associated with injection drug use, we propose that intranasal drug use be considered for inclusion in brief screeners.

Overall, it is important to note that our study, conducted in the context of routine primary care in a high-risk population, is congruent with the results obtained by Armstrong et al. in their US population-based sample, and it appears clear that a brief screener including injection drug use, elevated ALT, and transfusions before 1992 will be effective in identifying HCV

with or without the inclusion of intranasal drug use. Our results also concur with research by McGinn et al.[20] supporting risk-based testing; however, their study involved a 27-item questionnaire, whereas our focus on using a brief screener is more practical for implementation.

With the current policy focus on the medical home model and the role of PCPs in coordinating and taking responsibility for all aspects of a patient's care, the expectation will remain for PCPs to do more with less time. Thus, the challenge of integrating a new intervention to identify HCV in primary care settings remains. To minimize the impact on already-overtaxed PCPs, it is crucial to identify those elements most predictive of HCV positivity. We found that PCPs can perform effective HCV screening with a screener that includes many fewer risk factors than previously reported in the literature. Moreover, screening could be performed by ancillary providers, such as nursing staff, and this type of intervention could be easily generalized to other settings or other clinical conditions given its relative simplicity and the lack of technology required for implementation.

Limitations

Our study involved some limitations. First, it was difficult to sustain a high level of PCP adherence to the intervention, and PCPs were unable to do more than check a box on a screener (e.g., identify country of birth if outside the United States). Thus, it is important to consider whether screening could be conducted by other clinical staff. Second, because we were unable to track unused laboratory slips, we cannot determine whether untested patients with risk factors were referred for but did not undergo testing or whether these patients were not referred.

Third, this study was observational; without a comparison group, we cannot establish a causal link between the intervention and the increase in testing. Finally, the small number of cases of identified anti-HCV positivity limited our examination of the incremental value of each of the risk factors in creating a briefer risk screener.

Conclusions

We found that a brief risk screener with a paper-based clinical reminder was effective in increasing HCV testing in a primary care setting. With more effective treatments now available, it is critical that the process of identification of HCV be improved, given that care and treatment cannot be offered without diagnosis. Primary care is the front line of health care for most patients and the optimal location for simple risk screening.

Given the many challenges facing PCPs and the numerous preventive care activities expected of them, future efforts should focus on testing a more parsimonious risk screener and determining whether ancillary staff could conduct screening activities. In addition, there is a need for future research testing the use of HCV screening by different types of PCPs, including studies involving experimental designs. Studies are also needed to explore the actual utility of a brief screener, followed by validation of that screener. Finally, we recommend that the cost-effectiveness of our intervention be assessed; if it is cost-effective for HCV screening, it might serve as a model for primary care screening of other undiagnosed clinical conditions. ■

Abstract

Objectives To relate cancer since entry into the Framingham Heart Study with the risk of incident Alzheimer's disease and to estimate the risk of incident cancer among participants with and without Alzheimer's disease.

Design Community based prospective cohort study; nested age and sex matched case-control study.

Setting Framingham Heart Study, USA.

Participants 1278 participants with and without a history of cancer who were aged 65 or more and free of dementia at baseline (1986-90).

Main outcome measures Hazard ratios and 95% confidence intervals for the risks of Alzheimer's disease and cancer.

Results Over a mean follow-up of 10 years, 221 cases of probable Alzheimer's disease were diagnosed. Cancer survivors had a lower risk of probable Alzheimer's disease (hazard ratio 0.67, 95% confidence interval 0.47 to 0.97), adjusted for age, sex, and smoking. The risk was lower among survivors of smoking related cancers (0.26, 0.08 to 0.82) than among survivors of non-smoking related cancers (0.82, 0.57 to 1.19). In contrast with their decreased risk of Alzheimer's disease, survivors of smoking related cancer had a substantially increased risk of stroke (2.18, 1.29 to 3.68). In the nested case-control analysis, participants with probable Alzheimer's disease had a lower risk of subsequent cancer (0.39, 0.26 to 0.58) than reference participants, as did participants with any Alzheimer's disease (0.38) and any dementia (0.44).

Conclusions Cancer survivors had a lower risk of Alzheimer's disease than those without cancer, and patients with Alzheimer's disease had a lower risk of incident cancer. The risk of Alzheimer's disease was lowest in survivors of smoking related cancers, and was not primarily explained by survival bias. This pattern for cancer is similar to that seen in Parkinson's disease and suggests an inverse association between cancer and neurodegeneration.

Introduction

Limited data suggest that cancer survivors have a decreased risk of Alzheimer's disease and that people with Alzheimer's disease have lower rates of cancer.[1-6] Evidence of an inverse relation between Parkinson's disease and most cancers is now convincing.[7-13] A link between cancer and neurodegeneration is plausible as they share several genes and biological pathways, including inappropriate activation and deregulation of the cell cycle.[14-22] Signaling along these pathways results in opposite end points: in the case of cancer, uncontrolled cell proliferation, and in the case of neurodegeneration, apoptotic cell death. Proteins such as p53, a major regulator of apoptosis, and Pin1, which has a dual role in cell cycle control and protein folding, play a key part in the pathophysiology of both Alzheimer's disease and cancer.[15] A better understanding of the biological links between these two families of diseases is already opening new therapeutic horizons.

In one population based cohort study, people with prevalent cancer had a 43% lower risk of ever developing Alzheimer's disease, and those with prevalent Alzheimer's disease had a 69% lower risk of being admitted to hospital for cancer.[4] Although these results are intriguing, establishing a relation

Correspondence to: J A Driver jdriver@partners.org

between age related diseases is complex, and several issues must be dealt with before concluding that this represents a true association.[23] Because severe cognitive impairment leads to decreased screening and reporting of cancer symptoms,[24 25] it is difficult to know to what extent lower cancer rates in people with Alzheimer's disease are caused by decreased incidence or under-diagnosis. For this reason, assessing the incidence of Alzheimer's disease among cancer survivors who are cognitively intact at baseline is the preferable analysis. Here the major challenge is the problem of selective mortality, since cancer survivors may have a lower risk of Alzheimer's disease simply because they are more likely to die before they can develop it. Available studies have not sufficiently tackled the problems of selective mortality. Additional limitations of previous analyses are the exclusion from analysis of incident cancers that develop after baseline but before Alzheimer's disease and reliance on self report or medical record systems to identify cancer. We investigated the relation between cancer and Alzheimer's disease using data from the Framingham Heart Study, a prospective cohort with frequent examinations of participants, prospective validation of both Alzheimer's disease and cancer, and over 50 years of follow-up.

Methods

The Framingham Heart Study is a longitudinal community based cohort study of cardiovascular risk factors that started in 1948 in Framingham, Massachusetts, United States. The original cohort comprised 5209 participants (2336 men and 2873 women) aged 28-62 at the first examination. In 1971, children of the original cohort and their spouses were recruited to form the offspring cohort (5214 participants). Participants have undergone direct evaluations, including a medical history, physical examination, and laboratory testing every two years in the original cohort and about every four years in the offspring cohort. The study design and entry criteria for both cohorts have been described in detail elsewhere.[26] Participants of the original cohort aged 65 and older who were free of dementia and attended examination cycle 20 (1986-90) comprise the sample for our primary investigation (n=1278). We followed these participants for incident dementia for a mean of 10 years. The nested case-control study comprised participants from both the original and the offspring cohorts (n=1485). All participants gave written informed consent.

Ascertainment of cancer cases

We identified possible cancer cases in the Framingham study at routine examinations or, if participants did not attend an examination, by postal surveys or telephone interviews for updates on health history. Cases were also identified through surveillance of admissions to the local Framingham hospital and from death records. Once a case was identified, we confirmed the diagnosis from the patient's medical records, including pathology reports. Two independent people reviewed the medical records. Most cancers were confirmed by pathology reports, and fewer than 3.4% of diagnoses were based solely on death certificates or clinical diagnoses.[27] We coded primary cancers using the World Health Organization ICD-O (international classification of diseases) classification. For this analysis we did not include non-malignant neoplasms and non-melanoma skin cancers in the definition of cancer.

Ascertainment of dementia cases

Since examination cycle 14 in the original cohort and examination 2 in the offspring cohort, a dementia-free cohort of 7809 participants has been under continuous surveillance for the development of dementia and Alzheimer's disease. The Folstein mini-mental state examination[28] was administered at regular cycle examinations, and participants who scored below an education based cut-off point or had a 3 point decrement in their score from a preceding examination (or 5 point decrement overall) were referred for more indepth testing. Participants also underwent an indepth evaluation if they or someone in their family reported symptoms of memory loss or were referred by a Framingham study physician or staff member for evaluation of neurological symptoms. A panel of at least one neurologist and one neuropsychologist determined cases of dementia, dates of diagnosis, and subtypes using data, where available, from the neurologist's examination, neuropsychological test performance, Framingham study records, hospital records, information from primary care physicians, interviews with the families, computed tomography and magnetic resonance imaging records, and confirmation of autopsy findings. Dementia was required to be present for at least six months of follow-up before the diagnosis was confirmed. All participants identified as having dementia had at least mild severity by the clinical dementia rating score of 1 or more. Cases of Alzheimer's disease met the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association criteria for possible and probable Alzheimer's disease.[29] We classified dementia as any dementia (met the criteria for any dementia, including Alzheimer's disease), possible Alzheimer's disease (met the clinical criteria for Alzheimer's disease but with an atypical course or evidence of a second process contributing to the dementia), and probable Alzheimer's disease (met the criteria for Alzheimer's disease without evidence of another process contributing to the dementia).

Assessment of covariates

From the baseline visit (examination 20) we obtained data on personal characteristics (age, sex, and education) and laboratory test results (homocysteine levels and apolipoprotein E genotype). We collected information on cancer risk factors (tobacco use and body mass index) at baseline and updated this periodically throughout the study. For the case-control study, we used the covariates closest to the matching date.

Statistical analyses

Prospective cohort study

Participants contributed up to 22 years of follow-up from the baseline examination to the development of dementia, death, or the last evaluation. We used Cox proportional hazard models to determine the hazard ratio and 95% confidence intervals for the risk of any dementia, any Alzheimer's disease (possible or probable), and probable Alzheimer's disease in those with and without a history of verified cancer. The cancer history variable was updated to include cases of incident cancer that occurred during follow-up after baseline. We carried out separate analyses for participants with any cancer (excluding non-melanoma skin cancer), smoking related cancers (oral, pharynx, larynx, oesophagus, stomach, pancreas, lung, cervix, bladder, and kidney)[30], and non-smoking related cancers. The primary models were adjusted for age, sex, and smoking. We then repeated the analysis in a smaller subset of patients with data on other risk factors for Alzheimer's disease: apolipoprotein E4 status, educational level, and plasma homocysteine level.[30-32]

To explore whether the relation between cancer and Alzheimer's disease might be mainly due to selective mortality, we first

restricted the analysis to participants who survived at least to age 80. If the association was predominantly due to the death of cancer survivors, then it should be diminished when these patients were excluded. We then investigated the relation between history of cancer at examination 20 (baseline) and a different neurological outcome—namely, the subsequent risk of incident stroke. If a decreased risk of cancer in patients with Alzheimer's disease was primarily due to their increased mortality rate, then they would be expected to have a lower rate of stroke as well.

Nested case-control study

To evaluate the relation between dementia and subsequent cancer, we matched each dementia case with up to three controls of the same age and sex who were free of dementia at the time of dementia diagnosis of the case (index date). Both cases and reference participants were free of cancer as of the index date. Participants who eventually developed dementia were considered potential controls up to five years before their data of dementia diagnosis (to avoid subclinical dementia in controls). We used Cox models to determine the hazard of incident cancer in dementia cases compared with the reference participants. Models were adjusted for tobacco use and body mass index. Data on covariates was taken from the examination closest to the index date. We calculated the cumulative incidence of cancer in those with and without Alzheimer's disease adjusted for age, sex, body mass index, and smoking.

Results

At examination 20 (baseline), 1278 participants (38.8% men) aged 65 or older had normal cognitive status. The mean age among cancer survivors (n=176) was 77 years and among those with no history of cancer (n=1102) was 76 years (table 1⇓). Educational level, positivity for apolipoprotein E4, and homocysteine level did not differ substantially between those with and without cancer. Overall, 323 cases of dementia were diagnosed over a mean of 10 years of follow-up. Of these, 221 (86%) met the criteria for probable Alzheimer's disease and 36 for possible Alzheimer's disease (18 had Alzheimer's disease with stroke and 18 had both Alzheimer's disease and vascular dementia). Of the 66 patients with non-Alzheimer's disease, 24 had Lewy body dementia, 15 had vascular dementia, two had frontotemporal dementia, and 25 were classified as having "other" dementia.

Cancer history and risk of Alzheimer's disease

At baseline 176 participants had a history of cancer, and during follow-up an additional 247 people were diagnosed as having incident cancer but before the diagnosis of Alzheimer's disease. Cancers at baseline were more likely to be screening related and non-smoking related than incident cancers (table 2⇓). Cancers with high lethality such as those of the lung, pancreas, and brain were much more common among incident cancers. Cancer survivors had a substantially lower risk of probable Alzheimer's disease (hazard ratio 0.67, 95% confidence interval 0.47 to 0.97), adjusted for age, sex, and smoking (table 3⇓), but the lower risks of any Alzheimer's disease (0.81) and any dementia (0.83) did not reach statistical significance. The risk of probable Alzheimer's disease was lower among survivors of smoking related cancers (0.26, 0.08 to 0.82) than among those with non-smoking related cancers (0.82, 0.57 to 1.19). Further adjustment for education, apolipoprotein E4 genotype, and homocysteine level gave slightly higher risk estimates, but the loss of statistical significance was possibly due to limited power in this smaller subset (table 3). Limiting the analysis to participants who survived at least to age 80 did not change the inverse association between cancer history and probable Alzheimer's disease (0.68, 0.47 to 0.99, table 4⇓). In contrast with their substantially lower risk of Alzheimer's disease, survivors of smoking related cancer had an increased risk of incident stroke (2.18, 1.29 to 3.68), which was also seen among those who survived to age 80 (2.25, 1.29 to 3.95).

Incident Alzheimer's disease and risk of cancer

Overall, 495 cases of any dementia, 49 of possible Alzheimer's disease, and 327 of probable Alzheimer's disease were prospectively identified. Up to three dementia-free controls were matched to each case. Overall, 41 cases (8%) and 211 controls (14%) developed incident cancer. Table 5⇓ shows the frequency of individual cancer types by case-control status. In total, 6.9% (n=102) of controls were diagnosed as having screening related cancer compared with 3.4% (n=17) of cases. In the age matched group, the risk of subsequent cancer was substantially decreased for those with any dementia (0.44, 0.32 to 0.61), any Alzheimer's disease (0.45, 0.24 to 0.84), and probable Alzheimer's disease (0.39, 0.26 to 0.58, table 6⇓). When adjusted for smoking and body mass index, the decreased risk of cancer remained statistically significant and became even lower. Over the follow-up period, 57 controls (17%) developed probable Alzheimer's disease.

Discussion

In this prospective cohort study, cancer survivors had a 33% decreased risk of developing probable Alzheimer's disease compared with people without cancer. The "protective effect" of previous cancer was greater for smoking related cancers than for non-smoking related cancers. The inverse association did not change when participants who died were excluded, and was not seen when stroke was used as an alternative outcome, suggesting it was not simply an artefact of decreased survival in patients with cancer. In the case-control analysis, patients with probable Alzheimer's disease had a 61% decreased risk of incident cancer. When all dementias were included, the risk became slightly higher. Patients with dementia were less likely to develop screening related cancers than those without dementia, suggesting that at least some of the decreased risk is because of under-diagnosis.

Strengths and limitations of the study

Our analysis has several important strengths. We prospectively defined cancer and Alzheimer's disease in the Framingham Heart Study over its more than 50 years of follow-up, so that our cases represent incident disease. Nearly all malignancies in the population were captured. We updated our cancer variable to include the many incident cases that occurred after baseline, during follow-up. This strengthened the negative association between cancer and Alzheimer's disease (data not shown), and suggests that analyses that do not include incident cancer may underestimate the association. Finally, we carried out two specific analyses to tackle the critical problem of survival bias.

Several limitations should also be considered. Firstly, our cohort, by definition, did not include people who died of cancer before study baseline. It is unknown whether people who died of cancer before the age of 65 would have had the same risk as those of survivors. As in any longitudinal study, participants with long follow-up represent a select population, and this should be kept

in mind when interpreting our results. Even complex techniques used for missing data are not able to fully correct for this selection bias.[33] However, the inverse association observed in this study was not primarily due to survival bias, at least during follow-up. We did not have the power to look at the relation between Alzheimer's disease and individual cancer types, or to compare the relation between cancer and other types of dementia. Cohorts in which both Alzheimer's disease and cancer are carefully defined are by definition not of the size required for such analyses. We were unable to stratify our results by race, as the participants in our study were mainly white. Some cases of vascular dementia were present in those who met the criteria for possible Alzheimer's disease, but, if anything, this would have biased our results towards the null. Finally, owing to the relatively small numbers of patients with cancer in our analysis, we were not able to stratify analyses by whether patients had or had not received treatment for cancer.

Comparison with previous studies

Our findings are similar to those of the only two available prospective studies. In a longitudinal memory cohort of 594 patients, those with prevalent cancer at baseline seemed to develop Alzheimer's disease at a lower rate (hazard ratio 0.40, 95% confidence interval 0.12 to 1.13) than those with no history of cancer.[3] In an analysis of the cognition cohort of the Cardiovascular Health Study (n=3020), a history of cancer at baseline conferred a lower risk of probable Alzheimer's disease (hazard ratio 0.57, 95% confidence interval 0.36 to 0.90).[4] Similar to their results, we found that the inverse relation became stronger as we excluded non-Alzheimer's and mixed dementias. Our risk estimates for incidence of cancer among those with and without Alzheimer's disease were essentially the same as that of Roe and colleague's study (0.39, 0.21 to 0.74).[3] The inverse relation decreased only slightly when we included all other dementias, and it was clear in our cohort that patients with dementia had fewer screening related cancers. This suggests that under-diagnosis in people with cognitive impairment explains at least part of the decreased incidence of cancer in patients with Alzheimer's disease. However, it is unlikely to explain all of it. Two studies found a substantially decreased prevalence of cancer on autopsy among patients with Alzheimer's disease compared with age matched controls without dementia.[1 5] In their second study, Roe and colleagues found that admission to hospital for cancer was low among patients with Alzheimer's disease (hazard ratio 0.31, 0.12 to 0.86) but not in those with vascular dementia. Finally, in a unique study of 2222 Japanese survivors of the atomic bomb, people with clinically diagnosed Alzheimer's disease had a 70% decreased risk of previous cancer compared with age matched participants without dementia, whereas those with vascular dementia had a fourfold increased risk of cancer. Clearly it will never be possible to completely adjust for reporting and diagnostic bias in elderly patients with dementia, but together these findings suggest a specific inverse relation between cancer and Alzheimer's disease.

We found that survivors of smoking related cancer had a substantially lower risk of Alzheimer's disease than survivors of non-smoking related cancer—a pattern similar to that seen in Parkinson's disease. In a recent meta-analysis of 107 598 patients with Parkinson's disease, the aggregate relative risk was 0.73 (95% confidence interval 0.63 to 0.83) for any cancer, 0.61 (0.58 to 0.65) for smoking related cancers, and 0.80 (0.77 to 0.84) for non-smoking related cancers.[7] A lower rate of smoking related cancers might be expected in patients with Parkinson's disease owing to its well established negative association with smoking,[34] but, in the case of Alzheimer's disease, the association with smoking was strongly positive.[35] In our analysis, higher mortality among those with smoking related cancer did not explain the lower risk of Alzheimer's disease. Perhaps characteristics that allow someone to survive a smoking related cancer are particularly protective against neurodegeneration. That Alzheimer's disease and Parkinson's disease are associated with the same unusual pattern for cancer suggests the presence of as yet uncovered biological connections between neurodegeneration and carcinogenesis.

Biological plausibility

Although cancer survivors may have some protection from neurodegenerative diseases, the more hopeful significance of these findings will come from the underlying biology that explains this relation.[14 16] A genetic propensity against apoptosis might protect people from cancer while increasing their risk of neurodegeneration, as seen in some polymorphisms of the tumour suppressor gene p53.[36] A specific link between Alzheimer's disease and cancer is the protein Pin1, a unique enzyme that plays a part in protein folding as well as cell cycle control.[15 17 37 38] Many tumours in humans over-express Pin1,[39] whereas its function is low in the brain tissue of people with Alzheimer's disease.[39-42] As Pin1 is necessary for cell division, its inhibition causes regression of tumours,[43] whereas in mouse models of Alzheimer's disease its upregulation in postnatal neurons reverses neurodegeneration.[44] Moreover, Pin1 promoter single nucleotide polymorphisms that inhibit Pin1 expression are associated with an increased risk of Alzheimer's disease[45] but a decreased risk of cancer.[46] Drugs that can modulate Pin1 are being sought as novel therapeutic agents.

An interesting unanswered question is whether treatment for cancer modulates the risk of Alzheimer's disease. In theory, chemotherapy might protect neurons susceptible to Alzheimer's disease by suppressing inflammation[47] or blocking entry into the cell cycle,[48] both key steps in the pathway of neurodegeneration. However, to our knowledge there is no epidemiological evidence linking chemotherapy to a decreased risk of Alzheimer's disease. On the other hand, cognitive impairment is a well described complication of chemotherapy and has been associated with long term changes in brain structure and function in animal models.[49] Survivors of breast cancer who received adjuvant chemotherapy were more likely to develop dementia in one study[50] but not in another.[51] Cranial irradiation is clearly associated with neuronal damage and loss, not neuroprotection.[52] Thus, although we did not account for cancer therapy in our analysis, available evidence suggests that, if anything, it would have biased our results towards the null.

Conclusions and future work

The results of our analysis support the possibility of a true inverse relation between cancer and Alzheimer's disease. This study is, however, only exploratory and further work is needed to establish better the link between these two groups of diseases. Further insights will possibly be gained from analyses in large clinical and administrative databases with the power to look at the relation between Alzheimer's disease and individual types of cancer. The potential impact of cancer treatment on risk of Alzheimer's disease is another interesting area for future work. Presently there are few curative treatments for cancer and not even one disease modifying drug for Alzheimer's disease. Our data suggest that vulnerability to cancer may actually protect against neurodegeneration, and vice versa. A further understanding of the basis for this inverse relation may lead to

novel therapies and should remain a focus of intense basic and translational research.

Contributors: JAD, AB, KPL, and DPK conceived and designed the study. BEK, GLS, and PAW acquired the data. JAD, AB, RA, and SS analysed and interpreted the data. JAD drafted the manuscript. AB, RA, BEK, GLS, TK, DPK, KPL, SS, and PAW critically revised the manuscript. AB carried out the statistical analysis. JAD and PAW obtained the funding. RA, BEK, GLS, TK, DPK, KPL, SS, and PAW supervised the study. JAD and AB had full access to all the data in the study. JAD takes responsibility for the integrity of the data and the accuracy of the data analysis and is guarantor.

Funding: JAD was funded by a Veterans' Administration career development award. The Framingham Heart Study is supported by an National Heart, Lung, and Blood Institute contract (N01-HC-25195) and by grants from the National Institutes of Aging (AG16495 and AG08122) and National Institute of Neurological Disorders and Stroke (NS17950). The authors' work was independent of the funders. The funders had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; and preparation, review, or approval of the manuscript.

Competing interests: All authors have completed the ICMJE uniform disclosure form at www.icmje.org/coi_disclosure.pdf (available on request from the corresponding author) and declare: no support from any organisation for the submitted work; no financial relationships with any organisations that might have an interest in the submitted work in the previous three years; and no other relationships or activities that could appear to have influenced the submitted work.

Ethical approval: The Framingham study protocols and participant consent forms were approved by the institutional review board of Boston University School of Medicine.

What is already known on this topic

Parkinson's disease is associated with a decreased risk of most cancers, and growing evidence suggests that cancer and neurodegenerative diseases share genes and biological pathways

Limited data suggest an inverse relation between cancer and Alzheimer's disease

It is, however, unclear if the association might be result from selective mortality in cancer survivors or under-diagnosis in patients with Alzheimer's disease

What this study adds

Survivors of any cancer had a 33% lower risk of incident Alzheimer's disease and survivors of smoking related cancer had a 74% decreased risk, neither explained by survival bias

Participants with incident Alzheimer's disease had a 61% decreased risk of developing incident cancer, which may in part be due to under-diagnosis

This unusual pattern for cancer is similar to that seen in Parkinson's disease and suggests an inverse relation between cancer and neurodegeneration

Binge Drinking Intensity
A Comparison of Two Measures

Marissa B. Esser, MPH, Dafna Kanny, PhD, Robert D. Brewer, MD, MSPH, Timothy S. Naimi, MD, MPH

Background: Binge drinking (≥4 drinks for women; ≥5 drinks for men, per occasion) is responsible for more than half of the estimated 80,000 U.S. deaths annually and three-quarters of the $223.5 billion in costs in 2006. Binge drinking prevalence is assessed more commonly than binge drinking intensity (i.e., number of drinks consumed per binge episode). Risk of binge drinking–related harm increases with intensity, and thus it is important to monitor. The largest number of drinks consumed is assessed in health surveys, but its usefulness for assessing binge intensity is unknown.

Purpose: To assess the agreement between two potential measures of binge drinking intensity: the largest number of drinks consumed by binge drinkers (maximum-drinks) and the total number of drinks consumed during their most recent binge episode (drinks-per-binge).

Methods: Data were analyzed from 7909 adult binge drinkers from 14 states responding to the 2008 Behavioral Risk Factor Surveillance System (BRFSS) binge drinking module. Mean and median drinks-per-binge from that module were compared to mean and median maximum-drinks. Analyses were conducted in 2010–2011.

Results: Mean (8.2) and median (5.9) maximum-drinks were strongly correlated with mean (7.4) and median (5.4) drinks-per-binge ($r=0.57$). These measures were also strongly correlated across most sociodemographic and drinking categories overall and within states.

Conclusions: The maximum-drinks consumed by binge drinkers is a practical method for assessing binge drinking intensity and thus can be used to plan and evaluate Community Guide–recommended strategies for preventing binge drinking (e.g., increasing the price of alcoholic beverages and regulating alcohol outlet density).

Introduction

Excessive alcohol consumption is responsible for an average of 80,000 deaths in the U.S. each year[1] and $223.5 billion in economic costs in 2006.[2] More than half of these deaths and three-quarters of the economic costs are due to binge drinking[1,2] (≥4 drinks for women; ≥5 drinks for men, per occasion).[3,4] Binge drinking also is associated with a range of health and social problems, such as motor vehicle crashes, interpersonal violence, new HIV infections and sexually transmitted infections, liver cirrhosis, cancers, stroke, and alcohol dependence.[5–8]

The risk of binge drinking–related harm increases with the intensity of binge drinking (i.e., the number of drinks consumed).[9] Yet, adult binge drinkers often report drinking at levels that far exceed those used to define this pattern of alcohol consumption.[10,11] It is therefore important to routinely monitor binge drinking intensity to assess the public health impact of this behavior and to plan and evaluate evidence-based strategies to prevent it. However, questions on the number of drinks consumed by binge drinkers are not asked routinely in state health risk behavior surveys, such as the Behavioral Risk Factor Surveillance System (BRFSS). More commonly, health surveys include questions on the largest number of drinks consumed in a given time period (i.e., maximum-drinks),[12,13] but it is not clear whether these questions are useful for assessing binge drinking intensity.

doi: 10.1016/j.amepre.2012.03.001

The purpose of the present study was to assess the agreement between the following two measures of binge drinking intensity: the mean and median maximum-drinks reported by binge drinkers on any occasion and mean and median total drinks consumed by binge drinkers during their most recent binge episode (i.e., drinks-per-binge). If there is strong agreement between these two measures, maximum-drinks may be a way to routinely measure state-specific binge drinking intensity, thus improving public health surveillance on the number of drinks consumed by adult binge drinkers.

Methods

Data came from the 2008 BRFSS. Sampling design, purpose, and analysis descriptions are available at www.cdc.gov/brfss/. Binge drinkers were defined as current drinkers who reported consuming ≥4 drinks (women) or ≥5 drinks (men) on an occasion during the past 30 days in the BRFSS core survey. Maximum-drinks consumed was assessed in the core survey by the largest number of drinks consumed on any occasion during the past 30 days. In 2008, a total of 14 states administered an optional module to obtain information about binge drinkers' most recent binge episode, including the number of drinks consumed by beverage type. Drinks-per-binge was calculated by summing beverage-specific consumption (i.e., beer, wine, liquor, and pre-mixed flavored drinks) from that episode.

Analyses were restricted to binge drinkers from the 14 states who administered the 2008 binge drinking module. Respondents with missing information on beverage-specific consumption, or those who reported maximum-drinks or drinks-per-binge that were <4 for women or <5 for men were excluded. The final sample consisted of 7909 respondents.

Data analysis was conducted in 2010–2011 using SAS-callable SUDAAN 9.2. Results were weighted by age, gender, and race/ethnicity to be representative of people residing in the states and to the respondent's selection probability. Means and 95% CIs, medians, and Pearson correlation coefficients of the maximum-drinks and drinks-per-binge were assessed by sociodemographic characteristics and by state. Significant differences between means were determined by non-overlapping CIs.

Results

The study population of binge drinkers was predominantly male (58.0%); aged 18–54 years (76.9%); non-Hispanic white (83.3%); had at least some college education (63.9%); and had household incomes of ≥$50,000 (52.6%). There was a strong correlation between maximum-drinks (M=8.2; median=5.9) and drinks-per-binge (M=7.4; median=5.4) (r=0.57, p<0.001) (Table 1). These measures were strongly correlated for binge drinkers across most groups, except those with less than high school education (r=0.29, p<0.001); Hispanic race/ethnicity (r=0.38, p<0.001); and those who reported ≥5 binge drinking episodes in the past month (r=0.45, p<0.001). Mean and median maximum-drinks and drinks-per-binge were also strongly correlated in all states except Georgia (Table 2).

Discussion

Overall, binge drinkers' maximum-drinks correlated strongly with drinks-per-binge, an established measure of binge drinking intensity.[10] Measures generally correlated strongly within individual states as well. Further, the mean and median drinks-per-binge were approximately 90% of the mean and median maximum-drinks, respectively, further supporting the level of agreement between these two measures of binge drinking intensity. To our knowledge, this is the first study to assess the agreement between the largest number of drinks consumed by binge drinkers (maximum-drinks) and the number of drinks consumed during the most-recent binge drinking episode (drinks-per-binge) as measures of binge drinking intensity.

The findings of the current study have important implications for public health surveillance on binge drinking among adults because, unlike the drinks-per-binge measure, the maximum-drinks measure is assessed in all states annually. Therefore, it can be used routinely to assess binge intensity, and to plan and evaluate evidence-based binge drinking prevention strategies in states. Although the correlation between maximum-drinks and drinks-per-binge was generally quite strong across sociodemographic groups and within states, the correlations between these measures were weaker for respondents of Hispanic race/ethnicity and with less than high school degree, even though the mean and median maximum-drinks and drinks-per-binge within these strata were quite similar. This inconsistency may be due to the smaller sample sizes in these strata.

The greater binge drinking intensity of those reporting ≥5 binge drinking episodes/month relative to those reporting 1–2 episodes is consistent with other studies.[10] Among respondents reporting ≥5 episodes/month, the higher mean and median maximum-drinks than drinks-per-binge may reflect greater variability in binge intensity among frequent binge drinkers. Frequent binge drinkers (≥5 episodes/month) had more episodes in which the maximum-drinks could exceed the drinks-per-binge measure. Consequently, there was a greater likelihood that the most recent binge episode was not the most intense. However, correlations between binge intensity measures were still strong for those who reported ≥5 episodes/month, supporting the use of maximum-drinks to assess binge drinking intensity among frequent binge drinkers too.

The present study has limitations. First, restricting the sample to those who reported alcohol consumption at or above the binge drinking threshold on multiple measures may have reduced the generalizability of the findings. However, the binge intensity estimates were not substan-

[e]Non-Hispanic black, Asian, Native Hawaiian/Pacific Islander, American Indian/Alaskan Native, multiracial, and other

tially different from those reported in other publications and it therefore seems unlikely that the restricted study population substantially changed the relationship between the two evaluated binge drinking intensity measures.[10,11] Second, self-reported estimates of binge drinking intensity are likely to be underestimated because of recall bias[14]; social desirability response bias; nonresponse bias[15]; and because of the increasing number of cell phone–only households, particularly among young adults.[16,17] In fact, a recent study found that BRFSS alcohol consumption data accounted for a median of 22%–32% of state consumption based on alcohol sales.[18] Therefore, it seems unlikely that either of the measures of binge drinking intensity that were assessed in the current study overestimated the actual number of drinks consumed by adult binge drinkers in the U.S.

[a]Largest number of drinks consumed on any occasion during the past 30 days, among binge drinkers; data are from the BRFSS core section.
[b]Total number of drinks consumed in most recent binge drinking episode in the past 30 days; binge drinking was defined as consuming ≥4 drinks for women and ≥5 drinks for men per occasion in the past 30 days. Data are from the BRFSS binge drinking module.
[c]Correlation between maximum-drinks among binge drinkers and drinks-per-binge, within states; all *p*-values were significant at <0.001.

The present study affirms that binge drinkers generally drink at levels that are well above those used to define this behavior. Therefore, in addition to monitoring binge drinking prevalence and frequency, it is important to monitor binge intensity in states and nationwide, which routinely can be done with the maximum-drinks measure. This information can, in turn, be used to plan and evaluate strategies for preventing binge drinking and related harms, such as those recommended by the *Guide to Community Preventive Services* (e.g., increasing the price of alcoholic beverages and regulating alcohol outlet density).[19–21]

The authors thank the BRFSS coordinators from the 14 states that conducted the binge drinking module and members of the Survey Operation Team in the Division of Behavioral Surveillance; Public Health Surveillance Program Office; Office of Surveillance, Epidemiology and Laboratory Services; and CDC for their help in collecting the data used in this study.

Initially submitted March 18, 2011; accepted for publication August 16, 2011.

This study examined associations between mortality and demographic and risk characteristics among young injection drug users in San Francisco, California, and compared the mortality rate with that of the population. A total of 644 young (<30 years) injection drug users completed a baseline interview and were enrolled in a prospective cohort study, known as the UFO ("U Find Out") Study, from November 1997 to December 2007. Using the National Death Index, the authors identified 38 deaths over 4,167 person-years of follow-up, yielding a mortality rate of 9.1 (95% confidence interval: 6.6, 12.5) per 1,000 person-years. This mortality rate was 10 times that of the general population. The leading causes of death were overdose (57.9%), self-inflicted injury (13.2%), trauma/accidents (10.5%), and injection drug user-related medical conditions (13.1%). Mortality incidence was significantly higher among those who reported injecting heroin most days in the past month (adjusted hazard ratio = 5.8, 95% confidence interval: 1.4, 24.3). The leading cause of death in this group was overdose, and primary use of heroin was the only significant risk factor for death observed in the study. These findings highlight the continued need for public health interventions that address the risk of overdose in this population in order to reduce premature deaths.

Injection drug use has been associated with excess morbidity and mortality (1, 2). A number of studies have reported incidence that greatly exceeds that of the general population (3–5). Risk factors that have been associated with mortality among injection drug users (IDUs) from prior studies include infectious diseases, such as human immunodeficiency virus (HIV) and hepatitis C virus (HCV) (3, 6–8). Given improvements in medical care for HIV and HCV as well as more widespread implementation of public health interventions for IDUs (needle exchange, overdose prevention, opiate substitution treatment, and so on), current studies are needed to assess whether the incidence and causes of mortality have shifted over time. Additionally, studies of unique subpopulations such as young IDUs are needed to understand the patterns and risk factors for mortality in order to inform future tailored interventions.

The current study was undertaken to assess the incidence of mortality and risk factors for mortality among young injection drug users in San Francisco, California. Given that the UFO ("U Find Out") Study has been collecting detailed information on young IDUs since the late 1990s, it provides a unique opportunity to study mortality trends and risk factors for mortality in this population. The specific aims of the study were as follows: 1) to investigate trends in mortality incidence overall and overdose-specific mortality, 2) to calculate standardized mortality ratios, and 3) to identify risk factors for mortality in young injectors in San Francisco between 1997 and 2007.

MATERIALS AND METHODS

Beginning in 1997, young (<30 years) IDUs in San Francisco have been offered participation in multiple prospective studies under variations of the shared title known as the UFO Study and described previously (9–11). In brief, young IDUs were recruited by peer outreach workers familiar with neighborhoods in San Francisco where young IDUs congregate, using study invitation cards and flyers, contacts with youth friendly neighborhood groups and community providers, and word of mouth. Inclusion criteria for screening were the following: 1) less than 30 years of age; 2) self reported use of injection drugs in the past 30 days, 3) ability to provide informed consent, 4) understanding spoken English and, after 2005, 5) self-reported HCV-negative or unknown status. The UFO Study had 3 waves of data collection between November 1997 and December 2007. In the first wave from 1997 to 1999, subjects completed a baseline screening interview and underwent counseling and serologic testing for HIV, hepatitis B, and hepatitis C virus. Subjects without evidence of acute or chronic hepatitis B virus (HBV) infection or immunization to HBV were eligible for enrollment in a prospective study of HBV vaccination (UFO-2 Study). Starting in 2000, subjects who were HCV negative at the baseline screening were eligible for enrollment into the UFO-3 Study. The UFO-3 Study had 2 waves of recruitment, from 2000 to 2002 and from 2003 to 2007. Participants were included in this analysis only if they were enrolled prior to December 31, 2007, the end date for searching for death records. All research protocols and informed consent were approved by the Institutional Review Board of the University of California, San Francisco.

Survey instrument and measures

Eligible consenting participants were interviewed, counseled, and tested for antibodies to HCV (anti-HCV) and presence of viremia (HCV RNA) at baseline. Follow-up included monthly ''check-ins'' and quarterly study visits that included structured interviews to assess risk (principally drug-related and sexual) exposures, HCV status (including anti-HCV and HCV RNA testing), and risk reduction counseling and referrals. In the first and second study waves, testing for antibodies to HIV and HBV was performed at baseline and follow-up visits. Deaths were ascertained though the National Death Index (NDI) through the end of 2007. Methods for establishing a match are described in detail on the NDI Web site (http://www.csc.gov/nchs/ndi.htm). In brief, records are matched by first and last name, date of birth, sex, and state of birth. Causes of death were obtained from the NDI-Plus. The underlying cause of death was based on the *International Classification of Diseases* (ICD), Tenth Revision. The primary outcome for this analysis was date of death as identified by an NDI match. Causes of death were reviewed, and overdose death was defined as ICD, Tenth Revision, codes X42, X44, X62, and Y14. Sociodemographic variables included in the analyses were age, gender, race/ethnicity (Caucasian vs. non-Caucasian), educational level (less than high school vs. high school or greater), recent (past 3 months) homelessness, and incarceration. Starting in wave 2, participants were asked about participation in drug treatment programs in the past 3 months and in the past week in wave 3. Recent drug treatment programs included drug detoxification, residential treatment, methadone or buprenorphine maintenance, and 12-step programs. Risk-related exposures included duration of injection drug use; frequency of injection; injection of heroin, cocaine, methamphetamine, crack, or heroin mixed with methamphetamine or cocaine; noninjection crack use; and nonfatal heroin overdose. Overdose was defined as a loss of consciousness where at least one intervention was attempted by a third party.

Data analysis

We calculated mortality incidence overall and by demographic and risk characteristics reported at the baseline interview. Standardized mortality ratios were calculated in 3-year intervals adjusting for age, sex, and race by using national mortality statistics from the National Center for Health Statistics. Standardized mortality ratios were calculated overall, separately for males and females, and for overdose-related deaths only; 95% confidence intervals were calculated by assuming that the observed deaths followed a Poisson distribution. Cox regression models with time-varying covariates were used to identify predictors of mortality. Survival time was defined as the time from initiation of injection (self-reported as age at first injected drugs) to death. Given that subjects were current injectors at the start of the study, data were left truncated. Subjects entered into the analysis at the baseline visit, and they remained until the date of death or were censored at December 31, 2007, or the last interview date if the last interview was after December 31, 2007. Covariates were included in the multivariate model if the incidence rate ratio for mortality reached statistical significance at a level of $P < 0.10$ in the bivariate analysis or were potential confounders (study wave, age, gender, HCV status, and duration of injection drug use). Baseline characteristics including age, gender, duration of injection, and study wave were entered into the model as fixed covariates. Drug use and injection-risk behaviors, overdose, and HCV status were entered as time-varying covariates. All analyses were conducted with the Stata statistical software package (release 11.2; StataCorp LP, College Station, Texas).

RESULTS

A total of 644 participants completed a baseline interview and were enrolled in the prospective cohort from November 1997 to December 2007. The median age was 22.0 years (interquartile range (IQR): 19.8–25.0), and participants had injected for a median of 4.0 years (IQR: 1.7–6.7) at the baseline interview. Sixty-eight percent of participants were male, and 78% were Caucasian (Table 1); 47% had less than a high school education, and 68% reported being homeless or marginally housed. At the most recent interview, the drug most often injected in the past 30 days was heroin (63%) followed by methamphetamine (27%); 31% reported injecting every day in the past month, 68% used a syringe exchange in the past month, and 32% were anti-HCV positive.

We identified 38 deaths over the follow-up period through 2007 using the NDI. The overall mortality rate over 4,167

person-years of follow-up was 9.12 (95% confidence interval (CI): 6.63, 12.53) per 1,000 person-years of observation. In females, the mortality rate was 6.51/1,000 person-years of observation and, in males, 10.42/1,000 person-years of observation. The median age at death was 26 years (IQR: 23–30), and the median time from initiation of injecting until death was 7.7 years (IQR: 4.9–11.3).

Increased mortality was observed among those who identified heroin or heroin mixed with other drugs as the drug injected most days in the 30 days prior to the most recent interview, relative to those who injected methamphetamine (incidence rate ratio (IRR) = 3.03, 95% CI: 1.47, 6.23) (Table 1). The incidence of mortality was significantly higher in those who reported having an overdose in the past 3 months compared with those who did not (IRR = 2.71, 95% CI: 1.35, 5.47). Mortality rates were elevated among HCV-seropositive individuals compared with negatives but did not reach statistical significance (IRR = 1.66,

Abbreviation: CI, confidence interval.

95% CI: 0.88, 3.15) at $P < 0.05$. Mortality incidence did not differ by age, race/ethnicity, ever having overdosed, duration of injection, or incarceration in the past 3 months.

By use of national mortality as the reference, the overall adjusted standardized mortality ratio for 1999–2001 was 15.3 (95% CI: 7.6, 27.3), which decreased to 10.6 (95% CI: 5.8, 17.8) in 2002–2004 and 8.3 (95% CI: 4.4, 14.3) in 2005–2007 (Table 2). When data were stratified by wave of recruitment, temporal declines in mortality persisted (data not shown). In females, the adjusted standardized mortality ratios were higher than in males across all time bands. Furthermore, there did not appear to be a trend toward a decreasing standardized mortality ratio over time among women, as there appeared to be for men. Incidence of overdose mortality also declined between 2000 and 2007 (Table 3). However, women had lower rates of overdose mortality compared with men, and their rates did not appear to decline. The principal cause of death for the overall cohort was overdose (57.9%), followed by self-inflicted injuries (13.2%), other drug-related medical conditions (13.2%), trauma or accidents (10.5%), and other causes (5.3%).

In Cox regression with time-varying covariates adjusting for age and duration injecting, participants who used heroin or heroin mix most days or who had a recent overdose had elevated mortality (Table 4). Of these factors, heroin/heroin mix as the drug used most days in the past month was the only one independently associated with mortality (adjusted hazard ratio = 5.76, 95% CI: 1.37, 24.30) ($P < 0.05$). Having a recent nonfatal overdose was associated with higher relative hazards of death, although this did not quite meet statistical significance. After adjustment for other covariates, being HCV infected was not significantly associated with increased relative hazards of death.

DISCUSSION

This study of young IDUs in San Francisco between 1997 and 2007 found overall mortality rates 10 times higher than those in the general population. Mortality appeared to decline over the 10-year period; however, stratified results suggested that declines were restricted to males. The leading cause of death in this cohort was overdose, and primary use of heroin was the only significant independent risk factor for death that was observed in the study. Together, these findings highlight the substantial mortality risk associated with injecting drugs for young persons and point to a continued need for public health interventions that address the risk of overdose in this population in order to reduce premature deaths.

The overall mortality rate observed in this study of IDUs in San Francisco was 9.12 per 1,000 person-years of observation. Another study of young and recent-onset injectors that included data from 5 different cities in the United States

[b] Time frame is past year for participants surveyed in 1997–1999.

found a similar mortality rate (3). That study found an initial increase of mortality in the 2 years of the cohort study, followed by a decrease, which led the authors to hypothesize that the immediate years following initiation of drug use might be a period of higher risk. In contrast, our study found only a continuous decline in mortality over calendar periods. The prior study by Vlahov et al. enrolled only recently initiated IDUs (<5 years) and therefore did not include a range of age and duration of drug use to clarify period effects. Our study included participants with a wide range of injecting exposure time (median = 4 years, IQR: 1.7–6.7), and we performed multivariate Cox models to analyze the independent effects of age and duration of use. The results did not support an association between duration of use and mortality.

There are several potential explanations for the observed decline in mortality in our cohort of young injectors. First, it is possible that public health interventions could have led to fewer deaths over the years. In the past decade, several overdose prevention programs have been implemented in the United States including the distribution of the overdose-reversal drug, opiate antagonist naloxone (NARCAN; Endo Pharmaceuticals, Inc., Chadds Ford, Pennsylvania), to IDUs (12–16). One of the longest running naloxone prescription programs in the United States was implemented in San Francisco in 2003 and has provided overdose prevention training and prescribed naloxone to nearly 2,000 individuals as of December 2009 (16). Furthermore, improved access to treatment for opioid dependence may be a factor, as opioid substitution treatment in IDUs has been shown to be a significant factor in reducing the risk of mortality (17). There could have been a change in the purity of heroin over the years (18). Finally, because there was ongoing enrollment of our cohort, differences in mortality over time may be associated with unmeasured differences in the UFO Study population over time, such that subjects with lower risk were recruited during later phases of the study. To test this hypothesis, we included a variable for period of study recruitment in our Cox models. Although we did not find significant differences in the hazard ratios for death by enrollment wave, the hazard ratios were less than 1.0 comparing the later with earlier years, suggesting that this could be an underlying factor. Furthermore, when we investigated changes in the UFO Study population across the 3 waves of data collection, we found that participants in the first wave were more likely to inject heroin or heroin mixed with other drugs in the past month and were significantly less likely to inject methamphetamine in the past month at baseline (data not shown). Since primary use of heroin as the drug of injection was strongly predictive of death in our Cox models (hazard ratio = 5.76, 95% CI: 1.37, 24.30), this observed decline in heroin injection in later waves of study recruitment is a likely contributor to the decline in overdose mortality over time.

Our study of young injection drug users found the most common causes of death to be overdose and trauma, which is consistent with prior studies (3, 6, 7, 19). This supports a continued focus on overdose prevention in this age group. Of the risk factors examined in this study, only use of heroin as the main injecting drug was independently predictive of death. This contrasts with 2 prior studies of young IDUs that found HIV infection to be significantly associated with mortality (3, 6). This difference can likely be explained by the relatively small absolute number of participants included in our sample and the small number of persons with HIV. Also, HIV as a cause of death has been shown to have peaked in the 1990s (20, 21), before the advent of highly active antiretroviral therapy, and is less likely to impact mortality in young versus older injectors (7).

Our study showed differences in death rates between men and women. Although the incidence of death was higher among men compared with women, standardized mortality ratios were higher for women. Female injectors were 12 times more likely to die compared with females in the general US population; in contrast, male injectors were 8 times more likely to die compared with the male US population. A similar difference in sex-stratified standardized mortality ratios has been reported in a cohort of young IDUs in Canada (6). In addition, although rates of death appeared to decline over time among men, rates appeared relatively stable for women over the 10-year period. Sex-stratified results should be interpreted with caution however, as the sample size was relatively small and resulted in wide confidence intervals for period-specific mortality rates.

There were a number of important limitations to this study. Mortality rates may be underestimates because of deaths that were not captured by the NDI search criteria. A number of study participants were believed to have given pseudonyms rather than birth names, which would not allow matching, and incorrect birth dates may have been given. Causes of death were based on ICD codes on death certificates that may be inaccurate (22). Analyses used baseline predictor data, and some covariates measured constructs that could change over time (HIV and HCV infections, injecting behaviors, incarceration, and so on). Therefore, analyses of certain predictors should be interpreted with caution. Finally, the relatively modest sample size and small absolute number of deaths are limitations, particularly with regard to sex-stratified results.

In conclusion, this study of young IDUs in San Francisco demonstrated that injection drug use is associated with substantially increased risk for death, and that most of the excess risk is due to overdose and trauma. Results also suggest that, among young adult injectors in San Francisco, mortality rates are decreasing over time but are generally restricted to males. Research is needed to confirm these results and explore reasons for sex-specific differences in mortality in young IDUs.

ABSTRACT

Little is known about physicians' perception of the ease or difficulty of implementing electronic health records (EHR). This study identified factors related to the perceived difficulty of implementing EHR. 163 physicians completed surveys before and after the implementation of EHR in an externally funded pilot program in three Massachusetts communities. Ordinal hierarchical logistic regression was used to identify baseline factors that correlated with physicians' report of difficulty with EHR implementation. Compared with physicians with ownership stake in their practices, physician employees were less likely to describe EHR implementation as difficult (adjusted OR 0.5, 95% CI 0.3 to 1.0). Physicians who perceived their staff to be innovative were also less likely to view EHR implementation as difficult (adjusted OR 0.4, 95% CI 0.2 to 0.8). Physicians who own their practice may need more external support for EHR implementation than those who do not. Innovative clinical support staff may ease the EHR implementation process and contribute to its success.

Physicians who have not demonstrated 'meaningful use' of health information technology (HIT) by 2015 may face reduced future Medicare reimbursement.[1] Failure to implement electronic health records (EHR) may prove costly to individual physicians and may make it hard for them to engage in care redesign that will be needed under healthcare reform.[2 3] Awards up to US $44 000 through Medicare or even US$63 750 through Medicaid are currently available to physicians in office practice who demonstrate meaningful use of their EHR over 5 years.[1] To receive the maximum reimbursement providers must begin participating by 2012.

Through the federal government, health information technology regional extension centers (REC) are positioned across the country to offer technical support and best practices to at least 100 000 providers over 2 years.[4] In addition, approximately US$500 million has been awarded in federal support to states and territories to increase health information exchange.[5 6]

Earlier studies have identified factors that predispose practices to successful EHR adoption, namely larger practices, those affiliated with large hospitals, or those involved with teaching.[7–10] Physicians face numerous barriers to participating in the meaningful use program, including a bewildering number of choices when selecting an EHR.[11] It is unclear how fast providers will adopt. Ford *et al*,[12] using EHR adoption data from six previous surveys, found under their most optimistic scenario a predicted EHR adoption rate of 61% by 2014, far short of 'widespread adoption'.

In contrast to adoption, comparatively little is known about the factors that predict successful implementation, the installation of EHR and their incorporation into the usual operations of a functioning practice. Few data are available regarding what factors influence physicians' perception of the ease or difficulty of EHR implementation. This perception of ease or difficulty is important. It may influence the actual successfulness of EHR implementation or even the decision to complete an EHR implementation that is underway. Therefore, we undertook the present study, using data from practices in three communities participating in the Massachusetts eHealth Collaborative (MAeHC) EHR implementation project. Our objective was to identify factors present at baseline that were subsequently related to the perceived difficulty of implementing EHR.

METHODS

Study design

We carried out a pre–post evaluation of the MAeHC three-community intervention to promote physicians' adoption and implementation of EHR. We collected physician attitudes, demographic and practice characteristics and used post-intervention surveys to measure physicians' perceived difficulty of EHR implementation. The Partners HealthCare Human Research Committee approved the study protocol.

Intervention

The details of the MAeHC program have been described previously.[13–15] In summary, between 2006 and 2008, MAeHC installed robust EHR in physician practices in three Massachusetts communities. MAeHC provided extensive on-site consultation, at no cost to these practices, to facilitate workflow redesign and integration of the EHR into the practice. They also provided technical support related to hardware and software.

Settings and participants

The Massachusetts communities of Brockton, Newburyport and North Adams were selected for the MAeHC program through a competitive process described in detail in Goroll *et al*.[13] Briefly, MAeHC issued a request for applications to which 35 communities throughout Massachusetts submitted applications to participate. MAeHC selection committee members made site visits to

six finalist communities and ultimately selected the three participant communities. Selection criteria emphasized local physician leadership and community support of the application.

A total of 167 physician practices, representing 91% of all eligible primary care and specialty practices, participated. We identified all physicians in each of the participating practices for pre-intervention (2005) and post-intervention (2009) surveys. In the pre-intervention survey we identified 500 physicians from 167 practices; 355 completed the survey (response rate 77%).[16] In 2009, 468 physicians were eligible, of whom 319 completed the survey (response rate 68%). For this study we included only the 163 physicians from 134 practice sites who completed both the 2005 and 2009 survey questionnaires.

Survey design

The design and content of the pre and post-intervention surveys were based on similar statewide surveys of physicians described previously.[16 17] Briefly, the 2005 survey included items intended to measure physicians' attitudes toward the use of computers in healthcare, perceptions of the quality of care, physician demographics and practice characteristics. The post-intervention (2009) survey retained verbatim all of the items from the original survey and incorporated new items that would not have been relevant before the intervention. For example, new questions asked about health information exchange, the EHR implementation process and workflow analysis.

Survey administration and data collection

Survey administration and data collection methods in 2005 and 2009 were similar. In 2005, paper surveys were hand-delivered to physicians' offices by MAeHC practice consultants, who had been making routine visits to the practices in preparation for the anticipated implementation. Physicians had the option of returning the survey directly to practice consultants or by mail.[16] In 2009, the Survey Lab of the University of Chicago, a third-party research and consulting service, administered the survey to MAeHC physicians; these physicians returned the completed survey by mail or via the web to the Survey Lab in Chicago.

Main outcome measure

Our main outcome was the response to the following question in the post-intervention survey: 'Was the implementation process for your EHR… (a) very difficult; (b) somewhat difficult; (c) not difficult?'

Other variables

The pre-intervention survey included physician characteristics (age, sex, race, years in practice, number of outpatient visits per week); practice characteristics (number of physicians in practice, specialty, ownership, and financial resources available for expansion); and information on individual physician stressors (isolation from colleagues, working long hours, personal/job stress, and demoralization). Several dimensions of organizational culture were assessed, including innovation, initiative, quality improvement, evaluation, and risk assessment (see table 1). We requested information on the availability and physicians' use of 10 key functions of the EHR post-intervention to calculate an EHR usage score.[9] As in previous analyses, we calculated an EHR usage score as the number of functions reported as used most or all of the time, divided by the number of available functions. For example, physicians who reported using none of their available EHR functions would score 0, while those who reported using all of their available functions most or all of the time would score 1. In another example, physicians who reported using four of their eight available functions most or all of the time would score 0.5.

Table 1 Characteristics of physicians and practices

Characteristic	N (%)

††We are actively doing things to improve quality of care.
‡‡After we make changes to improve quality, we evaluate their effectiveness.
§§Our procedures and systems are good at preventing errors.

Statistical analysis

To identify potential confounders between our main outcome and additional covariates we calculated χ^2 tests or Fisher's exact test among categorical values and Wilcoxon rank-sum tests for continuous variables. Variables noted to be significantly associated ($p<0.05$) with the main outcome measure were included in the multivariate model. For multivariate analysis, we performed ordinal hierarchical logistic regression to account for the clustering of physicians within practice; the ordinal logistic regression assumption was met. We decided a priori to include sex and categorical age in the multivariate model. We validated use of

the ordinal model using the score test for proportional odds assumption.

RESULTS

Overall, 163 physicians completed both surveys in 2005 and 2009. Among these physicians, 156 physicians (96%) answered questions relating to our main outcome. The physicians were mostly men, and most had full or partial ownership stake in their practice (see table 1). Most participants (70%) had been in practice for at least 15 years, with a median of 22 years since graduation from medical school. A total of 22 physicians (15%) reported having a 'solo' practice; 99 physicians (63%) indicated that they practised in a primary care or single specialty group practice and 35 (22%) worked in multispecialty group practices. A total of 26 physicians (17%) indicated that their practice had at least moderate resources for expansion or improvements of any kind; only two physicians (1%) stated that their practice had extensive resources for expansion. The mean EHR usage score was 0.68 (SD=0.28).

Overall, 54 physicians (35%) reported that the implementation process for their EHR was very difficult. Eighty-four (54%) of the physicians found the process to be somewhat difficult; only 18 (12%) reported their implementation process was not difficult.

Factors associated with difficulty of EHR implementation in bivariate analyses are shown in table 2. Compared with physicians who were partial or full owners of their practice, those without any ownership stake in their practice were less likely to view the implementation process as difficult or very difficult (OR 0.5, 95% CI 0.2 to 0.9). In terms of absolute numbers, 26% of non-owners (14/54) indicated that implementation was very difficult, compared with 38% of owners (40/104).

Physicians who indicated that the office staff was innovative were less likely to view the implementation process as difficult or very difficult (OR 0.4, 95% CI 0.2 to 0.8), compared with physicians who did not indicate that their staff was innovative. Higher EHR usage scores were associated with lower likelihood of viewing the implementation process as difficult or very difficult (OR 0.3, 95% CI 0.1 to 0.9).

In multivariate analysis, however, physicians' EHR usage score was not associated with the perceived difficulty of EHR implementation. Physicians who were employed by their practice (ie, those who did not have partial or full ownership stake in the practice) were less likely to view EHR implementation as difficult (adjusted OR 0.5, 95% CI 0.3 to 1.0). Similarly, physicians who perceived their staff as innovative were less likely to view EHR implementation as difficult (adjusted OR 0.4, 95% CI 0.2 to 0.8). We did not find evidence of effect modification by practice size on owners' perception of difficulty (p=0.69).

Table 2 The odds of finding the EHR implementation process difficult by physicians in ambulatory practices*

	Unadjusted OR (95% CI)	Adjusted OR (95% CI)†
Male	1.0 (0.5 to 2.0)	0.7 (0.3 to 1.6)
Age >50 years	1.4 (0.8 to 2.5)	1.3 (0.7 to 2.5)
EHR usage score‡	**0.3 (0.1 to 0.9)**	0.3 (0.1 to 1.1)
Non-owners	**0.5 (0.2 to 0.9)**	**0.5 (0.3 to 1.0)**
Staff innovation	**0.4 (0.2 to 0.8)**	**0.4 (0.2 to 0.8)**

*Bold items indicate a statistically significant value at p≤0.05.
†Adjusted for sex, categorical age, calculated electronic health record (EHR) usage score, ownership, proportion of physicians who agree with the statement that their office staff are innovative.
‡Measured as a continuous variable.

DISCUSSION

We evaluated how physicians practising in three communities in Massachusetts perceived the EHR implementation process and factors that facilitated EHR implementation. In this setting, we found that physicians who were not owners of the practice and those who perceived their office staff to be innovative were less likely to view the implementation process as difficult or very difficult.

Earlier studies have demonstrated that physicians working in larger practices and those affiliated with hospitals are more likely to have adopted EHR and to use those systems meaningfully.[7 9 10] However, relatively little attention has been paid to the ease or difficulty physicians perceive when they implement EHR in their practices.

We found that physicians who were owners of their practice perceived their EHR implementation to be more difficult, compared with physicians who did not have an ownership stake. Because ownership is generally associated with greater levels of responsibility for day-to-day practice operations and management, these physicians probably experienced more underlying challenges associated with EHR implementation and workflow transformation. Physician owners probably bear financial risk for failure of implementation out of proportion to payers or publicly funded health plans who benefit from patient safety and quality but not as directly from practice efficiency or revenue cycle management.[18] These physician owners may need not only financial support but also training and expert consultation to bolster the implementation process.

The association between physicians' perception of having innovative staff and their report of less difficult EHR implementation deserves exploration. Having staff who are innovative may reflect an office culture that is committed to progress or potentially a marker for a physician who values the role of non-physician staff in ensuring the smooth operations of the office. Understanding the role of 'innovative staff' may uncover a potential facilitator for easing EHR adoption and implementation.

This study has several limitations. Although the sample includes a broad range of primary care physicians and specialists from three diverse communities across Massachusetts, the findings may not generalize to practices in other settings. It should be noted that the physicians in this study were part of a well-supported EHR implementation program. While the HITECH-mandated REC program is supporting practices, it is likely that most practices nationally will receive less support from their REC than the physician groups in our study. We also note the limitation as with any survey-based research, that our variables are self-reported perceptions, rather than objective measures, and subject to a variety of biases, such as social desirability. Nonetheless, these perceptions are important, because they can influence physicians' behavior.

CONCLUSIONS

Physicians who have ownership stake in their practices experience first-hand the challenges of EHR implementation, and they generally perceive EHR implementation as being more difficult than their colleagues who are employed by the practices in which they work. Physicians who report that their staff is innovative perceive less difficulty with EHR implementation, suggesting that office staff play a critical role in EHR implementation, as they do in any transformation effort. Efforts to expand EHR implementation should focus on the needs of physician owners, and future efforts should emphasize the important role that non-physician staff members play in the process of innovation and transformation.

Acknowledgments The authors would like to thank the physicians who participated in the MAeHC for completing the surveys. The authors also thank the anonymous peer reviewer who provided helpful suggestions to improve the manuscript.

Funding This study was funded in part by the Agency for Healthcare Research and Quality cooperative agreement no 1UC1HS015397 and the Massachusetts e-Health Collaborative. MF was supported by a Ruth L. Kirschstein National Research Service Award grant no T32 HP12706.

Background: Posttraumatic stress disorder has been linked to women's ill health, including headaches. Intimate partner violence, which may result in posttraumatic stress disorder, is often reported by women with headaches. Prior studies of intimate partner violence and headache have estimated lifetime but not 12-month prevalence. The researchers in this study examined the relationship between headache and posttraumatic stress disorder in a novel population, and estimated 12-month and lifetime prevalence rates of intimate partner violence. Methods: Patients were recruited from a women's headache center (n = 92) during 2006–07 and

completed the Migraine Disability Assessment measure of headache severity. Posttraumatic stress disorder was measured using a modified Breslau scale. Twelve-month and lifetime physical intimate partner violence were measured with the Partner Violence Screen and the STaT ("slapped, threatened and throw") measure. Multivariable regression determined factors independently associated with headache severity. Results: Among all participants, 28.3% screened positive for posttraumatic stress disorder; 9.8% and 36.9% of women endorsed recent and lifetime intimate partner violence. Posttraumatic stress disorder was strongly associated with headache severity ($\beta = 34.12$, $p = 0.01$). Patients reporting lifetime intimate partner violence exhibited a trend of nine additional days of disability due to headache over 90 days. Conclusions: Posttraumatic stress disorder and intimate partner violence occur among a sizable proportion of women referred for headache. The authors' findings reaffirm that clinicians treating women with headaches must be aware of the possibility of posttraumatic stress disorder and intimate partner violence in such patients.

KEYWORDS posttraumatic stress disorder, intimate partner violence, headache, chronic pain, disability

INTRODUCTION

Interpersonal trauma has a profound and lasting impact on women's long-term health (Schnurr & Green, 2004). Many forms of chronic pain have been linked to past traumatic experiences (Paras et al., 2009; Romans et al., 2002; Wuest et al., 2008; Walling et al., 1994). Headache is one of the most frequent forms of chronic pain, accounting for considerable disability and use of health services (Lipton et al., 2007), with a disproportionate impact on women (Diamond, 2007). Over the last decade, an enlarging body of work has examined the association between headache and exposure to many forms of interpersonal trauma (Anda et al., 2010; Tietjen et al., 2009a, 2009b; Golding, 1999). Emerging data has suggested that posttraumatic stress disorder (PTSD) is an important contributory factor in the relationship between trauma and resultant physical health sequelae (Schnurr & Green, 2004; Kimerling, Clum, & Wolfe, 2000; Dennis et al., 2009; Wuest et al., 2009). PTSD is prevalent in ambulatory medical populations; recent studies have found a prevalence ranging from 12% to 33% among primary care patients (Liebschutz et al., 2007; Alim et al., 2006; Stein et al., 2000).

PTSD is characterized by re-experiencing, avoidance, numbing, and arousal symptoms related to a significant traumatic event (American

Psychological Association, 2000), and may be accompanied by altered allostatic load (physiologic changes that result from chronic stress) (Glover, Stuber, & Poland, 2006), which is one recognized pathway to poor health_ (Rasmusson et al., 2010; Dennis et al., 2009; Dutton et al., 2006; Gill, Szanton, & Page, 2005) and chronic pain (Peterlin et al., 2008; Raphael & Widom, 2010; Otis, Keane, & Kerns, 2003; Sharp & Harvey, 2001). PTSD has a higher incidence among women (Tolin & Foa, 2006). Although PTSD appears to play a key role in the relationship between trauma and subsequent poor physical health and chronic pain (Kimerling, Clum, & Wolfe, 2000; Sharp & Harvey, 2001; Schnurr & Jankowski, 1999), it is frequently misdiagnosed or under-recognized outside of mental health treatment settings (Liebschutz et al., 2007). Thus, primary care providers caring for women may fail to recognize the presence of PTSD among their patients.

Headache and PTSD often co-occur (Peterlin, Nijjar, & Tietjen, 2011). A large general population study revealed that the 12-month odds of PTSD in women with migraine were increased nearly four-fold (3.82), and lifetime odds were increased three-fold compared to women not reporting headache (Peterlin, Rosso, et al., 2011). The published prevalence rates of PTSD among headache patients have ranged from 12.5% to 42.9% (de Leeuw, Schmidt, & Carlson, 2005; Peterlin et al., 2008, 2009; Peterlin, Nijjar, et al., 2011). In a multi-site study of primary care patients, participants with PTSD had a two-fold odds of reporting headache (Lowe et al., 2011). The presence of PTSD was also a risk factor for chronic (versus episodic) headache in the same clinic population (Peterlin et al., 2008, 2009) serving both genders with a majority of female participants. Estimates from an all-women's headache center are lacking in the literature.

One frequent form of interpersonal trauma resulting in PTSD is intimate partner violence (IPV; Dutton et al., 2006). While PTSD can result from multiple forms of interpersonal trauma, the authors focused on IPV in the current study due to the relative paucity of reports on IPV in clinical settings dedicated to treating headaches. IPV is a pattern of coercive behavior in which one person attempts to control another through threats or actual use of physical violence, sexual assault, and verbal or psychological abuse (Heron et al., 2003). The population-based National Intimate Partner and Sexual Violence Survey (NISVS) found a lifetime rate of any severe physical IPV of 24.3%, and a rate of recent IPV of 2.7% among women. When less severe forms of physical IPV were included, the prevalence rates were 30.3% and 3.6%, respectively (Black et al., 2011). IPV has well-known adverse health effects (Coker et al., 2002; Campbell et al., 2002). Acute physical injury often occurs, with head and neck injuries the most frequent subtype of musculoskeletal injury resulting from IPV (Tam et al., 2010). Abused women have 1.5 to 2 times higher risk of chronic pain, including headache (Coker et al., 2002) (see Figure 1).

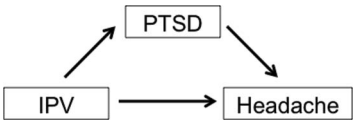

FIGURE 1 Relationship between headache severity, PTSD, and IPV.

Women who are victims of IPV are up to 60% more likely to suffer from headache than unabused controls (Coker et al., 2002; Cripe et al., 2011). A retrospective chart review of mostly female (90.1%) tertiary care headache patients in the United States found that nearly 35% reported a lifetime history of physical and/or sexual abuse (Peterlin et al., 2007). However, that study did not use standardized measures of abuse, making the results difficult to generalize. A recent study of post-partum hospitalized women in Peru found that 34.8% of migraine sufferers reported a lifetime history of IPV (Cripe et al., 2011). Neither of these studies ascertained recent or 12-month prevalence rates of IPV in the populations studied. Measurement of the prevalence of recent abuse would provide insight into the identification and management of women with headache who are recently and/or currently involved in abusive relationships. Intervention for women experiencing current or recent abuse differs from care needed by women with past history of IPV.

Given the growing popularity of outpatient, female-only clinics in the United States (American Hospital Association, 2000), including the expansion of dedicated primary care clinics for women veterans (Bean–Mayberry et al., 2003), examination of prevalence rates of IPV in ambulatory headache treatment settings that exclusively serve women would be useful. The majority of headache patients seen in primary care settings are not referred to specialists (Stokes et al., 2011). Therefore, describing the prevalence of potential PTSD and IPV in this setting could yield findings relevant to more severe headache patients who can be more challenging to manage in primary care.

Survivors of IPV and other forms of trauma may prefer women-only clinics because such patients are often hyper-vigilant and likely to overestimate the threat associated with being around men (Elwood et al., 2007). In previous studies of satisfaction with women-only practice settings versus traditional models, only a study performed in Veteran's Administration clinics demonstrated a strong patient preference for women-only centers (Bean–Mayberry et al., 2003); (Harpole et al., 2000; Phelan et al., 2000). This finding may support the possibility that populations with a high proportion of trauma-exposed women are more likely to prefer single-gender care settings and that the prevalence rates of PTSD could be higher in such settings. However, this has yet to be empirically proven.

The authors designed the current study to assess the prevalence of previously undetected screen positive, or suspected, PTSD and IPV in a dedicated women's headache treatment center population. This study replicates and

extends prior work (Peterlin et al., 2009) to a dedicated women's headache treatment setting. It also makes a novel contribution by estimating a 12-month rate of IPV among headache sufferers as prior studies only reported lifetime estimates. Researchers in the current study had several aims. First, they sought to estimate prevalence rates for PTSD and physical IPV (12-month and lifetime) in this all-female treatment setting. They expected that these rates would be higher than those reported previously. Secondly, they separately tested the associations between headache severity and PTSD and between headache severity and physical IPV. They theorized that the relationship between PTSD and headache severity would be stronger than that between physical IPV and headache severity because prior investigation supports that PTSD is more strongly linked to health problems than trauma per se (Schnurr & Green, 2004). In a study of primary care outpatients, trauma and extreme stress were linked to medical illness, but this effect was stronger for the subset of patients who had PTSD (Weisberg et al., 2002). PTSD itself appears to stress the affected individual, and traumatized women with PTSD have higher allostatic loads than traumatized women without PTSD (Glover, Stuber, & Poland, 2006).

MATERIALS AND METHODS

Study Sample

The authors conducted a cross-sectional survey study of a convenience sample of women presenting to a referral center for women with headache, based at an academic community hospital. Referred patients who presented with either migraine or tension variant headache to this treatment center in the greater Boston area between 2006 and 2007 were approached during regular operating hours of the clinic and asked if they would be willing to participate in a study on stress and headaches. The study was an unfunded exploratory study staffed by trained volunteer research assistants. Ninety-two female patients consented to complete the survey. Patients under the age of 18 years, pregnant women, and non-English speakers were eligible to participate, and were approached by a research assistant after an initial nursing intake form established eligibility. Participants gave written, signed informed consent administered by the research assistant prior to completing study questionnaires.

Data Collection

Those who chose to participate were asked basic demographic questions and also completed the Migraine Disability Assessment (MIDAS) questionnaire (Stewart, Lipton, Whyte, et al., 1999; Lipton et al., 2001) as part of their routine assessment. The MIDAS is a five-question self-report tool that

measures headache-related disability over the preceding 90 days in three domains: paid work/education, household/family matters, and social/leisure activities; the unit of measure is days (see Appendix). The MIDAS has been validated for use with both migraine and tension variant headaches (Stewart, Lipton, Kolodner, et al., 1999), and the highest possible score is 270 (Stewart et al., 2001). Respondents answered five questions about the impact of headache on their functioning, as measured in missed days of school/work, decrements in work and household productivity and interference in family, social, and leisure activities using a self-administered format. The total days of patient-reported disability were then summed into a point score. A score greater than 21 (days) indicated severe disability. The final MIDAS score has been validated as a measure of headache severity (Stewart, Lipton, Kolodner, et al., 1999; Lipton et al., 2001; Stewart et al., 2001).

PTSD was ascertained using a seven-item modified Breslau screening tool (Breslau et al., 1999) that has been validated in primary care outpatient settings against a clinician-administered structured interview measuring 17 core symptoms (CAPS; Kimerling et al., 2006) (Appendix). In the current study, the research assistant administered the questions to participants. The instrument was scored by summing all responses; the range of possible scores on this modified Breslau scale is 0–7. The cutoff score of 4 or greater for indicating PTSD was established using sensitivity, specificity, and likelihood ratios. A score over this cut point had a sensitivity (95% confidence interval) of 85% (73%, 97%) and a specificity of 84% (77%, 91%) (Kimerling et al., 2006).

Lifetime IPV was measured using the STaT ("slapped, threatened and throw"; Paranjape & Liebschutz, 2003), a three-question instrument developed by validation against a semi-structured interview, which had a sensitivity of 96% (90%, 100%); 89% (81%, 98%); and 64% (50%, 78%) for scores of 1, 2, and 3, respectively. The corresponding specificity is 75% (59%–91%), 100%, and 100%. The research assistant administered these questions. Endorsement of any item on the STaT was considered a positive screen for past or lifetime IPV. The semi-structured interview against which the STaT was validated included criteria measuring emotional control by an intimate partner. The research assistant also administered the Partner Violence Screen (PVS) to ascertain recent IPV. The PVS is a three-item instrument validated against the Index of Spousal Abuse (ISA) and the Conflict Tactics Scale (CTS) (Appendix). Compared with the ISA, the sensitivity of the PVS in detecting partner abuse was 64.5%; the specificity was 80.3% (Feldhaus et al., 1997). When compared with the CTS, sensitivity of the PVS was 71.4%; the specificity was 84.4%. Positive predictive values ranged from 51.3% to 63.4%, and negative predictive values ranged from 87.6% to 88.7%. For the PVS, any affirmative response was considered a positive screen when physical abuse was perpetrated by an intimate partner. Due to the need for brevity in this busy clinical setting, instruments expressly designed and validated to

measure emotional and sexual abuse were not included; researchers focused instead on measurement of physical abuse and the threat thereof.

Subsequently, the STaT responses were dichotomized into the past (lifetime) abuse variable, and the PVS responses formed the dichotomous variable for recent (12-month) IPV. Women who endorsed recent IPV received immediate safety planning and counseling, and those who reported any IPV or screened positive for PTSD were offered referrals to on-site mental health services.

A chart review was conducted to ascertain the MIDAS score (which was performed prior to the research interview by a clinician during the patient's medical visit on the same date of the study visit) along with the following variables: smoking, alcohol use history, marital status, and insurance type.

Statistical Analysis

Frequencies were calculated for survey and chart review data. To reduce potential bias from missing data on smoking and drinking habits, researchers performed multiple imputation modeling (Rubin, 1987). They first performed chi square tests on cross tabulations of categorical variables to test bivariate associations of the relationship between IPV and headache severity, and IPV and PTSD. In these analyses, headache severity (MIDAS score) was dichotomized into a categorical variable, using the cut point of 21 for these exploratory analyses to determine what percentage of women fell into the highest category of headache severity. Researchers calculated the needed sample size based on a theoretical 20-point clinical difference in MIDAS score between participants positive for, and those negative for PTSD. At the time the study began, no published literature was available on the likely magnitude of the relation of PTSD with headache. Using an *a priori* sample size calculator for multiple regression (Cohen et al., 2003), researchers estimated that with 80% power and $\alpha = 0.05$, a sample size of 70 would be sufficient to detect a theoretical 20-point difference in MIDAS score.

In all subsequent regression models, MIDAS was entered as a continuous variable to maximize statistical power. Next, researchers estimated unadjusted linear regression models to examine relationships between the dependent variable, MIDAS score, and PTSD, 12-month and lifetime IPV, age, insurance type, and tobacco and alcohol use. Statistical significance was set at $p = 0.05$. Covariates were retained in the final multivariable models based on their theoretical association with the dependent variable, headache severity as measured by the MIDAS (Peterlin, Nijjar, et al., 2011; Cripe et al., 2011; Peterlin et al., 2007; Coker et al., 2002; Domino & Haber, 1987; Aamodt et al., 2006; Schwartz et al., 1998; Diamond, 2007; Winter et al., 2012) as well as PTSD (Feldner, Babson, & Zvolensky, 2007; Kessler et al., 1995), and IPV (Gerber et al., 2005). Insurance type was included as a proxy for socioeconomic status (SES), which has also been associated with headache (Winter

et al., 2012), PTSD (Savoca & Rosenheck, 2000), and IPV (Cunradi, Caetano, & Schafer, 2002).

To determine whether recent and lifetime IPV could be entered into the same regression model, researchers estimated the correlation between the two. In the final step, they estimated three separate models: Model 1 examined the relationship between PTSD and headache severity (MIDAS), Model 2 examined recent IPV and headache, and Model 3 examined lifetime IPV and headache severity (MIDAS). Model fit was assessed by calculating an R^2 statistic. Analyses were conducted using SAS Version 9.2 [Cary, NC].

The study received Institutional Review Board approval at the Cambridge Health Alliance and VA Boston Healthcare System.

RESULTS

The mean age of the participants was 39 years (SD = 13.18, range 18–66 years), and the mean MIDAS score was 50.6 (SD = 52.46, range 0–240) (see Table 1). While participants came from a wide spectrum of socioeconomic strata, the majority of the participants in the study had private/commercial insurance (73%, 67/92). Most of the participants reported living with an intimate partner (73%, 67/92); 50% were married (46/92). Nine (9.8%) of the participants endorsed having experienced IPV within the preceding year, and 36.9% (34/92) reported lifetime IPV. The prevalence of a positive screen for PTSD was 28.3% (26/92).

PTSD was significantly associated with headache severity in bivariate analyses ($X^2 = 4.47$, $p = 0.03$). However, neither lifetime ($X^2 = 1.05$, $p = 0.3$) nor recent ($X^2 = 0.007$, $p = 0.9$) IPV was associated with headache severity in bivariate analyses. Researchers next examined the relationship

TABLE 1 Participant Characteristics, $n = 92$

Covariate	*N* (%) Mean (Standard Error)
PTSD screen positive (%) (cut point ≥4)	26 (28.3%)
MIDAS Score (mean) (SD)	50.6 (5.58)

Had commercial health insurance (%)	68 (73.9%)
Married (%)	46 (50%)
Non-smoker (%)	78 (92%)*
Non-drinker (%)	47 (58%)**
Lifetime IPV, screen positive (%)	34 (36.9%)
Recent/12-month IPV screen positive (%)	9 (9.8%)

*Imputed data estimate = 430/460 (93.5%).
**Imputed data estimate = 295/460 (64.1%).

TABLE 2 Unadjusted and Multiple Linear Regression Results (dependent variable MIDAS score)

	Unadjusted			Adjusted		
Covariate	Coefficient	SE	*p*-Value	Coefficient	SE	*p*-Value
Model 1: Relation of PTSD to MIDAS						
PTSD	31.80	11.82	0.01	26.40	12.21	0.04
Age (years)	−0.004	0.42	0.99	0.015	0.42	0.72
Health insurance	−2.29	9.60	0.81	1.77	9.84	0.86
Tobacco use	18.78	12.74	0.15	27.03	14.07	0.06
Any alcohol use	−23.5	11.35	0.046	−22.16	11.97	0.07
Model 2: Relation of recent IPV to MIDAS						
Recent IPV	1.93	16.04	0.91	0.66	15.94	0.97
Age (years)	−0.004	0.42	0.99	0.09	0.43	0.84
Health insurance	−2.29	9.60	0.81	1.19	9.94	0.91
Tobacco use	18.78	12.74	0.15	26.71	13.74	0.06
Any alcohol use	−23.50	11.35	0.046	−28.02	11.79	0.02
Model 3: Relation of lifetime IPV to MIDAS						
Lifetime IPV	7.75	5.07	0.14	6.62	5.13	0.20
Age (years)	−0.004	0.42	0.99	0.06	0.42	0.90
Health insurance	−2.29	9.60	0.81	3.19	9.90	0.75
Tobacco use	18.78	12.74	0.15	25.36	13.59	0.07
Any alcohol use	−23.50	11.35	0.046	−26.19	11.69	0.03

between IPV and PTSD. Lifetime exposure to IPV was associated with PTSD ($X^2 = 21.02$, $p = 0.0001$), but recent IPV was not ($X^2 = 3.14$, $p = 0.21$).

In the multivariable regression models (Table 2), PTSD remained strongly associated with headache severity ($\beta = 34.12$, $p = 0.01$), after adjustment for potential confounding variables. This beta coefficient translated into an average of 34 more days of headache-related symptoms in a 90-day period and a statistically significant higher degree of headache severity for participants with PTSD than for those without PTSD. Lifetime and recent IPV were correlated ($p = 0.399$), and were therefore added to two separate regression models to examine their association with headache severity separately. Neither form of IPV was significantly associated with headache severity ($p = 0.05$) in these two separate regression models (Table 2). A gradient was observed for model fit in the R^2 results: Model 1 (PTSD and headache) $R^2 = 13.74\%$, Model 2 (lifetime IPV and headache) $R^2 = 11.04\%$, and Model 3 (recent IPV and headache) $R^2 = 9.2\%$.

DISCUSSION

The authors found that 28.3% of participants presenting to a women's headache treatment center screened positive for PTSD, which is in concert

with the range of 12.5% to 42.9% reported in other dedicated headache treatment settings (Peterlin et al., 2008, 2009), and also falls in the range of 11.8% to 33% reported in various primary care settings (Liebschutz et al., 2007; Stein et al., 2000; Alim et al., 2006). The study participants also exhibited high prevalence rates of both lifetime (36.9%) and recent IPV (9.8%) when compared to estimates of 24.3% and 2.7% of women in the general population (Black et al., 2011). The current results replicated the prevalence rates of lifetime IPV (27.3% to 34.8%) that have previously been reported (Cripe et al., 2011; Peterlin et al., 2007), and augment the existing literature by presenting a 12-month prevalence rate for these clinical settings. It is not surprising that the prevalence rates of IPV in this study exceeded population rates, as women with chronic pain report higher rates of exposure to abuse than those derived in population studies (Wuest et al., 2008; Nicolaidis & Liebschutz, 2009; Coker et al., 2002). The 12-month prevalence rate of IPV in this headache center population was comparable to 12-month rates of 8.6% reported among women in the same metropolitan area in primary care settings (McCloskey et al., 2005) where women frequently present with headache (Lipton et al., 2007).

These findings contradicted researchers original expectation that higher prevalence rates of suspected PTSD and IPV would be found in this all-female headache setting. One reason for this may have been the high proportion of women represented in the previously published estimates in treatment settings for both male and female patients. It is also conceivable that patients presenting to an all-female clinical setting do not differ on trauma exposure and potential susceptibility to PTSD. However, researchers may also have underestimated the true prevalence of IPV in the current population by measuring primarily one domain of IPV (physical, not sexual or psychological). Although neither of the two prior studies of IPV and headache cited previously included emotional abuse estimates, both measured physical and sexual abuse (Cripe et al., 2011; Peterlin et al., 2007). It remains possible that had sexual abuse rates been measured in the current study, the observed prevalence rates of IPV may have been higher. It is also plausible that headache is more strongly associated with psychological abuse, and that the authors underestimated the magnitude of this relationship by using limited measures.

The current study also reaffirmed the findings from prior work demonstrating increased headache impact scores in participants with PTSD using a different measure of headache severity, the HIT-6 (Peterlin et al., 2009). In the current study, the mean MIDAS headache severity score of 50, well above the cut point of 21, suggests that study participants were experiencing a high degree of headache-related disability. PTSD status was statistically significantly associated with MIDAS score; participants who screened positive for PTSD had headache severity scores that were 34 points higher on average than those negative for PTSD, controlling for covariates.

This translates into 34 more days of headache-related disruption in activities over a 90-day period, or disabling headache more than 30% of the time. This degree of headache severity could affect treatment considerations. Within this population, IPV was not significantly associated with headache severity at the $p < 0.05$ level. Yet, patients who reported exposure to recent and lifetime IPV scored, respectively, 1.6 and 9 points higher on the MIDAS, suggesting that, despite lack of statistical significance, these women exhibited greater headache severity and more days of adverse impact from headache. This trend appears particularly salient for women who have experienced lifetime IPV.

These results may reflect that the development of PTSD (or suspected PTSD) is a more important factor in determining headache severity than the trauma alone (in this study, IPV exposure), as suggested previously (Schnurr & Green, 2004; Kimerling, Clum, & Wolfe, 2000). The normative response to trauma (including IPV) is resilience. Most trauma survivors recover naturally. In the minority of cases where PTSD develops, it puts "load" on the system and increases risk for headache over and above IPV exposure. Headache patients with PTSD may have higher allostatic load with accompanying physiologic changes that manifest as greater headache severity. These findings are consonant with the growing body of research documenting PTSD as a primary mechanism contributing to the relationship between IPV and physical health problems (Woods et al., 2008).

This referral population was relatively well insured, underscoring the fact that IPV affects women from all socioeconomic strata. This finding emphasizes that clinicians routinely caring for women with headaches must be attuned to the potential presence of IPV during their patient encounters. Clinicians and care teams should be prepared to offer resources and referrals when patients do disclose abuse. Additionally, because both headache and PTSD are conditions that occur more frequently in women, healthcare providers who routinely treat women need to be cognizant of the association between headache and PTSD, especially in women with chronic headaches who tend to have higher headache severity scores in the range reported by this study.

Limitations

In the current data, headache was not classified by formal International Classification of Headache Disorders (ICHD-2) diagnostic guidelines, as have been used in other studies (Peterlin et al., 2007, 2008, 2009; Peterlin, Rosso, et al., 2011; Cripe et al., 2011), because the authors felt that this information was often not available to primary care providers seeing women patients, and because the MIDAS has been validated in both tension variant and migraine headaches (Stewart, Lipton, Kolodner, et al., 1999). However, this limited the ability to compare current findings to those of other studies that have

stratified their results by headache type. In addition, data on head injury and depression were not available, both of which could be confounders due to their potential associations with physical trauma as well as headache. Further, statistical power to detect as statistically significant meaningful differences in headache severity by IPV exposure may have been limited by the small sample size. The small numbers of women who reported recent IPV in particular may have limited the researchers' ability to detect meaningful differences in headache severity. Additionally, as stated above, the PTSD screen did not determine whether the symptoms queried were anchored to IPV exposure specifically. Thus, it is possible that the positive PTSD screening data ascertained with this measurement was secondary to other types of trauma (including child abuse and sexual assault) not measured in this study. Other limitations included the cross-sectional design of the study, which prohibited assessment of the timing of the IPV and PTSD in relation to the development of headaches, and potential challenges to generalizeability, given that this was a clinical convenience sample from a unique treatment setting to which women with very severe headaches were referred. Participation bias was also possible; researchers did not collect data on all women approached in the clinic and on women who did not participate in the study, to be able to assess potential selection and participation biases. Finally, the administration of potentially sensitive trauma-related measures by a research assistant may have increased the possibility of reporting bias in the sample.

CONCLUSION

This study, conducted in a women's headache specialty center, contributes additional evidence to the existing literature linking PTSD to adverse health outcomes, notably headache severity. While the study did not confirm the prior expectation that prevalence rates of PTSD and IPV could be higher in a dedicated women's headache population, the restricted definition of IPV may have underestimated the true prevalence of all forms of IPV in this population. This study does contribute prevalence estimates using well-validated IPV measures, thus confirming prior observations that IPV is a salient issue for women with headaches. The data on rates of recent IPV contribute new evidence to the imperative that providers treating women with headaches be aware of recent physical abuse in their patient populations. Clinicians practicing in dedicated headache treatment settings may have a unique opportunity to address abuse history (Schulman, 2010).

Future work examining interventions for abused women with headache would be an important contribution to improving care for this patient population that is often treated not only by neurologists but primary care clinicians working in women's health. The strong association between headache severity and PTSD presents a potential multi-disciplinary treatment path where traditional headache treatment is augmented with empirically supported

treatments for PTSD, such as cognitive behavioral therapy. Informed by understanding that PTSD and chronic pain are linked, researchers have demonstrated that integrated treatment is beneficial for participants with these co-morbidities (Otis et al., 2009; Shipherd et al., 2003). Even effective treatment of PTSD alone may be helpful in improving chronic pain (Otis et al., 2003), suggesting that future intervention studies in populations with severe and chronic headaches could yield similar benefit.

APPENDIX

MIDAS (Migraine Disability Assessment) Test (Stewart, et al. 1999)

(1) On how many days in the last 3 months did you miss work or school because of your headaches?
(2) How many days in the last 3 months was your productivity at work or school reduced by half or more because of your headaches? (Do not include days you counted in question 1 where you missed work or school.)
(3) On how many days in the last 3 months did you not do household work (such as housework, home repairs and maintenance, shopping, caring for children and relatives) because of your headaches?
(4) How many days in the last 3 months was your productivity in household work reduced by half of more because of your headaches? (Do not include days you counted in question 3 where you did not do household work.)

(5) On how many days in the last 3 months did you miss family, social or leisure activities because of your headaches?

Total (Questions 1–5)

STaT (Paranjape & Liebschutz, 2003)

(1) Have you ever been in a relationship where your partner has pushed or slapped you?
(2) Have you ever been in a relationship where your partner has thrown, broken or punched things?
(3) Have you ever been in a relationship where your partner has threatened you with violence?

Partner Violence Screen (PVS; Feldhaus et al., 1997)

(1) Have you been hit, kicked, punched or otherwise hurt by someone in the past year? If so, by whom?
(2) Do you feel safe in your current relationship?
(3) Is there a partner from a previous relationship who is making you feel unsafe now?

Short Screening Scale for PTSD (Kimerling et al., 2006)

In your life, have you ever had any experience that was so frightening, horrible, or upsetting that, in the past month . . .

(1) Did you avoid being reminded of this experience by staying away from certain places, people, or activities?
(2) Did you lose interest in activities that were once important or enjoyable?
(3) Did you begin to feel more isolated or distant from other people?
(4) Did you find it hard to have love or affection for other people?
(5) Did you begin to feel that there was no point in planning for the future?
(6) After this experience were you having more trouble than usual falling asleep or staying asleep?
(7) Did you become jumpy or get easily startled by ordinary noises or movements?

Responses are YES = 1 or NO = 0. The scale is scored by summing all responses. Scale scores may range from 0 to 7.

Abstract

Background—Human immunodeficiency virus (HIV) screening is cost-effective and recommended in populations with low disease prevalence. However, because screening is not cost-saving, its financial feasibility must be understood.

Study Objectives—We forecast the costs of two Emergency Department-based HIV testing programs in the Veterans Administration: 1) implementing a non-targeted screening program and providing treatment for all patients thusly identified (Rapid Testing); and 2) treating patients identified due to late-stage symptoms (Usual Care); to determine which program was the most financially feasible.

Methods—Using a dynamic decision-analysis model, we estimated the financial impact of each program over a 7-year period. Costs were driven by patient disease-severity at diagnosis, measured by CD4+ category, and the proportion of patients in each disease-severity category. Cost per CD4+ category was modeled from chart review and database analysis of treatment-naïve HIV-positive patients. Distributions of CD4+ counts differed in patients across the Rapid Testing and Usual Care arms.

Results—A non-targeted Rapid Testing program was not significantly more costly than Usual Care. Although Rapid Testing had substantial screening costs, they were offset by lower inpatient expenses associated with earlier identification of disease. Assuming an HIV prevalence of 1% and 80% test acceptance, the cost of Rapid Testing was $1,418,088, vs. $1,320,338 for Usual Care (p = 0.5854). Results support implementation of non-targeted rapid HIV screening in integrated systems. Conclusions: This analysis adds a new component of support for HIV screening by demonstrating that rapid, non-targeted testing does not cost significantly more than a diagnostic testing approach.

HIV; screening; budget impact; Rapid Testing; Emergency Department

INTRODUCTION

It is estimated that there are 1–1.2 million people living in the United States with human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS), with 21% of them unaware of their disease status (1,2). Many HIV-positive persons are identified only when they develop symptoms, indicating that they are severely immunosuppressed and less likely to respond optimally to antiretroviral therapy. Screening programs that diagnose patients early and offer them treatment can therefore substantially improve health outcomes (3).

Recently, four separate analyses have indicated that HIV screening is cost-effective from a societal perspective compared to no screening and compared to current practice, prompting the Centers for Disease Control and Prevention (CDC) and the American College of Physicians to encourage routine HIV screening as a part of normal medical practice (4–9). However, although HIV screening has been found to be cost-effective, it is not cost-saving. Therefore, even though HIV screening is economically justifiable, it may not be a financially viable option for an organization. A Budget Impact Analysis (BIA) can provide information about the financial feasibility of a program by examining the economic value of the health investment and the resources needed for its implementation (10).

This study examines the budget impact of implementing a new HIV testing program in a Veterans Health Administration (VA) Emergency Department (ED) vs. the financial impact of following standard care. The standard care program examined is Usual Care, which in the ED setting involves blood-based diagnostic testing, or testing a patient when (s)he presents with symptoms suggestive of HIV/AIDS. The new program examined is Rapid Testing, or offering an HIV test to any previously untested patient in the ED, regardless of risk factors or symptoms (non-targeted testing). The rapid test in question is the OraQuick Advance HIV-1/2 Oral Specimen Collection Device (OraSure Technologies, Bethlehem, PA), a Food and Drug Administration-approved point-of-care test. Of particular interest for ED settings, the results of HIV rapid tests are available within 1 h, compared to the 24–48 h turnaround for blood-based testing.

This analysis estimates the number of people who would be identified as disease-positive through Rapid Testing at various levels of program intensity and HIV prevalence rates. The model forecasts treatment costs for patients in the Rapid Test program and compares them to the expenses incurred by these same patients were they to be identified at later stages of disease through Usual Care. The program with the lowest overall costs, both in terms of implementation costs and cost offsets, represents the most economically-efficient strategy.

MATERIALS AND METHODS

We built a first-order stochastic decision-analysis model to determine the costs of treating a hypothetical cohort of patients identified due to a Rapid Testing screening program vs. costs of treating this same cohort of patients were they identified due to symptoms of disease (Usual Care). Cohort size indicates the number of HIV-positive persons identified by the screening programs in the ED. The ED was chosen as the screening site due to its ability to access an otherwise difficult-to-reach population and its predicted higher prevalence of HIV infection compared to primary care locations (11,12). This analysis used cost and economic data from an urban VA ED and Infectious Disease clinic located in a major metropolitan

area. The VA was chosen due to the extensive data available from its cost databases and electronic medical records. Institutional Review Board approval was obtained from the VA system.

Due to the fact that the VA generally keeps patients for life, this analysis assumed all patients would be identified at some point in the system due to their symptoms. Therefore, sizes for the Rapid Test and Usual Care cohorts were identical. We modeled a variety of cohort sizes to reflect uncertainty in the number of patients offered testing, the percentage of patients accepting testing, and the prevalence of HIV (Table 1). This analysis evaluated the financial impact of three different offer rates: five per business day, 10 per business day, or universal. The former two rates were used to reflect realistic levels of testing that can occur in environments with existing capacity constraints; the latter was used in accordance with CDC recommendations. The model assumes HIV prevalence is independent of test acceptance.

Costs of Rapid Testing include both program implementation and treatment of disease. Costs of Usual Care include disease-treatment costs only, but health care utilization is more intensive in this population due to late identification of disease. Treatment costs were calculated for the following budgets: inpatient, outpatient, pharmacy, and global (where global indicates the sum of the former three sub-budgets). All treatment costs were assumed to be dependent upon disease severity at diagnosis (measured by CD4+ count). Disease severity was noted by the following four categories: CD4+ < 50, CD4+ 50–199, CD4+ 200–350, and CD4+ > 350 cells/mm^3 at diagnosis (where low CD4+ values indicate higher disease severity). Costs were projected over a time horizon of 7 years. A horizon of 7 years is longer than usual for BIAs; however, we felt this longer horizon was necessary to capture the delay between when patients are diagnosed through screening and when they begin accruing costs of treatment.

Treatment cost was a function of cost per disease-severity category and the proportion of cohort members in each disease-severity category. Estimated costs were calculated on an annual basis for each budget using 2007 dollars. The following equation was used to model the total estimated costs of treating disease:

$$Cj = \sum_{i=1}^{4} \sum_{t=0}^{6} (C_{jit} * N_{jit})$$

Where:

C_j is the average cost per case in sub-budget category j

i is the disease-severity category (CD4+) assigned at time of diagnosis

t is the year in which costs are accrued

C is the average cost per case of disease

N is the number of people

Cost per disease-severity category was determined by examining utilization patterns of HIV-positive patients and allocating VA-specific direct medical cost values to this utilization. VA-specific costs were used, following best practice recommendations for conducting BIAs. (10). Utilization data came from chart review of all treatment-naïve patients diagnosed and treated at this site from Fiscal Year (FY) 2000 to FY 2007 (n = 112). Although this number is small, the analysis required the use of these actual data, due to the dearth of literature available on treatment-naïve patients and the fact that data from treatment-experienced

patients would substantially overestimate treatment costs. Modeling HIV-related utilization over time also poses significant difficulties, given that drug treatment efficacy decreases over time, is influenced by patient adherence, and that the relationship between adherence and consequences of much highly active anti-retroviral therapy (HAART) is not fully understood (13). For example, partial adherence increases the risk of drug resistance more so than complete non-adherence (13).

Only HIV-related utilization was included in the model. All inpatient stays with HIV as a primary or secondary diagnosis were reviewed by two infectious disease physicians who had treated the majority of these patients; only those inpatient stays unanimously deemed to be due to HIV were included in this analysis.

Once the cost per disease-severity category was calculated, we populated the model with the program-specific CD4+ distributions. As Usual Care patients are diagnosed at later, more advanced stages of disease than are patients identified through Rapid Testing, the disease-severity distributions differed across the programs; a larger proportion of Usual Case patients had lower CD4+ counts at diagnosis. The CD4+ distribution for the Usual Care program was determined using patients from the national Veterans Aging Cohort Study (VACS) Virtual Cohort, which contains clinical data on all HIV-infected veterans in the country (14). Disease severity at diagnosis was obtained for VACS Virtual Cohort members who had ED visits in a VA facility before their HIV diagnosis (n = 3355), which represents the Usual Care patients in this model.

We used a back-calculation scheme to determine the CD4+ distribution for the Rapid Testing program. Annual CD4+ decline in the absence of treatment can be estimated by the following equation: CD4+^½ =− .0584 – 0.918 [log(vRNA/1000)] (15). Entering patients' viral load at diagnosis, CD4+ count at diagnosis, as well as the length of time elapsed between first ED visit and HIV diagnosis into the equation yields an estimate of patients' CD4+ count had they been diagnosed with HIV at the time of first ED visit (a Rapid Testing approach). For example, a patient presenting 2 years after his first ED visit with an initial CD4 count of 150 cells/mm^3 and viral load of 100,000 copies would be back-calculated to have had a CD4 of 292 cells/mm^3 had he been diagnosed at the time of initial ED visit (Table 2).

As identified HIV-positive patients, persons in the Rapid Testing arm begin accruing treatment costs immediately. However, it takes some time for Usual Care patients to display symptoms of disease, be diagnosed, and therefore start incurring treatment costs. Data from the VACS Virtual Cohort indicate a mean 1.25-year delay between the first ED visit and diagnosis of HIV. All estimated costs in the Usual Care program were adjusted back 1.25 years to reflect this delay to diagnosis. Over the entire analysis, the Rapid Test program therefore had 7 years of data, whereas the Usual Care program had 5.75 years of data.

In the outpatient and pharmacy models, cost values associated with the Usual Care and Rapid Test programs were identical. The model assumed drug costs and office visits were not driven by method of HIV diagnosis, but simply by the severity of patient illness. However, cost values for the inpatient and thus global models differed across the Usual Care and Rapid Testing programs; inpatient utilization, and cost, was dependent upon whether a patient was diagnosed through Rapid Testing or Usual Care. Inpatient stays within 3 months of HIV diagnosis were excluded from the Rapid Testing costs. These hospitalizations represent patients who were diagnosed due to opportunistic infections; their exclusion was more indicative of the clinical scenario of Rapid Testing patients, who are not diagnosed due to opportunistic infections and therefore would not have experienced such inpatient stays.

Once the model was populated with the cost per CD4+ category and the distributions of CD4+ counts, we ran the analysis and employed statistical techniques to mitigate the noise associated with small samples. Probabilistic sensitivity analyses (with 10,000 Monte Carlo iterations) were run to gain a more accurate estimate of cost per CD4+ category, with each iteration randomly sampling from each distribution of cost per CD4+ category. This re-sampling increases the likelihood that outlier cost inputs would not have an undue influence on cost estimates. Model analyses were conducted using TreeAge Pro 2008 software (TreeAge Software Inc., Williamstown MA).

Usual Care program costs were directly obtained from model results. Rapid Testing program costs were obtained by adding program implementation costs to model results. Implementation costs were determined by micro-cost estimates of resources used in offering and conducting HIV tests, including testing kits and labor. Time-and-motion data were obtained by direct observation of HIV rapid testing in the ED. An applied rate of 85% was used for all salary calculations. Two-tailed *t*-tests of significance were run on the total costs of each program to determine if the overall 7-year global costs of the Rapid Test program were significantly different from the Usual Care program. Tests of significance were run using STATA version 9.2 (StataCorp LP, College Station, TX).

To summarize, the following assumptions were made in conducting these analyses:

1. Patients can be properly stratified into four CD4+ count categories.
2. All health care utilization, and therefore cost, is contingent upon CD4+ count at diagnosis.
3. Utilization patterns of patients identified through these programs can be modeled using utilization data from past HIV-positive patients treated at the same location.
4. All persons diagnosed are immediately linked to treatment.
5. All patients identified by Rapid Test would be diagnosed an average of 1.25 years later in the Usual Care program.

RESULTS

At all test offer rates and cohort sizes, there is no significant difference in total 7-year estimated costs of the Rapid Test and Usual Care programs (Table 3). At lower cohort sizes, the Rapid Test program is more costly than the Usual Care program, across all offer rates. As cohort size increases, there is a threshold at which Rapid Testing becomes less costly than Usual Care. The threshold is not consistent across offer rates due to the inclusion of implementation costs, which do not increase linearly with cohort size.

Implementation costs are responsible for the higher Rapid Testing costs at lower cohort sizes, as the organization is spending money in screening many patients but finding few who are HIV-positive. At lower cohort sizes, treatment costs are smaller; implementation costs thus represent a large percentage of overall costs. As cohort size—or number of patients identified as HIV-positive—increases, treatment costs increase substantially, whereas implementation costs increase only slightly. This is due to the fact that implementation costs are driven by test acceptance rates, whereas cohort size is substantially driven by disease prevalence. Hence, at large cohort sizes, when treatment costs are substantial in relation to implementation costs, Usual Care becomes the more costly program. Estimated costs for the Rapid Testing program differ across the same cohort size for the same reason. For example, the overall Rapid Testing costs for a cohort of size 11 may be $464,529 or $485,701 or $561,386. The reason for this discrepancy is implementation costs; the cost of offering tests to 10 patients in the ED is higher than the cost of offering HIV tests to 5 ED patients.

An examination of the relative cost components of each program reveals that the higher cost for Usual Care patients is largely due to more inpatient stays, reflecting more hospitalizations for these patients due to opportunistic infections (Table 4). Outpatient costs represent approximately one-fifth of costs for both programs, whereas pharmacy comprises the greatest percentage of costs for both programs. However, total pharmacy costs are lower for the Usual Care program, due to the fewer years of cost data.

As noted previously, the Usual Care program had no implementation costs, and only 5.75 years of data. This biases the cost estimates in its favor, as implementation costs for the Rapid Testing program range from $18,211 to $141,002. As statistical tests revealed no significant difference in the overall costs of the two programs, this suggests that once Usual Care patients are identified, their costs are higher than those for Rapid Test patients. Estimates of cost per capita reveal global costs per Usual Care patient to be $7237 annually vs. $5836 annually per Rapid Test patients.

DISCUSSION

Results indicate that over a 7-year period, an HIV screening program using a Rapid Testing approach is financially equivalent to following a Usual Care approach within the VA system. Given that early detection of HIV and linkage to treatment is also associated with better health outcomes, this analysis provides support for the implementation of a non-targeted oral Rapid Testing program.

Inpatient costs were substantially lower for Rapid Testing patients, offsetting the costs of implementing screening, and resulting in similar costs for the two HIV testing programs. Patients in the Usual Care program had higher inpatient costs, due to the fact that many of them were hospitalized for opportunistic infections (OIs). When modeling utilization of the Rapid Testing cohort, we excluded any hospitalization occurring within 3 months of HIV diagnosis. The model's exclusion of these inpatient costs for the Rapid Testing patients is partly responsible for the lower inpatient costs for this program. This exclusion was warranted, as we sought to quantify the marginal cost of implementing a non-targeted HIV Rapid Testing program. Including the inpatient costs of patients who were diagnosed due to hospitalization from OIs would misrepresent the clinical scenario of Rapid Testing patients, as patients who have acute OIs would have been diagnosed by Usual Care regardless of whether a Rapid Testing program was in place.

This analysis provides support for a non-targeted screening-based program. Although the initial investment of such a screening program may be as high as $141,000, the smaller treatment costs of patients identified at lower disease-severity offset the initial financial impact. This observation is crucial, as data from the VA and other health care systems indicate that targeted (risk-based) testing fails to capture a significant portion of the HIV-positive population (13,16).

This analysis also provides support for rapid testing. Although costs of rapid tests are higher than conventional assays, oral rapid tests are particularly attractive for use in ED settings due to higher patient acceptance rates and virtually immediate turnaround (5). Short turnaround increases the likelihood that patients will receive tests results, which is especially important in an ED-using population, where continuity of care can be problematic and many patients have difficulties returning for test results. Studies indicate that 21–30% of patients testing positive and 25–39% of patients testing negative for HIV do not return for the results of their tests (17,18).

This analysis used clinical and economic data from the VA. The advantage of using VA-specific data is that the VA is a non-profit, non-revenue-generating organization, which

ensures that financial data used represent actual costs, rather than profit or cost-shifting from uncompensated care. Use of actual data, rather than projections, serves to more accurately demonstrate the relationship between a program and its clinical and economic effects. Therefore, the results shown here are more indicative of the true cost of screening. Furthermore, this analysis demonstrates that the initial costs of ED-based screening are offset by lower inpatient utilization—data that are applicable to any integrated health system. Such results can guide other integrated systems in providing support for HIV screening in high-prevalence locations (defined as 0.5% or greater).

Limitations

The major limitation of this analysis lies in the small sample size used to determine utilization and estimate costs. This analysis had a sample size of 112, divided up into four disease-severity categories. First-order probabilistic sensitivity analyses were employed to gain more accurate estimates of the means with a small sample, but could not mitigate variation around the mean. Variation in inputs results in large confidence intervals, therefore increasing the likelihood of non-significance.

However, there were also important benefits from using these actual data. First, use of actual data takes into account the various drug (and therefore cost) combinations of HAART therapy, as well as the cost of modifying HAART therapy over time. Second, it better captures the relationship between patient drug use and hospitalization than modeling practices. Use of actual clinical data also takes into account that although all HIV-positive patients are referred to care, some did not actually enter care or cycled in and out of the system, and that rates of adherence to care vary considerably. Lastly, use of actual clinical data captures true physician practice patterns; using clinical practice guidelines to model care does not take into account physician deviation from these guidelines. Use of actual cost data, rather than charges or billing data, provides a more accurate indication of the real economic impact of each program.

In a clinical setting, it is likely that some patients would be lost to follow-up and not initiate treatment. However, this model assumed that all patients diagnosed were linked to treatment, as we believed that an organization should be prepared to allocate enough funding to a program such that all patients can be offered proper care for their disease.

This analysis was conducted using data from the VA system, which may limit generalizability of cost results to other settings. However, perhaps even more important than producing actual cost estimates, this analysis demonstrates the relationship between non-targeted screening and usual care—and provides evidence that a non-targeted screening program does not pose a significant cost burden to the organization. These findings are of use for decision-makers in any integrated system.

Treatment patterns for HIV may have changed over time, raising the issue of the appropriateness of using past data to model future utilization. Although new drugs may have come to market from FY 2000 to FY 2007, analyses of these data indicate that annual pharmacy costs have not changed over time. Inpatient costs have also not changed significantly, suggesting that even if drug therapy has altered, neither its costs nor its effect on inpatient utilization have been modified. Therefore, using past utilization data to inform this model was appropriate.

CONCLUSION

This article demonstrates the practical, real-world effect of implementing evidence-based policies, and adds a new component of support for HIV screening, by demonstrating that an

HIV screening program that utilizes rapid, non-targeted testing in an ED will not cost substantially more than a diagnostic testing approach.

HIV = human immunodeficiency virus.

*Cohort size is dependent on four factors: the number of people visiting the Emergency Department annually, the percentage of patients offered testing, the percentage of patients accepting testing, and the prevalence of HIV. Due to uncertainty regarding the latter three rates, a variety of cohort sizes were modeled. Cohort size is calculated in the following manner: at an offer rate of 10 tests per business day, 2600 tests would be offered annually. If 55% of patients accept testing, 1430 tests would be conducted. At a 1% prevalence of disease, 14.3 patients would be identified as disease positive. Rounding up to the next whole person results in a cohort size of 15.

Table 2

Model Inputs: Percentage of Patients in Each CD4 Category

	CD4 < 50	CD4+ 50–199	CD4+ 200–350	CD4+ 350+

EDITORIAL

Screening, Brief Intervention, and Referral to Treatment (SBIRT) Curricular Innovations: Addressing a Training Gap

Unhealthy substance use, which includes the full spectrum of risky to dependent use of alcohol and other drugs, is common in patients cared for by health care providers in a variety of general health care settings. Early identification, assessment, treatment, and when indicated, referral to specialty care, of patients with unhealthy substance use can be challenging for both experienced health care providers as well as for health professional students and trainees. The clinical procedures of screening for unhealthy substance use, providing brief interventions to reduce unhealthy substance use, and referring for treatment patients in need of specialty treatment are evidence-based practices that are being promoted by research, policy, and service organizations in the United States. Despite this national movement, few health professional schools and programs have formal screening, brief intervention, and referral to treatment (SBIRT) curricula (1). This special issue is an early effort to describe and examine the outcomes of teaching SBIRT to health professionals and trainees.

Use of alcohol and illicit substances contributes to significant morbidity and mortality. Substance use has deleterious effects on common medical conditions (2–5), including diabetes mellitus, hypertension, sleep disorders, depression, chronic obstructive pulmonary disease, and osteoporosis (6–10). Moreover, unhealthy substance use increases risky behaviors, reduces access to preventive health care, reduces compliance with prescribed medical treatment, and adversely affects housing and employment (11–14). According to the 2009 National Survey on Drug Use and Health, of the almost 21 million people who needed treatment for illicit drug or alcohol use but did not receive it in 2008, 94% did not feel they needed treatment (15). The addiction specialist treatment system is not appropriate for all persons who have unhealthy alcohol use, or perhaps occasional substance use, nor can that system alone address the needs of all persons diagnosed with alcohol or substance use disorders. Other treatment modalities in a variety of clinical settings are needed.

SBIRT is an integrated, comprehensive, public health approach to addressing the full spectrum of unhealthy substance use in general health care settings. The core components of SBIRT include (1) screening—a strategy of early identification and assessment of individuals with unhealthy substance use through interview or self report; (2) brief intervention—a counseling approach that is focused on raising an individual's awareness of his or her unhealthy substance use and motivating that individual to a positive behavior change; and (3) referral to treatment—a proactive process that facilitates access to specialty addiction for individuals with substance use disorders.

In research studies, SBIRT for unhealthy alcohol use has demonstrated effectiveness, efficiency, and cost-effectiveness (16, 17). There is growing evidence for SBIRT for unhealthy drug use (18). Validated "single-item" screening questions make early identification of unhealthy substance use in busy general health care settings feasible (19, 20). Furthermore, models of implementation have been demonstrated for SBIRT in wide variety of general health care settings (21). SBIRT seems also to improve care coordination between general health care and specialty addiction services (22, 23). Yet despite evidence for the effectiveness of SBIRT, implementation of SBIRT into clinical settings has been slow (24, 25). An emerging body of literature aims to improve diffusion and application of SBIRT (26, 27). These guides promote interdisciplinary SBIRT planning and implementation teams, and additional calls have been made for the involvement of other health care professionals in SBIRT practices (28–30).

Although the Substance Abuse Mental Health Services Administration (SAMHSA), the Office of National Drug Control Policy (ONDCP), the United States Preventive Services Task Force (USPSTF), Institute of Medicine (IOM), and the Committee on Trauma of the American College of Surgeons (ACS) have promoted widespread SBIRT implementation, a variety of provider-, system-, and patient-level barriers to SBIRT delivery exist. These barriers include concerns about (1) lack of time and training for performing SBIRT, (2) perception or presence of more compelling clinical issues, (3) underutilization or lack of awareness of effective screening and treatment strategies, and (4) concerns about patient privacy and potential damage to the patient-provider relationship (31, 32). Additionally, providers may perceive that SBIRT for unhealthy substance use is simply ineffective, unsatisfying, uncomfortable, or not within their role responsibilities (26, 27).

SBIRT skills have been proposed as an addiction medicine core competency in generalist physician training (33). Recognizing the urgent need to train general health care providers in SBIRT, in 2008, the Substance Abuse and Mental Health Services Administration, Center for Substance Abuse Treatment (SAMHSA/CSAT) funded eleven 5-year SBIRT Medical Residency Program (SMRP) cooperative agreements to develop and implement training programs to "teach medical residents the skills to provide evidence-based SBIRT for patients who have, or are at risk for a substance use disorder [and] promote adoption of SBIRT through delivery of training to local and statewide medical communities for wider dissemination of SBIRT practices" (34).

Recognizing the critical need to disseminate curricular innovations regarding SBIRT training and evaluate the evidence of positive effects of SBIRT curricula on the learner- and patient-level outcomes, in January 2011, the Association of Medical Education and Research on Substance Abuse (AMERSA) led a call for papers of a special issue of the *Substance Abuse* journal. The special issue editors sought descriptions and evaluations of SBIRT curricula and training at health professional schools and residency and fellowship training programs, and targeting practicing health care professionals. Manuscripts describing innovative means to *develop*, *implement*, and *evaluate* SBIRT curricula were particularly sought. This special issue, "Screening and Brief Intervention for Substance Abuse," is the product of that call. In September 2011, we accepted 14 papers—4 full-length papers and 10 brief reports of curricular innovation—for publication.

The work contained in this special issue exemplifies early efforts to train health care professionals and their trainees in SBIRT skills. Skill proficiency of the learners in clinical practice is difficult to assess. Infusing SBIRT into academic curriculum can be challenging: the teachers of the curriculum often must be taught and making time for SBIRT knowledge and skill transfers may be difficult in the ever present setting of multiple competing curricular priorities. Pivotal questions such as who, when, and how to teach SBIRT to health care professionals need to be answered. For many of the educational projects described in this special issue, comprehensive outcome data have yet to be obtained. We will likely need to wait years to gain a full understanding of the effectiveness of various SBIRT curricula and training methods on changing health care providers' clinical practice. Ultimately

measuring SBIRT training on patient-level outcomes such as the number of patients receiving SBIRT services would be ideal. Yet, the work contained in the papers in this special issue reflect early attempts at describing curriculum development and implementation of addiction content into traditional learning environments. These educational program descriptions and early outcome assessments may serve as a template for diffusion of SBIRT curricula in other training environments. The authors of the work contained in this special issue should be commended for their pioneering SBIRT curriculum development and implementation efforts.

Background & Aims: Liver biopsy remains the standard, recommended method for assessing liver damage associated with chronic hepatitis C (HCV) infection. However, there is considerable debate about how liver biopsy should best be used, especially with the advent of more efficacious antiviral therapies. To identify the factors that influence the use of liver biopsy for HCV patients, we describe variations in liver biopsy use at the delivery system and patient level in a national VA sample.

Methods: We analyzed VA HCV registry data for 171,893 VA patients with confirmed chronic HCV. Delivery system characteristics included geographic region and specialist time. Patient characteristics included antiviral treatment indicators, contraindications, volume of healthcare visits, and demographic variables. Logistic regression was used to explore correlates of biopsy use.

Results: Liver biopsy use in the VA system increased from 1997 to 2003 but began declining in 2004. Rates of liver biopsy from 2004 to 2006 varied by VA region, ranging from 5% to 18%. Treatment contraindications and laboratory tests were significantly associated with more biopsies. Demographic variables (higher age, lower BMI, race/ethnicity, and less% service connected disability) were associated with fewer biopsies. Regional variability remained significant independent of volume of care and specialist time.

Conclusions: Liver biopsy rates in the VA system have variability that seems unrelated to clinical need. New antiviral therapies and non-invasive assessment techniques may create additional uncertainty for the role of liver biopsy, perhaps explaining its decline in recent years. The availability of more effective antiviral therapies may also affect biopsy rates in the future.

Introduction

Hepatitis C virus (HCV) infects about 1.8% of the US population, [1] with higher rates in the VA patient population [2], and often leading to severe medical consequences [3–5]. Liver complications may be avoided with effective antiviral treatment. Antiviral treatment eliminated the virus in 40–50% of patients [6,7] until the recent availability of new therapies that have cure rates of 65–73% for genotype 1 patients in clinical trials [8,9]. Although liver biopsy is used for a variety of purposes, the most common usage is for the assessment of liver damage to assist with antiviral treatment decisions.

Liver biopsy is the recommended method for assessing liver damage resulting from chronic HCV infection. Both the VA [10] and NIH recommend its use for evaluating and making treatment decisions for most HCV patients (genotype 1). Additionally, the American Association of Liver Disease guidelines state that liver biopsy should be performed "when the results will influence antiviral treatment recommendations" [11,12].

Despite established recommendations, other factors such as alanine aminotransferase (ALT) elevation may influence biopsy rates. Some studies purport that HCV-infected persons with normal ALT levels have less liver damage than those with abnormal ALT levels [13], and that liver biopsy may be of little value for those with normal ALT [14]. Others believe all patients, regardless of ALT level, should be biopsied [15].

Relative contraindications to antiviral treatment such as depression or substance abuse can impact biopsy rates. Biopsy may only be considered for good treatment candidates. Conversely, biopsy results could be used to motivate lifestyle change to produce better treatment candidates. The literature on variation of health procedures in other conditions would suggest that non-clinical factors like race/ethnicity or geography may be another factor [16,17].

More recently, less invasive methods of liver fibrosis assessment have received considerable attention. A recent review of non-invasive methods concluded that non-invasive methods cannot match the information obtained from a biopsy [18]. Others have suggested that liver biopsy should only be recommended as a secondary test, due to the utility of biochemical marker tests [19].

Emerging HCV treatment options likely add to uncertainty about the utility of liver biopsy. New antiviral treatment may almost double sustained virologic response rates while shortening treatment duration [9,20,21]. With these improvements, liver biopsy may play a lesser role in treatment decision making.

Thus, there may be significant variability in how liver biopsy is used at different locations. In a recent clinician poll, substantial variability was found in recommendations for a hypothetical HCV patient. Of 3216 health professionals from 115 countries, 44% voted to perform a liver biopsy, 34% voted for expectant management with periodic assessment of liver function, and 22% voted to initiate HCV therapy with peginterferon and ribavirin [22]. Thus, despite the recommendations of expert bodies, the optimal use of liver biopsy in HCV-infected patients remains unclear.

Our study objective was to examine clinical and patient characteristics associated with variability of liver biopsy use for HCV-infected patients in VA Healthcare System.

Patients and methods

Design

The study was a retrospective, large database analysis using data from the VA Hepatitis C Clinical Case Registry from 1997 to 2006. Data analyses were conducted and refined from 2009 to 2011. Data analyzed for the study included patient demographics, outpatient visits, inpatient services, procedure codes, laboratory results, diagnosis codes, and problem lists. IRB approval and informed consent waiver were obtained.

Setting and sample

Research consisted only of retrospective database analyses. The original sample consisted of 304,024 VA patients who had been entered into the VA Hepatitis C Registry under unique patient identifiers from 1997 to 2006. Of those patients, 266,866 had evidence of either HCV antibody or confirmation testing. A subset of those, 171,893 patients, had clear evidence of a positive confirmatory test for chronic hepatitis C infection. Confirmed HCV positive was defined as any positive result from genotype, qualitative RNA and quantitative RNA. If a subject is HCV+ in a study year, the subject is HCV+ after this study year.

We used all available data (10 years) when examining the frequency of liver biopsies performed over time. To examine correlates and variability of liver biopsy use, we focused on the three most recent years of data (2004–2006) as most representative of current practice. "Receiving VA care" was defined as having one or more recorded inpatient or outpatient visits during this time period. This resulted in a sample size of 136,269 subjects who were confirmed to have chronic HCV infection and received VA care for chronic HCV from 2004 to 2006. Subjects with liver biopsies in any prior year or who died before 7/1/2004 were excluded.

Procedures

The initial data set included all VA patients with a positive HCV test. Since many patients with positive antibody tests clear the virus on their own, the first step was to limit our sample to patients that had tested positive on an HCV confirmation test. Confirmatory testing was defined as a positive result on either a qualitative or quantitative HCV RNA test, or a positive HCV genotype test. Confirmatory tests with 76 different name variations were classified into one of the three types of confirmatory tests. Next, to reduce the chance of including test results that were labeled incorrectly, test result values were examined to ensure consistency with the type of test (qualitative test – yes/no answers, quantitative tests – numerical values within range, genotype tests – ranging from 1 to 6). Approximately 5% of the results were indeterminable or ambiguous and could not be used for analysis.

We defined receipt of liver biopsy as presence of the following codes in the outpatient or inpatient data files (50.11 – Closed Liver Biopsy, 50.12 or 50.121 – Open Liver Biopsy, 50.13 – Transjugular Liver Biopsy, 50.14 – Laparoscopic Liver Biopsy, 47000 – Needle Biopsy of Liver, 47001 – Needle Biopsy, Liver Add On, 47100 – Wedge Biopsy of Liver).

We then examined the variables associated with receipt of a liver biopsy. To identify predictors of liver biopsy, we began with a list of possible contraindications for antiviral treatment developed by Kanwal *et al.* for VA patients with HCV [23]. Possible contraindications were determined by ICD-9 codes and not actual treatment decisions. Because the goals of our study differed from the study cited, modifications were made to the coding of these contraindications. One modification was to differentiate current substance use and psychiatric disorders from long-term disorders because long-term or permanent disorders may not be a current problem or contraindication by themselves, but may be related to biopsy rates. A substance use or psychiatric disorder was considered "current" if any inpatient or outpatient visits between 2003 and 2006 had substance use or psychiatric ICD 9 codes. Substance use or psychiatric disorders that appeared on the medical record "problem list", but were not linked to visits between 2003 and 2006, were considered long-term. A second modification from the reference manuscript [23] was that laboratory data was not used in the algorithms for defining the presence of co-morbid conditions as contraindications. Laboratory variables were examined directly as independent correlates of receipt of liver biopsy (Table 1).

Demographic variables were recoded into the categories indicated in Table 3. Regional variation was examined using the 21 regions of the national VA healthcare system. To examine the effect of specialist time on biopsy frequency, we obtained data from the 2007 Survey to Assess Hepatitis C Care in VHA conducted by the VA Public Health Strategic Health Care Group. Responses from 141 "lead HCV clinicians" at VHA facilities indicated the "Number of weekly ½ days clinics covered" by 13 different types of healthcare providers. To account for differences in the number of patients served by each region, we divided the average number of ½ day clinics for hepatologists and gastroenterologists in each region by the number of HCV patients from that region.

Statistical analyses

We present raw numbers of biopsies over time and proportion of patients in the database who were biopsied each year between 1997 and 2006. We focused on raw numbers instead of the proportion because many new patients were added to the registry each year, making the proportion drop each year while the number of biopsies being conducted was increasing. To examine geographical variability, descriptive statistics and Chi-square analysis were used to describe and examine differences in the proportion of patients biopsied at each of the 21 VA healthcare regions between 2004 and 2006. We limited the analysis of regional variation to the most recent years to best represent current utilization.

Multivariate logistic regression was used to examine the effect of patient demographic and clinical characteristics, and geographic regions on the receipt of liver biopsy in HCV-infected patients. Because liver biopsy may be used for different reasons among distinct subgroups within our sample, we identified three patient subgroups (liver transplant, cirrhosis prior to biopsy, and those without transplant or cirrhosis prior to biopsy). Our final model (Table 3) focuses on HCV-infected patients without cirrhosis or liver transplant, representing over 90% of the sample.

Independent variables were first examined in bivariate analyses with presence of liver biopsy between 2004 and 2006 as the dependent variable. Variables with p-value <0.15 in bivariate analyses were included as predictors in multivariate logistic regression. Variables were entered into the final model in the following order: contraindications, labs, demographics and other variables (specialist time, geographic region). Stepwise backward model selection for main effects in the final model was performed. Variables for the initial model were selected using Akaike's Information Criterion. Then the variable with the largest p-value was removed from the model until all variables included in the model with p-values <0.05 were examined. Non-parametric rank sum tests confirmed that specialist time differed by geographic region. Analyses were performed with SAS (version 9.1) and the open source statistical package R (version 2.8.1).

Results

Rates of liver biopsy and patient characteristics

The raw number of liver biopsies conducted in the VA system nationally in 1997 was only 475. This number grew quickly in subsequent years and peaked at 4758 in 2004 before declining slightly in 2005 and 2006 (Fig. 1). As an overall proportion for the study period of 1997–2006, 16.7% (28,677 of 171,893) of VA patients with confirmed HCV infection received a biopsy.

Research Article

Table 1. Contraindication and laboratory variables.

Contraindications	ICD9 codes
Major, uncontrolled depressive illness	296.2x-3x (1 inpatient or 2 outpatient)
Current illicit drug/alcohol use	305.xx except 305.1 (1 inpatient or 2 outpatient)
Untreated hyperthyroidism	242.xx (1 inpatient or 1 outpatient)
Severe hypertension	401.xx-405.xx (1 inpatient or 1 outpatient)
Severe heart failure	428.xx (1 inpatient or 2 outpatient)
Significant coronary artery disease	414.xx (1 inpatient or 2 outpatient)
Poorly controlled diabetes	250.xx (2 inpatient or 2 outpatient)
Severe COPD	490.xx-496.xx (1 inpatient)
Severe psychiatric disease	300.xx, 309.81, 295.xx-298.xx (1 inpatient)
HIV co-infection	V08, 042 (1 inpatient or 1 outpatient)
Chronic renal disease	585.xx (1 inpatient or 1 outpatient)
Decompensated cirrhosis	571.2, 571.5-6 (1 inpatient or 1 outpatient)
Liver transplant	V42.7 (1 inpatient or 1 outpatient)
Renal, heart, and lung transplant	V42.0-1, V42.6, V58.44, E878.0 (1 inpatient or 1 outpatient)
Laboratory variables*	**Variable coding**
Hepatitis A	has been tested (Yes/No)
Hepatitis B	has been tested (Yes/No)
HCV genotype	1, 2, 3, or 4
Total bilirubin	high abnormal (Yes/No)
Aspartate aminotransferase (AST)	high abnormal (Yes/No)
Alanine aminotransferase (ALT)	high abnormal (Yes/No)
Platelet count	low abnormal (Yes/No)
Albumin	low abnormal (Yes/No)
Hemoglobin	low abnormal (Yes/No)
White blood count (WBC)	low abnormal (Yes/No)
Creatinine	high abnormal (Yes/No)

*For subjects with a liver biopsy from 2004 and 2006, laboratory tests between 1/1/2003 and the date of liver biopsy were used. For subjects without a liver biopsy from 2004 and 2006, laboratory tests conducted between 1/1/2003 and 09/30/2006 were used.

However, many of these individuals may have had contraindications for antiviral treatment, reducing the need for biopsy. Clinical and socio-demographic characteristics of the sample from 2004 to 2006 were compared for patients who did and did not receive a liver biopsy (Table 2). Given the large sample size, almost all variables were significantly different at the p <0.001 level.

Geographical variability in biopsy rates

To study geographical variability, we examined the proportion of HCV-infected patients who were biopsied by region from 2004 to 2006. The overall rate of biopsy among HCV patients in care from 2004 to 2006 was 9.3%. Overall data include many patients who had likely not been biopsied for specific reasons or refused (Fig. 2). When broken down by clinical subgroup, rates were 19.9% among liver transplant recipients (0.8% of the sample), 9.8% among HCV patients with cirrhosis (9.1% of the sample), and 9.2% among those without transplant or cirrhosis (90.1% of the sample). In initial models, patients with transplant (OR 3.29, <0.001) and cirrhosis prior to biopsy (OR 1.20, <0.001) were significantly more likely to be biopsied.

There was significant variation in the rates of liver biopsy across the 21 VA regions. While 17.8% of HCV patients in region U received a liver biopsy between 2004 and 2006, biopsy rates in regions G, H, and P were much lower, in the range of 5–7% (p <0.001). Removing all patients with a potential contraindication, increased the proportion of patients biopsied from 9.4% to 12.1% during that period. Regions B and U biopsied over 21% of patients without contraindications during this period while other regions were as low as 6.6%.

Factors associated with receipt of liver biopsy

Most contraindications were significantly associated with lower rates of liver biopsy in the final model. Recent organ transplant and advanced liver disease were significantly associated with higher rates of liver biopsy (Table 2).

As expected, genotype 2 and 3 patients were less likely than genotype 1 patients to receive a biopsy. Patients who had been tested for hepatitis A or B were more likely to be biopsied. HIV infection was not significantly associated with liver biopsy. Liver biopsy rates decreased slightly with each year of age, and increased slightly with increasing BMI and service connection

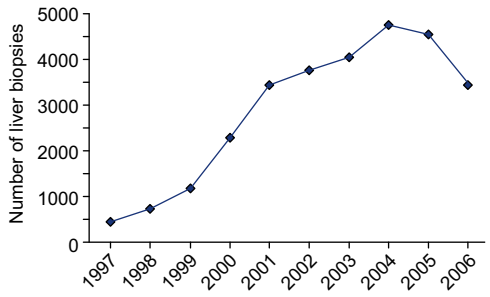

Fig. 1. Number of liver biopsies by year, national data.

percentage. When compared with non-Hispanic Whites, Hispanics, African-Americans, and patients of Other/Unknown race/ethnicity were significantly less likely to receive a biopsy.

In the next regression step, hepatologist and gastroenterologist specialist times were initially associated with more biopsies, but became non-significant when the mean number of healthcare visits (associated more liver biopsies) was entered into the analysis. Finally, the 21 categories of geographic VA region were entered while controlling for other variables in the model. Specialist time remained significant after geographic region was entered, indicating independent effects. With region A's biopsy rate of 13% as the reference group, only regions B, E, F, and M, were not significantly different. Fourteen regions had significantly lower biopsy rates while subject two regions (O, U) had higher rates.

To examine the univariate connection between liver biopsy rates and antiviral treatment rates, we examined correlation of the two rates by geographic regions. A significant correlation was found between liver biopsy rates and HCV antiviral treatment rates ($r(21) = 0.46$, $p = 0.036$).

Discussion

The burden of chronic hepatitis C continues to grow in the US, especially for the VA healthcare system, which treats more HCV-infected individuals than any other system. Liver biopsy has long been the gold standard for assessing the severity of liver damage among HCV-infected patients, and it is recommended for the evaluation of all HCV patients with genotype 1 virus [10], who comprise about 70% of all cases in the US. Despite these recommendations, our results indicate that only about 17% of all HCV-infected patients receiving care in the VA system had been biopsied.

There are a number of plausible clinical and policy-related reasons that doctors and patients may choose to forgo biopsy. One common reason is that the majority of VA patients are not immediate candidates for antiviral medications because of relative contraindications, most commonly substance use and psychological disorders [24]. Because liver biopsy can have side effects, result in complications, and consume healthcare resources, the benefits of a biopsy may or may not outweigh the "costs" when being considered by healthcare providers and their patients. In addition, motivated candidates for antiviral therapy may decide to start therapy regardless of the additional prognostic information they might get from biopsy, and thus might forgo it.

In our large national sample, liver biopsy use increased between 1997 and 2004 but began to decline in 2005 and 2006, despite the growing cumulative number of VA patients who have been confirmed with chronic HCV. Although the cumulative number of unbiopsied patients was increasing during the studied time period, these patients may have decided in conjunction with their providers to not get biopsied, so a majority of the most appropriate candidates for biopsy may have already received one. As laboratory and other non-invasive assessments of liver fibrosis become more accurate [25] and are recommended liver disease guidelines [26], some reduction in the need for liver biopsy may be expected [27].

Other possible factors that may influence the consistency of liver biopsy use in the VA Healthcare system include: (a) the emergence of less invasive techniques for assessing liver damage (b) the belief that all HCV patients should be treated; and (c) the ongoing development of new antiviral medications with fewer side effects and high SVR rates.

An interesting finding among analyses exploring predictors of biopsy was that Hispanics, African-Americans, and patients of Other/Unknown race/ethnicity were less likely to receive a biopsy than non-Hispanic Whites. It is important to note that the rates of biopsy in African-Americans were only slightly lower than those of non-Hispanic Whites, but were statistically significant because of the very large sample size. Future research is needed to explore whether these differences might be explained by cultural preferences, access to care, or provider behavior in connection with rates of antiviral treatment. Understanding the cultural preferences and access to care among these groups may improve the quality of care they receive.

Results also indicate that there is considerable variability between geographic regions in the proportion of HCV patients receiving biopsies. This is not surprising as variation in the rates of medical procedures and services has been well documented [28,29]. The variability patterns for biopsy in the VA systems are similar to the variability patterns in rates of antiviral treatment in the VA system [24,30], suggesting that higher rates of biopsy are associated with higher rates of treatment. Hepatologist and gastroenterologist specialist times were not associated with more liver biopsies once the overall volume of health care received entered the model as a significant co-variate. Notably, regional variability remained significant after controlling for clinical characteristics, patient demographics, or specialist time. Specialist time or overall volume of care has frequently affected procedure variability in other conditions, but does not always fully explain geographic differences [31–34]. Other explanations for regional variability in liver biopsies are not clear, but some evidence suggests that region U had the highest rates of biopsy and antiviral treatment because of a particular HCV care model developed at the main VA Medical Center in that region [35,36]. Other possible reasons for geographic variability in biopsy rates are differences in available resources, varying definitions of antiviral treatment candidacy, and varying beliefs about the utility of biopsy associated with proximity to large academic medical centers.

Our study confirms and strengthens the data above in demonstrating geographic differences in performance of a common and expensive diagnostic practice in a single uniform medical care system. Because it is within a single-payer and single administrative system, variables such as differences in market forces, financial incentives, and Medicare reimbursement policy

differences do not apply. In addition, because patient socio-demographic and health-related diagnoses were taken directly from the national computerized medical record, it is unlikely that important patient characteristics and diagnoses were missed or not taken into account. The present data strongly support the conclusion that geographic factors are associated with variation in biopsy use, independent of patient-related and administrative factors.

Although our results show that liver biopsy has been used inconsistently in the recent past, and many genotype 1 HCV-infected individuals have never received a biopsy, it is hard to determine the optimal rate of biopsy and the impact of these results on the quality of care provided. Liver biopsy correlates fairly well with antiviral treatment rates and is recommended by the VA and other organizations as an important step in antiviral treatment decision-making for genotype 1 patients [10,11,26]. A recent study on the quality of care in the VA system calls for higher treatment rates and efforts to improve SVR [37]. Thus, if the recommendations noted above are followed, liver biopsy use should increase as treatment rates increase. Although it remains possible that the higher SVR rates of the new antiviral therapies may lead to less reliance on liver biopsy as it does with genotype 2–3 patients, biopsy will likely retain an important role because of the need to prioritize patients for treatment, given available resources. Therefore, it seems important for VA and non-VA clinicians and researchers to study this use and provide more detailed guidance on the use of liver biopsy with HCV patients in the near future. The procedure will likely retain its value in some circumstances, but its utility must be weighed against its cost and potential for infrequent but significant side effects. Patient preferences and behaviors should also be considered when gauging optimal rates of liver biopsy.

A limitation of the data is that it relies upon the accuracy of the VA Hepatitis C Registry. Some lab tests may be mislabeled, and mistakes likely occur in the human data entry process. It is impossible to know the exact level of accuracy, but in general, after recoding obvious transpositional errors, we excluded data on only a couple thousand cases, constituting 1–2% of cases for overall analyses.

Our results include all available data from the VA Hepatitis C Registry. Although some data show that treatment rates and characteristics of patients with HCV do not differ much between

Research Article

the VA and community clinics [24], conclusions from our results should only be applied to the VA system and may not generalize to non-VA settings.

In conclusion, we found that many VA patients with HCV have not been biopsied and the number of liver biopsies being conducted within the VA system nationally has been declining despite a large pool of untreated patients with HCV. We also found that there is considerable variability in the rate at which liver biopsy is used among the 21 regions in the VA system and to a lesser extent by other factors seemingly unrelated to clinical need. Future research and policy should focus on developing more detailed guidance on the use of liver biopsy among HCV-infected patients, as non-invasive techniques develop and in light of the recent arrival of more efficacious antiviral treatments.

Effects of Alcohol Retail Privatization on Excessive Alcohol Consumption and Related Harms

A Community Guide Systematic Review

Robert A. Hahn, PhD, MPH, Jennifer Cook Middleton, PhD, Randy Elder, PhD, Robert Brewer, MD, MSPH, Jonathan Fielding, MD, MPH, MBA, Timothy S. Naimi, MD, MPH, Traci L. Toomey, PhD, Sajal Chattopadhyay, PhD, Briana Lawrence, MPH, Carla Alexia Campbell, MHSc, and the Community Preventive Services Task Force

Context: Excessive alcohol consumption is the third-leading cause of preventable death in the U.S. This systematic review is one in a series exploring effectiveness of interventions to reduce alcohol-related harms.

Evidence acquisition: The focus of this review was on studies evaluating the effects of the privatization of alcohol retail sales on excessive alcohol consumption and related harms. Using *Community Guide* methods for conducting systematic reviews, a systematic search was conducted in multiple databases up to December 2010. Reference lists of acquired articles and review papers were also scanned for additional studies.

Evidence synthesis: A total of 17 studies assessed the impact of privatizing retail alcohol sales on the per capita alcohol consumption, a well-established proxy for excessive alcohol consumption; 9 of these studies also examined the effects of privatization on the per capita consumption of alcoholic beverages that were not privatized. One cohort study in Finland assessed the impact of privatizing the sales of medium-strength beer (MSB) on self-reported alcohol consumption. One study in Sweden assessed the impact of re-monopolizing the sale of MSB on alcohol-related harms. Across the 17 studies, there was a 44.4% median increase in the per capita sales of privatized beverages in locations that privatized retail alcohol sales (interquartile interval: 4.5% to 122.5%). During the same time period, sales of nonprivatized alcoholic beverages decreased by a median of 2.2% (interquartile interval: −6.6% to −0.1%). Privatizing the sale of MSB in Finland was associated with a mean increase in alcohol consumption of 1.7 liters of pure alcohol per person per year. Re-monopolization of the sale of MSB in Sweden was associated with a general reduction in alcohol-related harms.

Conclusions: According to *Community Guide* rules of evidence, there is strong evidence that privatization of retail alcohol sales leads to increases in excessive alcohol consumption.

Context

Excessive alcohol consumption, including both binge drinking and underage drinking, is responsible for approximately 79,000 deaths per year in the U.S., making it the third-leading cause of preventable death in the nation.[1] In 2009, approximately 23% of adult drinkers (aged ≥18 years) in the U.S. reported binge drinking (consuming five or more drinks per occasion for men and four or more drinks per occasion for women) in the past 30 days, as did 25.2% of high school students.[2,3] Among full-time college students in 2008, 48.6% of men and 34.4% of women reported binge drinking.[4] In 2006,

doi: 10.1016/j.amepre.2012.01.002

the estimated economic cost of excessive drinking in the U.S. was $223.5 billion.[5] The reduction of excessive alcohol consumption is thus a matter of major public health and economic interest.

Following the end of Prohibition in the U.S. in 1933, some states continued prohibition at the state level. "Control" states allowed alcohol to be sold, but only through government-run retail stores; "license" states allowed retail sales by commercial interests.[6] In all states, wholesale of alcoholic beverages is under state control. Currently, no states prohibit alcohol sales, and the number of states that have retained control over retail sales has been reduced through privatization. However, in all states with government control over certain beverage types, government control is restricted to *off-premises* sales outlets (i.e., outlets where alcohol is sold for consumption elsewhere); government control does not affect the *on-premises* sale of alcohol in any state.

In the U.S. and Canada, privatization most often affects wine and spirits (e.g., vodka and whiskey). In the U.S., all states and counties that permit the sale of alcohol allow privatized retail sales of beer, and most allow privatized retail sale of all alcoholic beverages. In contrast, in the Scandinavian countries where most other studies of privatization have been conducted, privatization and re-monopolization generally affect beer sales. The National Alcohol Beverage Control Association (NABCA; www.nabca.org) classifies state retail alcohol sales control policies as shown in Table 1.

The predominant trend in the U.S. and elsewhere is toward relaxing government control over the sale of alcoholic beverages, including by privatizing alcohol sales. The formation of the European Union has also led to a loosening of national control and increased privatization in some member nations.[7,8] However, because privatization could plausibly lead to increases in excessive alcohol consumption and related harms, a public health intervention of possible interest to some jurisdictions and decision makers may be the reversal of privatization (*re-monopolization*) or the maintenance of government control where it exists currently.

This review addresses three research questions related to the effect of privatizing retail sales of alcoholic beverages. (1) Does retail privatization of a specific type of alcoholic beverage increase its excessive consumption and associated harms (e.g., alcohol-impaired driving, assaults, and cirrhosis of the liver)? (2) Does privatization of sales of one type of alcoholic beverage also reduce excessive consumption of alcoholic beverages for which sales are not privatized (e.g., does the retail privatization of wine sales lead consumers to reduce their consumption of liquor, if liquor sales are still subject to government control)? (3) Does the re-establishment of state control over the retail sales of an alcoholic beverage (re-monopolization) reduce the excessive consumption of that beverage and the harms related to excessive consumption?

Findings, Recommendations, and Directives from Other Reviews and Advisory Groups

The 2010 WHO-sponsored review *Alcohol: No Ordinary Commodity*,[8] a consensus narrative review of a broad array of alcohol interventions, assessed government control of the retail sale of alcohol, and rated it 3+ (the highest rating) for effectiveness in reducing excessive alcohol consumption and related harms and for the extent of research supporting the finding and 2+ on cross-cultural testing, suggesting generalizability across settings. The cost of implementing government control was rated as low. The reviewers concluded that "the evidence is quite strong that off-premise government control systems limit alcohol consumption and alcohol-related problems,

and that elimination of government off-premise monopolies can increase total alcohol consumption."[8] The present analysis adds more recent evidence on effects of privatization and applies a more formal protocol to the evaluation and synthesis of available scientific evidence on this topic. The intervention reviewed here may be helpful in addressing several national health objectives related to substance abuse prevention, as specified in *Healthy People 2020*.[9]

Evidence Acquisition

The *Guide to Community Preventive Services* (*Community Guide*) systematic review process was used to assess whether privatization leads to increases in excessive alcohol consumption and related harms. More details on the *Community Guide* review process are presented elsewhere.[10,11] In brief, this process involves forming a systematic review development team; developing a conceptual approach to organizing, grouping, and selecting interventions; prioritizing these interventions; searching for and retrieving the existing research evidence on the effects of the interventions; assessing the quality of each study; abstracting information from each study that meets qualifying criteria; drawing conclusions about the body of evidence on intervention effectiveness; and translating the evidence on effectiveness into recommendations. To help ensure objectivity, the systematic review development team consists of systematic review methodologists and subject matter experts from a range of agencies, organizations, and academic institutions. The review team works under the oversight of the nonfederal, independent Community Preventive Services Task Force (Task Force), which directs the work of the *Community Guide*.

The systematic review development team collects and summarizes evidence on (1) the effectiveness of interventions in altering the health-related outcomes of interest; and (2) benefits and harms of the intervention on other health and nonhealth outcomes. When an intervention is shown to be effective, information is also included about (3) the applicability (or generalizability) of the evidence to diverse population segments and settings; (4) the economic impact of the intervention; and (5) barriers to implementation. The systematic review development team then presents the results of this review process to the Task Force, which considers all of the evidence presented and determines whether it is sufficient to warrant a recommendation for practice or policy.[10] The rules of evidence under which the Task Force makes its determination require consideration of several aspects of the body of evidence, including the number of studies of different levels of design suitability and execution, as well as judgments regarding the consistency of the findings, the public health importance of the overall effect size, and the balance of the outcome of interest with other consequences of the intervention.

Conceptual Approach and Analytic Framework

Six intermediate consequences of privatization are hypothesized to affect alcohol consumption (Figure 1). First, privatization generally leads to increases in the density of off-premises alcohol outlets.[12] Second, privatization may increase the availability of alcohol by increasing the days and hours during which it is sold.[13,14] Third, privatization may increase the availability of specific types and brands of alcoholic beverages.

Fourth, privatization may affect the retail price of alcohol because of various factors that may either increase or decrease prices; overall, prices tend to increase with privatization.[13,14] However, the wider range of alcohol products typically available in privatized systems may result in more low-priced products that would appeal to high-volume or high-risk drinkers, even if the average price for all alcohol products were similar in state-owned and privatized systems. Fifth, because it introduces competition among alcohol outlets, privatization may lead to increased alcohol advertising in various venues, including TV, radio, billboards, and at the point of purchase.[13] Sixth, because of increased numbers of outlets and less direct governmental control, privatization may lead to decreased enforcement of and compliance with sales regulations (e.g., minimum-drinking-age laws).[15]

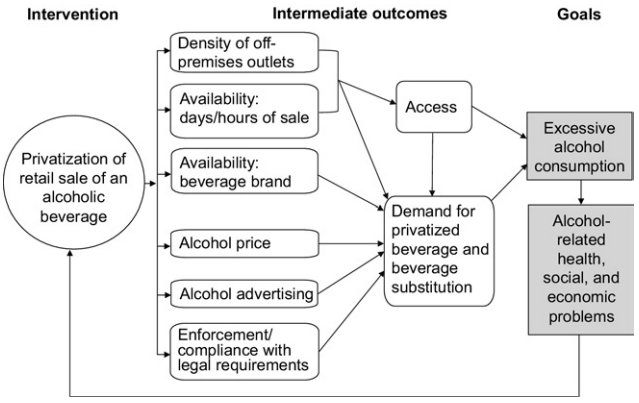

Figure 1. Analytic framework

Note: Privatization of retail sales of alcoholic beverages: Oval indicates intervention; rectangles with rounded corners indicate mediators or intermediate outcomes; rectangles indicate health outcomes.

Many of these consequences of privatization may increase the demand for the privatized beverage, substitution to or from other beverages, and access to alcoholic beverages. In turn, these consequences may affect excessive consumption and related harms. In contrast, re-monopolization is expected to have effects opposite to those of privatization.

Inclusion and Exclusion Criteria

To qualify as a source of primary evidence for this review, a study had to meet several criteria. It had to evaluate retail privatization or renewed government control; be conducted in a country with a high-income economy[16]; be primary research (rather than a review of other research); be published in English; and have a comparison group and/or compare conditions before and after privatization. Optimally, alcohol consumption in locations that experienced changes in government control (e.g., privatization) would be compared with alcohol consumption in similar locations that did not experience this change.

A study also had to report outcomes related to excessive alcohol consumption or related harms. Some specific harms of interest included alcohol-related medical conditions (e.g., liver cirrhosis), alcohol-impaired driving and alcohol-related crashes, unintentional injuries, intentional injuries, and crime. Government reports were included, but unpublished papers were not, as they may be difficult for others to access and are not peer-reviewed.

When studies assessed multiple outcomes of interest, those with the strongest known association with excessive alcohol consumption were given more weight. Outcome measures in the studies that had the strongest association with excessive alcohol consumption included binge drinking, heavy drinking, liver cirrho-

sis mortality, alcohol-related hospital admissions, and alcohol-related motor vehicle crashes (or strong proxies for such crashes, e.g., single-vehicle nighttime crashes for alcohol-related motor vehicle crashes).[17] Less-direct measures included per capita ethanol consumption, a well-recognized proxy for estimating the number of excessive drinkers in a population[8,18,19]; unintentional injuries; suicide; and crime (e.g., homicide and aggravated assault).

Cross-sectional and panel studies in which the sequence of events was not taken into account (e.g., counting year as an ordinal variable) were considered secondary evidence in this review. Secondary evidence was regarded as useful for generating hypotheses and for strengthening or weakening conclusions based on primary evidence, but was insufficient alone for assessing intervention effectiveness. Many of the studies qualifying for this review used per capita alcohol sales as a proxy for excessive drinking. In assessing the quality of study execution, a penalty (described below) was assigned to studies that assessed changes in population-level consumption rather than changes in excessive drinking by individuals. This was a conservative approach because excessive drinking and per capita alcohol consumption are strongly related both theoretically and empirically.[18–20]

This empirical relationship is conceptualized in the "single distribution theory," which asserts that excessive drinkers, including binge and heavy drinkers, account for a consistent proportion of the drinking population in a given setting,[19] such that the prevalence of excessive alcohol consumption is directly related to per capita alcohol sales. Further, the theory proposes that the relationship between per capita sales and "heavy" or excessive drinking is quadratic, meaning that, "If population A has twice the average consumption of population B, then A has about four times (i.e., 2^2) the prevalence of heavy drinking." Cook and Skog[19] report evidence from multiple countries supporting this proposition. Thus, changes in per capita alcohol consumption would be expected to have a greater effect on excessive alcohol consumption, including binge drinking, than on non-excessive alcohol consumption. This evidence supports the Task Force's use of per capita alcohol consumption based on sales as an outcome measure for assessing the impact of privatization on excessive alcohol consumption.

Search for Evidence

The following databases were searched for this review: Econlit, PsycINFO, Sociology Abstracts, MEDLINE, Embase, and EtOH. All years were searched up to October 2007. (Details of the search strategy are available at www.thecommunityguide.org/alcohol/supportingmaterials/SSalcoholuse.html.) This search was updated in the ISI Web of Knowledge through December 2010 by the Alcohol Epidemiology Program at the University of Minnesota. Reference lists of articles reviewed as well as lists in review articles were searched, and subject matter experts were consulted.

Assessing the Quality and Summarizing the Body of Evidence on Effectiveness

Each study that met the criteria for candidate studies was read by two reviewers, who used standardized criteria (available at www.thecommunityguide.org/about/methods.html) to assess suitability of study design and threats to validity. Uncertainties and disagreements between reviewers were reconciled by consensus among the team members. The team's classification of the designs of studies reviewed corresponds with the research questions of the review and the standards of the *Community Guide* review process[11] and may differ from the classification reported in the original studies.

The quality of studies that were candidates as primary evidence for this review was evaluated both in terms of design and execution. Studies with greatest design suitability were those in which data on exposed and comparison populations were collected prospectively; studies with moderate design suitability were those in which data on exposed and comparison populations were collected retrospectively or in which there were multiple pre- or post-intervention measurements, but no concurrent comparison population; and studies with least-suitable designs were cross-sectional studies or those in which there was no comparison population or only a single pre- and post-measurement in the intervention population. On the basis of the number of threats to validity—such as poor measurement of exposure or outcome, lack of control of potential confounders, or high attrition—studies were characterized as having good (at most one threat to validity), fair (two to four threats), or limited (five or more threats) quality of execution. Studies with good or fair quality of execution and any level of design suitability (greatest, moderate, or least) qualified for the body of evidence.

Effect estimates were calculated as relative percentage change using the following formulas:

- For studies with before–after measurements and concurrent comparison groups:

$$\text{Effect estimate} = \left[\left(I_{post}/C_{post}\right)/\left(I_{pre}/C_{pre}\right) - 1\right] \times 100\,\%$$

where:

I_{post} = last reported outcome rate or count in the intervention group after the intervention;
I_{pre} = last reported outcome rate in the intervention group before the intervention;
C_{post} = last reported outcome rate in the comparison group after the intervention;
C_{pre} = last reported outcome rate in the comparison group before the intervention.

- For studies with before–after measurements but no concurrent comparison:

$$\text{Effect estimate} = \left[\left(I_{post} - I_{pre}\right)/I_{pre}\right] \times 100\,\%.$$

Several events of privatization (e.g., the privatization of wine in Iowa in 1985) were assessed by more than one team of researchers, thus resulting in multiple studies of the same event. Effect estimates are reported for each research group, noting which were associated with a single event. Median effect sizes are calculated using the means of privatization events with differing findings from different researchers.

Evidence Synthesis

Intervention Effectiveness

The effects of 12 distinct privatization events were assessed in 17 studies and reported in 13 publications.[14,21–32] In addition, there was one study of re-monopolization, described separately below.[33] The privatization events assessed were in seven U.S. states (Alabama, Idaho, Iowa [two events], Maine, Montana,

New Hampshire, West Virginia); two Canadian provinces (Quebec [two events] and Alberta); and Finland. Several publications described a single privatization event, and several publications each assessed more than one privatization event.

All studies used alcohol sales data as an index of population-level alcohol consumption except one[25] that assessed changes in individual-level consumption (in Finland). Fitzgerald and Mulford[14,22] also assessed changes in self-reported consumption in addition to sales data (in Iowa). However, as they note, their measures of alcohol consumption were problematic (e.g., separate cross-sectional studies collected under different sampling procedures with different interview procedures), and thus only the assessments of changes in alcohol sales from their study are included in this review.

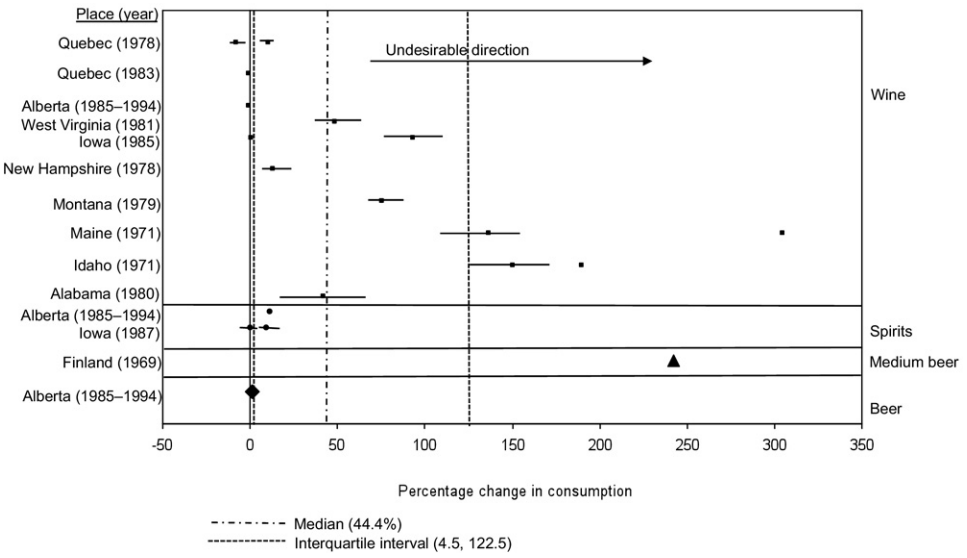

Figure 2. Percentage change by location of privatization event in consumption of privatized alcoholic beverages attributable to privatization

Note: Bars on the point estimate represent 95% CIs when reported or calculated.

In the U.S., privatized beverages were limited to wine and spirits, as beer was already privatized. In Canada, sale of beer was privatized in addition to sales of wine and spirits, and in Scandinavia, privatization (and re-monopolization) focused on beer sales. The privatization events assessed in these studies occurred between 1950 and 2000. Three studies used autoregressive integrated moving average (ARIMA) time series.[27–29] Fourteen studies (presented in eight publications)[14,23,26–30,32] were of greatest design suitability; three studies (presented in two publications)[24,25] were of moderate design suitability. All studies were of fair quality of execution.

The qualifying studies provided information on several of the intermediate consequences of privatization discussed above (Figure 1). These consequences include increased numbers of alcoholic beverage outlets, increased hours and days of sale, advertising, greater brand selection, and acceptance of alternate forms of payment (e.g., credit card).[13,14,23,26–30,32,34] All of these intermediate outcomes would be expected to result in increased consumption.

Most studies reviewed reported generally higher prices for alcoholic beverages in the privatized than in the state control setting. The higher prices may be the consequence of relative inefficiencies of scale (e.g., multiple smaller outlets and increased overhead expenses).[35] In contrast to other intermediate outcomes, higher prices would be expected to result in decreased consumption. However, Fitzgerald and Mulford[21] assessed whether the increase in the price of spirits following privatization of retail sales in Iowa had affected consumers' purchasing behavior, and found that only 37.4% of those surveyed who purchased liquor in the past month recognized that prices had increased, and <2% of Iowa consumers reported increasing their purchase of liquor from adjacent states.

Effects of privatization on consumption of privatized beverages. Overall, the median increase in per capita sales of privatized beverages was 44.4%, with an interquartile interval of 4.5% to 122.5% (Figure 2). Some differences, however, were observed across studies in the impact of privatization on retail sales of privatized beverages and in the relationship between privatization and other public health outcomes, described below.

Studies assessing the effects of the privatization of wine (1985) and spirits (1987) sales in Iowa had inconsistent findings. Wagenaar and Holder[31] reported that wine consumption increased 93.0% (95% CI=69.3%, 120.2%) from baseline to 44 months after privatization of wine sales in Iowa, with no decrease in spirits or beer consumption. Following the subsequent privatization of spirits sales in Iowa 2 years later, these researchers[23] reported a 9.5% (95% CI=3.5%, 15.9%) increase in spirits consumption, along with a 12.1% (95% CI= −20.6%, −2.7%) decrease in wine consumption and no change in

beer consumption. They[23,31] also found no evidence that privatization affected alcohol purchasing across state lines (effect estimate 0.1%, 95% CI= −3.1%, 6.2%).

In contrast, Mulford and Fitzgerald[27] found that wine privatization was associated with a nonsignificant long-term increase of only 0.5% (95% CI= −6.8%, 8.3%) in wine sales, and that spirits privatization was associated with a nonsignificant long-term increase of 0.7% (95% CI= −1.9%, 3.4%) in spirits sales. For both beverages, the nonsignificant long-term effects were preceded by 3-year spikes in sales. The differences between the conclusions of these two research teams about the effects of the privatization of wine and spirits in Iowa may be the consequence of different modeling strategies, different time periods covered, and different forms of alcoholic beverages included—particularly the inclusion of "wine coolers" in measures of wine sales by Wagenaar and Holder.[31,32]

Finally, Makela[25] assessed the impact on alcohol consumption of a law in Finland that allowed the sale of medium-strength beer (MSB) in grocery stores. This was the only study included in the review that assessed changes in self-reported alcohol consumption by individuals over time. Survey participants were specifically asked about their levels of consumption before implementation of the new law and then again in the year following its implementation. The researchers stratified their findings based on drinking patterns of respondents before and after privatization. Consumption of all alcoholic beverages (not just the privatized beverage) increased by a mean of 1.7 L of pure alcohol per year per person interviewed (approximately 137 ounces of 80° proof liquor). Makela reports that 86% of the increase in overall alcohol consumption was attributable to increases in the privatized beverage (MSB). The greatest increase in alcohol consumption after privatization was observed among those who reported drinking between 17 and 68 ounces of pure alcohol per year at first interview. However, there was also an increase in consumption in the population that reported no alcohol consumption within the past 30 days when first interviewed.

Effects of privatization on alcohol-related harms. Two studies assessed the association between retail privatization and motor vehicle crashes. One study estimated that incremental privatization over a 20-year period was associated with a nonsignificant 11.3% (95% CI= −33.9%, 19.0%) decrease in traffic fatalities in Alberta, Canada.[29] This study estimated the degree of privatization over a long period preceding final privatization in 1994, had only 1 year of follow-up, and used a proxy outcome measure.

A second study assessed changes in alcohol-related harms associated with the Iowa privatization of wine in 1985 and spirits in 1987.[14,26] The researchers compared the period before 1985 with the period after 1989, when both wine and spirits sales were privatized. Despite increased per capita sales of both wine and spirits, there was a reported 1.6% decline in nighttime motor vehicle crashes and a 5.5% decline in liver cirrhosis. However, initial mortality data were for 1985—the same year in which the privatization of wine occurred; thus these data included deaths both prior to and following privatization, weakening the analysis. Moreover, no comparison data were provided to adjust for national or regional trends in these outcomes over the time period evaluated.

Effects of privatization on the consumption of *nonprivatized* alcoholic beverages. Many of the studies[14,25,26,31,32,36] reviewed also assessed the effect of privatizing the sale of one type of alcoholic beverage on the sale of other nonprivatized beverages. In the seven settings assessed, the sales of nonprivatized alcoholic beverages decreased a median of 2.2%, with an interquartile interval ranging from a decrease of 6.6% in sales to a decrease of 0.1% (Figure 3). These decreases are not of sufficient magnitude to offset the overall increase in per capita sales of privatized beverages.

Effects of re-monopolization on alcohol-related outcomes. One study in Sweden[33] directly assessed effects of a 1977 re-monopolization of the sale of MSB (2.26%–3.50% alcohol by volume; beer in the U.S. is generally 4%–6% alcohol by volume). The study was of moderate design suitability and fair execution. Re-monopolization resulted in a substantial decline in the number of outlets for MSB, from 11,550 to 300. The effects of this policy change on hospitalization for several alcohol-related outcomes (alcoholism, alcohol intoxication, alcoholic psychosis, hospitalizations for acute alcohol intoxication, suicides, falls, motor vehicle crashes, and assaults) were assessed using time-series design, comparing the 4 years before and after re-monopolization. The results were stratified by four age categories (10–19 years, 20–39 years, 40–59 years, and ≥60 years), and the study did not provide data to allow aggregation across age groups.

The researchers identified a number of positive changes in health outcomes following re-monopolization. Hospital admissions for the treatment of alcoholism, alcohol intoxication, and alcohol psychosis decreased across all age groups ($p>0.05$), and there was a 20% decline ($p<0.05$) in these outcomes among people aged 10–19 years. Hospitalizations for acute alcohol intoxication decreased across all ages from 3.5% to 14.7% ($p>0.05$). Suicides decreased from 1.7% to 11.8% ($p>0.05$). Falls decreased from 3.6% to 4.9% ($p>0.05$). Motor vehicle crashes decreased 14% ($p<0.05$) for three age categories (10–19 years, 40–59 years, and ≥60 years) and by 4.4% for those aged 20–39 years ($p>0.05$). In contrast, assaults *increased* from 6.9% to 14.8% ($p>0.05$)

in three of four age categories, and decreased by 1.4% among those aged 20–39 years ($p>0.05$). In summary, the re-monopolization of MSB in Sweden was associated with reductions in most of the alcohol-related harms assessed across all age groups; however, many of these effects were not significant.

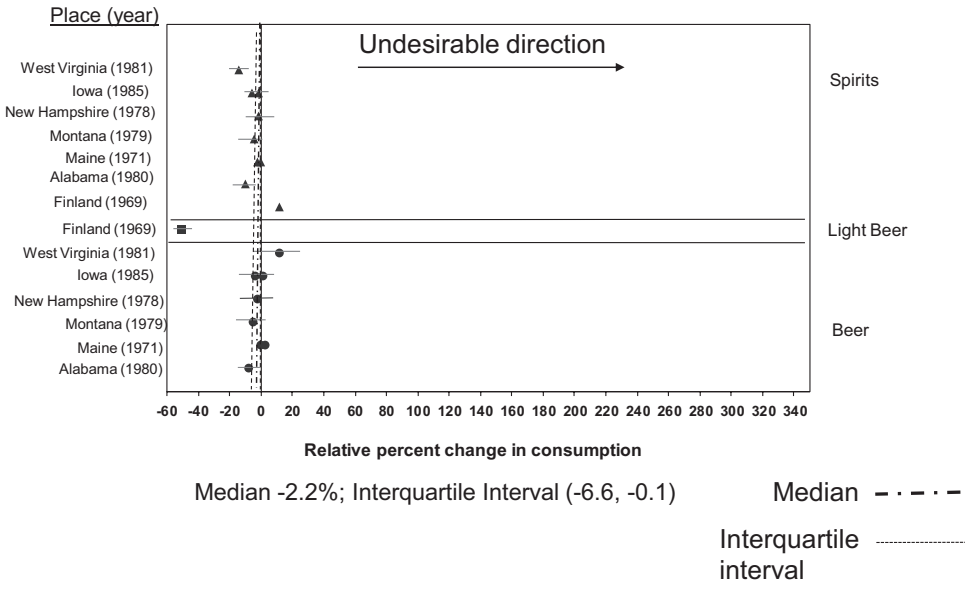

Figure 3. Percentage change in consumption of nonprivatized alcoholic beverages attributable to privatization of other alcoholic beverages

Note: Bars on the point estimate represent 95% CIs when reported or calculated.

Cross-sectional studies, panel studies, and summarized studies in translation. The team found 20 cross-sectional and panel studies[29,35,37–54] assessing the association of privatization with alcohol consumption and related harms; five studies[35,38,43,47,48] had multiple outcomes. (Panel studies were included in this section if they did not include time as an ordinal covariate or compare alcohol-related outcomes before and after events of privatization.) Seventeen studies[29,35,37,38,40,42–48,50–54] found that privatization was associated with greater consumption (nine were significant,[37,40,42–44,46,48,52,53] seven were not,[29,35,38,45,47,50,54] and one[51] did not report significance). Four studies found decreased consumption (three were significant,[40,43,44] one not[38]). Three studies[37,41,50] assessed the association of privatization with cirrhosis mortality; all were positive and two[37,41] were significant. Finally, two studies assessed the association of privatization with motor vehicle fatalities,[39,46] and both found a positive, but nonsignificant association; one study found a negative, significant association of privatization and drunk driving. Overall, this evidence is consistent with evidence from primary studies indicating positive associations between privatization and increased population-level consumption and between privatization and alcohol-related harms.

Makela, Rossow, and Tryggvesson[36] published (in English) a review of studies conducted in Finland, Sweden, and Norway that were not published in English translation and thus were not included in this review. These studies examined the effect of either privatizing or re-monopolization of the sales of medium or strong beer between the mid-1960s and the early 1990s on various kinds of alcohol-related harms (e.g., arrests for drunkenness and alcohol-related illnesses).

The researchers found that when beer sales were privatized, there were increases in alcohol consumption and alcohol-related harms such as arrests for drunkenness and alcohol-related illnesses. They also found that re-monopolization generally resulted in decreased population-level consumption of the affected alcoholic beverage, decreases in excessive alcohol consumption, and decreases in alcohol-related harms. In addition, they found that when a particular strength of beer became more or less accessible, consumers tended to purchase the beverage type that was more readily accessible. This beverage substitution effect appeared to be stronger among different strengths of beer than among different types of alcoholic beverages.

Summary of Intervention Effectiveness

Across the studies qualifying for this review, the privatization of off-premises retail sales of an alcoholic beverage was associated with a median 44.4% increase (interquartile interval 4.5%, 122.5%) in the per capita sales of the beverage and with a 2.2% decline (interquartile interval −6.6%, −0.1%) in the per capita sales of beverages for which sales were not privatized. One study (in Finland)[25] found that the increases in consumption occurred among drinkers at all consumption levels. A single study[33] evaluating the effects of re-monopolization of alcohol sales found that this change was associated with a subsequent decrease in several alcohol-related harms (e.g., hospitalizations for acute alcohol intoxication).

Other Harms and Benefits

Government control over retail alcohol sales generally results in lower alcohol outlet density. In addition to potential public health benefits, lower outlet density may improve quality of life by reducing property damage and public disturbance (e.g., public intoxication). However, the studies reviewed did not assess these effects. The review team did not postulate any serious harms associated with the maintenance of government control over retail alcohol sales.

Applicability

Consistent evidence of the association between privatization and increased per capita alcohol sales comes from studies done in multiple settings in the U.S., Canada, and Europe. Most of these studies evaluated the effects of privatizing the sales of wine and spirits. Only one Swedish study[33] specifically assessed the impact of re-monopolization (of MSB). The findings from the current review apply most directly to the impact of privatizing the sale of wine and spirits in high-income nations such as the U.S.

Economic Efficiency

The present systematic economic review identified one study[55] in Canada that used simulation modeling to estimate healthcare and law enforcement costs and costs of lost productivity due to disability and premature mortality in the event all Canadian provinces and territories were to privatize alcohol sales. The study was judged to be satisfactory by *Community Guide* economics criteria (www.thecommunityguide.org/about/EconAbstraction_v5.pdf). Study authors concluded that these costs were substantially greater than the tax and mark-up revenue gained from increased sales associated with privatization; however, benefit data were not documented.

Research Gaps

Although the studies reviewed have demonstrated an association between privatization and increases in the per capita consumption of the privatized beverages without substantial reductions in consumption of other alcoholic beverages, additional research is needed to clarify the relationship between privatization and various patterns of excessive alcohol consumption (e.g., binge drinking) as well as harms related to it. Most useful would be cohort studies in the U.S. similar to the one conducted by Makela et al.[25] in Finland, assessing the effects of privatization on patterns of excessive alcohol consumption (e.g., binge drinking) and alcohol-related harms. It would also be useful to evaluate the impact of increased government control over alcohol sales (e.g., re-monopolization) on excessive alcohol consumption and related harms, were such events to occur in the U.S. or other high-income nations.

Privatization has assumed different forms in different states and localities. Thus, it would be useful to determine how the effects of privatization observed in this review vary by the degree of government regulation and other specific parameters of the privatization. Although, in general, government control establishes a greater degree of regulation over retail alcohol sales than systems in which sales have been privatized, Her et al.[13] have noted that "privatization might involve a change from a very restrictive alcohol management system to a loosely regulated private one; it would also potentially involve a change from a commercially orientated public system to a private sector operation that is heavily regulated."

No peer-reviewed studies were found that evaluated economic effects of privatizing the sale of alcoholic beverages in the U.S. The anticipated effects of privatization include a large, but short-term, source of revenue to states; a potential increase in healthcare and criminal justice costs; and productivity losses from expected increases in excessive alcohol consumption owing to greater availability and/or lower prices. Studies assessing these economic impacts would be useful for informing future discussions of this issue. It would be useful to assess the effects of different specific approaches to privatization on state revenues associated with sales and taxes on alcoholic beverages.

Conclusion

The evidence consistently showed that privatization of retail alcohol sales was associated with a substantial increase in per capita sales of the privatized beverages, a well-established proxy for excessive alcohol consumption. There was also evidence that re-monopolization is associated with a decrease in alcohol-related harms. Therefore, according to *Community Guide* rules of evidence, there was strong evidence that retail privatization of alcohol sales leads to increases in excessive alcohol consumption.

In the U.S., many states have privatized the retail sales of alcoholic beverages. Currently, three states control the off-premises consumption retail sales of both wine and spirits, and an additional ten states maintain control over the retail sale of spirits alone. In addition, one county in the state of Maryland has county-level control over the retail sale of spirits and wine. The findings of the present report are based solely on evidence related to the public health consequences of privatization, which may be one of several factors considered in making decisions on whether to privatize retail alcohol sales. The maintenance of government control of off-premises sale of alcoholic

beverages is one of many effective strategies to prevent or reduce excessive consumption, which is one of the leading causes of preventable death and disability.

We would like to thank Steve Wing (SAMHSA) and Ralph Hingson, ScD, MPH, National Institute of Alcohol Abuse and Alcoholism, for participation in this review. We also thank our team of consultants for their comments: Edward Bernstein, MD, Boston University School of Public Health; Richard J. Bonnie, LLB, University of Virginia; Raul Caetano, MD, MPH, PhD, University of Texas at Dallas; Frank Chaloupka, PhD, University of Illinois at Chicago; Norm Giesbrecht, PhD, Centre for Addiction and Mental Health, Canada; Thomas Greenfield, PhD, National Alcohol Research Center/Alcohol Research Group, California; Joel Grube, PhD, and Harold Holder, PhD, Pacific Institute for Research and Evaluation (PIRE), California; Mel Kohn, MD, Oregon Department of Human Services; Jurgen Rehm, PhD, Centre for Addiction and Mental Health, Canada; Robin Room, PhD, Stockholm University; Henry Saffer, PhD, National Bureau of Economic Research; Leslie Snyder, PhD, University of Connecticut; Tim Stockwell, PhD, University of Victoria; Alex Wagenaar, PhD, University of Florida College of Medicine.

Massachusetts Reform and Disparities in Inpatient Care Utilization

Amresh D. Hanchate, PhD,† Karen E. Lasser, MD, MPH,†‡ Alok Kapoor, MD, MSc,† Jennifer Rosen, MD,§ Danny McCormick, MD, MPH,‖ Meredith M. D'Amore, MPH,† and Nancy R. Kressin, PhD*†*

Background: The 2006 Massachusetts health reform substantially decreased uninsurance rates. Yet, little is known about the reform's impact on actual health care utilization among poor and minority populations, particularly for receipt of inpatient surgical procedures that are commonly initiated by outpatient physician referral.

Methods: Using discharge data on Massachusetts hospitalizations for 21 months before and after health reform implementation (7/1/2006–12/31/2007), we identified all nonobstetrical major therapeutic procedures for patients aged 40 or older and for which $\geq 70\%$ of hospitalizations were initiated by outpatient physician referral. Stratifying by race/ethnicity and patient residential zip code median (area) income, we estimated prereform and postreform procedure rates, and their changes, for those aged 40–64 (nonelderly), adjusting for secular changes unrelated to reform by comparing to corresponding procedure rate changes for those aged 70 years and above (elderly), whose coverage (Medicare) was not affected by reform.

Results: Overall increases in procedure rates (among 17 procedures identified) between prereform and postreform periods were higher for nonelderly low area income (8%, $P = 0.04$) and medium area income (8%, $P < 0.001$) cohorts than for the high area income cohort (4%); and for Hispanics and blacks (23% and 21%, respectively; $P < 0.001$) than for whites (7%). Adjusting for secular changes unrelated to reform, postreform increases in procedure utilization among nonelderly were: by area income, low = 13% (95% confidence interval (CI) = [9%, 17%]), medium = 15% (95% CI [6%, 24%]), and high = 2% (95% CI [−3%, 8%]); and by race/ethnicity, Hispanics = 22% (95% CI [5%, 38%]), blacks = 5% (95% CI [−20%, 30%]), and whites = 7% (95% CI [5%, 10%]).

Conclusions: Postreform use of major inpatient procedures increased more among nonelderly lower and medium area income populations, Hispanics, and whites, suggesting potential improvements in access to outpatient care for these vulnerable subpopulations.

Key Words: health reform, disparities, utilization, inpatient care, access to care, socioeconomic status, race, ethnicity

(*Med Care* 2012;50: 569–577)

A central policy assumption in the United States is that expanding health insurance coverage will improve access to health care and outcomes, and make each more equitable for all Americans.[1] Massachusetts (MA) is the site of a key policy-relevant natural experiment[2–8]; recent legislation has resulted in nearly all (96.5%) of the state's residents obtaining health insurance.[9] However, little is known about MA reform's impact on health care utilization, particularly among poor and minority populations, whose access to care the reform sought to increase.

The number of uninsured MA residents fell sharply after the reform was implemented.[10] Among adults aged 18–64, the population targeted by the reform, uninsurance rates declined from 8.4% (2006) to 3.4% (2009) overall, but from 18%–9% among the poorest population quintile, from 15%–5% among blacks, and 20%–13% among Hispanics.[9,11,12] However, the limited evidence of the reform's impact on access to and use of health care, based largely on population surveys, provides a mixed picture. Self-reported rates of a usual source of care and of preventive care visits

improved postreform; however, lower income respondents and Hispanics with limited English proficiency reported higher rates of unmet need due to difficulty in finding a health care provider or due to unaffordable cost.[12–14] Although the evidence of the impact of health reform on emergency department use is mixed, hospitalizations for conditions preventable by appropriate outpatient care decreased.[15–18]

There have not yet been reports on the use of inpatient surgical procedures whose receipt is sensitive to outpatient physician referral. Changes in receipt of such surgical procedures after MA health reform could be a measure of access to outpatient care that may improve with expanded insurance coverage.[19] Thus, we focused on the use of such procedures among vulnerable subpopulations—those living in low-income areas and racial/ethnic minorities. These groups are known to underutilize elective inpatient care,[20–22] and were specifically targeted for larger gains in coverage expansion from the MA health reform.[23] We hypothesized that the entire reform package, including increased population rates of insurance coverage, would be associated with increased rates of receipt of surgical procedures most commonly initiated through outpatient physician referral, and that such gains would be greater among vulnerable populations.

METHODS

Overview

We estimated longitudinal population rates of receipt of referral-dependent procedures by combining comprehensive state-level inpatient administrative data with census population data. We estimated prereform and postreform rates of procedure use among nonelderly subpopulations stratified by cohorts defined by race/ethnicity and income of the area of patient residence. To isolate the impact of health reform from secular trends, we contrasted postreform change among the nonelderly with changes among the elderly. We chose this control group because most elderly residents were covered by Medicare both prereform and postreform, and therefore the change in their procedure use reflects secular changes unrelated to health reform.

Prereform and Postreform Periods

The MA health reform was multifaceted and included measures to expand insurance coverage, such as individual and employer mandates, establishment of an insurance exchange, income-related premium subsidies for newly created private insurance, and loosened eligibility criteria for Medicaid coverage.[2] Implementation of MA health reform began on 7/1/2006 with expansion of Medicaid to cover previously "enrollment capped" low-income populations, culminating in a penalty-enforced mandate of individual insurance coverage effective 1/1/2008.[24] We examined inpatient procedure use for 21 months (1/1/2008–9/30/2009) following this mandate ("postreform" period) and contrasted it with data for 21 months (10/1/2004–6/30/2006) preceding reform ("prereform" period), excluding the middle, transition period.

Data Sources and High Referral Rate (HRR) Procedures

We focused on hospitalizations for surgical procedures that are predominantly scheduled by outpatient referral, that we term "HRR procedures." While similar to the previously defined concept of "referral-sensitive procedures,"[19] we found that for some referral-sensitive procedures (eg, coronary artery bypass graft) the proportion arising from outpatient referral was no higher than 50% (See Appendix, Supplemental Digital Content, http://links.lww.com/MLR/A311). Using all hospitalizations with discharges during the prereform and postreform periods as raw data (MA Inpatient Discharge Data for 2004–2009),[25] we included MA-residing patients aged 40 or older (those with significant risk for the procedures examined) undergoing a major therapeutic surgical procedure [using Agency for Healthcare Research & Quality Procedure Classes system; Clinical Classifications Software (CCS)], as illustrated by Figure 1.[26] These procedures' International Classification of Diseases-Ninth Edition-Clinical Modification diagnosis codes were classified into the 231-category Agency for Healthcare Research & Quality CCS.[27] To minimize chance misclassification we only included procedures with aggregate volume of ≥ 500. We excluded obstetrical procedures as their usage has been universally covered in MA.

On the basis of the "source of admission" field, we defined HRR procedures as those with an outpatient physician referral rate $\geq 70\%$, reasoning that this threshold would represent a large majority of procedures. We excluded some nonspecific HRR procedures—for instance, "Other operations of the ovary"—that captured a broad range of procedures. To minimize chance fluctuations in procedure use, we grouped the HRR CCS procedures into International Classification of Diseases-Ninth Edition-Clinical Modification procedure categories[27] and excluded those with ≤ 200 surgeries for each area income or race/ethnicity cohort.

Information on patient race/ethnicity was part of the discharge data submitted by each hospital; as such identification is likely based on multiple sources including, patient self-report and administrative records. We found longitudinal consistency in the reporting patterns over years, not only for the main racial/ethnic groups (whites, blacks, and Hispanics), but also for proportion with missing race/ethnicity; the proportion of all discharges in a year with race/ethnicity missing or "other" (ie, not white, black, or Hispanic) ranged between a low of 5.32% (2004) to 6.06% (2006) of the study period years (2004–2006, 2008–2009).

Analytic Data Structure

To estimate prereform and postreform procedure use we produced 2 analytic datasets, 1 for performing comparisons by race and ethnicity and another for comparisons by area income. The first dataset was obtained by stratifying the state population into cohorts stratified by race/ethnicity, age, sex, county, and time period (ie, prereform/postreform). We stratified patients by the 3 largest race/ethnic cohorts: Hispanics, non-Hispanic whites, and non-Hispanic blacks (See Appendix, Supplemental Digital Content, http://links.lww.com/MLR/A311). Categorizing patient age (in years) into 10 five-year age groups aged 40–84 years (eg, 40–44 y), we excluded the 65–69-year age group; as the postreform study period lasts 21 months, inclusion of both 60–64- and 65–69-year age cohorts may overestimate reform effect on procedure use if those initially aged 63 or 64 then age into the 65–69-year age group and became eligible for Medicare before the end of the 21st month. Excluding this age group also eliminates the sharp increases in procedure use previously noted for new Medicare age-65 enrollees.[28,29] To adjust for geographic heterogeneity across MA in factors determining procedure use, we stratified the state into 11 county-based areas, as this is the finest substate level for which annual census population counts are available.[30] This allowed us to perform a finer grained analysis than that at the larger state level. With each county stratified into 54 cohorts (based on sex, 9 age groups and 3 racial/ethnic groups), there was a total of 594 observations each for the prereform and postreform periods ($N = 1188$).

For the second analytic dataset, we followed a similar process but replaced race/ethnicity strata by area income strata. In the absence of individual income, we followed previous work and used the median income (2000 census) for each patient's residence zip code to stratify all patients into 3 area income groups: lowest quartile (ie, all residents of zip codes in the poorest quartile, henceforth referred to as "low area income" population), second lowest quartile (medium area income), and top 2 quartiles combined (high area income).[22,31–33] As the number of area income cohorts ($N = 3$) is the same as that number of race/ethnicity cohorts, the second analytic dataset has the same number of observational units ($N = 1188$).

Procedure Rates

Our primary outcome measure was a procedure rate for each cohort of interest, derived from the ratio of (1) the number of HRR procedures for each cohort in the inpatient discharge data; and (2) the census population of this cohort, and then multiplying this ratio by 10,000 so as to obtain the procedure rate per 10,000 census population.

Analysis

We estimated prereform and postreform procedure rates for all HRR procedures combined and for each individual procedure category, for subpopulations by area income or race/ethnicity; we adjusted for compositional

TABLE 1. High Referral Rate Procedures: Volumes and Referral Rate

Procedure Category	# Procedures in Study Period	Average Referral Rate (%)	# Individual Procedures in Category	Individual Procedures (% Share of Category Volume)
Musculoskeletal	80,688	95	4	Knee arthroplasty (40%), spinal fusion (31%), hip replacement (22%), and partial excision bone (7%)
Urinary/genital	51,088	95	6	Hysterectomy (32%), oophorectomy (32%), repair of cystocele and rectocele (12%), transurethral resection of prostate (12%), genitourinary incontinence procedures (8%), and nephrectomy (2%)
Nervous	29,372	88	1	Laminectomy (100%)
Cardiovascular	20,914	80	4	Heart valve procedures (34%), endarterectomy (32%), peripheral vascular bypass (19%), and aortic resection (15%)
Digestive	19,845	73	2	Colorectal resection (98%) and gastrectomy (2%)
All procedures	201,907	90	17	

Procedures are categorized by ICD-9-CM procedure chapters. No eye, ear, and nose/throat procedures met the high referral rate criteria. Urinary, male genital, and female genital system procedures have been combined into 1 category.

Study period comprises prereform and postreform periods (10/1/2004–6/30/2006 and 1/1/2008–9/30/2009, respectively).

procedures indicates the state-wide volume performed during hospitalization stays in the prereform and postreform periods.

Average referral rate indicates the % of hospitalizations (during which procedure was performed) based on outpatient referral.

differences in sex and age by direct standardization.[34] These adjusted rates were estimated separately for nonelderly and elderly cohorts. We first measured overall change (%) in procedure use—the percentage change between prereform and postreform procedure rates. To estimate net change (%) associated with health reform, we adjusted for secular changes using the elderly as the comparison cohort ("difference-in-difference" estimation).[35,36] We used a count regression (Poisson) model with procedure count as the outcome measure and census population count as the population at risk. We specified a county-level fixed effects regression structure (with clustering-adjusted SEs) to capture nesting of cohorts within county.[35,37] Regression covariates included indicators of age, sex, race/ethnicity or area income, time period (prereform/postreform), and interaction between the elderly/nonelderly indicator and time period (to estimate the net change). Statistical significance was assessed at the level of $P < 0.05$. All estimation was performed using Stata Version 11.1.[37] We performed several sensitivity analyses to assess the robustness of findings to (a) inclusion of 65–69 age group; (b) alternative count regression (ie, negative binomial) specification; and (c) state-level aggregated unit of analysis (ie, without county-level stratification). To address potential bias from regression to the mean or differential changes in the characteristics of the study over time, we also estimated an alternative model on the basis of segmented time-series specification of postreform effects that allowed for level and trend effects. This study was approved by the Boston University Medical Campus Institutional Review Board.

Note that the comparison groups were based on age, not whether the patient held Medicare coverage, so dual eligibles were included with their respective age groups. Our estimates are based on change in procedure rate (say, among nonelderly or elderly patients) between the prereform and postreform period. It may well be that the subgroup of, say, elderly with dual eligibility may have different procedure rates than their counterparts without dual eligibility; however, to the extent that prevalence of dual eligibility remained similar in the prereform and postreform periods, it does not impact the net estimates that we have estimated.

RESULTS

We identified 17 HRR procedures, in 5 clinical categories, with an aggregate volume of 201,907 surgeries during the prereform and postreform periods (Table 1). The overall referral rate for all procedures was 90%.

Table 2 summarizes the number of people undergoing HRR procedures, the number of people in the population at risk, and each group's sociodemographic composition prereform and postreform. Whereas the nonelderly accounted for 60% of prereform surgeries, their share increased to 64% in the postreform period; however, the nonelderly share of the population at risk remained at 78%. The share of blacks and Hispanics increased both among procedure recipients (6.4%–8.2%) and the population at risk (9.0%–9.8%); share by area income cohorts did not change.

Procedure Rates and Overall Postreform Change by Area Income

Prereform use of HRR procedures was similar among nonelderly area income subgroups (Table 3). After reform, overall increases in procedure rates were higher for low area income (8%, $P = 0.04$) and medium area income (10%, $P < 0.001$) cohorts compared with that for their high area income counterparts (4%). Adjusting for secular changes, the impact of health reform for the nonelderly income cohorts (or the net change in procedure rate) was: 13% (low area income, 95% confidence intervals (CI) = [9%, 17%]), 15% (medium area income, 95% CI = [6%, 24%]), and 2% (high area income, 95% CI = [−3%, 8%]).

Procedure Rates and Overall Postreform Change by Race/Ethnicity

Prereform use of all HRR procedures was significantly lower among nonelderly Hispanics (118 procedures per 10,000 population; $P < 0.001$) and blacks (149; $P = 0.05$) compared with whites (157). After reform, overall change in procedure rates among the nonelderly was greater among Hispanics (23%, $P < 0.001$) and blacks (21%, $P < 0.001$) compared with that among whites (7%). Adjusting for secular trends, the net change in procedure rate was 22% (95%

TABLE 2. Counts of High Referral Rate Procedures and Population at Risk, by Sociodemographics

Characteristics	Total # Procedures (Prereform and Postreform Periods)	Distribution of Procedures		# Population at Risk, Person-Years (Prereform and Postreform Periods)	Distribution of Population at Risk	
		Prereform (%)	Postreform (%)		Prereform (%)	Postreform (%)
All (age 40+ y)	201,907	100	100	10,072,992	100	100

Study period comprises prereform and postreform periods (10/1/2004–6/30/2006 and 1/1/2008–9/30/2009, respectively).
Total # procedures indicates the number of high referral rate procedures performed during hospitalizations in the prereform and postreform periods.
Population at risk indicates the aggregate census population (person-years) during the prereform and postreform periods.
Area income cohorts are defined as: low = lowest quartile zip codes, medium = second quartile, and high = top 2 quartile.

CI = [5%, 38%]) for Hispanics, 5% for blacks (95% CI = [−20%, 30%]), and 7% for whites (95% CI = [5%, 10%]).

Postreform Change by Procedure Categories

Table 4 presents analogous findings for each procedure category by area income and race/ethnicity. There is considerable variation in overall and net changes across categories, with some indicating secular decrease in procedure rates, but statistical precision of estimates is also reduced because of relatively smaller volumes within individual procedure categories. For musculoskeletal and urinary/genital procedures, both low and medium area income cohorts experienced significant increase in overall postreform procedure rates. Although not statistically significant, we found that compared with the high area income group, the estimated net increase (%) was larger or net decrease smaller for all 5 procedure categories among the lowest area income cohort and for 4 procedure categories among the medium area income cohort. Comparisons by race/ethnicity indicate that compared with whites, the estimated net change (%) was greater for 3 of the procedure types (musculoskeletal, urinary/genital, and nervous) among Hispanics, but only for digestive procedures among blacks—and statistically significant only for nervous system procedures among Hispanics.

Sensitivity analyses indicate that all main findings reported are robust to (a) inclusion of those aged 65–69; (b) alternative count regression specification to permit overdispersion; and (c) aggregation of procedure counts to state instead of county level (See Appendix, Supplemental Digital Content, http://links.lww.com/MLR/A311). Segmented time-series Poisson model indicated similar patterns in postreform change, with no significant transition period effects for any of the cohorts (See Appendix, Supplemental Digital Content, http://links.lww.com/MLR/A311).

DISCUSSION

We compared prereform and postreform utilization of major therapeutic inpatient surgical procedures predominantly scheduled by outpatient referrals among nonelderly MA adults, and found greater overall increases for lower area income cohorts compared with the highest area income cohort, and for Hispanics compared with whites. Before reform, both blacks and Hispanics had lower rates of these procedures compared with whites. We estimated the net change in procedure use associated with health reform among the nonelderly accounting for secular trends, finding significant increases for lower area income groups and Hispanics and whites but not among blacks or the highest area income group. As 90% of all surgeries came from outpatient physician referral, these findings suggest a meaningful improvement in access to outpatient care for the surgeries studied, especially those living in lower income areas, Hispanics, and whites.

Our findings of greater net increases in procedure use among lower area income groups and Hispanics are consistent with previous randomized[38,39] and natural experiments of expanded public insurance programs or similar policy changes; however, few prior studies have explicitly examined whether increased insurance coverage reduces income or racial/ethnic disparities in access to or use of care.[36,40] A recent study of Oregon's lottery-selected expansion of Medicaid to uninsured low-income nonelderly

Prereform = [October 2004, June 2006] and postreform = [January 2008, September 2009].

Procedure rates, adjusted for sex and age differences, are estimated by direct standardization method.

Overall change (%) in procedure rate is the simple % change in the prereform and postreform procedure rates. Difference in overall change by race/ethnicity and area income are obtained by comparing overall change.

Net change (%) in procedure rate among nonelderly due to health reform are calculated from a separate (county fixed effects) Poisson regression with a difference-in-difference specification using combined nonelderly and elderly cohort data. Confidence intervals are based on bootstrapped SEs (N = 1000 iterations) to adjust for clustering of observations within county.

Area income cohorts are defined as: low = lowest quartile zip codes, medium = second quartile, and high = top 2 quartiles.

adults in 2008 found that hospital admissions increased by 30% in 1 year; this effect is nearly identical to that found in the RAND randomized study in the 1970s.[38,39] More relevant to our study is the finding from Oregon that the increase in inpatient admissions was "disproportionately concentrated" among admissions "that do not originate in the emergency room"; we note that these primarily include admissions based on outpatient physician referral, including those for HRR procedures examined here.[39]

More appropriate for comparison with our study are findings of quasi-experimental expansions of public health insurance.[28,40–42] Studies examining the impact of Medicare enrollment at age 65 have noted increased use of inpatient and outpatient care among the previously uninsured[29] and also the previously insured (because of the relative "generosity" of Medicare).[28,40] One study documented a 10% increase in hospitalizations in the year after Medicare enrollment, with larger increases in use of "elective" procedures such as bypass surgery and joint replacement.[28] This suggests that our finding of increased procedure use may reflect a combination of pent-up unmet need and need arising from new diagnoses after increased access to outpatient care.

Although the 17 surgical procedures examined represent a broad spectrum of inpatient procedures, our main focus here was on their role as markers of access to care. In combining these procedures for evaluating the differential impact of health reform in access to care across subpopulations, we recognize heterogeneity in the procedures in other respects, including acuity of conditions targeted, impact on quality of life, and value in terms of clinical benefit per dollar. Reflecting this heterogeneity, we found considerable differences in postreform changes in rates, with several categories of procedures experiencing decrease in utilization while some others had sharp increases ($\geq$ 25%). As estimates of net increases by individual procedure categories had wide CIs due largely to small numbers, we cannot rule out potentially large differences among subpopulations. Nevertheless, statistically significant net increases associated with health reform were found for musculoskeletal and urinary/genital procedures among lower area income cohorts and whites, and for urinary/genital procedures among Hispanics.

TABLE 4. Impact of Health Reform on Use of High Referral Rate Procedures by *Area* Income, Race/Ethnicity & Procedure Category

Overall change (%) in procedure rate is the simple % change in the prereform and postreform procedure rates. Difference in overall change by race/ethnicity and area income are obtained by comparing overall change. The figures for the all cohort are identical to those in Table 3.

Net change (%) in procedure rate among nonelderly due to health reform are calculated from a separate (county fixed effects) Poisson regression with a difference-in-difference specification using combined nonelderly and elderly cohort data. Confidence intervals are based on bootstrapped SEs (N = 1000 iterations) to adjust for clustering of observations within county.

Area income cohorts are defined as: low = lowest quartile zip codes, medium = second quartile, and high = top 2 quartiles.

HRR indicates high referral rate.

For Hispanics, the overall postreform increase in procedure use among the nonelderly was considerably higher than that for their elderly counterparts, particularly for musculoskeletal, urinary/genital, and nervous system procedures. For blacks, whereas the changes for both groups were similar for musculoskeletal and urinary/genital procedures, the magnitude of the change is large and comparable with that for the nonelderly Hispanics. Therefore, it is the similar increase in the use of these procedures among the elderly blacks that leads to the results of no significant net change (for nonelderly) attributable to the reform. Reasons for the similar increase among all blacks (elderly and nonelderly) are unclear and merit further examination.

There is considerable debate on whether more medical care leads to better health.[43] However, most studies of natural experimental policy changes have found that expansions of health insurance result in health improvements for individual health measures or subpopulations.[36] Given the natural experimental setting of MA reform, we instead examined disparities in health care utilization and focused on vulnerable subpopulations and selected inpatient procedure categories for which underutilization of care is known to be associated with uninsurance or underinsurance. Research has documented higher rates of clinically unmet need among minorities and lower income patients for many inpatient procedures, including those for cardiac,[44] cancer,[45,46] and musculoskeletal[22] care. Our findings are among the first to show that expanded insurance coverage on a population level is associated with increase in use by such vulnerable populations.

Our study has several important limitations. First, we cannot differentiate overuse of procedures from clinically appropriate use. We suspect that our findings of increased procedure use among minorities do not reflect overuse, as Dartmouth Atlas comparisons of regional differences for Medicare beneficiaries for 12 common inpatient surgeries found MA procedure rates were below average for 6, near average for 5, and above average for only 1 procedure.[47] Second, as our data is observational, the possibility of potential confounding from unobserved factors remains. However, as we adjust for changes among the elderly, our estimates are robust to unobserved factors (including practice pattern changes) that affect all age groups. Also, comparison of nonelderly and elderly rates of use may not be clinically meaningful for some procedures. However, our findings do include same-age group comparisons by race/ethnicity and area income cohorts. Further, we did not include individual-level data on insurance status, because of the inability to infer population rates of insurance status by the subgroups of interest from our data on health care users only. Identification of patient race/ethnicity is not necessarily based on patient self-report and may vary across hospitals; however, as this is likely to affect both nonelderly and elderly patients in each hospital, our methodology of contrasting changes among nonelderly patients with those for elderly patients provides robustness of findings to the potential heterogeneity in race/ethnicity identification. Also, in the absence of data on individual income, we have used zip code–level income as the measure of socioeconomic status; however, this approach has been used in numerous previous studies.[31–33] Finally, our focus on the use of inpatient procedures may underestimate use of procedures performed in outpatient settings.

Nonetheless our findings have implications for national health reform (Affordable Care Act, 2010) which shares many key elements with MA health reform.[1] Notably, before health reform, MA had lower uninsurance and better safety-net funding compared with other states.[48,49] Depending on the extent to which similar subpopulations gain from insurance expansion from the national reform, the potential for improved access is considerably larger or smaller, as is the potential for higher costs. Our study examined utilization only in the first 2 years after the reform, and therefore may include sharp increases in utilization from nonelderly patients with prior unmet need. Whether these increases will taper-off in the longer run is unknown. Actual changes also depend on other factors, including provider supply and practice patterns, which also vary considerably across states.

In conclusion, our findings of significant postreform expansion in procedure use for Hispanics and lower area income patients are consistent with the relatively larger gains in insurance coverage among these subpopulations. These findings suggest potentially improved access to outpatient care and may reflect demand built up before reform when individuals were uninsured. Whether such improved access—a crucially important first step to improving equity in access and outcomes—translates into improved clinical outcomes at a reasonable cost merits further study.

Comparison of Ischemic Stroke Outcomes and Patient and Hospital Characteristics by Race/Ethnicity and Socioeconomic Status

Amresh D. Hanchate, PhD; Lee H. Schwamm, MD, FAHA; Wei Huang, MPH, MA; Elaine M. Hylek, MD, MPH

Background and Purpose—Current literature provides mixed evidence on disparities by race/ethnicity and socioeconomic status in discharge outcomes after hospitalization for acute ischemic stroke. Using comprehensive data from 8 states, we sought to compare inpatient mortality and length of stay by race/ethnicity and socioeconomic status.

Methods—We examined all 2007 hospitalizations for acute ischemic stroke in all nonfederal acute care hospitals in Arizona, California, Florida, Maine, New Jersey, New York, Pennsylvania, and Texas. Population was stratified by race/ethnicity (non-Hispanic whites, non-Hispanic blacks, and Hispanics) and socioeconomic status, measured by median income of patient zip code. For each stratum, we estimated risk-adjusted rates of inpatient mortality and longer length of stay (greater than median length of stay). We also compared the hospitals where these subpopulations received care.

Results—Hispanic and black patients accounted for 14% and 12% of all ischemic stroke admissions (N=147 780), respectively, and had lower crude inpatient mortality rates (Hispanic=4.5%, blacks=4.4%; all $P<0.001$) compared with white patients (5.8%). Hispanic and black patients were younger and fewer had any form of atrial fibrillation. Adjusted for patient risk, inpatient mortality was similar by race/ethnicity, but was significantly higher for low-income area patients than that for high-income area patients (odds ratio, 1.08; 95% confidence interval, 1.02–1.15). Risk-adjusted rates of longer length of stay were higher among minority and low-income area populations.

Conclusions—Risk-adjusted inpatient mortality was similar among patients by race/ethnicity but higher among patients from lower income areas. However, this pattern was not evident in sensitivity analyses, including the use of mechanical ventilation as a partial surrogate for stroke severity. **(*Stroke*. 2013;44:469-476.)**

Key Words: ethnicity ■ ischemic stroke ■ inpatient mortality ■ length of stay ■ race ■ risk factors ■ socioeconomic status

Although key to understanding the long-term racial/ethnic disparities in stroke mortality rates, evidence on differences in case fatality after stroke has remained mixed.[1,2] Death certificate data have long indicated that the national death rate from stroke is higher (+48% in 2007) among non-Hispanic blacks (henceforth referred to as blacks) and lower (−20% in 2007) among Hispanics than among non-Hispanic whites (henceforth referred to as whites).[3] Higher stroke mortality can arise from higher incidence or higher case fatality or both.[4,5] Findings from several well-known epidemiological studies over the last 2 decades have uniformly indicated that stroke incidence rate is higher among blacks and Hispanics compared with whites[5–11]; however, the magnitude of disparity in stroke incidence is much smaller than that in stroke mortality.[4,5] Although this would suggest higher case fatality rates among blacks compared with whites, previous studies have been largely inconclusive, with studies finding higher, similar, or lower case fatality among blacks compared with whites across different study populations.[4–8,10,12–15] Evidence on differences between Hispanics and whites is also mixed.[12,16] In the absence of a population-representative data source that is both national in scope and has sizable number of minority patients, these differing findings could plausibly be reflective of regional differences, unrepresentative convenience patient cohorts, or inadequate sample size, thereby limiting comparability and generalizability.[4] Of particular importance is the need to accurately capture low-income cohorts in the study population; owing to higher incidence of low incomes among racial and ethnic minorities, they may be underrepresented in survey-based population studies.[4]

With a view to capture a broader national population, including larger numbers of minority populations, we pooled

administrative data of all ischemic stroke discharges from 8 states, which together accounted for 73% of national Hispanic and 37% of national black populations. We examined inpatient mortality as the indicator of case fatality; in addition, length of stay (LOS) was also examined as a secondary patient outcome measure.[12,13] We compared outcomes by race/ethnicity and socioeconomic status (SES). We examined for systematic differences in the type of hospitals where minority and low-income area patients received care.

Methods

Data Sources

The primary data sources were the state-level inpatient discharge databases (2007) from Arizona, California, Florida, Maine, New Jersey, New York, Pennsylvania, and Texas. These cover the universe of all admissions to all nonfederal acute care hospitals.[17] These states were selected based on their sizable minority population and completeness of race and ethnicity data; the proportion of acute ischemic stroke admissions with patient race/ethnicity missing (or coded as unknown) was 2.8% and ranged from 0.3% (Texas) to 7.6% (New York). In addition, we obtained zip code-level data on median household income from the 2000 Census.[18] We obtained data on hospital characteristics from the American Hospital Association Annual Survey (2007).[19]

Study Population

To identify acute ischemic stroke admissions for adults ≥18 years of age, we followed other recent studies by including admissions with the principal discharge code (*International Classification of Diseases, Ninth Revision*, Clinically Modified) of 433.x1, 434.x1, and 436.[12,13] To minimize confounding from scheduled admissions for discretionary treatment (for instance, carotid endarterectomy), we only considered inpatient admissions arising either from admission to the emergency department or transfer from another acute care facility. To avoid 2 admissions being associated with the same outcome, we excluded hospitalizations that resulted in transfer to another acute care hospital. For comparability of patient outcomes by subpopulations, especially by SES, we included admissions of patients who were state residents. From the resulting cohort, we excluded 4.9% admissions with missing key measures; compared with the included cohort, patients in this 4.9% excluded cohort were broadly similar (Appendix in the online-only Data Supplement).

Measures

The primary outcome measures were inpatient death and LOS of the index hospitalization for acute ischemic stroke. We examined LOS as a dichotomous measure indicating longer LOS (ie, 1=LOS >median LOS) because it is more robust to outliers and skewed distribution.[12] Patient risk factors were characterized by comorbid conditions captured by the secondary discharge diagnosis codes (*International Classification of Diseases, Ninth Revision*, Clinically Modified).[13,20] We identified patients with the following comorbid conditions: atrial fibrillation, coronary heart disease, congestive heart failure, diabetes mellitus, and hypertension.[21] Indications for other comorbid conditions were collectively grouped using the Charlson comorbidity index.[22] Discharge data from all states included separate indicators of race and ethnicity, which were together used to uniformly define 4 population cohorts: Hispanics, non-Hispanic whites, non-Hispanic blacks, and others; the others included those with missing race/ethnicity.[23] Given the absence of individual measures of SES, we followed previous research and used the census-based median zip code income, matched with patient residence zip code, to stratify patients from each state into 3 groups based on population quartiles[24,25]: lowest quartile zip codes (low-income area), second lowest quartile (medium), and top 2 quartiles (high).[25] On the basis of previous research on the role of hospital characteristics, we examined several structural measures: number of inpatient beds, number of intensive care unit beds, nursing staff (number of patients per nurse), mean daily emergency department admission volume, ownership, teaching status, and safety-net status (defined as >20% of discharges from the hospital covered by Medicaid).[26]

Estimation

The unit of all analyses was the index patient admission for acute ischemic stroke. We performed bivariate comparisons of patient and hospital characteristics by race/ethnicity and SES. We obtained 2 sets of risk-adjusted estimates of differences in the outcomes across population subgroups stratified by race/ethnicity and SES; in the first, we adjusted for patient risk factors, and in the second, we also adjusted for hospital characteristics.[12] Each was estimated by hierarchical logistic regression to adjust for clustering within hospitals. We estimated these models for all patients and for subgroups formed by the interaction of race/ethnicity and SES. Standard errors and confidence intervals (CIs) were estimated to account for heterogeneity across subpopulations. Statistical significance was defined as $P \leq 0.05$.

Across patient risk factors, we found relatively larger differences in age and comorbidity of atrial fibrillation between whites and minorities. To assess their relative impact on outcomes, we estimated racial/ethnic differences in outcome rates adjusted for only these 2 factors.

Sensitivity Analyses

Ideally, we would have liked to adjust for initial stroke severity. In the absence of available data on stroke severity, we performed a post hoc sensitivity analysis adjusted instead for the use of mechanical ventilation, which has been previously shown to be a valid proxy for stroke severity.[27] In addition, we also examined whether LOS differences by cohorts were associated with inpatient mortality rate differences; for this, we re-estimated the LOS regression model, including inpatient mortality as a covariate. Because of space limitation, additional findings are reported in an Appendix in the online-only Data Supplement. All the statistical analyses were performed using Stata Version 12.1. This study was approved by the Boston University Institutional Review Board.

Results

We identified 147 780 hospitalizations for acute ischemic stroke during 2007 in the 8 states. Their distribution by race and ethnicity was whites=67%, blacks=14%, Hispanics=11%, and others=8% (Table 1).

Patient Risk Factors by Race/Ethnicity and SES

Comparing whites with minorities, we found relatively larger differences in age and prevalence of atrial fibrillation (Table 1). Although 58% of whites were ≥75 years of age, this proportion was 29% and 37% for blacks and Hispanics, respectively ($P<0.001$). Among individuals 18 to 64 years of age, whites comprised 23% of all admissions, compared with 48% and 40% among blacks and Hispanics, respectively. Prevalence of atrial fibrillation was significantly higher among whites (27%) than blacks (12%) and Hispanics (15%; $P<0.001$). This pattern in the 2 factors was persistent in every state (Figure). Patients also exhibited considerable differences by SES (Table 1). Low-income area patients were more often younger and had a higher prevalence of hypertension, diabetes mellitus, and congestive heart failure, but lower prevalence of atrial fibrillation and coronary heart disease.

Hospital Characteristics

Systematic differences were also found in the hospitals where whites and minorities received care (Table 1). Of the 1282 hospitals with acute ischemic stroke admissions in the

All acute ischemic discharges for patients age ≥18 years of age in all nonfederal hospitals in AZ, CA, FL, MA, NJ, NY, PA, and TX. Of the 147 780 discharges, 11 762 were for other race and ethnicity. Owing to heterogeneity of this cohort, characteristics are not reported here. However, the other cohort was included in all the statistical analyses. Charlson score excludes congestive heart failure, cerebrovascular, and diabetes mellitus because these are individually specified. ED indicates emergency department; and ICU, intensive care unit.

P value is for the test of comparison across race and ethnicity.

8 states, all admissions for blacks and Hispanics occurred in 954 and 892 hospitals, respectively. In terms of hospital size, blacks and low-income area patients more frequently received care in teaching and safety-net hospitals and hospitals with higher bed size, more intensive care unit beds and emergency department volume, compared with whites and Hispanics.

Differences in Inpatient Mortality Rate

The overall average crude inpatient mortality rate was 5.5%; it was significantly lower for blacks (odds ratio [OR], 0.75; 95% CI, 0.70–0.80) and Hispanics (OR, 0.76; 95% CI, 0.70–0.82) than for whites (Tables 1 and 2). The hierarchical logistic regression model to adjust for patient risk factors indicated very good discrimination (c-statistic=0.74); it also indicates

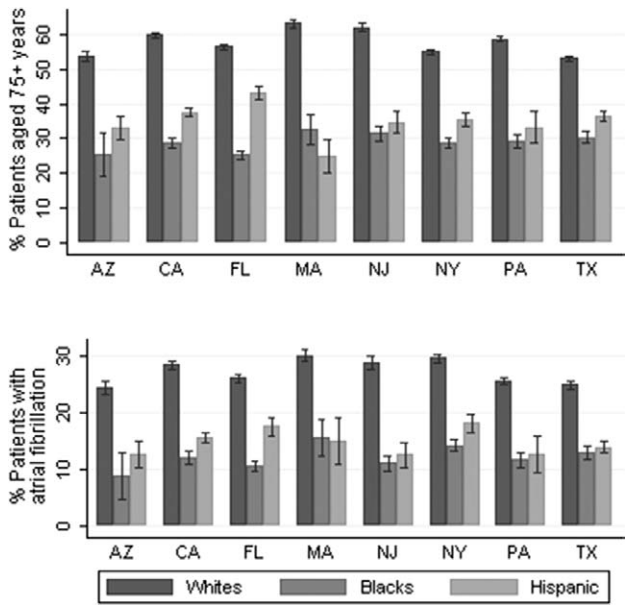

Figure. Prevalence of older age and atrial fibrillation by race and ethnicity, 2007. Note: reported figures are average prevalence rates (%) and 95% confidence intervals.

that only a small share (3.0%) of the residual inpatient mortality differences across patients were associated with the hospital where patients were treated (Appendix in the online-only Data Supplement). Adjusting for patient risk factors, inpatient mortality rates for blacks (OR, 1.02; 95% CI, 0.94–1.10) and Hispanics (OR, 0.98; 95% CI, 0.91–1.07) were similar to that for whites. In assessing the impact of different risk factors in mitigating observed differences in inpatient mortality, we note that whites have higher prevalence of older age, atrial fibrillation, coronary heart disease, and congestive heart failure; in addition, hypertension and diabetes mellitus, conditions for which prevalence was higher among minorities, were either protective or equivocal of inpatient mortality risk.

We also performed comparisons by race/ethnicity separately among patients stratified by SES. Across all 3 SES cohorts, crude inpatient mortality rates were significantly lower for blacks and Hispanics relative to that for whites (Appendix in the online-only Data Supplement). However, adjusted inpatient mortality was generally similar by race/ethnicity among all SES strata; one exception was medium area income Hispanics who had significantly lower mortality (OR, 0.80; 95% CI, 0.67—0.96) relative to whites. We repeated this comparison analysis separately for each of the 8 states and found similarity in risk-adjusted inpatient mortality rates among blacks in all states and among Hispanics in 7 states; however, because of smaller cohort sizes, precision of estimates was lower (Appendix in the online-only Data Supplement).

Similar comparison by SES indicated a converse pattern; although crude inpatient mortality rates were similar by SES cohorts, adjusted rate was higher among low-income area patients (OR, 1.08; 95% CI, 1.02–1.15) when compared with high-income area patients (Table 2). A similar pattern of higher adjusted inpatient mortality for low-income area patients was found among whites, blacks, and Hispanics, although statistical significance was present only for whites, the largest cohort.

The hierarchical logistic regression model to adjust for hospital structural factors and patient risk factors indicated similar discrimination (c-statistic=0.74) compared with the model

Table 2. Unadjusted and Adjusted Inpatient Mortality Rates by Race/Ethnicity and Socioeconomic Status

Adjusted mortality rates obtained by hierarchical logistic regression of inpatient mortality on patient factors (age, sex, and comorbidities) and hospital characteristics (nursing staff, intensive care unit beds, teaching status, and safety-net hospital indicator). In addition, indicators of cohorts compared (race/ethnicity or SES) were included. Separate regression models were estimated for each population stratum examined. Indicator for state was included in all regressions. SES indicates socioeconomic status.

adjusting for patient factors. Further, additional adjustment for hospital factors had little impact on the relative differences in inpatient mortality compared with those obtained by adjusting only for patient risk factors.

Differences in LOS

Although overall mean LOS was 6.2 days, differences by race/ethnicity were significant: whites=5.9, blacks=7.4, and Hispanics=6.3 (P=0.003; Table 1). Correspondingly, rate of longer LOS (LOS >4 days, the median LOS) was significantly higher among blacks (OR, 1.41; 95% CI, 1.37–1.46) and Hispanics (OR, 1.08; 95% CI, 1.04–1.11) compared with whites (Table 3). The regression model to adjust for patient risk factor indicated good discrimination (c-statistic=0.70; Appendix in the online-only Data Supplement). Adjusting for patient risk factors, the relative rate of longer LOS remained higher among blacks (OR, 1.36; 95% CI, 1.31–1.41) and Hispanics (OR, 1.19; 95% CI, 1.14–1.24). This pattern of higher rate of longer stays among minorities was persistent among subpopulations stratified by SES. Further, comparison among all patients of rates of longer LOS indicated higher crude and adjusted rates of longer stay among low SES patients (OR, 1.15; 95% CI, 1.12–1.19) than among high SES patients; this pattern was persistent separately among whites, blacks, and Hispanics (Appendix in the online-only Data Supplement). Further adjustment to also account for differences in hospital characteristics, using hierarchical logistic regression model, indicated little change in the relative rates of longer stay by race/ethnicity and SES. Sensitivity analyses indicated that aforementioned cohort differences in LOS were not associated with differences in inpatient mortality.

Adjusted mortality rates obtained by hierarchical logistic regression of inpatient mortality on patient factors (age, sex, and comorbidities) and hospital characteristics (nursing staff, intensive care unit beds, ownership type, teaching status, and safety net status). Indicator for state was included in both regressions.

Role of Older Age and Atrial Fibrillation

In mitigating the observed differences in inpatient mortality, we evaluated the relative role of the 2 risk factors, older age and presence of atrial fibrillation, whose prevalence was markedly lower among blacks and Hispanics compared with whites (Table 4). Re-estimating the regression, with adjustment made only for these 2 patient factors, we found similar inpatient mortality by race/ethnicity. In contrast, a converse specification with adjustment made for all patient factors excluding age and presence of atrial fibrillation indicated persistence of lower inpatient mortality among blacks (OR, 0.76; 95% CI, 0.71–0.83) and Hispanics (OR, 0.83; 95% CI, 0.78–0.91; Table 4).

Sensitivity Analyses

When added to the model, the use of mechanical ventilation was highly correlated with inpatient death (OR, 28.9; 95% CI, 27.1–30.9; Appendix in the online-only Data Supplement). The pattern of disparities in adjusted inpatient mortality rates was different from that without including the use of mechanical ventilation; adjusted inpatient mortality rates are significantly lower for blacks and Hispanics (compared with whites) but similar for lower income area patients (compared with high-income area patients).

Discussion

Comparing patient outcomes from acute ischemic stroke by race/ethnicity and SES, this study indicates that after adjusting for patient risk factors: (1) inpatient mortality rates are similar among whites, blacks, and Hispanics, but 8% higher among low-income area patients compared with high-income area patients and (2) rates of LOS >4 days are higher among blacks (+36%) and Hispanics (+19%) compared with whites, and among low-income area patients (+15%) compared with high-income area patients. Minorities and lower income area patients more frequently received care at hospitals with larger bed capacity and patient volumes and those with teaching and safety-net status. However, differences in hospital setting were not associated with differences in patient outcomes by race/ethnicity or SES.

Compared with whites, although observed inpatient mortality rates were 27% and 25% lower among blacks and Hispanics, respectively, they were almost completely mitigated after adjusting for patient risk factors. Among the risk factors that differed between whites and minorities, most significant were older age and atrial fibrillation, both of which were markedly less prevalent among blacks and Hispanics. We found that adjusting only for age and atrial fibrillation contributed to most of the mitigation of differences in inpatient mortality by race/ethnicity.

Our findings of lower observed inpatient mortality rates among blacks are qualitatively similar to previously reported differences in stroke subtypes among blacks and whites.[14,28] One recent study, based on brain imaging, found fewer cardioembolic strokes and fewer strokes from large vessel atherosclerosis among blacks compared with whites.[28] As in our study, blacks were younger and had a higher prevalence of hypertension and diabetes mellitus and a lower prevalence of atrial fibrillation, which lends support to the etiologic subtype of small vessel disease.[5,14,29]

Comparisons performed for subpopulations stratified by SES produced the same pattern of racial and ethnic differences in observed inpatient mortality rates, which were nearly completely mitigated after adjustment for patient risk factors (except for medium-income area Hispanics). Our findings of higher rates of LOS >4 days among blacks and Hispanics, relative to whites, are consistent with previous findings.[12,13]

In contrasting our findings with those from previous studies, we distinguish studies based on population-representative data sources (for instance, administrative data) from those based on convenience data (for instance, registry of voluntarily participating providers). Evidence from the former data source type indicates mixed patterns of similar[30] or lower[13,30,31] inpatient mortality among minorities. Of particular relevance are studies that examined administrative data from some of the same states as in this study.[13,30] Using administrative data from New York (2005–2006), a recent study found lower risk-adjusted inpatient mortality among blacks (OR, 0.77; 95% CI, 0.61–0.98) compared with whites.[13] This contrasts with the finding of similar mortality among blacks (OR, 1.0; 95%,

0.87–1.17) for the New York patient subgroup in our study; this may be because of differences in study design and methods. Specifically, that study excluded 39% of admissions from 57% of hospitals based on rural hospital location or low hospital volume (<10) of black and white stroke patients; in contrast, no such exclusions are made in the current study because our interest is in epidemiological outcome differences regardless of the hospital setting where care was received. Evidence using convenience data on disparities in outcomes is also mixed.[12,14,32] On the basis of data from a large national registry of 1181 hospitals, a recent study found lower inpatient mortality among blacks and similar mortality among Hispanics, relative to that for whites.[12]

Our findings of higher risk-adjusted inpatient mortality among lower income area patients are consistent with most previous studies, although these studies are based on non-US data.[33,34] Mechanisms underlying this association are not well known and seem complex, as noted in the broader literature on disparities by income.[35,36] Unobserved patient factors, including higher stroke severity or lower health literacy, and different attitudes toward life-sustaining therapies among lower income area populations, may underlie higher risk-adjusted inpatient mortality; however, this finding has also been noted in other studies using more detailed clinical indications, including stroke severity.[37]

Our finding of more frequent LOS >4 days among blacks and Hispanics, compared with whites is consistent with previous studies.[12,13] Stratified analysis also indicated that these differences are prevalent among all 3 income area groups. The factors underlying these differences are now well understood. Longer LOS among minorities could be attributable to unmeasured confounders of small vessel stroke or socioeconomic factors (including insurance coverage) that may affect timing of discharge to home or subacute care.[38]

Previous studies have noted the potential role of hospital factors in modifying subgroup differences in stroke outcomes.[12,13,34] Racial and ethnic differences in structural characteristics of hospitals found in this study mirror those in the other studies: minority patients are more likely to receive care in larger hospitals (number of beds, number of intensive care unit beds, and admission volume), including teaching and safety-net hospitals.[12,13] However, these differences were not associated with a measurable change in the pattern of differences in outcomes by race/ethnicity or SES.

This study has several limitations. First, the administrative data used contain limited clinical information on stroke severity. Sensitivity analysis with use of mechanical ventilation as a proxy indicator of patient severity affects the trends in disparities for adjusted inpatient mortality, indicating lower rates for blacks and Hispanics compared with whites and similar rates by SES. The use of mechanical ventilation as measured in the study may not be an accurate proxy of initial stroke severity because it is not possible to distinguish between mechanical ventilation on admission versus a later complication. When present at admission, it may be a valid marker of severe stroke or perhaps of severe comorbid lung disease which is decompensated even by minor stroke. Alternatively, if it results from poor oral hygiene, inadequate dysphagia screening and aspiration pneumonia, then adjusting for its presence may in fact adjust away markers of poor stroke care. Nevertheless, these results point to the potential sensitivity of our main findings to unobserved stroke severity. Another limitation is that the diagnosis codes are not confirmed by patient charts.[39] However, we found that patient differences in only 2 of the risk factors, age and presence of atrial fibrillation, mitigated most of the observed differences in inpatient mortality; additional patient comorbidity indicators did not influence relative differences markedly. Also, our data do not capture important behavioral risk factors (smoking, physical activity, and obesity).[2] Not only is smoking strongly associated with stroke severity, but also its prevalence varies considerably by race/ethnicity and SES. Our cases of acute ischemic strokes, identified by administrative diagnosis codes, were not confirmed by patient charts.[40] Another limitation is that our data cannot distinguish first strokes from secondary strokes. Even though secondary strokes are associated with higher mortality,[21] previous evidence indicates only a moderate black–white difference (33% vs 30%) in the rate of secondary strokes.[12] Also, our data do not include out-of-hospital strokes. Two previous studies reported similar rates (nearly 10%) of strokes (all subtypes) ascertained only in out-of-hospital settings[6,28]; these rates were similar among whites and blacks.[28] The accuracy and consistency of race and ethnicity information, including the extent to which they are patient reported, are also likely to vary across hospitals. Our selection of the 8 states was partly based on completeness of race and ethnicity data; also, all these states had adopted the current federal guidelines for reporting race and ethnicity information.[17,23] In addition, our measure of SES is not an individual measure but based on area-level (zip code) income; also, zip codes are more heterogeneous than census tract or block area units,[41] the latter are not available in the inpatient discharge data.

To summarize, we found that the significantly lower rates of observed inpatient mortality among blacks and Hispanics, compared with that among whites, are primarily associated with differences in patient risk factors; specifically, adjusting for younger age and lower rate of atrial fibrillation among blacks and Hispanics completely mitigates the differences in observed inpatient mortality. Also, we found significantly higher risk-adjusted rates among low-income area patients compared with high-income area patients. However, this pattern was not evident in sensitivity analyses, including the use of mechanical ventilation as a partial surrogate for stroke severity. Further research in potential differences in patient severity or process of care is needed to identify the sources of this differential outcome rate by race/ethnicity and SES.

Comparison of Ischemic Stroke Outcomes and, Patient and Hospital Characteristics by Race/Ethnicity and Socioeconomic Status

Table A1. Comparison Included and Excluded Observations

(N=155,539 discharges for Acute Ischemic Stroke in all non-federal hospitals in AZ, CA, FL, MA, NJ, NY, PA and TX, 2007)

	Included	Excluded
# admissions	147,780	7759
Female%	53.7	42.8
Age (%)		
18-64	29.4	41.2
65-74	20.7	20.5
75-84	29.8	23.9
85+	20.2	14.4
Race/ethnicity (%)		
Whites	66.7	62.9
Blacks	13.9	17.4
Hispanics	11.5	14.1
Other	8.0	5.6
Comorbidity (%)		
Atrial fibrillation	23.2	18.1
Hypertension	77.6	75.9
Diabetes	34.2	32.3
Coronary Heart Disease	27.5	23.8
Congestive Heart Failure	13.7	12.3
Charlson Score		
0	47.8	47.5
1	14.6	13.8
2	24.1	25.0
3+	13.4	13.7
Inpatient Mortality (%)	5.5	4.6
LOS, Median	4	4

Summary

Background Emerging data from longitudinal studies suggest that low sex steroid concentrations in men are associated with increased cardiovascular risk and mortality. The impact of longitudinal trajectory patterns from serial sex steroid and gonadotrophin measurements on the observed associations is unknown to date.

Methods We prospectively evaluated 254 elderly men (mean age, 75·5 years) of the Framingham Heart Study with up to four serial measurements of serum total testosterone (TT), dehydroepiandrosterone sulphate (DHEAS), follicle-stimulating hormone (FSH), luteinizing hormone (LH) and total estradiol (EST); and constructed age- and multivariable-adjusted Cox proportional hazard regression models relating baseline hormone concentrations and their mean, slope and variation over time (modelled as continuous and categorized into quartiles) to the incidence of clinical cardiovascular disease (CVD) and all-cause mortality at 5- and 10-year follow-up.

Results We observed no association between baseline concentrations of sex steroids, gonadotrophins and their trajectories with incident clinical CVD over 5- and 10-year follow-up. Although higher baseline TT concentrations were associated with lower mortality risk at 5 years (hazard ratio per quartile increment, 0·74; 95% confidence interval, 0·56–0·98), correction for multiple statistical testing ($P < 0·005$) rendered this association statistically nonsignificant. Repeat analyses at the 10-year follow-up time point also demonstrated no significant association between sex steroids, gonadotrophins or their trajectories and mortality.

Conclusion Investigating longitudinal trajectory patterns of serial sex steroid and gonadotrophin measurements, the present study found no consistent associations with incident clinical CVD and all-cause mortality risk in elderly men from the community.

(Received 17 February 2012; returned for revision 25 April 2012; finally revised 06 June 2012; accepted 9 August 2012)

Introduction

Emerging data suggest that reduced circulating total testosterone (TT) concentrations in men are associated with increased cardiovascular risk and mortality.[1] Longitudinal epidemiological studies have consistently reported positive associations between low serum TT concentrations and hypertension,[2] metabolic syndrome,[3, 4] type 2 diabetes[5] and dyslipidaemia.[6] In contrast to these relations between low circulating TT concentrations in men and increased cardiometabolic risk factor burden, studies relating TT concentrations to incident cardiovascular disease (CVD) and mortality have remained inconclusive. While some longitudinal studies[7–10] reported an association between low TT concentrations and increased mortality risk, others like the Massachusetts Male Aging Study[11] or Caerphilly study[12] observed no such associations. Similarly, some longitudinal studies showed inverse associations between testosterone and cardiovascular events in elderly men,[13, 14] whereas a recent systematic review concluded that there was no association between testosterone and CVD risk in middle-aged men.[15] Furthermore, because a high CVD risk factor burden itself is associated with decreased TT concentrations,[16] there is a possibility of reverse causality when one considers the relations of circulating TT concentrations to CVD risk.

Analysing biomarker trajectories have previously been shown to offer additional insights into the assessment of the risk of CVD and mortality. For instance, in the Cardiovascular Health Study, a steep decline and extreme variability in dehydroepiandrosterone sulphate (DHEAS) concentrations were associated with increased mortality risk, whereas the baseline DHEAS concentration itself was not.[17] These findings raise the possibility that information regarding absolute hormone concentrations at a single point in time may be complemented by analysing serial measurements including hormone trajectories. Thus, we analysed up to four serial hormone measurements obtained over a 10-year period in elderly men from the original cohort of the Framingham Heart Study (FHS), to investigate longitudinal trajectory patterns of sex steroids and gonadotrophins. We hypothesized that low baseline and mean concentrations, as well as a steep decline and extreme variability in sex steroids and gonadotrophins are associated positively with incident clinical CVD and mortality.

Methods

Study population

The FHS is a longitudinal epidemiological study initiated in 1948 in Framingham, Massachusetts, to investigate risk factors for heart disease in a community-based epidemiological cohort design. The selection criteria and the study design of the FHS have been described previously.[18] Written informed consent was obtained at each examination and the Institutional Review Board of the Boston University Medical Center approved the study protocol. The present study focused on men who attended the biennial original cohort examination cycles 17 (1981–1983) through 20 (1987–1989) with two or more hormone measurements. Of the 1401 baseline attendants at examination 20, we excluded 866 women (our analyses were confined to men), 229 men with prevalent CVD, 32 men with missing hormone or covariate data and 20 men with less than two hormone measurements, yielding a final study sample of 254 men for the present investigation.

Measures

Single nonfasting blood samples were taken all-day from attendees at the original cohort's 17th–20th examination cycles between May 1981 and December 1989 and were stored at −20 °C until assays of sex hormones and gonadotrophins between October 1984 and March 1990. The maximum storage length (for only a portion of the samples) was about 5 years. Concentrations of serum TT, DHEAS, follicle-stimulating hormone (FSH), luteinizing hormone (LH) and total estradiol (EST) were measured using radioimmunoassays (Diagnostic Products Corp., Los Angeles, CA, USA) in the Boston University laboratory of Dr. Sawin. The interassay coefficients of variation in the Sawin laboratory were as follows: for TT, 11%; DHEAS, 11%; FSH, 5%; LH, 6%; and EST, 4%, as previously described.[19] The vast majority of the studied 254 men contributed four repeated measurements for TT (two measurements, 4; three, 41; four, 209), DHEAS (two measurements, 55; four, 199), FSH (two measurements, 4; three, 44; four, 206), LH (two measurements, 4; three, 42; four, 208) and EST (two measurements, 5; three, 44; four, 205).

Socio-demographic, behavioural and anthropometric characteristics as well as medical history, laboratory measures and medication use were assessed by standardized methods at the Heart Study examinations. Clinical CVD was assessed according to previously reported standardized criteria [including coronary heart disease (recognized or unrecognized myocardial infarction, angina pectoris, coronary insufficiency or coronary heart disease death), cerebrovascular disease (stroke or transient ischaemic attack) or congestive heart failure] and confirmed, together with information about vital status, by a three-physician adjudication panel with the aid of medical histories, physical examinations at the study clinic, hospitalization records and communication with personal physicians.[20]

Statistical analyses

Clinical CVD and mortality outcomes were assessed prospectively over 5- and 10-year follow-up periods starting from the 20th examination cycle (Fig. 1). To understand the nature of sampling bias because of nonattendance at serial exams or because of nonrandom measurement of hormones at serial exams, we compared clinical characteristics of men with two or more serial hormone measurements to those with less than two measurements using χ^2 tests for categorical data or two-sample *t*-tests for continuous data.

We used age- and multivariable-adjusted Cox proportional hazard regression models to relate baseline and mean hormone concentrations and their trajectories over time to clinical CVD incidence and all-cause mortality at the 5- and 10-year follow-up, by assessing (1) *baseline level:* sex steroid and gonadotrophin concentration from the first available baseline examination of

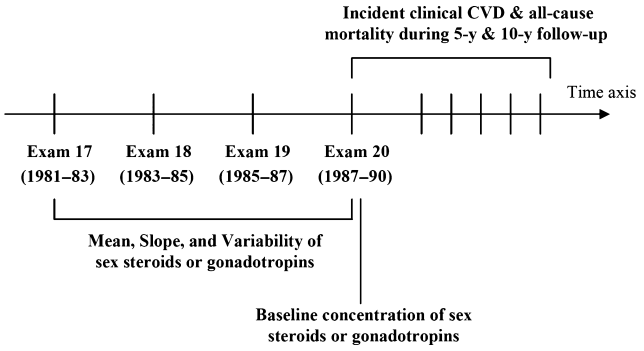

Fig. 1 Study design. Baseline concentrations of sex steroids and gonadotrophins, as well as covariates were measured at the 20th examination cycle of the Framingham Heart Study. From the 17th to 20th examination cycle, serial hormone measurements were used to assess their mean, slope and variability (separate analyses for each of the hormones). Incident clinical cardiovascular disease and all-cause mortality were analysed at the 5- and 10-year follow-up, respectively.

examination cycles 17–20 (most from the 20th examination cycle); (2) *mean:* average sex steroid and gonadotrophin concentration calculated in each individual using measures from at least two and up to four examination cycles; (3) *slope*: calculated using at least two available measures and the following regression formula: $y_i = a_i + \beta_i x_i$ where y_i is the predicted hormone concentration in the individual, a_i is the hormone concentration at the first examination, x_i is the number of years after the first examination and β_i is the hormone concentration's slope; and (4) *variability*: calculated using SAS RMSE (Root Mean Square Error; SAS Institute Inc., Cary, NC, USA) function to estimate the square root of the variance of the residuals based on at least three available measures ($n = 250$ for TT, FSH and LH; $n = 199$ for DHEAS; $n = 249$ for EST). We categorized the different predictor variables 1–4 into quartiles and included them as a continuous variable into the models. Effects are presented as hazard ratios (HR) and their 95% confidence intervals (95% CI).

Multivariable modelling included *covariates* measured in the 20th examination cycle: age, body mass index, smoking, total cholesterol, high-density lipoprotein cholesterol, type 2 diabetes, systolic blood pressure and antihypertensive medication. We confirmed that the proportional hazards assumption was satisfied by visual inspection of log-log plots and a test based on Schoenfeld residuals. As the probability of experiencing the event of interest (incident clinical CVD) may be altered by an alternative event (death), we conducted competing risk analyses for death in the Cox models relating sex steroids, gonadotrophins and their trajectories to incident clinical CVD.

To identify additional clinical and laboratory parameters predictive of incident CVD and all-cause mortality, we modelled baseline clinical and laboratory parameters (age, BMI, smoking status, systolic blood pressure, antihypertensive medication, type 2 diabetes, total cholesterol/high-density lipoprotein cholesterol (HDL-C) ratio, and sex steroid and gonadotrophin concentrations) with incident CVD and all-cause mortality at both 5- and 10-year follow-up in multivariable models. All statistical analyses were performed using SAS statistical software (SAS Institute Inc.). We used a minimal $P < 0{\cdot}005$ to indicate statistical significance because we evaluated five different hormones and two outcomes (0·05/10). The present study of 254 elderly men from the original cohort of the FHS had 80% power to detect a hazard ratio of 2·43 per quartile increment of any sex hormone/gonadotrophin for 10-year risk of incident CVD. For 10-year all-cause mortality, this study had 80% power to detect a hazard ratio of 1·76 per quartile increment.

Results

The baseline characteristics of our sample of older men are displayed in Table 1. Comparing participants included in the present analysis to the participants not included, we observed statistically significant differences with higher lipid levels and blood pressure, as well as a lower prevalence of diabetes and antihypertensive medication use in the first compared with the latter group. At the 5-year follow-up, we observed 56 incident clinical CVD cases and 42 deaths. We found no association between concentrations of sex steroids, gonadotrophins and their trajectories with incident clinical CVD (Table 2). Higher baseline TT concentrations were borderline significantly associated with lower all-cause mortality risk (HR per quartile increment, 0·74; 95% CI, 0·56–0·98; *P*-value, 0·034) in multivariable-adjusted, but not in age-adjusted models (HR per quartile increment, 0·81; 95% CI, 0·61–1·07; *P*-value, 0·134; Table 2). None of these results met the minimal $P < 0{\cdot}005$ criterion for statistical significance accounting

for multiple testing. At the 10-year follow-up, we observed 92 incident clinical CVD cases and 104 deaths. However, repeat analyses at the 10-year follow-up also showed no consistent statistically significant associations between sex steroids, gonadotrophins and their trajectories with incident clinical CVD or all-cause mortality risk (Table 3). Adjusting the analyses for competing risks of incident clinical CVD at the 5- and 10-year follow-up showed no impact on the observed estimates (data not shown). Similarly, subgroup analyses stratified by BMI status (normal weight: BMI < 25 kg/m², 32·3%; overweight: BMI 25: <30 kg/m², 48·0%; obese: BMI: ≥30 kg/m², 19·7%) showed no association of sex steroids and gonadotrophins with incident 10-year CVD and all-cause mortality risk in any of the BMI strata (data not shown). Other clinical and laboratory predictors for incident CVD were age and smoking, and for all-cause mortality age and type 2 diabetes (data not shown).

Discussion

Leveraging the unique data set and design of the community-based FHS, the present study is the first to investigate longitudinal trajectory patterns of serial sex steroid and gonadotrophin measurements and their associations with 5- and 10-year risk of incident clinical CVD and all-cause mortality. We observed no consistent association of sex steroids, gonadotrophins and their trajectories with incident clinical CVD or all-cause mortality risk in 254 elderly men in the community.

In contrast to previous longitudinal studies[13, 14] and a recent meta-analysis[15] suggesting inverse associations between testosterone and cardiovascular events in elderly men over 70 years of age (with an estimated summary relative risk of 0·84 (0·76–0·92) per one SD increase in TT), the present and previous other longitudinal studies were not able to detect any statistically significant associations between TT concentrations and incident CVD.[21–23] In a 10-year follow-up of 2084 middle-aged men from the FHS, the results also suggested no association between TT or DHEAS concentrations and incident CVD.[21] Similarly, we found no consistent associations between baseline sex steroids, gonadotrophins and their longitudinal trajectory patterns with 5- and 10-year all-cause mortality risk. A recent meta-analyses summarized the reported associations between low TT concentrations and increased mortality risk and concluded that the considerable between-study heterogeneity related to study and participant characteristics limit the ability to provide valid sum-

mary estimates or to draw any firm conclusions.[1] However, because of the advanced age and small size of the present study sample, competing risks of CVD and mortality risk and the limited statistical power may potentially explain the lack of association in our sample.

The present study is the first to analyse longitudinal trajectory patterns and their association with incident clinical CVD and mortality, but we did not observe any associations of mean hormone concentrations, their slope and variability with incident adverse events. In contrast, a previous study reported that a steep decline and extreme variability in DHEAS concentrations, but not the actual baseline level, were associated with increased all-cause mortality risk.[17] However, given the considerable potential for residual confounding (no adjustment was performed for BMI, BP or smoking) in that previous study and the negative finding for trajectory patterns as predictor of incident CVD and mortality in the present study, the postulated advantage of serial measurements over a single baseline measure is questionable.

The strengths of the present study include the use of four serial measurements of sex steroids and gonadotrophins from a well-characterized community-based sample of elderly men, enabling not only the analyses of baseline concentrations but also longitudinal trajectory patterns. For the proper interpretation of the present study, some important limitations must also be mentioned. Single nonfasting serum samples that were drawn through out the day at each individual examination were used to measure concentrations of sex steroids and gonadotrophins. Although we sought to limit artifactual changes in sex hormone concentrations across serial examinations by performing measurements in one central laboratory, following the same collection protocol, and using the same laboratory assays, measurement bias remains a possibility. However, a recent cross-sectional study of 95 elderly men aged 70 years also found no associations between sex steroid concentrations measured by liquid chromatography/tandem mass spectrometry and prevalent CVD.[24] Additionally, we did not measure sex hormone-binding globulin or androgen receptor polymorphisms (that may affect sex hormone concentrations and effects) or assess symptoms of low TT concentrations for the clinical diagnosis of primary hypogonadism or secondary hypogonadotrophic hypogonadism. Finally, the external validity or generalizability of our findings to other age groups or ethnicities is limited given our study sample of elderly Caucasian men.

In conclusion, the present study showed no association of baseline sex steroids, gonadotrophins and their longitudinal trajectory patterns with incident clinical CVD and all-cause

mortality in elderly men. Given the relatively small sample size, the advanced age of the study sample and the high rates of CVD and mortality, limited statistical power and competing risks hampered the detection of possible associations. However, the potential role of sex steroid concentrations in men as useful biomarkers of general health, cardiovascular risk factor burden and subclinical CVD progression warrants further investigation.

Summary

Low serum concentrations of sex steroids and gonadotropins in men have been associated with increased cardiometabolic risk and mortality, but the clinical correlates of these hormones in men over late adulthood are less clearly understood. We analysed up to five serial measurements of total testosterone (TT), dehydroepiandrosterone sulphate (DHEAS), follicle stimulating hormone (FSH), luteinizing hormone (LH) and total estradiol (EST) in older men in the original cohort of the Framingham Heart Study to determine the short- (2-years; 1,165 person-observations in 528 individuals) and long-term (up to 10-years follow-up; 2520 person-observations in 835 individuals with mean baseline age: 71.2 years) clinical correlates of these sex steroids and gonadotropins using multilevel modelling and Generalized Estimating Equations. Age, body mass index and pre-existing type 2 diabetes were inversely related to long-term TT concentrations, whereas higher systolic blood pressure showed a positive association. Furthermore, age and pre-existing cardiovascular disease (CVD) were inversely associated and HDL cholesterol concentrations positively associated with long-term DHEAS concentrations respectively. Analyses of short-term changes revealed age was inversely related to DHEAS, but positively related to FSH and LH concentrations. Our community-based study identified modifiable correlates of decreasing TT and DHEAS concentrations in elderly men, suggesting that maintenance of a low CVD risk factor burden may mitigate the age-related decline of these hormones over the late adulthood.

Introduction

Low serum concentrations of total testosterone (TT) in men have been associated with increased cardiometabolic risk factor burden including a greater prevalence of dyslipidemia (Haring *et al.*, 2011), hypertension (Torkler *et al.*, 2011), metabolic syndrome (MetS) (Kupelian *et al.*, 2006; Haring *et al.*, 2009), type 2 diabetes (Vikan *et al.*, 2010; Schipf *et al.*, 2011) and atherosclerosis (Svartberg *et al.*, 2006; Vikan *et al.*, 2009), as well as mortality risk (Araujo *et al.*, 2007; Laughlin *et al.*, 2008; Haring *et al.*, 2010b). In addition, prostate cancer patients who undergo long-term androgen deprivation therapy are at greater risk of developing dyslipidemia, insulin resistance, hyperglycaemia and MetS, suggesting potentially beneficial effects of endogenous TT on cardiovascular disease (CVD) risk factor burden (Hakimian *et al.*, 2008). But prospective studies relating sex steroids to incident CVD have yielded inconsistent results (Muller *et al.*, 2003b) and an initial trial of testosterone therapy was discontinued after it showed adverse cardiovascular events in the treatment group (Basaria *et al.*, 2010). Furthermore, the interpretation of temporality of associations is challenging based on cross-sectional data because of the possibility of reverse causality. Thus, low TT concentrations are associated with incident MetS (Haring *et al.*, 2009) or type 2 diabetes (Vikan *et al.*, 2010; Schipf *et al.*, 2011), whereas these conditions are also associated with decreased TT concentrations (Laaksonen *et al.*, 2005; Corona *et al.*, 2011). Although it has been widely observed that TT and

other sex steroids in men decline with age (Gray *et al.*, 1991; Harman *et al.*, 2001; Feldman *et al.*, 2002; Svartberg *et al.*, 2003), other contributing factors have also been proposed (Andersson *et al.*, 2007; Travison *et al.*, 2007b; Haring *et al.*, 2010a), suggesting a likely multifactorial basis for the decline in circulating TT concentrations in ageing men (Snyder, 2008).

Overall, there is a gap in our current knowledge about whether low TT serum concentrations in men are causal or the consequence of CVD. Also, the clinical correlates of longitudinal tracking of TT concentrations in men from the general population have been less well studied (Snyder, 2008). Accordingly, we examined the longitudinal profile of sex steroids and gonadotropins in older men from the Framingham Heart Study (FHS) using up to five serial hormone measurements over a 10-year follow-up period, and evaluated the clinical correlates. Specifically, we assessed both the short-term (2-year) change and the long-term (10-year) tracking for these steroid and non-steroid hormones.

Methods

Study population

The FHS is a longitudinal epidemiological study that was initiated in 1948 in Framingham, Massachusetts, to investigate risk factors for heart disease in the community. The selection criteria and study design of the original FHS cohort have been described previously (Dawber *et al.*, 1951). Written informed consent was obtained from attendees at each examination and the Institutional Review Board of the Boston University Medical Center approved the study protocol. The present study focused on men who attended at least two of the biennial examination cycles 17 (1981–1983) through 21 (1990–1992). We excluded observations with missing outcome or covariate information. We did not use information regarding testosterone therapy or hypogonadism as additional exclusion criteria as such data were not systematically collected at these examinations. Correlates of short-term change in sex steroids and gonadotropins (over any 2-year period) were investigated pooling 1165 person-observations from 528 unique participants who attended two consecutive examinations. Long-term tracking of sex steroids and gonadotropins (over the course of 10 years) was analysed in 835 unique participants (2520 person-observations) (Fig. 1).

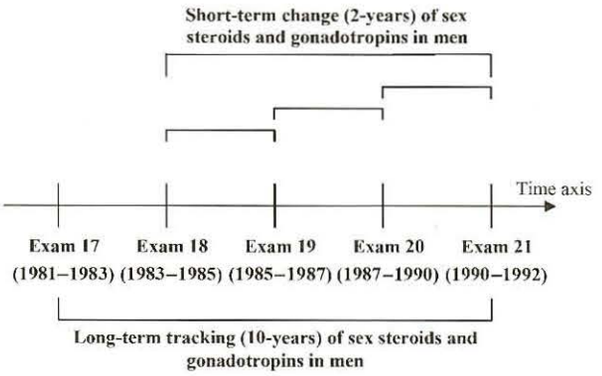

Figure 1 Study design. Short-term change in sex steroids and gonadotropins was evaluated in 528 men (1165 person-observations). Long-term tracking of sex steroids and gonadotropins was performed in 835 men who attended up to five serial examination cycles (2520 person-observations).

Laboratory measurements

Single non-fasting blood samples were obtained throughout the day from attendees at the original cohort's 17th – 21st examination cycles between May 1981 and December 1989, and the biosamples were stored at −20 °C until measurement of sex hormones and gonadotropins between October 1984 to March 1990. The maximum storage length (for only a portion of the samples) was about 5 years. Concentrations of serum TT, DHEAS, follicle stimulating hormone (FSH), luteinizing hormone (LH) and total estradiol (EST) were measured using radioimmunoassays (Diagnostic Products Corp., Los Angeles, CA, USA) in the Boston University laboratory of Dr. Sawin. The interassay coefficients of variation in the Sawin laboratory were: for TT, 11%; DHEAS, 11%; FSH, 5%; LH, 6%; and EST, 4%, as previously described (Amin *et al.*, 2000).

Clinical correlates

At each FHS examination, socio-demographic and behavioural characteristics (such as age, smoking status etc.), as well as medical history and medication use were assessed using standardized interviews. Height and weight were measured and body mass index (BMI) was calculated (kg/m^2). Blood pressure (BP) was measured twice in the left arm of the seated subject with a mercury column sphygmomanometer. The average of the two readings was used as the exam BP, and hypertension was defined as systolic BP ≥140 mmHg or a diastolic BP ≥90 mmHg or the self-reported use of antihypertensive medications. Type 2 diabetes was defined by a non-fasting glucose >200 mg/dL, or self-reported use of insulin or oral hypoglycemic medications. Plasma total cholesterol and high-density lipoprotein (HDL) cholesterol concentrations were measured using standard enzymatic methods, as previously described (McNamara & Schaefer, 1987). Pre-existing CVD was defined according to previously reported standardized FHS criteria (including coronary heart disease, cerebrovascular disease, intermittent

claudication or congestive heart failure) and confirmed with the aid of medical histories, physical examinations at the study clinic, hospitalization records and communication with personal physicians as previously described (Kannel *et al.*, 1979).

Statistical analyses

Correlates of short-term change of sex steroids and gonadotropins in men

We naturally logarithmically transformed serum DHEAS, FSH, LH and EST concentrations to normalize their distributions. Generalized Estimating Equations (GEE) were used to determine clinical correlates of short-term change in sex steroids and gonadotropins during a 2-year follow-up period (Fig. 1). In these multivariable models, we related hormone concentrations (dependent variable; each hormone considered individually) to the following clinical covariates (independent variables): age, BMI, systolic BP, antihypertensive treatment, smoking status, type 2 diabetes, total cholesterol, HDL cholesterol and pre-existing CVD. These variables were chosen based on their previously reported associations with steroid and non-steroid hormone concentrations in the literature (Travison *et al.*, 2007a; Haring *et al.*, 2010a). To account for potential temporal trends in sex steroids and gonadotropins across different examination cycles, we carefully adjusted all statistical analyses for examination cycle. Furthermore, we provided boxplots for the median sex steroid and gonadotropin concentrations over time for a reference age group of individuals aged 65–75 years at each examination cycle, indicating no large variability across the different examination cycles (Supplemental Fig. S1). Interaction terms between age and each clinical covariate were investigated using multivariable models. To analyse patterns of missingness we compared characteristics of the study sample according to the number of missing examinations (Supplemental Tables S1 and S2).

Effects are presented as regression coefficients and their corresponding 95% confidence interval (95% CI).

Correlates of long-term tracking of sex steroids and gonadotropins in men

We performed multilevel statistical modelling (SAS PROC MIXED; using an unstructured correlation matrix) to identify clinical correlates of long-term tracking of sex hormone concentrations over a 10-year period. Accommodating participants with missing data at some of the serial examinations over the 10-year follow-up period, this analytical approach allows the maximization of the available number of observations in a longitudinal study design and accounts for a hierarchical data structure that varies on the individual level. Multivariable models incorporated the same set of covariates and interaction terms as used in the short-term analyses described above. While change in covariates is captured in the long-term follow-up analysis, the short-term analysis used "baseline" covariate data and only the hormone data from the baseline and the subsequent examination cycle. For the paired 2-year data, participants had to attend consecutive examinations while for the 10-year data no such sequential follow-up was mandated (not every individual has to attend every examination), which is why the latter approach provided more person observations. We examined and detected statistically significant random age effects for DHEAS, FSH, LH and EST, and modelled age as a random and a fixed effect accordingly. We also examined non-linear age effects, by including the 'squared age' term into the regression models and assessing the *p*-value for the term. As the 'squared age' term was not statistically significant in any of the models, we did not include it in further regression modelling.

Graphical representation of long-term sex steroids in men

To illustrate the impact of an individual's risk factor burden on long-term TT concentrations, graphical displays show the adjusted (for all significant variables from the long-term analyses) mean TT concentrations with increasing age stratified by 'high' vs. 'low' risk factor burden. The covariates used to define high and low risk factor status (age, BMI, systolic BP, type 2 diabetes and smoking) were selected on the basis of their statistically significant associations with TT concentrations in the final regression model. All statistical analyses were performed using SAS statistical software (SAS Institute Inc., Cary, NC, USA), and the figures were generated using Excel (Microsoft Office 2003, Redmond, WA, USA).

Results

The baseline characteristics of our sample of older men are displayed in Table 1.

Correlates of short-term change in sex steroids and gonadotropins in men

We identified age as the main correlate of short-term change in sex steroids and gonadotropins (Table 2), inversely associated with change in log-DHEAS (β per 1 year increase in age, −0.007; 95% CI, −0.012 to −0.002) and positively associated with change in log-FSH and log-LH concentrations (β per 1 year increase in age, 0.005; 95% CI, 0.001–0.008 and 0.007; 95% CI, 0.002–0.012, respectively). BMI was inversely associated with change in TT concentrations (β per one unit increase in

Table 1 Baseline characteristics of the study population with 10-year follow-up[a]

Characteristic	
Age, years	71.2 ± 6.4
Body mass index, kg/m^2	26.6 ± 3.8
Current smoker, %	16.5
Systolic blood pressure, mmHg	141.6 ± 18.5
Diastolic blood pressure, mmHg	78.0 ± 10.0
Antihypertensive medication, %	41.2
Hypertension, %	68.4
Type 2 diabetes, %	12.7
HDL cholesterol, mg/dL	44.3 ± 13.6
Total cholesterol, mg/dL	216.6 ± 37.4
Ratio total : HDL cholesterol, mg/dL	5.3 ± 1.6
Prevalence of cardiovascular disease, %	34.3
Total testosterone, ng/mL	4.9 (3.9; 5.9)
DHEAS, mg/dL	91.2 (56.8; 137.0)
FSH, IU/L	9.0 (6.2; 13.4)
Luteinizing hormone, IU/L	8.6 (6.2; 12.0)
Total estradiol, pg/mL	30.2 (21.3; 39.2)

Data are percentages, mean ± SD, or median (Q1; Q3).
[a]Baseline characteristics are presented for the sample with the largest available data for sex steroids and gonadotropins: total testosterone, N = 834; dehydroepiandrosterone sulphate (DHEAS), N = 657, follicle stimulating hormone (FSH), N = 835, luteinizing hormone, N = 835; estradiol, N = 834. Values for these hormones are reported based on availability of each hormone.

Table 2 Directionality of correlates of short-term change and long-term tracking of sex steroids and gonadotropins in men based on multivariable analyses

Correlates	Short-term change (over any 2-year period)	Long-term tracking (complete 10-year period)
Age	↓ DHEAS, ↑ FSH, ↑ LH	↓ TT, ↓ DHEAS, ↑ LH
Body mass index	↓ TT	↓ TT
Current smoking		↑ LH
Systolic blood pressure	↑ DHEAS	↑ TT, ↑ EST
Antihypertensive medication		↑ EST
Type 2 diabetes		↓ TT
HDL cholesterol		↑ DHEAS
Pre-existing cardiovascular disease		↓ DHEAS

BMI, −0.02 ng/mL; 95% CI, −0.04 to −0.007 ng/mL) and systolic BP was positively associated with change in log-DHEAS concentrations (β per 10 mmHg increase in systolic BP, 0.02; 95% CI, 0.01–0.03).

Correlates of long-term tracking of sex steroids and gonadotropins in men

Age, BMI, smoking, systolic BP, hypertension treatment, type 2 diabetes, HDL cholesterol concentrations and pre-existing CVD were identified as significant correlates of changes in sex steroids and gonadotropins over the 10-year follow-up period (Tables 2 and 3). With regard to long-term TT concentrations, we found inverse associations with age, BMI and type 2 diabetes, and a positive association with systolic BP respectively. The interaction between age and smoking was statistically significant, indicating that the inverse effect of age on TT concentrations varies according to smoking status (smokers have a greater age-related decline in TT concentrations compared with non-smokers). Consistent with the analyses of short-term change, age was inversely associated with log-DHEAS concentrations and positively associated with log-LH concentrations in long-term analyses. Furthermore, HDL cholesterol concentrations were positively and pre-existing CVD inversely associated with log-DHEAS concentrations in long-term analyses. Other correlates and their directionality are listed in Tables 2 and 3. Finally, Fig. 2 illustrates the conjoint effect of multiple risk factors (categorized into two groups for example) on TT concentrations over the 10-year period.

Discussion

Our longitudinal study identified various clinical correlates of short-term changes and long-term tracking of sex steroids and gonadotropins in older men respectively. Analyses of short-term changes revealed age as inversely related to DHEAS, but positively related to FSH and LH concentrations. Age, BMI and type 2 diabetes were inversely related to long-term TT concentrations, whereas higher systolic BP showed a positive association. Thus, our study offers important insights into the correlates of long-term progression of sex steroids and gonadotropins in community-dwelling older men over their late adulthood.

Our study confirms previous longitudinal data reporting age as the main correlate of sex steroids and gonadotropins in men (Gray *et al.*, 1991; Morley *et al.*, 1997; Leifke *et al.*, 2000; Harman *et al.*, 2001; Muller *et al.*, 2003a; Lapauw *et al.*, 2008; Wu *et al.*, 2008; Cappola *et al.*, 2009), showing inverse associations with TT (Harman *et al.*, 2001) and DHEAS (Cappola *et al.*, 2009) concentrations, and positive associations with FSH (Morley *et al.*, 1997; Lapauw *et al.*, 2008) and LH (Morley *et al.*, 1997; Lapauw *et al.*, 2008; Wu *et al.*, 2008) concentrations. The fact that age was the only consistent correlate in our analyses of short-term changes may be explained by the

CVD, cardiovascular disease, TT, total testosterone; DHEAS, dehydroepiandrosterone sulphate; FSH, follicle-stimulating hormone; LH, luteinizing hormone; EST, total estradiol.

Any non-significant covariates were retained in the model if they contributed to a significant interaction term.

Age was centred at the mean of all participants at all exams (73 years) to reduce multicollinearity between regression coefficients.

DHEAS, EST, FSH, and LH were naturally log transformed, therefore the coefficient (coef.) indicates an e^{β}-fold change in the respective sex steroid or gonadotropin. For example: β for age (log-DHEAS) = −0.03 → $e^{-0.03}$ = 0.97 fold decrease in DHEAS concentration per year increase. TT was used untransformed, therefore a one-unit increase in body mass index resulted in a 0.04 ng/mL decrease in TT concentration.

The effect of variables that are included in statistically significant interaction terms needs to be interpreted taking into account the respective interaction terms. For example, the effect of age on TT depends on smoking status (because of the presence of the statistically significant age × smoking interaction term in the model), therefore a 1-year increase in age results in a 0.1 ng/mL decrease in TT among smokers and a 0.04 ng/mL decrease in TT among non-smokers.

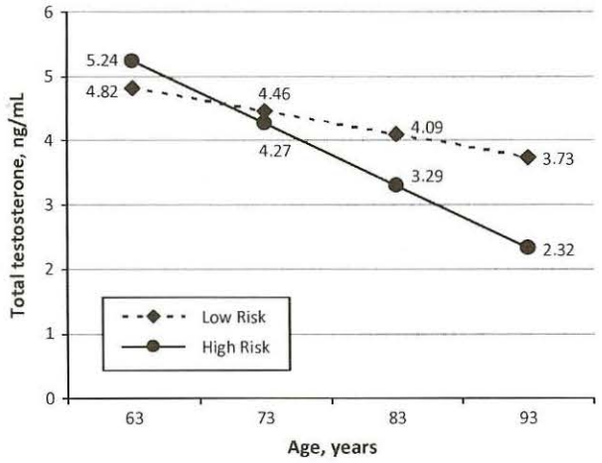

Figure 2 Adjusted mean total testosterone concentrations with increasing age. Long-term tracking of total testosterone concentrations in men with low and high CVD risk factor burden. Low risk factor burden: body mass index, 25 kg/m^2; systolic blood pressure, 130 mmHg; non-smoker; no pre-existing type 2 diabetes; high risk factor burden: body mass index, 30 kg/m^2; systolic blood pressure, 150 mmHg; smoker; pre-existing type 2 diabetes.

relatively short follow-up time of 2 years, limiting our ability to elucidate the effects of other covariates on sex steroids and gonadotropins in men. But besides ageing alone, the clinical correlates of long-term TT concentrations identified in this study are consistent with previous studies reporting visceral obesity (Derby *et al.*, 2006; Mohr *et al.*, 2006; Travison *et al.*, 2007a; Wu *et al.*, 2008), MetS (Laaksonen *et al.*, 2005; Haring *et al.*, 2010a), type 2 diabetes (Vermeulen *et al.*, 1996; Haring *et al.*, 2010a) and comorbidity (Svartberg *et al.*, 2003; Derby *et al.*, 2006; Haring *et al.*, 2010a) related to decreased TT concentrations. In contrast to previous studies reporting an inverse association between TT concentrations and BP among middle-aged men (Barrett-Connor & Khaw, 1988; Yarnell *et al.*, 1993; Torkler *et al.*, 2011), the present study is the first to report a positive association between systolic BP and TT among elderly men, whereas others did not observe any association at all (Zmuda *et al.*, 1997; Khaw *et al.*, 2007). However, these inconsistencies may relate to differences in study design, study sample, characteristics of the study population including age and underlying comorbidity or confounders adjusted for. Concerning DHEAS concentrations, a 9-year follow-up of 989 older men and women (mean age 85.2 years) from the Cardiovascular Health Study also showed that pre-existing CVD was associated with greater incident DHEAS decline (Sanders *et al.*, 2010). Furthermore, our finding of a positive association between HDL cholesterol and DHEAS concentrations in

long-term analyses was consistent with previous results from small cross-sectional studies (Haffner *et al.*, 1993; Yasui *et al.*, 2008).

Special attention belongs to our finding that BMI showed an inverse association with TT concentrations. It has been previously shown that a 4–5 kg/m^2 increase in BMI is associated with declines in TT concentrations comparable to that associated with approximately 10 years of ageing (Travison *et al.*, 2007a). Furthermore, we observed, consistent with previous longitudinal studies that pre-existing type 2 diabetes (Laaksonen *et al.*, 2005; Corona *et al.*, 2011) and pre-existing CVD (Sanders *et al.*, 2010) are associated with lower TT and DHEAS concentrations. Given the previously shown associations of low TT and DHEAS concentrations with incident type 2 diabetes (Schipf *et al.*, 2011; Vikan *et al.*, 2010) and pre-existing CVD (Barrett-Connor *et al.*, 1986) respectively, the present results provide further evidence for bidirectional influences between sex steroids and chronic diseases (Yeap, 2009).

Our reported positive associations between age and LH concentrations and also between smoking and LH concentrations confirms previous cross-sectional findings from the European Male Ageing Study among 3,220 men aged 40–79 years (Wu *et al.*, 2008) and extends them using serial longitudinal observations. As LH stimulates the Leydig cells to secrete testosterone and the quantity of testosterone secreted increases approximately in direct proportion to the amount of LH available, the effects of smoking are tightly linked for both steroid and non-steroid hormones in men (Mendelson *et al.*, 2003); which could possibly explain the observed positive associations between current smoking, LH (Wu *et al.*, 2008) and TT (Vermeulen *et al.*, 1996; Wu *et al.*, 2008).

Strengths and limitations

The strengths of the present investigation include the use of multilevel modelling in a unique community-based sample of older men with up to five serial measurements of sex steroids and gonadotropins over a 10-year period. Some important limitations also have to be mentioned. First, we used single serum samples and radioimmunoassays to measure circulating steroid and non-steroid hormone concentrations. However, because changes were related to baseline measures, the necessity of repeated testing at single time points to characterize borderline hormone concentrations does not apply to our study aims (Rosner *et al.*, 2007). Furthermore, we sought to limit artifactual changes in sex steroids and gonadotropins across serial examinations by performing measurements in one central laboratory, following the same collection protocol, and using the same laboratory assays for serum samples that were stored at −70 °C. In addition, we carefully adjusted all our analyses for "examination cycle" to account for potential measurement bias. Second, we did not measure sex-hormone binding globulin and were therefore not able to examine its correlates and interplay with the identified correlates of steroid and non-steroid hormone concentrations in men. Third, the external validity or generalizability of our findings to other populations, age groups or ethnicities is limited because of a community-based study sample of predominantly white older Caucasian men.

Conclusions

Given the accumulating evidence suggesting that low sex steroid concentrations in men may be associated with greater cardiometabolic risk, it is crucial to characterize their correlates. But the identified correlates influencing long-term steroid and non-steroid hormone concentrations in older men also constitute major cardiometabolic risk factors associated with CVD onset and progression. Thus, reverse causation might explain some of the observed associations in the literature, wherein adverse cardiometabolic risk factor profiles influence (lower) TT concentrations, which in turn may affect cardiometabolic risk factor burden. To further elucidate the potential role of low TT as a causal CVD risk factor (and the direction of causality), future research from large randomized controlled clinical trials of testosterone replacement therapy is needed. However, the present findings assert that prevention strategies should focus on health maintenance including a low cardiometabolic risk factor burden, instead of testosterone replacement therapy for improving CV health and lowering CVD risk.

Abstract

Introduction: A younger age at menarche and an older age at menopause are well established risk factors for breast cancer. Recent genome-wide association studies have identified several novel genetic loci associated with these two traits. However, the association between these loci and breast cancer risk is unknown.

Methods: In this study, we investigated 19 and 17 newly identified single nucleotide polymorphisms (SNPs) from the ReproGen Consortium that have been associated with age at menarche and age at natural menopause, respectively, and assessed their associations with breast cancer risk in 6 population-based studies among up to 3,683 breast cancer cases and 34,174 controls in white women of European ancestry. In addition, we used these SNPs to calculate genetic risk scores (GRSs) based on their associations with each trait.

Results: After adjusting for age and potential population stratification, two age at menarche associated SNPs (rs1079866 and rs7821178) and one age at natural menopause associated SNP (rs2517388) were associated with breast cancer risk (p values, 0.003, 0.009 and 0.023, respectively). The odds ratios for breast cancer corresponding to per-risk-allele were 1.14 (95% CI, 1.05 to 1.24), 1.08 (95% CI, 1.02 to 1.15) and 1.10 (95% CI, 1.01 to 1.20), respectively, and were in the direction predicted by their associations with age at menarche or age at natural menopause. These associations did not appear to be attenuated by further controlling for self-reported age at menarche, age at natural menopause, or known breast cancer susceptibility loci. Although we did not observe a statistically significant association between any GRS for reproductive aging and breast cancer risk, the 4th and 5th highest quintiles of the younger age at menarche GRS had odds ratios of 1.14 (95% CI, 1.01 to 1.28) and 1.13 (95% CI, 1.00 to 1.27), respectively, compared to the lowest quintile.

Conclusions: Our study suggests that three genetic variants, independent of their associations with age at menarche or age at natural menopause, were associated with breast cancer risk and may contribute modestly to breast cancer risk prediction; however, the combination of the 19 age at menarche or the 17 age at natural menopause associated SNPs did not appear to be useful for identifying a high risk subgroup for breast cancer.

Introduction

A younger age at menarche and an older age at menopause are well-established risk factors for the development of breast cancer [1]. In the general population, the risk of breast cancer decreases by 10% for each 2-year delay in menarche [2] but increases by 3% for each year that menopause is delayed [3]. These associations are consistent with the hypothesis that breast cancer risk is related to the extent of steroid hormone exposure during a woman's reproductive years, which drives breast mitotic activity and determines the probability of tumorigenic somatic events [4].

Recently, genome-wide association studies (GWAS) have identified several new common genetic loci

Full list of author information is available at the end of the article

associated with either age at menarche or age at natural menopause. Four independent GWAS of age at menarche have identified two novel loci at *LIN28B* and 9q31.2 [5-8], and two GWAS of age at natural menopause have identified four novel loci on chromosomes 5, 6, 19, and 20 [5,9]. Most recently, the ReproGen Consortium, which consisted of these initial GWASs and many additional studies, has conducted expanded meta-analyses for age at menarche [10] and age at natural menopause [11] and reported more new loci identified for each trait. Given the well-established associations of age at menarche and age at natural menopause with breast cancer risk, we set out to assess whether these common genetic loci influence breast cancer risk and whether a genetic risk score (GRS) for these reproductive events might be useful for identifying a high-risk subgroup for breast cancer. Furthermore, since the reproductive risk factors have been observed to be differentially associated with breast cancer by tumor histological subtypes [12-16], we assessed these genetic associations by tumor histological subtypes defined by estrogen receptor (ER) status.

We therefore conducted a meta-analysis of six population-based studies to investigate the association between genetic loci associated with age at menarche or age at natural menopause and breast cancer risk. We assessed 19 and 17 single-nucleotide polymorphisms (SNPs) that have been previously reported to be linked to age at menarche [10] and age at natural menopause [11], respectively, among up to 3,683 breast cancer cases and 34,174 controls in women of European ancestry and evaluated whether these SNPs were differentially associated with breast cancer subtypes defined by ER status in two studies in which such data were available.

Materials and methods

Study population

The ReproGen Consortium was formed by more than 30 studies in the US and Europe to investigate the genetics of reproductive aging traits [10,11]. Our analysis used data from six population-based studies from the ReproGen Consortium: the Nurses' Health Study (NHS), the Women's Genome Health Study (WGHS), the SardiNIA Breast Cancer Study (SardiNIA), the Rotterdam Study I and II (RSI+II), the Framingham Heart Study (FHS), and the Atherosclerosis Risk in Communities Study (ARIC). Each study had at least 200 breast cancer cases. Four studies were prospective cohort studies, one was a nested case-control study, and one was a case-control study. A description of the six studies is provided in Table 1, and more information is given in Additional file 1. Briefly, breast cancer cases occurring in defined populations during specific periods of time were identified by structured questionnaires, medical records, or linkage with a nationwide registry of cancer or death index or both. By the time we conducted this study, the majority of the women in these studies had passed through menopause. As most of the participants in these studies were European whites, we restricted analyses to women of European ancestry. We excluded subjects with missing information on age. Two studies (NHS and WGHS) provided information on the ER status of the breast tumors for a subset of the cases. This information was extracted from medical records. Each study was approved by the relevant local institutional review boards.

Genotype data

We analyzed genotypes for 19 and 17 independent SNPs with reported associations with age at menarche and age at natural menopause, respectively, in the ReproGen Consortium, in which all SNPs achieved genome-wide significance in the meta-analysis of each trait (combined stage 1 and replication P value of less than 1×10^{-8}) [10,11]. None of these SNPs has been reported to be associated with breast cancer risk in previous GWAS and this is likely because of the very stringent P value threshold used to declare genome-wide significance (usually, P values were less than at least 1×10^{-7}). As positive controls, 10 SNPs with consistently reported

associations with breast cancer as shown in recent GWAS were included [17-19]. All 46 SNPs are listed in Table S1 of Additional file 2. Genotypes used in this analysis have been previously described [10,11]. Complete genotype data from a total of up to 3,683 cases and 34,174 control subjects were available for analysis after the exclusions described in the 'Study population' section.

Breast cancer risk factors

The six studies from the ReproGen Consortium provided information on one or more of the following risk factors for breast cancer: age (continuous, at study entry or diagnosis), age at menarche (continuous, between 9 and 17 years), age at natural menopause (continuous, between 40 and 60 years), age at first live birth (less than 20, 20 to 24, 25 to 29 or no birth, at least 30 years), family history of breast cancer in first-degree relatives (yes/no), alcohol consumption (less than 5, 5 to 15, 15 to 30, at least 30 g/day), parity (0, 1 to 2, at least 3), menopausal hormone therapy (ever/never), oral contraceptive (OC) use (ever/never), and adult body mass index (BMI) (continuous).

Genetic risk score computation

The GRS was calculated on the basis of the 19 and 17 independent SNPs identified in previous studies as being associated with age at menarche and age at natural menopause, respectively [10,11]. As a younger age at menarche and an older age at menopause are independently associated with an elevated breast cancer risk, we computed separate GRSs for a younger age at menarche and an older age at natural menopause. The risk allele was defined as an allele that was associated with a younger age at menarche or an older age at natural menopause. Two methods were used to determine the GRS: a simple count method (count GRS) and a weighted method (weighted GRS). We assumed an additive genetic model for each SNP, applying a linear weighting of 0, 1, or 2 to genotypes containing 0, 1, or 2 risk alleles, respectively. The count method assumes that each SNP contributes equally to the risk of breast cancer. The count GRS was calculated by simply summing the number of risk alleles of each SNP. For the weighted GRS, each SNP was weighted by β-coefficients obtained from the replication studies of recent meta-analyses of two traits [10,11]. The weighted GRS was calculated by multiplying each β-coefficient by the number of corresponding risk alleles (0, 1, or 2) and then summing the products. To simplify interpretation and facilitate comparison with the count GRS, the weighted GRS was further divided by twice the sum of the β-coefficients and then multiplied by the total number of risk alleles. To provide a positive control and also to control for potential confounding by known breast cancer-associated genetic variants, a count GRS was computed on the basis of the 10 SNPs with consistently reported associations with breast cancer [19]: rs2981582, rs3803662, rs11249433, rs7716600, rs13387042, rs889312, rs13281615, rs999737, rs3817198, and rs1045485.

Statistical analysis

In each of the six studies, we performed logistic regression to evaluate the association with breast cancer for each of the 46 candidate SNPs, assuming an additive genetic model. Logistic regression was also used to analyze the association between GRS and breast cancer by including both GRSs for age at menarche and age at natural menopause in the model as the main effects. The GRSs were modeled as continuous variables or categorized into quintiles, and the cutoff points for quintiles were based on the WGHS population, which is the largest prospective cohort population among all participating studies. This approach was applied to each of the six participating studies. Odds ratios (ORs) and 95% confidence intervals (CIs) were estimated from logistic regression. To control for potential confounding by population stratification, we adjusted for the top principal components of genetic variation chosen for each study. We adjusted for age in the main model. To examine whether the genetic association of each of the candidate SNPs or GRSs with breast cancer is mediated through the onset of menarche or natural menopause, we then adjusted for self-reported age at menarche and age at natural menopause in the main model. Other conventional risk factors for breast cancer - including age at first live birth, family history of breast cancer in first-degree relatives, alcohol consumption, parity, menopausal hormone therapy, OC use, and adult BMI - were further included in the model to control for potential confounding in studies which had such data available. To examine whether these genetic associations differ by breast cancer subtypes, in each of the two studies that provided information on ER status, we then investigated the genetic association of each of the candidate SNPs or GRSs with breast cancer in subgroup analysis by ER histological status (positive or negative).

Forest plots were used to present study-specific ORs and 95% CIs. We then performed meta-analyses by using the fixed-effects model to estimate summary ORs from study-specific estimatesthat were weighted by the inverse of the variance of each study. As the meta-analyses restricted to prospective cohort studies or case-control studies yielded similar results, we present results from only the meta-analysis of all six participating studies. We also tested the heterogeneity of associations across studies as well as across different tumor subtypes by using the Q test [20].

All statistical analyses were performed by using SAS version 9.1 software (SAS Institute Inc., Cary, NC, USA). Power calculations were carried out by using Quanto (University of Southern California, Los Angeles, CA, USA). All *P* values were based on two-sided tests and were considered statistically significant if less than 0.05. Because SNPs were selected on the basis of an *a priori* hypothesis, adjustments for multiple comparison tests were not performed.

Results

The six participating studies contributed 3,683 breast cancer cases and 34,174 controls of self-reported white women of European ancestry (Table 1), all with available data on age and the 46 candidate SNPs, and at least one of the conventional risk factors considered. Of the 3,683 cases, about 52% were from the four prospective cohort studies (WGHS, RSI+II, FHS, and ARIC), about 30% were from the nested case-control study in NHS, and about 18% were from the population-based case-control study in SardiNIA. ER status was known for 2,087 cases in the NHS and the WGHS. On average, compared with the controls, the cases had a younger age at menarche and an older age at natural menopause. The expected associations with breast cancer were generally observed for the conventional risk factors across all of the studies (Table S2 of Additional file 3). The associations of the 46 candidate SNPs with age at menarche or age at natural menopause in the six studies were consistent with the original findings from the two meta-analyses [10,11].

Table 2 shows the risk allele frequency and the corresponding per-risk-allele OR of breast cancer for each of the 46 candidate SNPs. The results are arranged in order of the strength of statistical significance (*P* value). The allele frequency for each SNP in the controls was similar to those reported for populations of European descent [21-23]. After adjusting for age and potential population stratification, we found that, among the 19 candidate SNPs for a younger age at menarche, two SNPs, rs1079866 and rs7821178, were significantly associated with breast cancer risk and had corresponding per-risk-allele ORs of 1.14 (96% CI = 1.05 to 1.24; *P* value = 0.003; *P* for heterogeneity = 0.37) and 1.08 (95% CI = 1.02 to 1.15; *P* value = 0.009; *P* for heterogeneity = 0.43), respectively. The SNP rs1079866 is located about 250 kb away from the *INHBA* gene on chromosome 7, whereas SNP rs7821178 is about 181 kb away from the *PXMP3* gene (also known as *PEX3*) on chromosome 8. The strongest GWAS hit for age at menarche, rs7759938 at *LIN28B* on chromosome 6, was not found to be associated with breast cancer risk (*P* value = 0.60). Of the 17 candidate SNPs associated with an older age at natural menopause, one SNP, rs2517388, was significantly associated with breast cancer risk with a per-risk-allele OR of 1.10 (95% CI = 1.01 to 1.20; *P* value = 0.023; *P* for heterogeneity = 0.08). This SNP is an intronic SNP in the *ASH2L* gene on chromosome 8. The study-specific and summary ORs for the three associated SNPs are shown in Figure 1. Further adjustment for conventional risk factors - including age at menarche, age at natural menopause, age at first live birth, family history of breast cancer in first-degree relatives, alcohol consumption, parity, menopausal hormone therapy, OC use, and adult BMI - did not change the results substantially. For candidate loci for age at menarche and age at natural menopause, the findings did not differ materially when we further adjusted for known breast cancer-associated SNPs.

To evaluate the combined effect of candidate SNPs on breast cancer risk, we calculated a GRS for each trait by using either a count GRS or a weighted GRS approach. The mean values of count and weighted GRSs were 20.41 and 20.03, respectively, for age at menarche and 16.21 and 14.32, respectively, for age at natural menopause (Table 3). Based on the count GRS for a younger age at menarche, the OR for breast cancer associated with each point scored, corresponding to 1 risk allele, was 1.01 (95% CI = 1.00 to 1.03) after age and potential population stratification were adjusted for. ORs did not increase linearly across quintiles of GRS for age at menarche (*P* for trend = 0.06). Compared with women in the lowest quintile, women in the fourth and fifth quintiles had ORs for breast cancer of 1.14 (95% CI = 1.01 to 1.28) and 1.13 (95% CI = 1.00 to 1.27), respectively. Results were similar when analyses were performed by using weighted GRS. Overall, we did not observe statistically significant associations between breast cancer risk and age at natural menopause when either count or weighted GRS was used.

In secondary analyses, we then determined whether the associations of the 46 candidate SNPs with breast cancer vary across tumor subtypes defined by ER status in the NHS and the WGHS (Table 4). For the two SNPs (rs1079866 and rs7821178) that had reported associations with age at menarche and that were associated with overall breast cancer risk, we found no statistically significant evidence that the associations differed across subtypes (*P* for heterogeneity = 0.31 and 0.66, respectively), although rs1079866 appeared to have a stronger association with ER^+ tumors (per-allele OR = 1.26; 95% CI = 1.12 to 1.41) than with ER^- tumors (per-allele OR = 1.11; 95% CI = 0.89 to 1.38). Of note, one SNP that had a reported association with age at menarche, rs17188434, had a significantly stronger association with ER^- tumors (per-allele OR = 1.51; 95% CI = 1.15 to 1.98) than with ER^+ tumors (per-allele OR = 1.08; 95% CI = 0.92 to 1.26; *P* for heterogeneity = 0.035). Another SNP that had a reported association with age at

[a]Nearest gene(s); [b]the risk allele refers to the allele associated with a younger age at menarche, an older age at natural menopause, or an increased risk of breast cancer; [c]effect allele frequency; [d]effect allele frequency in case or control subjects, respectively; [e]per effect allele change in log odds ratio (OR) of breast cancer; [f]*P* value from meta-analysis with additive genetic coding after adjustment for age and top genetic principle components; [g]direction of effect allele association with breast cancer in the six studies in order: Nurses' Health Study, Women's Genome Health Study, SardiNIA Breast Cancer Study, Rotterdam Study I and II, Framingham Heart Study, and Atherosclerosis Risk in Communities Study; [h]*P* value from heterogeneity test across studies with 5 degrees of freedom. CI, confidence interval; SE, standard error; SNP, single-nucleotide polymorphism.

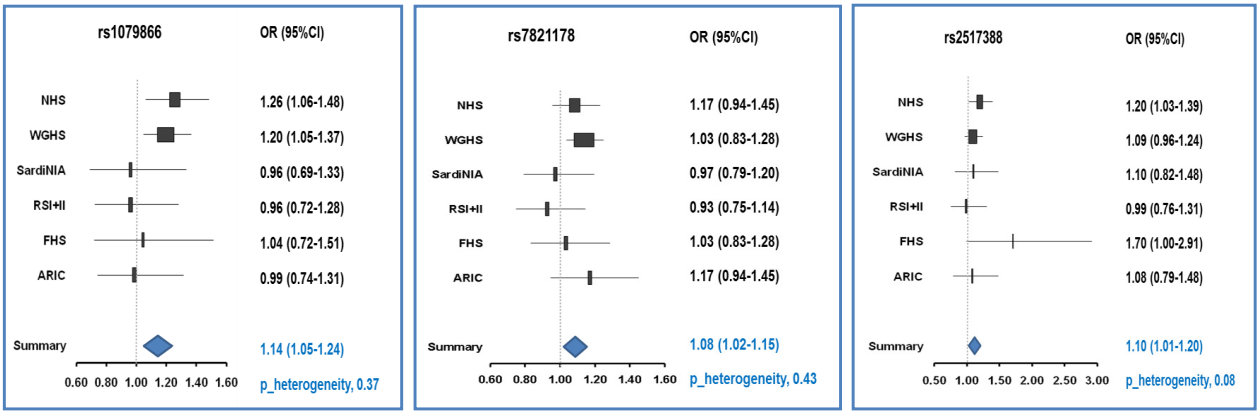

Figure 1 Forest plots for the three candidate loci (rs1079866, rs7821178, and rs2517388) in association with breast cancer risk. Per-risk-allele odds ratios (ORs) and 95% confidence intervals (CIs) were obtained from unconditional logistic regression in each study, and age and potential population stratification were adjusted for. The size of the box is inversely proportional to the standard error of the log OR estimate. *P* values for heterogeneity across studies are 0.37, 0.43, and 0.08, respectively. ARIC, Atherosclerosis Risk in Communities Study; FHS, Framingham Heart Study; NHS, Nurses' Health Study; RSI+II, Rotterdam Study I, II; SardiNIA, SardiNIA Breast Cancer Study; WGHS, Women's Genome Health Study.

Table 3 Association between genetic risk score and risk of breast cancer

[a]Per-risk-allele odds ratio (OR) of breast cancer; [b]*P* value from meta-analysis of the Nurses' Health Study (NHS) and the Women's Genome Health Study (WGHS) with additive genetic coding after adjustment for age and potential population stratification; [c]*P* value from heterogeneity test across estrogen receptor-positive (ER^+) and ER^- tumors; [d]total number of cases or controls in the NHS and the WGHS. CI, confidence interval; SNP, single-nucleotide polymorphism.

menarche, rs17268785, was associated with a decreased risk of ER^- tumors (per-allele OR = 0.83; 95% CI = 0.68 to 1.00) but an increased risk of ER^+ tumors (per-allele OR = 1.07; 95% CI = 0.96 to 1.19; *P* for heterogeneity = 0.023). For the SNP that had a reported association with age at natural menopause and that was associated with overall breast cancer risk, we observed a stronger association with ER^- tumors (per-allele OR = 1.32; 95% CI = 1.09 to 1.61) than ER^+ tumors (per-allele OR = 1.11; 95% CI = 1.00 to 1.24); however, the test for heterogeneity was not statistically significant (*P* for heterogeneity = 0.12). When the count GRS for age at menarche or age at natural menopause was applied to ER^+ and ER^- breast cancer separately, the trend in the OR for ER^+ tumors was very similar to that for overall breast cancer. The ER^- tumor data suggested a somewhat different pattern, although the statistical power was limited for this subtype (Figure 2).

Of the 10 candidate SNPs with consistently reported associations with breast cancer risk, five SNPs (rs11249433, rs3803662, rs2981582, rs13387042, and rs999737) appeared to have a stronger association with ER^+ tumor than ER^- tumors, and rs3803662 reached statistical significance (*P* for heterogeneity = 0.008) with per-risk-allele ORs of 1.26 (95% CI = 1.16 to 1.37) and 0.98 (95% CI = 0.82 to 1.16) for ER^+ and ER^- tumors,

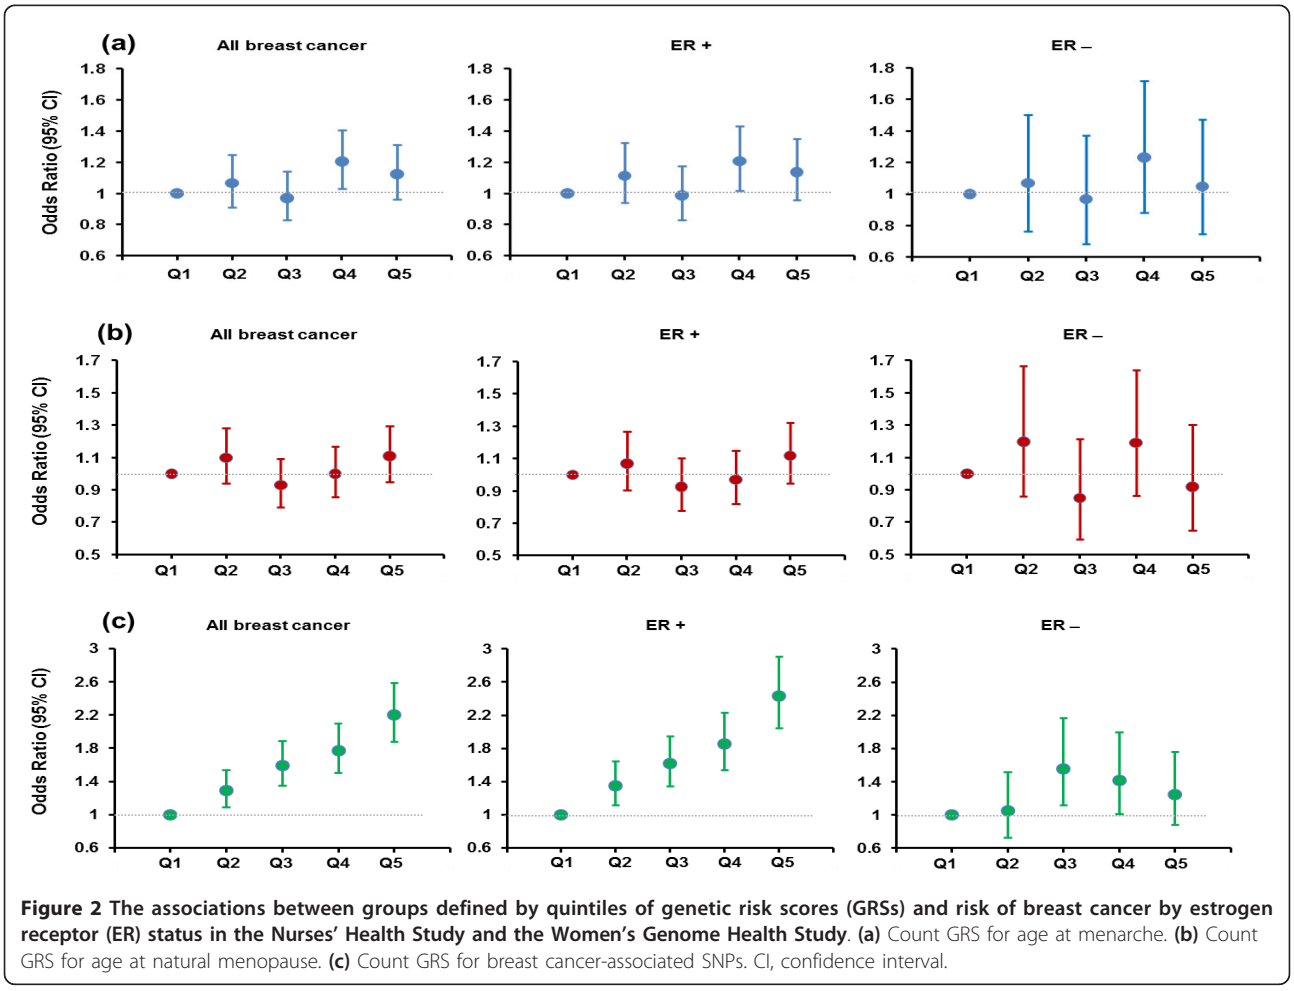

Figure 2 The associations between groups defined by quintiles of genetic risk scores (GRSs) and risk of breast cancer by estrogen receptor (ER) status in the Nurses' Health Study and the Women's Genome Health Study. **(a)** Count GRS for age at menarche. **(b)** Count GRS for age at natural menopause. **(c)** Count GRS for breast cancer-associated SNPs. CI, confidence interval.

respectively (Table 4). Two breast cancer candidate SNPs, rs1045485 and rs3817198, did not show statistically significant associations with overall risk. However, rs1045485 appeared to have a stronger association with ER^- tumors (per-allele OR = 1.20; 95% CI = 0.95 to 1.52) than ER^+ tumors (per-allele OR = 1.06; 95% CI = 0.95 to 1.19; *P* for heterogeneity = 0.35), and rs3817198 was associated with a decreased risk of ER^- tumors (per-allele OR = 0.88; 95% CI = 0.74 to 1.04) but an increased risk of ER^+ tumors (per-allele OR = 1.06; 95% CI = 0.98 to 1.15; *P* for heterogeneity = 0.047).

In these analyses, we further confirmed statistically significant associations with breast cancer risk for 8 of the 10 candidate SNPs that were identified previously in published GWAS of breast cancer (most *P* values were less than 0.001) (Table 2). We did not observe a statistically significant association for either *LSP1*-rs3817198 or *CASP8*-rs1045485 (both with *P* values of 0.13) in our study, although the direction of the associations was consistent with that of previous reports [21,22]. We also calculated, as a positive control, a count GRS based on these 10 SNPs. We found that each score point increase, corresponding to one-risk-allele increase, was significantly associated with an OR of 1.13 (95% CI = 1.11 to 1.15) for breast cancer (Table 3). Compared with women in the lowest quintile, women in the highest quintile had an OR for breast cancer of 1.89 (95% CI = 1.67 to 2.14). For this GRS, the trend in log odds was significantly steeper for ER^+ than for ER^- tumors (*P* for heterogeneity < 0.001), and the OR across quintiles was no longer monotonic in ER^- tumors (Figure 2).

Discussion

In this large meta-analysis of six population-based studies, we investigated whether 19 loci linked with age at menarche and 17 loci linked with age at natural menopause were associated with breast cancer risk among up to 3,683 breast cancer cases and 34,174 controls. We found that two SNPs with reported associations with age at menarche and one SNP with a reported association with age at natural menopause were significantly associated with breast cancer risk. However, no statistically significant associations were found for GRSs that combined all 19 or 17 loci associated with each trait, although the association for age-at-menarche GRS was marginally statistically significant. We confirmed most of the candidate loci for breast cancer which were identified in previous GWAS. Some of these associations appeared to differ by tumor subtypes defined by ER status.

In our analyses, most of the candidate SNPs, including the strongest GWAS hit for age at menarche or age at natural menopause, were not found to be associated with breast cancer risk. This is not necessarily surprising given that age at menarche and age at natural menopause are relatively weak risk factors [2,3], and all candidate SNPs collectively explain only a small portion of the variation of each trait [10,11]. However, two candidate SNPs for age at menarche, rs1079866 and rs7821178, and one candidate SNP for age at natural menopause, rs2517388, were found to be associated with breast cancer risk. These associations were not attenuated after we further adjusted for self-reported age at menarche and age at natural menopause, suggesting these three genetic loci were associated with breast cancer risk independently of their associations with age at menarche or age at natural menopause. It is possible that these genetic loci have pleiotropic effects on reproductive timing as well as other biological processes leading to breast cancer, and the observed associations might be due largely to other biological consequences of these risk variants that do not manifest themselves as changes in age at menarche or age at natural menopause. Alternatively, it is also possible that the relatively crude assignment of these reproductive events to a single chronological year is not sufficiently accurate to capture the biological effect of these processes on breast cancer risk and the genetic variants contribute independent information on the underlying biological risk. The three candidate SNPs also contributed to breast cancer risk independently of the known susceptibility loci for breast cancer, as further adjustment for breast cancer loci did not materially alter the results.

We found statistically significant evidence of association with breast cancer for eight of the 10 breast cancer susceptibility loci examined: *FGFR2*-rs2981582, *TNRC9*-rs3803662, 1p-rs11249433, 5p-rs7716600, 2q35-rs13387042, *MAP3K1*-rs889312, 8q24-rs13281615, and *RAD51L1*- rs999737. The direction and magnitude of these associations were consistent with those of previous reports [17,18,22-25]. We did not observe a statistically significant association for either *LSP1*-rs3817198 or *CASP8*-rs1045485. However, these two SNPs had relatively small reported effects that our study might not have been able to detect. When the 10 candidate SNPs were combined by using a polygenic risk score, the relative risk for women in the highest quintile was about twice that in the lowest quintile, and this is in accordance with other published results [19,26]. In this study, none of the 10 breast cancer susceptibility loci was significantly associated with age at menarche or age at natural menopause, and this is in line with a previous report [27].

Given that most of the candidate loci for age at menarche and age at natural menopause were not associated with breast cancer risk, it is not surprising that there were no statistically significant associations for the polygenetic risk scores that combined all candidate loci

for each trait. To conduct a *post hoc* and exploratory analysis, we created a polygenetic risk score by including only the three candidate loci associated with either age at menarche or age at natural menopause and with breast cancer risk and found that each risk allele increment was associated with an approximately 17% increased risk for breast cancer. Women with four or more risk alleles had an approximately 60% increased risk for breast cancer in comparison with those with two risk alleles or less. When we further combined the three associated SNPs with the 10 breast cancer susceptibility loci to create a polygenetic risk score, each risk allele increment was associated with an approximately 18% increased risk for breast cancer. For women with 14 or more risk alleles (the highest quintile), the risk for breast cancer increased threefold in comparison with those with 10 or less (the lowest quintile). Because the former group constitutes approximately 20% of the study population, the GRS that combines the three candidate SNPs for age at menarche and age at natural menopause and the identified breast cancer susceptibility loci might be useful for identifying a subgroup of women with a high genetic risk for breast cancer. Further research is needed to confirm this finding.

It has been hypothesized that the risk of ER^+ breast cancer is positively associated with a woman's cumulative lifetime exposure to endogenous ovarian hormones [28]. A younger age at menarche [12,15,29] and an older age at menopause [30] have been observed to be more consistently associated with ER^+ than ER^- tumors. In this report, we found that candidate loci for age at menarche and age at natural menopause may also be differentially associated with tumor subtypes defined by ER status. Of the three candidate loci that were found to be associated with overall breast cancer risk, rs1079866 was more strongly associated with ER^+ tumors, rs7821178 was equally associated with both, whereas rs2517388 was more strongly associated with ER^- tumors, although differences were not statistically significant. Importantly, two candidate loci for age at menarche, rs17188434 and rs17268785, had significantly different associations with ER^+ and ER^- tumors. Whereas both SNPs were not significantly associated with overall and ER^+ breast cancer, the former showed a statistically significant positive association with ER^- tumors, whereas the latter showed a statistically significant inverse association with ER^- tumor. These findings provide further support for the notion that ER^+ and ER^- tumors are the result of different etiologic pathways [31].

Although common genetic variants that influence the intermediate phenotypes or risk factors have been hypothesized to subsequently affect disease risk, few studies have assessed the association between these genetic variants and disease risk or, furthermore, whether these associations are mediated through the intermediate phenotypes. Chen and colleagues [32] investigated obesity-linked genetic variants in relation to breast cancer risk but found no statistically significant association. To our knowledge, ours is the first study to evaluate the associations of candidate loci for age at menarche and age at natural menopause with breast cancer risk. One of the strengths of our study is the relatively large combined sample size achieved through international collaboration. We had adequate statistical power (80%) to detect an OR of 1.12 for SNPs with a minor allele frequency (MAF) of 0.10 and an OR of 1.09 for SNPs with an MAF of 0.20. However, our analysis of ER^+ tumors was less adequately powered, as the ER status was not available for all cases, and the study had limited statistical power for ER^- tumors. One limitation in our study is the multiple comparisons that could lead to false-positive results. Although none of the candidate SNPs with a reported association with age at menarche or age at natural menopause survived Bonferroni correction in the test of breast cancer association, this correction is considered to be overly conservative given that the candidates were chosen on the basis of promising hypotheses. Another potential limitation of our study comes from differences in the study population and designs and methods of collecting risk factors and genetic marker data across studies. However, the findings were generally consistent across studies, arguing for the robustness of our results. Finally, as our analyses were restricted to women of European ancestry, results from this study may not be generalizable to other ethnic groups.

Conclusions

In summary, in this large analysis of the association of several novel candidate loci for age at menarche and age at natural menopause with breast cancer risk, we observed that three loci - two for age at menarche and one for age at natural menopause - were significantly associated with breast cancer risk independently of their associations with each trait and independently of known breast cancer susceptibility loci. These associations may differ by tumor subtypes defined by ER status. A combination of all 19 loci associated with age at menarche or 17 loci associated with age at natural menopause did not appear to be helpful for identifying a high-risk subgroup for breast cancer.

Acknowledgements

The NHS breast cancer GWAS scan was performed as part of the Cancer Genetic Markers of Susceptibility initiative of the National Cancer Institute (NCI). We particularly acknowledge the contributions of Robert Hoover, Amy Hutchinson, Kevin Jacobs, and Gilles Thomas. The present research is supported by CA 40356 and U01-CA98233 from the NCI. We acknowledge the study participants in the NHS for their contribution in making this study possible. The WGHS is supported by HL 043851 and HL69757 from the National Heart, Lung, and Blood Institute (NHLBI) and CA 047988 from the NCI, the Donald W Reynolds Foundation, and the Fondation Leducq, and collaborative scientific support and funding for genotyping were provided by Amgen (Thousand Oaks, CA, USA). We thank Joseph Miletich and Alex Parker and the technical staff at Amgen for their collaboration and scientific support in performing the genotyping for the WGHS. The SardiNIA Breast Cancer Study was funded by National Institutes of Health (NIH) contract NO1-AG-1-2109 from the National Institute of Aging (NIA) to the SardiNIA team (principal investigator: Manuela Uda). We thank Grazia Palomba, Antonio Cossu, Francesco Tanda, Mario Budroni, and the other members of the Sardinian Translational Oncology Group for their contribution in collecting Sardinian patients with breast cancer. The generation and management of GWAS genotype data for the Rotterdam Study are supported by The Netherlands Organisation for Scientific Research (NWO) Investments (175.010.2005.011 and 911-03-012). This study is funded by the Research Institute for Diseases in the Elderly (RIDE2) (014-93-015) and The Netherlands Genomics Initiative/NWO project 050-060-810. We thank Pascal Arp, Mila Jhamai, Marijn Verkerk, Lizbeth Herrera, and Marjolein Peters for their help in creating the GWAS database and Karol Estrada and Maksim V Struchalin for their support in creation and analysis of imputed data. The Rotterdam Study is funded by the Erasmus Medical Center and Erasmus University, Rotterdam; the Netherlands Organisation for Health Research and Development (ZonMw); the Research Institute for Diseases in the Elderly (RIDE); the Ministry of Education, Culture and Science; the Ministry for Health, Welfare and Sports; the European Commission (DG XII); and the Municipality of Rotterdam. The authors are grateful to the study participants, the staff from the Rotterdam Study, and the participating general practitioners and pharmacists. The authors acknowledge the essential role of the Cohorts for Heart and Aging Research in Genome Epidemiology (CHARGE) Consortium in the development and support of this manuscript. CHARGE members consist of The Netherlands' Rotterdam Study, the FHS, the Cardiovascular Health Study, the NHLBI's ARIC study, and the NIA's Iceland Age, Gene/Environment Susceptibility (AGES) study. The FHS phenotype-genotype analyses were supported in part by the NIA (Genetics of Reproductive Life Period and Health Outcomes, R21AG032598; JMM, KLL). The FHS of the NHLBI of the NIH and Boston University School of Medicine was supported by NHLBI's FHS contract N01-HC-25195 and its contract with Affymetrix, Inc. (Santa Clara, CA, USA) for genotyping services (contract N02-HL-6-4278). Analyses reflect intellectual input and resource development from the FHS investigators participating in the SNP Health Association Resource (SHARe) project. A portion of this research was conducted by using the Linux Cluster for Genetic Analysis (LinGA-II) funded by the Robert Dawson Evans Endowment of the Department of Medicine at Boston University School of Medicine and Boston Medical Center. The ARIC study is carried out as a collaborative study supported by NHLBI contracts N01-HC-55015, N01-HC-55016, N01-HC-55018, N01-HC-55019, N01-HC-55020, N01-HC-55021, N01-HC-55022, R01HL087641, R01HL59367, R01HL086694, and RC2 HL102419; National Human Genome Research Institute contract U01HG004402; and NIH contract HHSN268200625226C. The authors thank the staff and participants of the ARIC study for their important contributions. Infrastructure was partly supported by grant UL1RR025005, a component of the NIH, and NIH Roadmap for Medical Research.

Risk of Community-Acquired Pneumonia in Veteran Patients to Whom Proton Pump Inhibitors Were Dispensed

John A. Hermos,[1,2] Melissa M. Young,[1] Jennifer R. Fonda,[1] David R. Gagnon,[1,3] Louis D. Fiore,[1,2] and Elizabeth V. Lawler[1,4]

[1]Pharmaco-epidemiology Group, Massachusetts Veterans Epidemiology Research and Information Center, VA Cooperative Studies Program, VA Boston Healthcare System; [2]Department of Medicine, Boston University School of Medicine; [3]Department of Biostatistics, Boston University School of Public Health; and [4]Department of Medicine, Harvard Medical School, Boston, Massachusetts

Background. Observational studies linking proton pump inhibitor (PPI) exposure with community-acquired pneumonia (CAP) have reported either modest or no associations. Accordingly, we studied PPI exposure and CAP in veteran patients, using a retrospective, nested case-control design.

Methods. From linked pharmacy and administrative databases of the New England Veterans Healthcare System, we identified 71 985 outpatients newly prescribed PPIs between 1998 and 2007; 1544 patients met criteria for CAP subsequent to PPI initiation; 15 440 controls were matched through risk-set sampling by age and time under observation. Crude and adjusted odds ratios comparing *current* with *past* PPI exposures, as well as tests for interactions, were conducted for the entire and stratified samples.

Results. Current PPI use associated with CAP (adjusted odds ratio [OR], 1.29 [95% confidence interval {CI}, 1.15–1.45]). Risks were not substantially altered by age or year of diagnosis. Dementia (n = 85; $P = .062$ for interaction) and sedative/tranquilizer use (n = 224; $P = .049$ for interaction) were likely effect modifiers increasing a PPI-CAP association; conversely, for some chronic medical conditions, PPI-associated CAP risks were reversed. PPI exposures between 1 and 15 days increased CAP risks, compared with longer exposures, but PPI initiation also frequently occurred shortly after CAP diagnoses. Prescribed PPI doses >1 dose/day also increased PPI-associated CAP risks.

Conclusions. Among the veterans studied, current compared with past PPI exposures associated modestly with increased risks of CAP. However, our observations that recent treatment initiation and higher PPI doses were associated with greater risks, and the inconsistent PPI-CAP associations between patient subgroups, indicate that further inquiries are needed to separate out coincidental patterns of associations.

Community-acquired pneumonia (CAP) is a common cause of morbidity and mortality, particularly among elderly individuals and those with medical comorbidities [1–3]. Gastric acid suppression is purported to provide a mechanism for increasing risks for CAP by facilitating bacterial colonization of the stomach and upper intestine, potentially leading to colonization of the upper aerodigestive tract with pathogens [4–7]. Among current gastric acid suppressants, proton pump inhibitors (PPIs) provide the most potent and effective management of peptic ulcers, gastroesophageal reflux, and other acid-peptic–related diseases [8, 9]. PPIs have few overt side effects but are often initiated and continued without proven indications [10–13].

Results from retrospective, observational studies within the past decade have been inconclusive regarding the possible association of PPI exposure with CAP [14–19]. Community-based studies from the Netherlands [14], Denmark [15], and Great Britain [16] reported an increased CAP risk of 50%–75% for patients currently prescribed PPIs. Conversely, 3 studies from Great Britain [17] and the United States [18, 19] failed to show such an association. Two meta-analyses of short-term, prospective PPI trials showed no association of PPI use with respiratory infections [20, 21], but recent studies have demonstrated increased risks of recurrent CAP [22] and hospital-acquired pneumonia [23] with

PPI exposures. Thus, evidence linking PPI exposure to CAP and to other respiratory infections remains unsettled.

We have tested the association of PPI use and CAP in a population of US military veterans in a retrospective, nested case-control design. Our objectives were to determine whether current exposure to PPIs increased risks for CAP and whether the duration of current PPI exposure and PPI doses influenced risks. We believed that veteran patients, frequently burdened by chronic medical conditions, would be particularly vulnerable to pneumonia and its consequences and, hence, to this possible associated risk for CAP with PPI use.

METHODS

Setting

We analyzed the linked pharmacy and administrative databases from the New England Veterans Healthcare System (VISN 1) from October 1996 through September 2007. The New England region consists of 8 medical centers and affiliated clinics providing inpatient and outpatient care. VISN 1 pharmacy files were obtained from Information Resource Management (Boston, Massachusetts). Data elements of the outpatient pharmacy files pertinent to our analysis include patient identification, date of birth, drug name and dose, administration route, quantity, date of original prescription, days' supply, refill date(s), and discontinuation date(s). Data on comorbidities were captured by accessing the VA administrative databases (Patient Treatment File and Outpatient Care File) located at the Austin Automation Center (Texas). Analyses were conducted at the Massachusetts Veterans Epidemiology Research and Information Center, VA Boston Healthcare System (Massachuetts). The study was approved by the Institutional Review Board of the VA Boston Healthcare System.

Study Design

We used a retrospective, nested case-control design in which both cases and controls had exposure to a new PPI prescription and from which a definite period of observation was accrued from the first PPI dispense date until the onset of a qualified CAP case or until no VA services were recorded for 18 months. PPI exposures were classified as *current* or *past* in relation to the date of the CAP diagnosis, and comparative risks of current versus past PPI exposures were determined for cases and controls for the entire sample and for stratified samples.

Study Population

Establishment of the cohort is described in Figure 1. Among 103 597 VISN 1 patients receiving a PPI prescription between 1 October 1997 and 30 September 2007, we identified 71 985 meeting criteria for a new outpatient PPI prescription; this required that no PPI prescription had been filled in the VA in the prior calendar year, for established VA patients, or in the first year of recorded VISN 1 treatment, for patients new to VISN 1 after 1 October 1996. These exclusions were done to establish that PPI users who developed CAP and matched controls could be reasonably classified as new users and observed within a measurable period of PPI exposure (see "Exposure Measurement," below). After excluding patients with missing age and those with no follow-up time after their initial prescription, there were 70 042 patients with qualifying new PPI prescriptions. Within this population were identified 2785 cases with coded pneumonia diagnoses and appropriate antibiotic treatment so as to be classified as CAP (see "Outcome Measurement," below), of which 1235 cases preceding the initial PPI prescription were excluded. The resulting number of patients with CAP following PPI initiation was 1544 (6 were excluded because of a gap of ≥18 months following filling of the PPI prescription). Ten controls for each case were selected by risk-set sampling on the basis of age and time under observation from the initial PPI prescription.

Among excluded cases, 147 patients with CAP diagnoses both before and after PPI initiation were not included in the primary analysis as it was felt that many of these patients would represent recurrent CAP cases, making them at risk for PPI-associated recurrent pneumonia [22]. A sensitivity analysis including these cases was conducted to determine whether there was an increase in the overall association of current PPI exposure with CAP.

Outcome Measurement

CAP was established from *International Classification of Diseases, Ninth Revision, Clinical Modification* (ICD-9-CM) inpatient and outpatient diagnostic codes 480–482, 485, and 486, which include bacterial pneumonias, specified and unspecified, and exclude specific mentions of viral pneumonia and influenza. To exclude hospital-acquired pneumonias, inpatient pneumonias were required to be primary admitting diagnoses. To be designated as a CAP case, we required that an outpatient antibiotic appropriate for treating CAP was dispensed at hospital discharge or concurrent with the coded outpatient diagnosis. Classes of confirming antibiotics included quinolones, macrolides, β-lactams, and the following specific agents: trimethoprim-sulfamethoxazole, doxycycline, and tetracycline. Whereas these criteria do not include radiologic or culture confirmation [22], we considered them to be relevant evidence of CAP diagnosed and treated in practice and unlikely to bias results either toward or against PPI exposure.

Exposure Measurement

Exposure to a PPI in relation to CAP was categorized as current if the PPI prescription end date occurred after the index case date, or as past if the prescription end date preceded the index case. Sensitivity analysis (performed using an earlier, overlapping sample of CAP cases) allowing for 15-, 30-, and 90-day intervals between the PPI prescription end date and the CAP diagnosis to

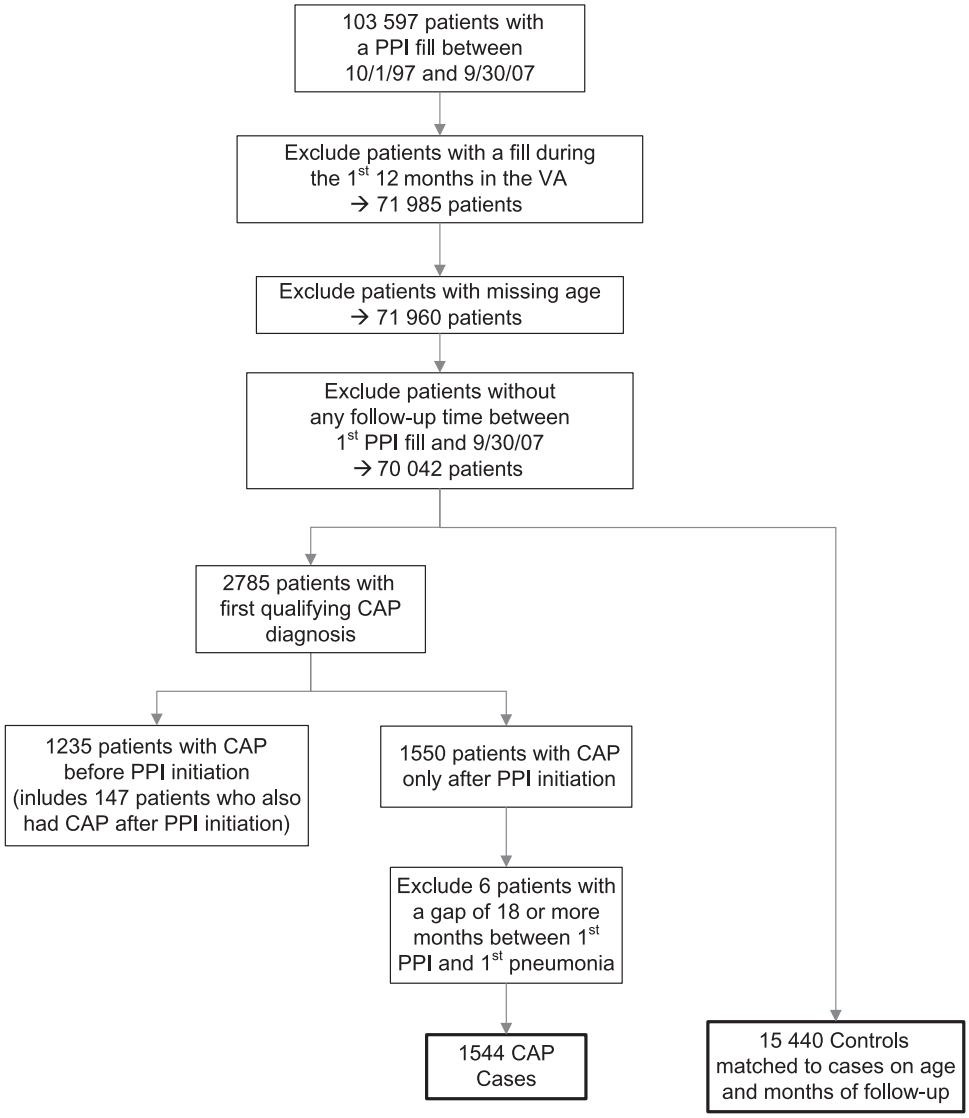

Figure 1. Study population selection. Abbreviations: CAP, community-acquired pneumonia; PPI, proton pump inhibitor.

distinguish current and past use showed no differences or trends in outcomes, so we chose the most conservative criteria. PPI agents in the VA formulary during the observation period and usual prescribed daily doses were omeprazole 20 mg, esomeprazole 20 mg, lansoprazole 15 or 30 mg, pantoprazole 40 mg, and rabeprazole 20 mg. Histamine-2 receptor antagonists (H-2RAs) were not included as a primary exposure because they were available over the counter at reasonable costs so that their use either before or concurrent with PPI use was unknown.

Covariates

Age and comorbidities, including chronic obstructive pulmonary disease (COPD; ICD-9-CM codes 490–494 and 496), congestive heart failure (428), ischemic heart disease (410–414), diabetes (250), lung cancer (162–163.90), nonlung and nonskin malignancies (140–203, excluding 162–163.90 and 173), chronic kidney diseases (585 and 586), cirrhosis (571), dementia (294, 290.40–290.43, 290.0, and 290.10–290.13), alcohol and drug abuse/dependence (303, 304, and 305), gastroesophageal reflux and/or reflux esophagitis (530.81 and 530.1–530.3), and peptic ulcer diseases (531–533), were analyzed as potential confounders as were VA hospital admissions in the 90 days before the index CAP case. Medications active at baseline, H-2RAs, systemic corticosteroids, immunomodulators/immunosuppressants, tranquilizers/sedatives, and antipsychotics, as well as antibiotics prescribed ≤90 days before baseline, were similarly analyzed as covariates.

Data Analysis

Descriptive statistics and odds ratios (ORs) were used to characterize and distinguish cases and controls. Conditional logistic regression was used for all analyses, with all stratified and subgroup analyses performed on the entire matched study population by

Table 1. Baseline Characteristics of Patients With Community-Acquired Pneumonia and Controls

requesting specific contrasts in PROC LOGISTIC. We used past PPI users as the reference groups among both cases and controls. Specific stratifying variables included age group (<65 years and ≥65 years), to examine the role of Medicare eligibility, and year of CAP diagnosis (fiscal years 1998–2003 and 2004–2007), to account for potential PPI exposures from nonprescription formulations purchased over the counter during recent years. Finally, we used conditional logistic regression on stratified samples to evaluate statistical interaction for covariates. These analyses were in some cases limited by small stratified samples and were not necessarily expected to reach statistical significance at $P < .05$, but they could show potential trends as effect modifiers.

We calculated unadjusted and adjusted ORs comparing durations of current PPI exposures before the index case. To further describe the time course of PPI use in relation to new CAP diagnoses, we provide frequency distributions among CAP patients that describe the timing of PPI initiation. To conduct this analysis, we included all available CAP cases, including those occurring before PPI initiation (1235 cases were excluded; Figure 1) and those occurring subsequent to PPI initiation (1544 cases). We also compared risks between 196 CAP cases receiving >1 standard PPI dose per day to 434 cases receiving 1 standard PPI dose per day. This analysis excluded 238 patients receiving lansoprazole, as 2 dose formulations, 15 mg and 30 mg, were dispensed in varying amounts, precluding our establishing "standard" daily doses.

All analyses were performed using SAS software, version 9.2 (SAS Institute). We used *P* values <.05 and 95% confidence intervals (CIs) to test for statistical significance.

RESULTS

Patient Characteristics

The study population of 1544 cases and 15 440 controls was approximately 96% male, with a mean age (standard deviation) of 65.8 (12.2) years. (Table 1). With the exception of esophageal reflux diagnoses, cases were more likely than controls to have each and >1 coded medical comorbidity, to have been hospitalized ≤90 days before the index case date, and to be prescribed each of the designated medications.

Table 2. Unadjusted and Adjusted Odds Ratios Associating Proton Pump Inhibitor Exposure and Community-Acquired Pneumonia

Population	PPI Exposure	Cases, No.	Controls, No.	Unadjusted OR (95% CI)	Adjusted OR[a] (95% CI)

Abbreviations: CI, confidence interval; FY, fiscal year, OR, odds ratio; PPI, proton pump inhibitor.

[a] Adjusted for sex; age; FY of end date (1998–2003 or 2004–2007); baseline *International Classification of Diseases, Ninth Revision, Clinical Modification* diagnoses of chronic obstructive pulmonary disease, diabetes, congestive heart failure, lung cancer, nonskin and nonlung cancers, ischemic heart disease, chronic kidney disease, chronic liver disease, dementia, alcohol/drug dependence or abuse, peptic ulcer, and reflux/esophagitis; admission ≤90 days before end date; active use at baseline of H2-receptor antagonist, systemic corticosteroid, immunomodulator/immunosuppressant, tranquilizer/sedative, and antipsychotic agents; and antibiotic use ≤90 days before baseline.

Patient Population Pneumonia Risks

For the total population of cases, the crude and adjusted odds of CAP among those currently using PPIs were modestly elevated relative to the odds among those with past PPI use (adjusted OR, 1.29 [95% CI, 1.15–1.45]), with no substantial differences in crude and adjusted risks when stratified by age or year of CAP diagnosis (Table 2). When the 147 cases who had CAP both before and subsequent to initiation of PPIs were included in the analysis, the risks were modestly elevated (adjusted OR, 1.40 [95% CI, 1.26–1.56]), indicating an increased PPI-CAP association with recurrent cases.

Confounding and Effect Modification by Comorbidities and Medications

To determine potential confounding and effect modification, adjusted risks and tests for interaction were conducted for comorbidities and medications (Table 3). Cases receiving immunosuppressants showed the highest relative risks for current PPI use, but the number of cases was too small (n = 13) to demonstrate statistical significance. For patients with dementia (n = 85; $P = .062$ for interaction), use of sedatives/tranquilizers (n = 224; $P = .049$ for interaction), and, to a lesser extent, patients with chronic liver disease (n = 71, $P = .257$ for interaction) and use of antipsychotics (n = 124; $P = .258$ for interaction), there was possible effect modification favoring a PPI-CAP association. Of interest, confounding by congestive heart failure, COPD, lung cancer, and chronic kidney disease diagnoses, and having ≥3 comorbidities, showed reduced adjusted risks of CAP with current PPI exposures (ie, a potential protective effect), with congestive heart failure demonstrating effect modification ($P = .014$ for interaction). There was no evidence of confounding or effect modification for esophageal reflux and peptic ulcer diagnoses; for diagnoses of other chronic medical conditions, specifically diabetes, ischemic heart disease, and nonlung and nonskin cancers; and for use of other medications, specifically H-2RAs, corticosteroids, and antibiotics (data not shown).

Duration of Exposure

We determined the ORs for increasing durations of current PPI exposure for predicting pneumonia, using a >180-day exposure as the reference group and including past exposure in the analysis model (Table 4). Those in the exposure group of 1–15 days demonstrated increased risks, compared with those with longer exposures; this short-term exposure group represented only 6.9% of the 868 cases who were exposed to PPIs at the time of their pneumonia. The remaining larger group of patients with longer durations of current PPI exposure also had increased risks for CAP, compared with those patients with past PPI exposures. We determined the frequency distribution of CAP cases occurring both before (n = 1235) and after (n = 1544) PPI initiation, and it showed a time-dependent distributions of cases (Figure 2). Among 330 CAP cases occurring within 90 days before PPI initiation, half occurred within 13 days, which is further indication that CAP cases were likely to occur closely before, as well as closely after, the time of PPI initiation.

Dose Effect

CAP cases were more likely to be currently prescribed PPIs at doses >1 standard dose per day than at doses ≤1 standard dose per day (adjusted OR, 1.33 [95% CI, 1.06–1.65]; $P = .012$) (see Methods for exclusion of 238 patients prescribed lansoprazole at 15-mg or 30-mg doses) (Table 5).

DISCUSSION

From a nested cohort of US veteran patients who predominantly were male, we found a 30% increased risk of CAP with current

Abbreviations: CI, confidence interval; COPD, chronic obstructive pulmonary disease; OR, odds ratio; PPI, proton pump inhibitor.

[a] Adjusted for sex; age; fiscal year of end date (1998–2003 or 2004–2007); baseline *International Classification of Diseases, Ninth Revision, Clinical Modification* diagnoses of chronic obstructive pulmonary disease, diabetes, congestive heart failure, lung cancer, nonskin and nonlung cancers, ischemic heart disease, chronic kidney disease, chronic liver disease, dementia, and alcohol/drug dependence or abuse; admission ≤90 days before end date; active use at baseline of H2-receptor antagonist, systemic corticosteroid, immunomodulator/immunosuppressant, tranquilizer/sedative, and antipsychotic agents; and antibiotic use ≤90 days before baseline.

[b] Model includes age, sex, given covariate, and interaction term.

[c] Excludes esophageal reflux and peptic ulcer diseases.

compared with past PPI exposures; these findings are between those from prior observational studies that showed positive [14–16] and no [17–19] associations. Three large, community-based, case-controlled studies from the Netherlands (adjusted OR, 1.73 [95% CI, 1.33–2.25]) [14], Denmark (adjusted OR, 1.5 [95% CI, 1.3–1.7]) [15], and Great Britain (adjusted OR, 1.55 [95% CI, 1.36–1.77]) [16] associated current PPI exposure with CAP. Conversely, 3 recently published studies from Great Britain [17] and the United States [18, 19] reported no statistically significant associations between PPI exposures and CAP. In 2 of these latter studies, only patients aged ≥65 years were included [18, 19]. The 3 studies with negative findings included as potential confounders current smoking status [17–19], past year hospitalizations and office visits [17, 19], and a measure of functional status [19], variables potentially attenuating any independent risks conveyed by PPI use. We used common comorbidities, medications, and recent hospitalizations as potential confounders, but we recognize that other key confounders may not have been included.

There was apparent effect modification for patients with dementia and for those receiving sedatives/tranquilizers, each independently increasing this association, perhaps because of impaired swallowing and increased reflux of acid-suppressed stomach contents [24–26]. We also found potential confounding with chronic liver disease and immunosuppressant use, but tests for interactions were limited by small sample sizes. We cannot readily explain our findings that, for other chronic medical conditions, the association between current PPI exposure and CAP was "protective," but it is possible that the inherent risks for CAP with these conditions preclude any added risks incurred by

Table 4. Duration of Current Proton Pump Inhibitor Exposure and Community-Acquired Pneumonia

PPI exposures [1–3]. These seemingly contradictory findings with respect to specific comorbidities, in this study and others, weaken the argument for a convincing PPI-CAP association in patient populations in which multiple confounders, entered into or omitted from analyses, could alter results.

We, and others [14, 15, 17], found that short-duration current PPI use increased the association with CAP, compared with longer-duration current use; in the other prior observational studies, dose effects were not tested [16, 18, 19]. This finding raises the question as to whether the association results from PPIs being newly prescribed for either early, nonspecific symptoms of pneumonia, for gastric protection, or for new-onset or worsening reflux, or whether it simply occurs because patients are in medical care settings where PPI are commonly prescribed. Our time-interval data from CAP cases that preceded PPI initiation suggests that this may well be the case, as PPI initiations frequently follow CAP diagnoses in the context of clinical care of symptomatic patients. However, >90% of current PPI exposures in our sample were >15 days and also carried modestly increased risks for CAP, compared with risks among past users.

Two prior studies [14, 17] and ours demonstrated a PPI dose–dependent association with CAP. Whereas this finding indicates enhanced, more-potent gastric acid suppression, it is possible that increased PPI dosing is in response to symptomatic gastroesophageal reflux, which might in itself increase risks for chronic aspiration and lower respiratory tract infections [27, 28]. Because we found that PPI prescribing often followed CAP diagnoses, it is likely that some clinicians initiated high-dose PPIs in this clinical context.

Our findings must be viewed with caution because our exposure and outcome measures are subject to limitations inherent in database dependent observational studies. We were not able to determine PPI compliance or supplementation with other PPIs or gastric acid suppressants; however, because of the low costs of VA copayments, it is unlikely that many patients would use non–VA-prescribed prescriptions. We could not identify the indication for PPI use explicitly, although we collected an exhaustive list of conditions potentially related to PPI use or CAP development. We did not validate our CAP cases with documentation of radiographic findings, which is typically necessary for randomized trials [29]. Dublin et al [19], using only coded CAP diagnoses, reported a 30% increased risk for CAP with PPI exposure, but this association was negated using only chart-reviewed, validated CAP cases. However, Gulmez et al [15] found no difference in increased PPI-associated risks in a comparison of patients with and patients without positive chest radiographic findings. We required timely prescribing of antibiotics appropriate for treatment of CAP to establish our CAP cases, but this practice, although certainly indicative of clinically relevant CAP, may considerably vary between physicians and institutions. Even without radiography or other means for case validation, it seems unlikely that misclassifications of CAP cases would bias results toward patients receiving PPIs.

Despite these limitations, our study has considerable strengths. The veteran patient population studied is large, and our 8-year window of observation is long. The VA pharmacy database allows for an accurate determination of physician-entered

Table 5. Association Between Proton Pump Inhibitor Dose at End Date and Community-Acquired Pneumonia

PPI Dose	Cases, No. (%)	Controls, No. (%)	Unadjusted OR (95% CI)	*P* Value	Adjusted OR[a] (95% CI)	*P* Value
>1 standard dose[b]	196 (31.1)	1498 (23.4)	1.42 (1.16–1.73)	<.0001	1.33 (1.06–1.65)	.012
≤1 standard dose[b]	434 (68.9)	4902 (76.6)	Reference		Reference	

Data exclude patients receiving lansoprazole as PPI at end date (see text).

Abbreviations: CI, confidence interval; OR, odds ratio; PPI, proton pump inhibitor.

[a] Adjusted for sex; age; fiscal year of end date (1998–2003 or 2004–2007); baseline *International Classification of Diseases, Ninth Revision, Clinical Modification* diagnoses of chronic obstructive pulmonary disease, diabetes, congestive heart failure, lung cancer, nonskin and nonlung cancers, ischemic heart disease, chronic kidney disease, chronic liver disease, dementia, and alcohol/drug dependence or abuse; admission ≤90 d before end date; active use at baseline of H2-receptor antagonist, systemic corticosteroid, immunomodulator/immunosuppressant, tranquilizer/sedative, and antipsychotic agents; and antibiotic use ≤90 d before baseline.

[b] Standard dose is defined as 1 pill/day of basic dose of each PPI formulation (see Methods for exposure variables).

prescriptions that are actually dispensed. Our study design is conservative in that we used time under observation, used risk set sampling for our overall and stratified analyses, and excluded known recurrent CAP cases. By identifying cases and selecting matched controls only from PPI users, cases and controls likely had reasonably similar indications for initial PPI prescribing, although these could not be identified explicitly. As PPIs are commonly prescribed and continued for protracted periods without clear indications [9–13], even a small or uncertain added risk for CAP could translate into many CAP cases. Along with the risks reported from observational studies for other infections, specifically *Clostridium difficile* infection [30–32], other enteric infections [33], spontaneous bacterial peritonitis [34], recurrent CAP, and hospital-acquired pneumonia [23], consideration of reasons for starting or continuing PPIs or for alternative gastric acid suppression may be warranted [10–13]. Prospective, randomized trials to test these associations would necessarily be prolonged and costly. Thus, additional observational studies, with well-considered potential confounders and targeted, stratified subsamples, that can further test for the existence and extent of associations of PPI exposure with serious infections are needed.

Comparative effectiveness research (CER) aims to provide decision makers with the evidence needed to evaluate the benefits and harms of alternative clinical management strategies. CER has become a national priority, with considerable new research funding allocated. Cardiovascular disease is a priority area for CER. This workshop report provides an overview of CER methods, with an emphasis on practical clinical trials and observational treatment comparisons. The report also details recommendations to the National Heart, Lung, and Blood Institute for a new framework for evidence development to foster cardiovascular CER, and specific studies to address 8 clinical issues identified by the Institute of Medicine as high priorities for cardiovascular CER.
(J Am Coll Cardiol 2012;60:569–80)

Comparative effectiveness research (CER) has recently emerged as a national priority, spurred by healthcare reform and economic stimulus legislation. Congress appropriated $1.1 billion for CER as part of the American Recovery and Reinvestment Act of 2009 and is anticipated to enable additional annual spending of $500 million as part of the newly established Patient-Centered Outcomes Research Institute. According to congressional legislation, the Patient-Centered Outcomes Research Institute will give priority for project management to the National Institutes of Health and the Agency for Health Research and Quality. Therefore, the National Heart, Lung, and Blood Institute (NHLBI) may have new opportunities to advance CER related to cardiovascular disease, which remains the leading cause of death and disability in the United States today.

The NHLBI sponsors workshops to solicit input and recommendations on important topics, so on July 13 and 14, 2010, the Division of Cardiovascular Sciences convened a workshop on CER in cardiovascular disease. The workshop brought together 25 outside experts from a variety of disciplines (clinical trials, epidemiology, biostatistics, health services research, and clinical medicine) to discuss a range of future opportunities that NHLBI could consider in CER as it relates to cardiovascular disease and the specific priorities for CER in cardiovascular disease that were identified by the Institute of Medicine (IOM). The discussions at the workshop, therefore, represent the opinions and recommendations of the participants and are not necessarily the policy or priorities of NHLBI.

CER = comparative effectiveness research
CT = computed tomography
IOM = Institute of Medicine
NHLBI = National Heart, Lung, and Blood Institute
RCT = randomized controlled trial(s)

This report summarizes the deliberations and recommendations to the NHLBI of this workshop: "Future Directions for Cardiovascular Disease Comparative Effectiveness Research." The report is divided into several sections, including: 1) an overview of CER data sources and methods; 2) a proposed framework for CER at the NHLBI (Fig. 1); and 3) possible approaches to 8 priority CER topics identified by the IOM in the areas of cardiovascular and peripheral vascular disease.

Overview of CER

Comparative effectiveness research has been defined as "the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care. The purpose of CER is to assist consumers, clinicians, purchasers and policy makers in making informed decisions that will improve healthcare at both the individual and population levels" (1). CER can focus on care at the patient level or the system level, but regardless of its scope, CER is intended to provide information that can facilitate medical decision making and improve health outcomes (2).

There is great public value in rigorous studies comparing alternative strategies for diagnosis and treatment, as demonstrated by many landmark NHLBI-sponsored clinical trials (3–13). Nevertheless, comparative effectiveness studies that would facilitate healthcare decisions are not performed as often as they are needed, and gaps persist between the production of scientific evidence and the needs of consumers and healthcare providers for evidence on CER. Because there are limited resources to support biomedical research, it is necessary to prioritize key clinical questions that can be answered with comparative effectiveness studies, while expanding as much as possible the pool of investigators capable of performing CER.

Study Designs for CER

A variety of methods are used in CER, including randomized trials, observational studies, simulations and models, systematic reviews, meta-analyses, and collaborative pooling of individual patient data from multiple studies. Randomized trials can be used to compare a management strategy (preventative, diagnostic, therapeutic) with the best alternative strategy. Analyses of data from clinical registries, electronic health records, and administrative databases can address CER questions regarding situations in which randomization may be difficult. Whereas observational studies using existing data may be simpler and less expensive to conduct, they are more susceptible to bias introduced by selection of patients for alternative treatments. Statistical approaches to analysis of observational data can be used to

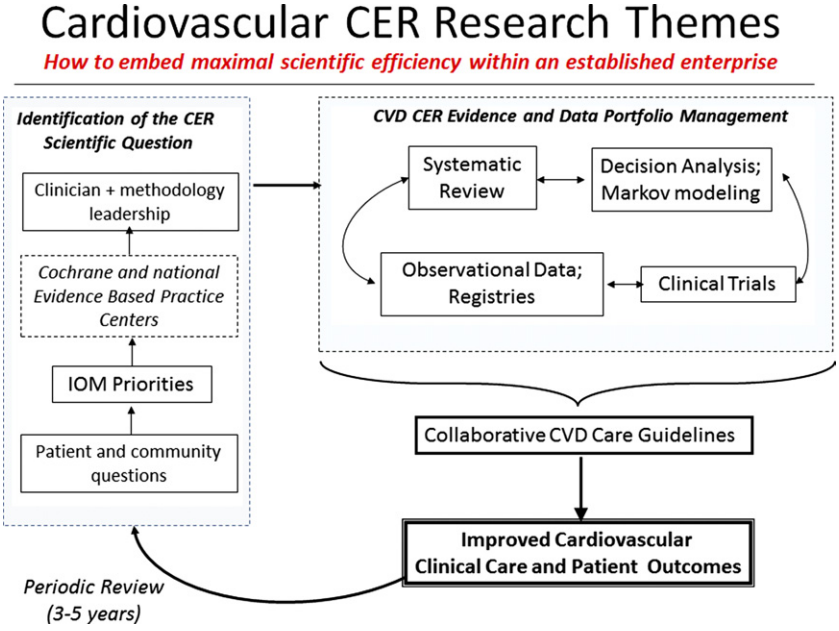

Figure 1 Conceptual Framework for CER

CER = comparative effectiveness research; CVD = cardiovascular disease; IOM = Institute of Medicine.

minimize these biases, but these methods need to be further developed. Decision models and simulations may also be very useful methods in CER. The workshop participants explored the unique opportunities, strengths, and limitations of these methods for use in CER, as summarized herein.

Randomized trials. Randomized clinical trials (RCT) may be applied in CER to compare treatments (e.g., use of a drug, device, procedure, or a behavioral intervention), clinical evaluation strategies (e.g., biomarkers, imaging), healthcare delivery methods (e.g., disease management programs, specialist vs. generalist care), and policy interventions (e.g., copayments, formulary restrictions, regionalization of procedures). The strengths of the RCT include its use of a prospective protocol, standardized data collection, complete follow-up, and random treatment assignment, each of which enhances its "internal validity." An RCT is particularly appropriate when a high level of evidence is required to change practice, such as when optimal management is controversial, the effect of the treatment on outcomes is modest, or the intervention is costly. Although RCT often involve highly selected patients and atypical practice settings, which can limit generalizability, RCT can be designed to enroll more representative patient populations and can be performed in more typical practice settings.

There are many practical barriers to conducting large, representative clinical trials in the United States. The focus on delivering care efficiently and uniformly may not readily accommodate clinical research in routine clinical practice. Building the infrastructure to perform multicenter clinical trials can be difficult, time-consuming, and costly. Thus, exploring strategies to promote more efficient clinical trials is important, such as adopting "large practical trial designs" or fostering the conduct of a range of CER trials by existing investigator or site teams. Use of real-world settings, such as private practice groups, community health centers, and integrated healthcare systems, may enhance recruitment of representative patients in CER trials.

Monetary barriers can impede the conduct of clinical trials, because the cost of research data collection, clinic visits and tests, and follow-up is high. Thus, identifying ways to streamline data collection while maintaining accuracy and validity over the length of follow-up would enhance the ability to conduct CER trials. Health insurers may balk at covering the costs of clinic visits and tests for patients in a clinical trial, which increases the cost to the research budget and may lead patients to drop out of the study. Furthermore, in some instances, financial incentives in healthcare may not be aligned for randomized trials; for example, trials that randomize patients to procedures compared with medical therapy may result in foregone procedural fees. The duration of follow-up in clinical trials is also constrained by cost, which limits collection of long-term data on comparative efficacy and safety.

Barriers for CER trials also include lack of time in busy practices to enroll participants in research studies and low levels of academic recognition for site investigators who are just 1 member of a large trial team. Whereas institutional review boards are needed to protect participants in clinical trials, the multiplicity of jurisdictions across multisite trials complicates the conduct of the trial. Centralized or simplified institutional review processes for multicenter studies should be explored, particularly for comparative trials of existing, approved interventions.

Clinical registries. A clinical registry is the prospective collection of standardized data on the clinical characteristics and outcomes of patients defined by a particular disease, diagnosis, procedure, or exposure. Clinical registries share some features with randomized trials, such as standardized data collection, but unlike clinical trials, they do not dictate patient treatment by either random assignment or a strict protocol. Clinical registries can have broader inclusion criteria than clinical trials do, and, therefore, they may better represent the diversity of patients, providers, and practice settings found in contemporary clinical care. Clinical registries occupy a middle ground between the formal structure of a randomized trial and the collection of relatively unstructured data from medical charts, electronic health records, or claims data.

Clinical registries have evolved from small case series to national (or international) collaborations that enroll thousands to millions of patients. Standardized data definitions and data collection methods are key features of a high-quality clinical registry, as they ensure comparable levels of details about each patient enrolled. Documenting outcomes—particularly outcomes that occur late after a single episode of care—is also essential if clinical registries are to be used in CER. Longer follow-up can be obtained actively by contacting patients (as is done in clinical trials) or passively by linking registry data to electronic health records, claims data, or state and national mortality files.

Clinical registries have been used to define contemporary practice patterns, document disparities in care, and assess the safety of cardiovascular drugs, devices, and procedures in clinical practice. Clinical registries can also be analyzed to compare alternative treatments, but these studies require advanced biostatistical methods to reduce the biases introduced by nonrandomized patient selection for treatment.

Clinical registries may also be linked with randomized clinical trials, as when a registry prospectively collects data on patients screened for entry into a trial or on patients eligible for a trial who decline to be randomized (14). Randomized trials can also capitalize on an ongoing clinical registry, which can be used to identify eligible patients and capture clinical data. Hybrid registry trial designs may be particularly powerful tools for CER, as they permit efficient patient enrollment and provide information of the generalizability of trial results.

The resources required to establish and maintain clinical registries have been provided by a variety of mechanisms. Professional societies have sponsored notable clinical registries often supported by hospital-paid fees for participation,

such as the American Heart Association's Get with the Guidelines Programs (in cardiovascular disease, heart failure, and stroke), the Society of Thoracic Surgeon's National Cardiothoracic Surgery databases (covering coronary bypass surgery, valve surgery, thoracic surgery, and congenital heart surgery), and the American College of Cardiology's National Cardiovascular Data Registries (including percutaneous coronary intervention, implantable defibrillators, and carotid stenting, as well as diseases such as congenital cardiovascular disease and acute coronary syndromes). State governments have also sponsored clinical registries, such as the New York State Registry for cardiac surgery and percutaneous coronary intervention. Clinical registries have also been established using federal research funding (e.g., the NHLBI-sponsored Dynamic Registry). Industry has sponsored clinical registries on particular drugs or devices (e.g., stent registries), as well as specific diseases (e.g., the NRMI [National Registry of Myocardial Infarction], the ADHERE [Acute Decompensated Heart Failure National] registry, and the REACH [Reduction of Atherothrombosis for Continued Health] registry).

Health system data. Electronic health records and the administrative records of insurers or integrated health plans are valuable sources of observational data for CER. These "found data" are generated in the routine practice of medical care for billing purposes, public reporting, or clinical care and are not produced primarily for research purposes. For instance, the diagnoses and procedures during hospitalization are recorded using the nomenclature of the International Classification of Diseases, Clinical Modification (ICD-9-CM) and reported to public authorities and health insurers. These administrative data are not subject to the standardization and quality control applied to clinical trial or clinical registry data, although these data are usually recorded by trained medical records abstractors and required for provider reimbursement. Some integrated healthcare organizations have additional sources of clinical data, such as drug prescriptions, outpatient claims, and computerized laboratory results. Linkage of several of these data sources can give a very detailed picture of medical care provided to a representative, relatively unselected population of patients.

The advent of fully electronic health records offers the possibility of capturing greatly detailed clinical information about individual patients, such as symptoms, vital signs, and results of imaging studies. There are formidable technical challenges in extracting specific data elements from electronic health records, because clinical notes are typically entered as free text rather than using a controlled vocabulary. Advances in medical informatics, such as studies on natural language processing, will likely facilitate the use of electronic health records for research purposes. Nevertheless, the use of electronic records for research purposes does not overcome the well-recognized fundamental limitations of retrospective chart review studies: namely, that key data may not have been recorded at all; and that the data that were recorded are unlikely to be standardized or quality controlled.

Analysis of observational data. A weakness of all observational CER studies (including analyses of clinical registries, electronic health records, and administrative data) is the absence of randomized assignment of treatments. In contrast to a randomized trial, clinicians and patients represented in observational databases select treatments for a variety of reasons, which may not be recorded in the chart. Treatment selection can lead to differences in patient prognosis between treatment groups, so their subsequent clinical outcomes may differ, even in the absence of a treatment effect. Methods for addressing selection biases, whether due to known or unknown factors, are evolving. One simple step is to restrict the study patient population to newly treated patients and to patients eligible for either treatment; these restrictions narrow any pre-treatment differences between patients receiving alternative therapies (15). Modeling the selection of treatment by using a propensity score or a disease risk score can balance treatment groups on large numbers of measured clinical covariates (16,17). Marginal structural models with inverse weighting by propensity for treatment have been used to estimate the effect on outcomes of treatments that vary over time, such as use of prescription drugs (18). Each of these statistical methods relies on adjusting for clinical characteristics that were recorded in the data and, therefore, may not adjust fully for clinical factors that were not recorded (e.g., patient frailty or socioeconomic status) or that are difficult to capture (e.g., degree of social support). Instrumental variable methods and multilevel analyses have been used in an attempt to adjust for unmeasured confounders (19–21). These approaches identify variables that are strongly related to the likelihood of receiving a specific treatment, but do not directly affect clinical outcomes (e.g., inclusion of specific drugs in a formulary, distance to a referral hospital). The workshop participants recognized the need for further advances in statistical methods in order to conduct high-quality CER that minimizes confounding and residual selection bias in observational treatment comparisons.

Systematic reviews and decision models. Systematic reviews and meta-analyses of existing effectiveness and safety data are an important tool for CER. Systematic reviews can identify evidence gaps, including a lack of evidence or unclear evidence for an important clinical question, which suggest a new trial is warranted (22) and when there is "too much evidence," which suggests further trials may be unnecessary (23). Network meta-analysis (mixed treatment comparison meta-analysis) may be used to compare interventions even when direct "head-to-head" trials are not available (24). This new statistical approach is promising, but it is still being examined for its validity as a method to compare treatments.

The potential for treatment efficacy to vary significantly according to patient characteristics (e.g., age, sex, diabetes, or genetic markers) is an important dimension of CER, as

it provides evidence to "personalize" treatment decisions. Very large sample sizes are required to investigate potential variation in treatment effects across populations, which can be accomplished by pooling individual patient-level data from several trials. Further research could address the practical and methodologic challenges of collaborative studies that pool data from multiple studies of cardiovascular treatments.

Decision models and simulation studies are also valuable methods to foster CER. These techniques start with the best available evidence on a clinical question and typically rely on the results of systematic reviews, meta-analyses, and pooling studies to provide the needed data. Models and simulation studies are particularly well suited to identify evidence gaps and the value of information by pinpointing which clinical factors have the greatest impact on the clinical effectiveness and cost-effectiveness of treatment alternatives. Studies can subsequently be designed to address the most important evidence gaps, which will be particularly valuable in meeting the CER objective of "comparing benefits and harms of alternative methods [of care]."

Proposed Framework for CER

The workshop participants proposed a new framework for evidence development (Fig. 1) to foster cardiovascular CER. This framework identifies gaps between the evidence needed for practice and the research available to support it. A "portfolio analysis" of the current state of knowledge, by using clinical guidelines, evidence reviews, and decision models to identify key evidence gaps, could focus CER on key questions through a variety of research designs, including observational studies, clinical registries, and randomized trials. This cycle of portfolio analysis, identification of key evidence gaps, and research addressing these gaps could repeat over time (Table 1).

The proposed framework (Fig. 1) involves a multiple stakeholder process to identify questions for CER and is consistent with recent changes on the political as well as scientific landscape. For example, the creation of the new Patient-Centered Outcomes Research Institute suggests that the model for setting research priorities may be changing from an investigator and industry driven process to one with broader patient and clinician input.

Table 1 General Recommendations to Foster Comparative Effectiveness Research

Conduct portfolio analyses in key clinical areas
Identify knowledge gaps
Strengthen relationships among stakeholders
Leverage the strength of different research methods: trials, registries, simulations, evidence synthesis
Advance analytic methods for comparative effectiveness research
Promote knowledge discovery as part of clinical practice
Foster training and careers in comparative effectiveness research

The proposed framework implies that knowledge gaps could be identified through systematic reviews of existing evidence, meta-analyses, and decision analytic models. These types of studies could be efficient and timely opportunities to focus on important comparative effectiveness studies (Table 1).

The proposed framework also implies that interactions among potential funders and stakeholders, such as the Agency for Healthcare Research and Quality, the Centers for Medicare and Medicaid Services, and the Centers for Disease Control and Prevention could help foster CER focused on cardiovascular disease. The Cochrane Collaboration is an international organization that conducts systematic reviews and promotes methodologic development, and it could assist in assessing evidence gaps and areas of focus for research. The professional societies (e.g., the American College of Cardiology, the American Heart Association, and the Society of Thoracic Surgeons) now operate clinical registries that may be well suited to cardiovascular CER, and they develop clinical guidelines, performance measures, and appropriate-use criteria that could potentially translate CER findings into practice.

Expand the scope of discovery. CER focuses on developing scientific knowledge that will be useful during the course of patient care. The creativity and innovation that characterize investigator-initiated research have served medical science well. However, because the research questions of CER focus on addressing the needs of practitioners and patients, the scope of discovery may need to expand to include not only specific topics of interest to individual investigators and experts, but also topics driven by clinical evidence gaps.

The implications of developing a CER portfolio that focuses on knowledge gaps are far reaching. The evolution of a research question from model to meta-analysis to mega-trial to implementation underscores the contributions of methodologic research as well as research on specific clinical questions. Whereas some clinical questions may be addressed in large randomized clinical trials, other pivotal questions may not be amenable to randomized studies and, therefore, require alternative methods.

Create a culture of research. The broad scope of CER implies similar breadth in thinking about the research enterprise, such that the development of new knowledge about optimal practice becomes an intrinsic part of the healthcare system. Because CER aims to address patient and provider needs, health systems, providers, and patients should embrace the need to perform CER and recognize its value. A culture of research may be fostered when it is recognized that there is uncertainty regarding what constitutes optimal care, so that alternative forms of management may be reasonable and acceptable—the concept of clinical equipoise. While clinical systems and caregivers face challenges incorporating research as part of daily practice, they should recognize that improving the quality of care through discovery and learning from experience should be part of

their professional and institutional obligations. Integrating research into routine care might be further fostered by focusing on quality improvement, aligning incentives within health systems, and, in the larger healthcare enterprise, by establishing policies such as coverage with evidence development and pay for performance.

The collection of observational data as part of a prospective clinical registry is an example of how research can be incorporated into daily practice. Clinical registries cover only specific clinical populations, however, and a broader knowledge base could advance CER. Fully interoperable electronic health records, with promotion of standardized clinical terminology, would facilitate CER, particularly if electronic health records, clinical registries, image repositories, clinical trial data, and longitudinal claims can be linked to create study cohorts. To this end, further development of health informatics and its application to cardiovascular disease is an opportunity to advance CER.

Nurture the national CER workforce. Individuals from many distinct backgrounds are needed to meet the challenges of CER, ranging from skilled investigators to inquisitive clinicians, knowledgeable patients, and practical methodologists. Thus, "team science" is integral to the success of CER. Paralleling the need for more diverse research partners is the opportunity to collaborate with nontraditional research venues and partners, including those usually focused only on care delivery or education, rather than scholarly research.

As CER is relatively new field, there is a great need for more investigators who are well trained in its methods. Training, mentoring, and professional development programs aimed specifically at expanding the pool of investigators skilled in the methods of cardiovascular CER are possible ways to cultivate this field. Furthermore, nontraditional stakeholders may be valuable contributors to the development of the portfolio of CER studies.

Institute of Medicine Priorities

The workshop addressed 2 broad questions. 1) How might the NHLBI foster CER related to cardiovascular disease in general? 2) How might the NHLBI respond to the specific CER priorities in the area of cardiovascular disease identified by the IOM? In this section, we summarize the workshop participants' recommendations on the second broad question—what types of studies could potentially address the IOM priorities (1)? The workshop participants were charged to identify examples of 1 or 2 study ideas for each IOM area.

NHLBI convenes working groups of experts to provide recommendations and input on specific topic areas, which the Institute then carefully reviews. The suggestions of this workshop represent a list of important areas for investigator-initiated and/or Institute-initiated projects. The Institute carefully considers these and other recommendations as it sets its priorities and attempts to maintain a balanced portfolio across its entire mission; no NHLBI funding commitment is made or implied by inclusion of the topics in the report of this workshop. The workshop recognized that the NHLBI is particularly able to organize CER studies free of conflicts of interest related to specific drugs, devices, or management strategies and has great experience in conducting comparative studies of alternative management strategies to treat cardiovascular disease.

The IOM priority areas discussed at the workshop include:

- Compare the effectiveness of treatment strategies for atrial fibrillation including surgery, catheter ablation, and pharmacologic treatment;
- Compare the effectiveness of anticoagulant therapies (e.g., low-intensity warfarin, aspirin, injectable anticoagulants) for patients undergoing procedures;
- Compare the effectiveness of treatment strategies for vascular claudication (e.g., medical optimization, smoking cessation, exercise, catheter-based treatment, open surgical bypass);
- Compare the effectiveness of aggressive medical management and percutaneous coronary interventions in treating stable coronary disease for patients of different ages and with different comorbidities;
- Compare the effectiveness of innovative treatment strategies (e.g., cardiac resynchronization, remote physiologic monitoring, pharmacologic treatment, novel agents such as CRF-2 receptors) for congestive heart failure;
- Compare the effectiveness of different treatment strategies (e.g., modifying target levels for glucose, lipid, or blood pressure) in reducing cardiovascular complications in newly diagnosed adolescents and adults with type 2 diabetes;
- Compare the effectiveness of traditional risk stratification for coronary heart disease and noninvasive imaging (using coronary artery calcium, carotid intima media thickness, and other approaches) on outcomes; and
- Compare the effectiveness of computed tomography (CT) angiography and conventional angiography in assessing coronary stenosis in patients at moderate pre-test risk of coronary artery disease.

Atrial Fibrillation

Atrial fibrillation is a highly prevalent condition associated with increased cardiovascular mortality and a high risk of stroke. The NHLBI has previously supported comparative treatment trials for atrial fibrillation, including the completed AFFIRM (Atrial Fibrillation Follow-Up Investigation of Rhythm Management) trial (4) and the ongoing CABANA (Catheter Ablation Versus Antiarrhythmic Drug Therapy for Atrial Fibrillation) trial (NCT00911508). The NHLBI is also funding a clinical registry of atrial fibrillation in 2 large integrated health plans to address specific comparative

effectiveness research issues, and it will expand on a previous atrial fibrillation registry (25) and epidemiologic studies of atrial fibrillation. Despite these and other studies of atrial fibrillation, key knowledge gaps remain, including: 1) the generalizability of trials to the larger population of patients with atrial fibrillation; 2) whether the treatment approach ought to vary depending on the subtype of atrial fibrillation; and 3) the effect of treatments on expanded outcomes, such as stroke, dementia, heart failure, quality of life, healthcare utilization, and cost-effectiveness.

The workshop participants recommend that 1 approach to fill these gaps could be a robust clinical registry with broader representation of patients with atrial fibrillation, with a particular focus on patients with new onset disease, to better define risks for adverse outcomes in relation to patient characteristics, subtype of atrial fibrillation, biomarkers, and treatment. In conjunction with the registry, a comprehensive decision model of atrial fibrillation management, as outlined in Figure 2, could be used to identify priority areas for additional CER studies, including clinical trials. There is also the potential to build on ongoing studies of other conditions and treatments by adding atrial fibrillation as a secondary outcome measure.

Anticoagulant Therapies

Anticoagulant and antithrombotic therapies are increasingly used to prevent thromboembolism in patients with atrial fibrillation, deep vein thrombosis, or pulmonary embolism. Management of these therapies at the time of invasive procedures and surgery poses a difficult problem in balancing the bleeding risk due to treatment and the thromboembolic risk due to the underlying disease (26). Furthermore, immobilization after surgery promotes venous thromboembolism, which is particularly increased by hip or knee joint replacement procedures. Management decisions have been further complicated by the introduction of several novel anticoagulant drugs that lack specific antidotes and whose anticoagulant intensity cannot be reliably assessed by laboratory tests. The NHLBI is currently supporting the BRIDGE (Effectiveness of Bridging Anticoagulation for Surgery) trial (NCT00786474), and the GIFT (Genetics Informatics Trial of Warfarin to Prevent DVT) trial (NCT01006733), which tests low-intensity warfarin properties following orthopedic surgery.

The workshop participants felt that a large "real-world" registry of patients undergoing specific surgical procedures would be of benefit to document risk factors for bleeding, cardiac events, and thromboembolism. This registry could be used to assess the effect of different treatments on those outcomes, particularly among patients under-represented in randomized trials (Online Fig. 1). Assessment of adverse orthopedic outcomes such as joint hemorrhage, periprosthetic infection, and repeat procedures would provide critical information needed to balance risks and benefits of anticoagulant treatment. The registry could capitalize on substantial practice variations to perform observational treatment comparisons and assess the effects of treatment on cost, quality of life, and cost-effectiveness.

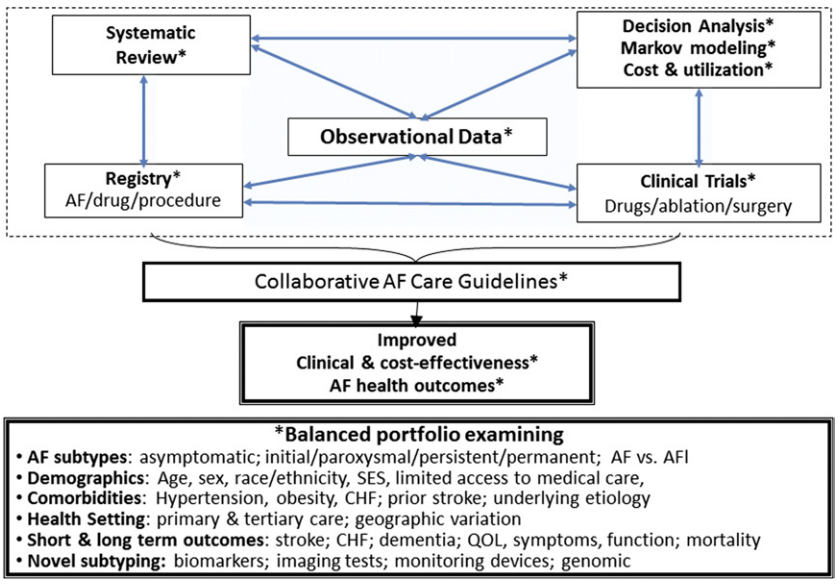

Figure 2 AF CER Evidence and Data Portfolio Management

The general framework for CER (see Fig. 1) is applied to atrial fibrillation (AF). Examples of registries might include an AF clinical care registry, registry of individuals screened but not randomized to a clinical trial, or individuals followed after completion of a clinical trial. An example of an ongoing AF clinical trial is the CABANA (Catheter Ablation Versus Anti-Arrhythmic Drug Therapy for Atrial Fibrillation Trial) (NCT00911508). AFl = atrial flutter; CHF = congestive heart failure; QOL = quality of life; SES = socioeconomic status; other abbreviations as in Figure 1.

JACC Vol. 60, No. 7, 2012
August 14, 2012:569–80

Peripheral Artery Disease

Lower extremity peripheral artery disease is a common, costly condition that is associated with high morbidity and mortality. The pathophysiology of exertional limb claudication is analogous to that of exertional angina pectoris, but claudication has not received as much attention as angina in either clinical investigation or the development of new drugs and devices. There have been relatively few CER studies of claudication treatments, apart from the ongoing NHLBI-sponsored CLEVER (Claudication: Exercise Versus Endoluminal Revascularization) trial (NCT00132743). CLEVER compares exercise therapy with endovascular stenting for treatment of a documented lesion in a specific proximal aortoiliac site that is amenable to stent therapy (27). CLEVER does not, however, address the larger question of whether a strategy of mechanical limb revascularization (using any combination of endovascular techniques and surgery) leads to better clinical outcomes than the alternative strategy of optimal medical management (including exercise, lifestyle modification, and drug therapy). A large practical randomized trial comparing these distinct approaches to claudication could address this priority area (Online Fig. 2). This trial could enroll relatively unselected patients with claudication, whether new onset or after prior revascularization, without requiring prior angiography or any specific anatomic findings. The major outcomes of this trial could be patient functional capacity and quality of life, with secondary outcomes of major clinical complications, cardiovascular risk factor control, medical care utilization and cost, and cost-effectiveness.

Severe limb ischemia, including acute or chronic critical limb ischemia syndromes, represents another major clinical manifestation of peripheral artery disease, in which tissue necrosis is threatened due to reduced resting blood flow. There are newer therapeutic options for severe limb ischemia, but few reliable data on their long-term clinical outcomes or comparative effectiveness. Severe limb ischemia is particularly suitable for the process of priority setting outlined in Figure 1: performing a systematic review of evidence; modeling to identify critical parameters; and collecting observational data on epidemiology, treatment patterns, and determinants of clinically important outcomes. Establishment of a clinical registry of patients with severe limb ischemia could foster CER on this topic by identifying patient, provider, and treatment predictors of outcome. Such a registry could provide the basis for initiating subsequent, targeted clinical trials of evaluation and management strategies for severe limb ischemia.

Stable Ischemic Heart Disease

Coronary artery disease is well recognized as a major health problem in the United States and has been the subject of numerous clinical investigations. The NHLBI has sponsored pivotal CER clinical trials, including the CASS (Coronary Artery Surgery Study) (28) and BARI 2D (Bypass Angioplasty Revascularization Investigation Two, Diabetes) (NCT00006305) (7) to compare coronary revascularization with medical therapy among patients with ischemic heart disease. The NHLBI has also sponsored trials comparing bypass surgery with coronary angioplasty (BARI [29] and EAST [Emory Angioplasty Versus Surgery Trial] [9]). Despite extensive investigation in this field, numerous knowledge gaps persist about optimal management of patients with stable ischemic heart disease. In particular, prior clinical trials have required knowledge of the coronary anatomy prior to randomization, but the decision to perform an invasive coronary angiogram has often been tantamount to the decision to perform coronary revascularization. The NHLBI just announced funding for the ISCHEMIA (International Study of Comparative Health Effectiveness with Medical and Invasive Approaches), a trial that will randomize patients with stable coronary disease and objective evidence of myocardial ischemia to an invasive strategy of early coronary angiography or a conservative strategy of initial optimal medical therapy, with angiography reserved for development of refractory symptoms or a clinical event (Online Fig. 3), in order to address a need for further evidence on this important decision point.

In addition to a large practical trial of coronary revascularization, many questions remain about how to define and deliver optimal medical management for patients with stable ischemic heart disease. In particular, it has been challenging to promote drug adherence and behavior change (diet, exercise, smoking cessation) in the setting of a busy outpatient practice. One approach to consider is to apply insights from behavioral economics to investigate the effect of economic incentives to clinicians (e.g., structuring of payment) or patients (e.g., copayments for drugs or visits, the costs of improving exercise and diet) on clinical outcomes.

As a third consideration, formal analysis of evidence gaps and opportunities in stable ischemic heart disease using the processes of evidence review, model building, and analysis of clinical registries (Fig. 1) would allow the identification of additional opportunities for CER in this area.

Heart Failure

Heart failure continues to be the most common reason for hospital admission among Americans 65 years of age and older, and the prevalence of heart failure has continued to rise, even though other forms of heart disease have been declining. The NHLBI has sponsored numerous CER investigations in heart failure, including the SOLVD (Studies of Left Ventricular Dysfunction) trial (30), the SCD-HeFT (Sudden Cardiac Death in Heart Failure) (NCT00000609) trial (11), and, more recently, the STICH (Surgical Treatment of Ischemic Heart Failure) (NCT00023595) trial (12). Many other studies of the effects of drugs and devices on clinical

outcome in patients with heart failure have been sponsored by industry.

A hallmark of heart failure is that many patients are frequently rehospitalized to treat exacerbations of the disease, at great expense to the system and considerable distress to patients and their families. There are major gaps in knowledge about how to address this problem, so the workshop participants proposed that 1 study to consider is enhanced disease management and transition of care with monitoring (remote or biomarker) as a means of improving clinical outcomes. A large practical trial (Fig. 3) could enroll unselected patients with heart failure at the time of hospital discharge and randomize them either to usual care or to enhanced disease management with tailored therapy guided by remote monitoring (e.g., weight, heart rate, blood pressure, biomarkers). An associated registry of patients with heart failure could be established in conjunction with the randomized trial to collect additional data on the full spectrum of patients with heart failure and thereby assess the generalizability of the trial results.

The proposed study could use a cluster randomized design (31), in which clinical sites rather than individuals are randomized. The cluster randomized design is well suited to evaluation of interventions that target behavior or processes of care. Cluster randomized trials are particularly useful when it is difficult to conceal the nature of the intervention from the clinic staff and to mask patients to the intervention. The novel research designs that may be required for CER entail unique challenges (32). Despite such challenges, the workshop participants encouraged use of such novel research designs, as they provide several advantages, including simpler patient recruitment and "real-life" data directly applicable to clinical practice.

Diabetes

The incidence of diabetes continues to rise, driven in large part by the epidemic of obesity in the United States. Most patients with diabetes die of heart disease, yet the optimal approach to prevention and treatment of cardiovascular disease in patients with diabetes is not well established. Despite the recent publications of the results of the ACCORD (Action to Control Cardiovascular Risk in Diabetes Trial) (33), ADVANCE (Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation) (34), VADT (Veterans Affairs Diabetes) trial (35), long-term follow-up from UKPDS (United Kingdom Prospective Diabetes Study) and Steno 2 Study (36), and the ongoing Look AHEAD (Action for Health in Diabetes) trial (NCT00017953), the comparative effectiveness of tight glycemic control versus more liberal control of diabetes, of lifestyle management versus early drug treatment, of different initial drug treatments, and of different systems of care are all uncertain in patients with *newly* diagnosed diabetes. The workshop participants felt that the IOM priority could potentially be addressed by the following 2 trials.

The first trial could compare 2 strategies for initial treatment in patients with newly diagnosed type 2 diabetes: intensive lifestyle intervention versus immediate metformin (Online Fig. 4). A third arm of this trial could include both interventions. A second trial could focus on the comparative

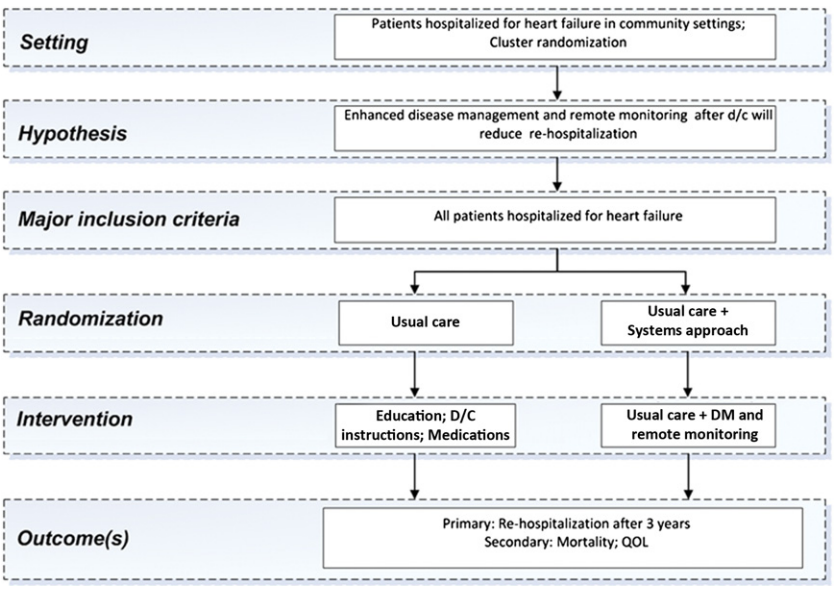

Figure 3 Proposed Cluster Randomized Trial for the Management of Heart Failure

DC = discharge; DM = disease management; QOL = quality of life.

effectiveness on cardiovascular outcomes of using different classes of glucose-lowering drugs as second agents in patients in whom metformin monotherapy fails (Online Fig. 5). Metformin therapy is the current evidence-based standard for initial pharmacotherapy, but multiple medications are usually needed to maintain durable hemoglobin A1C control. In this trial, participants would be randomized to second stage treatment with incretin mimetics versus a thiazolidinedione versus a secretagogue, with insulin withheld for third-line use.

Potential outcomes in each study could include noninvasive measures of atherosclerosis (e.g., coronary artery calcium), progression of diabetes, quality of life, and satisfaction with treatment. In light of unexpectedly higher rate of total mortality in the more intensively treated group in ACCORD, any early differences in subclinical disease markers or surrogate outcomes ought to be confirmed by subsequent assessments of clinical outcomes. Clinical cardiovascular events (cardiac death, myocardial infarction, and stroke) could be potential outcomes as well, although the group recognized that potentially low event rates might require large sample sizes and long follow-up. Depending on the outcome and participant characteristics, this simple trial could range from as few as 1,000 to 2,000 to as many as 40,000 to 50,000 participants.

A registry could also be useful for post-marketing surveillance of cardiovascular disease events among patients prescribed drugs to treat diabetes.

Risk Stratification for Coronary Artery Disease

The current paradigm for prevention of coronary disease in asymptomatic adults is based on individual risk assessment using a standard risk predictor (such as the Framingham Risk Score) and intervening with drug therapy among the individuals identified as being at highest cardiovascular risk (37). The optimal management for the patient at intermediate risk in this paradigm remains uncertain. Additional risk stratification of individuals at intermediate cardiac risk, with drug treatment of individuals with "positive markers," may substantially improve outcomes. There are many candidate risk markers that could be applied at the population level, but coronary calcification on CT is quite promising, as it provides high levels of incremental information and risk reclassification. Consequently, the workshop participants considered a large trial of coronary calcium screening among individuals found to be at intermediate risk on conventional evaluation (Online Fig. 6), with individuals found to have elevated coronary calcium receiving intensive drug therapy and lifestyle modification, and individuals without elevated coronary calcium scores undergoing lifestyle modifications alone. The trial could follow patients for up to 5 years, with the primary outcome of major cardiac events. Secondary outcomes could include quality of life, adherence to drug and lifestyle management, cost, and cost-effectiveness.

The current paradigm of individual risk assessment includes pharmacological therapy for those with elevated Framingham risk scores, but most of the high-risk group will not have a cardiovascular event in the subsequent 10 years. Additional testing of individuals with high Framingham risk scores might identify a subgroup that would not benefit sufficiently to justify lifelong pharmacological therapy. Optimal management of these individuals might be improved by imaging to document the severity of the underlying disease process. The workshop participants also suggest that a comprehensive evidence review and decision modeling of the application of imaging the disease substrate (e.g., by CT coronary angiography or coronary calcium measurement) could help to further stratify risk and guide therapy. This investigation would fit within the framework outlined in Figure 1 and assist in determining the potential value of larger CER studies to address this question.

CT Coronary Angiography

Coronary angiography can now be performed noninvasively with recent generation CT scanners, and in several case series, CT angiography has demonstrated high sensitivity and good specificity when compared with invasive coronary angiography as a reference standard (38,39). These data suggest that CT angiography may be very useful in the evaluation of patients with symptoms of coronary disease. The effect of CT angiography on clinical outcomes is uncertain, however, because visualization of coronary obstructions may well lead to unnecessary or inappropriate coronary revascularization, the value of detecting incidental noncardiac findings is unknown, and the ionizing radiation from CT scanning may lead to adverse events. Consequently, outcome-based studies of the comparative effectiveness of CT coronary angiography and alternative diagnostic strategies would address an important gap in the evidence. The NHLBI is currently funding the PROMISE (Prospective Multicenter Imaging Study for the Evaluation of Chest Pain) trial (NCT01174550), which is randomizing symptomatic patients suspected of having coronary artery disease to either usual stress testing (functional) or CT angiography (anatomic).

Another study to address this IOM priority could be a large clinical trial of patients with symptoms suggestive of coronary disease without high risk features, in which patients would be randomized to either invasive coronary angiography or to CT coronary angiography after a stress test that had either inconclusive or "not high risk" results (Online Fig. 7). Patients in the invasive angiography arm of the study would receive coronary revascularization according to current usual care, whereas in the CT angiography arm of the study, only patients with specific anatomic findings (left main disease, severe 3-vessel disease) would be recommended to receive coronary revascularization (and invasive angiography if needed to further define coronary anatomy). The primary endpoint of this trial study would be major

cardiovascular events (cardiac death, myocardial infarction, stroke), for which the noninferiority of CT angiography would be tested. Secondary endpoints could include quality of life, cost, and cost-effectiveness, for which superiority of CT angiography would be tested. The workshop participants suggest that any research infrastructure created for the proposed trial could be used as an "advanced cardiovascular imaging network" to conduct efficiently other CER studies of imaging, as has been undertaken by the Canadian Atherosclerosis Imaging Network and the Medical Imaging Trials Network of Canada.

The workshop also identified a clinical registry of CT coronary angiography procedures, ideally as an extension of the ongoing National Cardiovascular Disease Registries sponsored by the American College of Cardiology, as a further opportunity to promote CER on this topic.

Conclusions

The recent recognition of the importance of comparative effectiveness research places increasing emphasis on studies that directly inform and improve patient care. The Workshop on Cardiovascular Comparative Effectiveness Research was designed to propose approaches for the NHLBI to consider, using both an overall framework for CER and specific study designs as examples.

The approach to actionable research outlined by workshop participants implies a cycle of research and its application (Fig. 1). The 4 important linked steps in this cycle are: 1) the prospective articulation of research questions based on identifying gaps in knowledge about optimal patient care, incorporating input of stakeholders, including patients; 2) the development of evidence by a variety of research methods to address key evidence gaps; 3) application of the evidence in practice guidelines and standards of care; and 4) determination whether quality of care and patient outcomes are improved.

Several important points follow logically from this vision, beginning with consideration of a new research paradigm. Following that, relationships can be created to identify important research questions and infrastructure developed to perform studies, such as large-scale registries and CER trials, which can foster translation of research results into practice. The training and development of CER researchers and the creation of a culture of learning healthcare systems are important steps in furthering CER. Finally, clear identification of evidence gaps and key questions will help guide the performance of high-quality research.

The IOM has begun this process by identifying several research priorities in cardiovascular disease. This workshop has advanced this process by proposing research ideas to address each of the 8 IOM priority areas. These range from systematic reviews, to secondary analyses of existing data, to registries, to large-scale clinical trials; each could add important evidence needed to improve patient care. The workshop participants hope that these recommendations will provide valuable information to investigators and funding agencies as they seek to advance the nation's commitment to cardiovascular comparative effectiveness research.

Acknowledgments

The authors would like to acknowledge the NHLBI staff, Drs. Denise Bonds and Jean Olson, as well as student volunteer, Mr. Jared Lucas, for their efforts in planning and conducting of this workshop.

BACKGROUND: Breast pain is a common complaint to primary care and breast specialists. Literature recommends imaging to provide reassurance of benign etiology. The effect of imaging on reassurance and subsequent healthcare utilization has not been described.
OBJECTIVE: To determine if initial imaging for breast pain reduces subsequent utilization.
DESIGN: Retrospective cohort study at a hospital-based breast health practice.
PATIENTS: Women referred for breast pain from 2006–2009.
MAIN MEASURES: Imaging ordered at initial provider visit; clinical utilization, defined as the number of follow-up visits, diagnostic imaging studies, and biopsies completed within 12 months following initial visit.
KEY RESULTS: Sixty-percent of women were age 40 or younger, 87% were from racial/ethnic minority groups. Twenty-five percent had imaging ordered at initial visit. Of those who received initial imaging, 75% had normal radiographic findings, yet 98% returned for additional evaluation. In adjusted analyses, women with initial imaging had increased clinical services utilization (OR 25.4, 95% CI: 16.7, 38.6). Women with normal clinical breast exams who received initial imaging exhibited increased odds for subsequent clinical services utilization (OR 23.8, 95% CI: 12.9, 44.0). Six cancers were diagnosed; imaging in the absence of clinical breast exam abnormalities did not result in any cancer identification.
CONCLUSIONS: Initial imaging for women with breast pain increased the odds of subsequent clinical utilization and did not increase reassurance in ruling out malignancy.

KEY WORDS: breast pain; mammography; breast cancer.

BACKGROUND

Women often seek medical attention for breast pain due to concerns of breast cancer.[1–3] Breast pain accounts for 45–70% of breast-related complaints in the primary care setting.[4–6] Given that breast pain as a sole complaint has low risk of breast cancer (0-3%),[7–9] reassurance of non-malignancy is appropriate.[2,10,11] Nevertheless, reaching definitive diagnosis in patients with breast pain represents a dilemma, as the causes and treatments of breast pain are inadequately defined.

Current guidelines recommend imaging for breast pain if clinically indicated, such as in conjunction with a palpable mass.[12] Previous research has also recommended imaging in patients in need of reassurance,[9,11,13,14] and suggested that after initial imaging, the majority of women require no intervention following reassurance that evaluation findings are normal.[1,15] No studies have examined the effect that initial imaging for evaluation of breast pain has on provider or patient assurance in ruling out malignancy, as well as subsequent clinical management in women with breast pain.

The aim of the present study was to determine how imaging impacts clinical management of breast pain. We assessed whether initial imaging increases reassurance in ruling out breast cancer, as measured by subsequent clinical utilization. We posited that reassurance in ruling out breast cancer would be reflected in reduced subsequent clinical utilization.

METHODS

Study Setting and Population

We conducted a retrospective chart review of women referred for breast pain to internists practicing in a hospital-based diagnostic breast health practice at an academic medical center from January 1, 2006 to December 31, 2009. This specialty practice includes internists trained in breast health and a triage protocol that results in the majority of benign referrals triaged to internists.[16] Referrals are scheduled with a provider who follows a woman longitudinally through subsequent breast care received. Data were abstracted from the electronic medical record (EMR) or scheduling system. This study was approved by the Institutional Review Board of Boston University School of Medicine.

Measures

Initial imaging was defined as the completion of a physician-ordered diagnostic mammogram, ultrasound, or magnetic resonance imaging (MRI) within 3 months of initial clinical visit. Screening mammograms were distinguished from diagnostic mammograms through provider-input orders in the EMR. Screening mammograms were excluded from this and our outcome metric.

The outcome of interest was clinical services utilization. Clinical services utilization served as a proxy for reassurance, and was quantified as the number of subsequent diagnostic services completed in the 12 months following initial provider visit. The following discrete clinical variables were included in defining clinical utilization: (1) additional imaging tests completed (diagnostic mammograms, ultrasounds, or MRIs) (2) biopsies completed (fine needle aspiration, core needle, and excisional biopsies), and (3) additional clinical visits to a breast specialist over 12 months of follow-up. These three variables were summed to yield a summary "clinical services utilization score." This summary measure was categorized into 3 levels: 0: no further clinical utilization, 1: one additional follow-up measure, and 2: two or more additional follow-up measures, all over 12 months of follow-up. The components of clinical utilization were also analyzed individually as dichotomous variables: any receipt of additional diagnostic imaging, any biopsy completed, and categorical number of additional visits (no additional visits, one additional visit, and two or more additional visits), all over 12 months of follow-up.

The number of cancers diagnosed during 12 months of follow-up was descriptively analyzed, including clinical presentation, clinical evaluation and diagnostic testing, and timing of diagnostic testing and diagnoses. Cancer diagnoses were confirmed from pathology reports in the EMR. All women in the study were cross-referenced with the Boston Medical Center Cancer Registry to ensure no cancer diagnoses were missed.

Since abnormal clinical breast exam results could confound analyses by clinical indication, the study population was stratified based on the following categories of clinical exams: (1) normal clinical breast exam, (2) mass on clinical breast exam and (3) abnormality other than mass on clinical breast exam (including breast skin changes, nipple changes, nipple discharge). Stratification in this way allowed for restricted analyses on women with normal clinical breast exams.

Covariates in analyses included demographics and risk factors for breast cancer: age ($\geq$ 40 or <40 years), language (English or non-English speaking), race/ethnicity (White, Black, Hispanic, or Other), insurance (private, public, or no insurance), family history of breast cancer, current hormone therapy use, and current oral contraceptive use. Race/ethnicity minority status was included as it has been associated with delays in cancer screening,[17] diagnosis,[18,19] and treatment.[19–21] Year of referral was included in analyses to account for potential secular trends in imaging and diagnostic utilization.

Statistical Analyses

Demographic differences between women with and without initial imaging were identified using the chi-square test or t-test. Subsequent clinical services utilization was compared between the women who received initial imaging and those who did not. These associations were examined within each of the three strata of clinical breast exam results. Unadjusted logistic regressions determined the odds of each measure of clinical utilization in women who received initial imaging compared to those who did not receive initial imaging.

Multivariate ordinal logistic regression models assessed the effect of initial imaging on subsequent clinical utilization, controlling for demographic and clinical variables. Multivariate models were applied to the study population as a whole and the three clinical breast exam result strata. Variables that were not associated with the outcome at the $p<0.05$ level and variables that did not change effect estimates by greater than 10% were removed from the model.

Sensitivity analyses were conducted to rule out alternative explanations of findings. For women with normal clinical breast exams, we compared the subgroup with no initial imaging to the subgroup with normal initial imaging results (Breast Imaging-Reporting and Data System (BIRADS) 1 or 2). Using age as a proxy for menopausal status, we conducted a stratified analysis of women less than and equal or greater than 50 years of age. Provider seen at initial visit was included in analyses to account for provider-specific practices in managing breast pain. Because of the small number of patients seen by some providers, cluster analysis was not possible. Instead, we stratified the analyses by one outlier provider with a higher rate of initial imaging compared to the other providers. All data were analyzed using Statistical Analysis System version 9.1 (SAS Institute, Cary, NC).

RESULTS

Breast pain accounted for 32% of new patient referrals seen by internal medicine breast providers from January 2009–December 2009. The mean age was 39 ±13 years with 60% of women under age 40, 87% were of minority race/ethnicity, 55% were English speaking, and 73% had no insurance or public health insurance (Medicaid or Medicare) (Table 1). Twenty percent of women reported current oral contraceptive use, and 2% reported current postmenopausal

hormone therapy use. Over half had a normal clinical breast exam (55%); 12% had a palpable mass noted on clinical breast exam.

Receipt of Initial Imaging

Twenty-five percent of women were referred for diagnostic imaging at initial provider visit (Table 1). Women who received initial imaging were more likely to be white race/ethnicity ($p=0.02$), English-speaking ($p=0.008$), have a mass on clinical breast exam ($p<0.0001$), and have a family history of breast cancer ($p=0.02$) than women who did not receive initial imaging. Receipt of initial imaging was associated with provider seen at initial visit ($p<0.0001$). When the association between provider and initial imaging was stratified by clinical breast exam results, this association was not significant in women with a mass on clinical breast exam ($p=0.06$), but remained in women with normal clinical breast exams ($p<0.0001$).

Subsequent Clinical Services Utilization

Women who received initial imaging were more likely to have subsequent imaging, biopsies, additional visits, and higher clinical services utilization than women who do not receive initial imaging (Table 2). Ninety-eight percent of women who received imaging initially had additional clinical services utilization, versus 26% of women who did not receive imaging ($p<0.0001$). After adjusting for clinical breast exam results, age, family history, and provider, the odds of having a higher level of clinical services utilization for women who received initial imaging were 25.4 (95% CI: 16.7,38.6). While race and language were significantly associated with receipt of initial imaging

(Table 1), these variables did not change the estimate of the effect size in the models and therefore were not included in final models.

When the study population was stratified by clinical breast exam results, the adjusted association between initial imaging and subsequent clinical services utilization remained (Tables 3, 4, and 5). Women with normal clinical breast exams who received initial imaging had 23.8 (95% CI: 12.9, 44.0) times the odds of increased clinical utilization than women who did not receive initial imaging, controlling for age, family history, and provider. Looking at the specific components of utilization (diagnostic imaging, biopsies, and visits), these women had 10.4 (95% CI: 5.5, 19.2) times the odds of receiving additional imaging, 3.7 (95% CI: 1.1, 12.2) times the odds of receiving a biopsy, and 2.3 (95% CI: 1.4, 3.9) times the odds of having additional visits.

Eight providers delivered care to women in the study sample. Four providers saw the majority (87%) of women

during the study. The variability in imaging ordering behaviors varied among both the low- and high-volume providers. The percent of patients receiving initial imaging ranged from 5–31% among providers. Since the subjects seen by Provider 2 made up 46% of the population that received imaging, we performed a sensitivity analysis separating this provider from the other seven providers. The odd ratios of adjusted subsequent imaging was 6.3 (adjusted for age and family history, 95%CI: 2.8, 14.3) compared with the adjusted OR for all other providers (7.7, 95% CI: 4.6, 13.1), suggesting that the findings were not attributable to this provider.

We did not control for imaging results in our analyses, as BIRADS results were significantly associated with all outcome measures. Of the 229 women who received initial imaging, 25% had results that required follow-up (BIRADS

0, 3, 4, or 5), while 97% went on to receive subsequent diagnostic evaluation (clinical, radiographic, or biopsy). When comparing the 437 women with normal clinical exam and no initial imaging to the 58 women who had a normal exam and initial imaging that revealed normal findings (BIRADS 1 or 2), the adjusted OR remained high at 18.0 (95%CI: 9.4, 59.0), indicating that with normal imaging results, increased subsequent utilization remains. Stratifying women by age greater than 50 years (adjusted OR=12.3, 95% CI: 5.2, 36.8) or less than 50 years (adjusted OR 5.4, 95% CI: 3.3, 8.821) did not show major differences in subsequent additional imaging.

Breast Cancer Diagnoses

Six (0.6%) breast cancers were diagnosed in this study population during the study timeframe, four ductal carcinoma in situ (DCIS) and two invasive ductal carcinoma (IDC, Tables 6 and 7). Cross-referencing with the hospital cancer registry revealed no additional cancer diagnoses in the study cohort. Five of the 6 women initially presented with an abnormal clinical breast exam; 4 with a mass and one with focal tenderness. Four of these women were diagnosed through imaging that was initiated as result of a mass found on clinical breast examination. Table 6 and 7 shows that three of them had timely diagnostic services as a result (Cases 1, 2, 3), while one had almost one year delay due to development of cellulitis and two missed appointments (Case 4). One of these cancers (Case 3) was diagnosed in the breast contralateral to the pain, so that only three of these four cancer diagnoses were concordant with the presenting symptoms. One woman presented with focal tenderness (Case 5) but no discrete mass on initial clinical breast exam and had diagnostic imaging that was read as normal. At a follow-up visit 92 days later, a mass was found on the breast contralateral to the initial site of pain. The patient declined a breast biopsy twice and did not keep one appointment, resulting in a delay in her diagnosis. Only one cancer was diagnosed in a woman who presented with a normal clinical breast examination (Case 6). This case

presented with bilateral pain and an age-appropriate screening mammogram (not considered initial imaging in this study) was performed which revealed an incidental finding of Stage 2 IDC. In summary, three of the women had incidental cancer diagnoses (the cancer site did not correspond with the patient-reported area of pain or clinical findings); three had a cancer concordant with their clinical presentation and exam findings.

DISCUSSION

This is the first study to date that measures outcomes in addition to cancer diagnoses in women with breast pain. Our results indicate that initial imaging in the evaluation of breast pain increases subsequent clinical utilization, regardless of clinical breast exam findings. Women who received initial imaging were significantly more likely to undergo additional diagnostic evaluation. Most importantly, women with normal clinical breast exams had increased odds of clinical utilization if they received initial imaging, with no benefit of increased cancer detection. The findings did not change when the data was stratified by age as a proxy for menopausal status, or stratified by one provider with higher rates of initial imaging.

These results support existing data demonstrating a low probability of malignancy in women presenting with breast pain as a primary complaint.[9–11] The number of cancers diagnosed represents 0.6% of the study population, within the range of 0-3% previously documented in the medical literature.[7–9] Three of the 6 cancers were detected with initial imaging showing a lesion that corresponded with a mass at the site of breast pain; one had a negative initial mammogram with imaging three months later finding a contralateral DCIS, while two were detected through screening mammography (not considered diagnostic imaging in analyses). Diagnostic imaging in women with breast pain and normal clinical exams yielded no cancer diagnoses.

Previous studies in women with breast pain have sought to describe the causes, prevalence, and treatment of breast pain. Studies analyzing imaging in evaluation of breast pain have focused on cancer diagnosis as the outcome, and have demonstrated low yield of imaging in the setting of normal findings on clinical examinations.[8–11,14,22] Nevertheless, imaging has been recommended for reassurance purposes,[9] with no data describing its effect on the management of breast pain. By looking at clinical utilization outcomes, we measured the effect imaging has on clinical management of breast pain. Our data show that imaging in the initial evaluation of breast pain leads to increased clinical utilization without increased breast cancer detection. While initial imaging in women with breast pain has been recommended for reassurance purposes, there is significant increased subsequent utilization in women who receive initial imaging, without increased diagnostic yield.

Overutilization of diagnostic imaging is a concern, particularly as healthcare reform demands efforts to curtail overutilization.[23,24] In addition, normal test results do not necessarily lead to reassurance, and in some cases can increase anxiety levels and do harm.[25–27] With efforts to improve health care quality while decreasing costs, it is important to determine if imaging for patients with breast pain is of value in reassuring patients and providers, as reflected in subsequent utilization. The fact that individual provider behaviors vary within the same clinic in the management of women with breast pain and normal clinical breast exams (this variation was absent in women with mass on clinical breast exam), suggests a need for establishment of guidelines for women with breast pain.

Past studies have posited that the goal of imaging in breast pain is to provide reassurance of benign etiology to the patient and provider. This implies that diagnostic certainty of non-malignancy should increase. Previous research has demonstrated a link between diagnostic certainty and provider clinical actions, such that reduced test-ordering behaviors are directly influenced by providers' increased certainty regarding diagnoses.[28–30] Applying this association to our study, with reassurance and diagnostic certainty, subsequent testing should decrease. The increased utilization observed in this study suggests the opposite, that initial imaging does not provide reassurance or increase diagnostic certainty.

Several limitations should be considered when interpreting study findings. Study data did not allow for breast cancer risk adjustment. Using a tool such as the Modified Gail Model[31] was not age-appropriate for all women and there was incomplete data for variables in the tool, including age at first pregnancy, menarche, and menopause. Clinical services provided outside of the institution were not included in analyses. Systematic data to categorize non-malignant diagnoses (i.e. fibroadenoma, cyst) were not available and therefore not included in analyses. Clinical services and additional visits during 12 months of follow-up attributed to complaints other than breast pain could not be ascertained, and therefore we were not able to exclude these visits from analyses.

A potential referral bias exists in this population in that only women with breast pain referred to a specialty practice were included. Providers in this practice have expertise in clinical breast exams and are likely to have a higher sensitivity and specificity of their exams than most primary care providers. Markers of patient concern or anxiety were not collected and therefore could not be controlled for in analyses. Using clinical utilization as a proxy for diagnostic certainty does not elucidate whether the patient or provider is driving increased utilization. Patients who received diagnostic imaging following initial provider visit may have demonstrated a higher level of anxiety or concern than patients who did not. Similarly, providers themselves may

be uncertain about the underlying etiology of breast pain and therefore order additional diagnostic tests. Future studies that prospectively assess anxiety and reasoning for subsequent imaging are needed to address these concerns.

While past studies have indicated the main value of breast imaging in women with painful breasts to be that of reassurance, our results show that initial imaging leads to additional evaluation. Our results support previous research demonstrating that the prevalence of cancer in patients with breast pain is low and suggest that following normal clinical exam, diagnostic imaging is not required to either rule out cancer or provide reassurance in ruling out cancer. As importantly, these results support the critical role of clinical breast exam skills in the evaluation of breast pain.

ABSTRACT

Introduction: Identifying major bleeding is fundamental to assessing the outcomes of anticoagulation therapy. This drives the need for a credible implementation in automated data for the International Society of Thrombosis and Haemostasis (ISTH) definition of major bleeding.
Materials and Methods: We studied 102,395 patients who received 158,511 person-years of warfarin treatment from the Veterans Health Administration (VA) between 10/1/06-9/30/08. We constructed a list of ICD-9-CM codes of "candidate" bleeding events. Each candidate event was identified as a major hemorrhage if it fulfilled one of four criteria: 1) associated with death within 30 days; 2) bleeding in a critical anatomic site; 3) associated with a transfusion; or 4) was coded as the event that precipitated or was responsible for the majority of an inpatient hospitalization.
Results: This definition classified 11,240 (15.8%) of 71, 338 candidate events as major hemorrhage. Typically, events more likely to be severe were retained at higher rates than those less likely to be severe. For example, Diverticula of Colon with Hemorrhage (562.12) and Hematuria (599.7) were retained 46% and 4% of the time, respectively. Major, intracranial, and fatal hemorrhage were identified at rates comparable to those found in randomized clinical trials however, higher than those reported in observational studies: 4.73, 1.29, and 0.41 per 100 patient years, respectively.
Conclusions: We describe here a workable definition for identifying major hemorrhagic events from large automated datasets. This method of identifying major bleeding may have applications for quality measurement, quality improvement, and comparative effectiveness research.

Introduction

Hemorrhage is a frequent complication of anticoagulant therapy [1]. Therefore, understanding rates of bleeding in patients receiving anticoagulation is an essential ingredient in assessing the risks and benefits of such therapy. The ability to assess rates of bleeding is important for diverse applications, including comparative effectiveness studies of different anticoagulants and efforts to measure and improve quality of anticoagulation care.

A common approach to detecting any diagnosis, especially in administrative datasets, involves using International Classification of Disease (ICD-9-CM) codes. In examining the accuracy of ICD-9-CM codes to identify complications of anticoagulation therapy, Arnason and colleagues reported a PPV of 87% for major bleeding, which increased to 96% when the bleeding code was listed as the 'most responsible diagnosis' or the 'admitting diagnosis' [2]. This study suggests that automated data alone can be sufficient to identify true-positive episodes of major hemorrhage rivaling that of chart review, particularly when additional strategies are employed to boost PPV.

The majority of previous studies assessing the accuracy of ICD-9-CM codes for identifying major hemorrhage have used chart review as a gold standard [2–6]. Additionally, the most prominent definition

of major bleeding provided by the International Society of Thrombosis and Haemostasis (ISTH) also presupposes chart review [7]. While chart review is highly accurate, it is resource intensive. A national database of Medicare beneficiaries, for example, would require chart reviews at every hospital in the United States, which is clearly not practical. To fully harness the power of large databases to inform practice, we cannot always rely upon chart review. To our knowledge, there have been no previous attempts to adapt the ISTH definition of major hemorrhage for use with automated data.

Therefore, the objective of our study was to develop a method for identifying major hemorrhagic events in a linked Veterans Health Administration (VA)-Medicare dataset [8]. We explored the impact of different definitions and strategies upon the apparent incidence of major hemorrhage in this automated dataset and compared the rates found in our study with those reported in previous randomized and observational studies. We expected that the results of this effort would pave the way to unlocking the power of large automated datasets to track major hemorrhage for comparative effectiveness research and quality assurance/quality improvement.

Methods

Data

The data for this study included all 122,159 patients who received warfarin therapy from the VA between 10/1/06 and 9/30/08, including patients new to warfarin and those who were already experienced users. Details regarding how we built this database appear elsewhere [9]. This included demographics, ICD-9-CM diagnosis codes, and dates of service (from both sources), as well as laboratory data and pharmacy records (VA data only). This study was approved by the Institutional Review Board of the Bedford VA Medical Center.

Since we used a merged VA-Center for Medicare and Medicaid Services (CMS) dataset, we can be assured of nearly complete capture of all relevant care received by this group [8]. Out of these 122,159, 19,764 patients enrolled in Medicare Advantage program were excluded, because unlike patients participating in this capitated program would not produce itemized claims data, leading to undercounting of events. After excluding patients enrolled in Medicare Advantage, our final sample consisted of 102,395 patients who received 158,511 person-years of warfarin treatment from the VA.

For this study, we defined a period when each patient was considered to be "on warfarin" and therefore eligible to record a bleeding event. The date of warfarin inception is taken to be the first time warfarin is dispensed by the VA pharmacy or the first INR test, whichever comes first. The period begins with the latter of date of warfarin inception and 10/1/06; it ends at the latest date of a pharmacy fill plus 30-day grace period (to account for the duration of use) or an INR test, up to a maximum of 9/30/08. These 2 dates define a "window" for each patient, and only bleeding events that occur during this window can be included.

Overview of Strategy to Identify Major Hemorrhage

Our strategy was to approximate the ISTH definition for major hemorrhage as closely as possible [8], given the nature of our data. The ISTH definition uses the following criteria to define major bleeding: 1. Fatal bleeding, and/or, 2. Symptomatic bleeding in a critical area or organ such as intracranial, and/or, 3. Bleeding causing a fall in hemoglobin level of 20 g L^{-1} or more, or leading to transfusion of two or more units of whole blood or red cells [7]. For the current study, candidate bleeding codes were identified from the inpatient and outpatient ICD-9-CM codes recorded in VA and Medicare datasets. We required these codes to fulfill at least one of four criteria to be considered a major hemorrhagic event: 1) bleeding associated with death within 30 days; 2) bleeding into a critical anatomic site which necessarily would threaten life or limb; 3) bleeding associated with a transfusion of packed red blood cells or whole blood; or 4) a bleeding event characterized in our datasets as either the primary reason for a hospital admission (VA data) or the main condition (commonly known as the "principal diagnosis") for which the services are provided during a hospital stay (Medicare data).

ICD-9-CM Codes for Major Hemorrhage

We began by examining the lists of ICD-9-CM codes used by several previous studies to identify major hemorrhage, including Schalekamp et al. [5], Boulanger [6], and Arnason [2]. Thus, we began with a comprehensive list of candidate codes building on prior research. Several codes were subsequently excluded as they were felt to not be representative of major hemorrhage, e.g. 593.81, Vascular Disorders of the Kidney.

Deletion of Duplicate Events

To avoid counting multiple mentions of a single event, we developed decision rules for selecting a single record out of multiple records close in time. For example, this might occur if the course of care for a bleeding event involved 2 locations, such as a transfer from a non-VA hospital to a VA hospital. We considered records to denote a single event if they occurred on the same day or within 7 days in either direction and used the same 5-digit ICD-9-CM code. We also developed an algorithm to determine which event to retain when two conflicted; details can be found in Appendix A.

Finally, we developed an algorithm to assign a "primary" type of bleeding when codes for different types of bleeding occurred on the same date. We created five main categories of bleeding, namely intracranial bleeding, gastrointestinal bleeding, hemarthrosis, urinary bleeding, and bleeding from the throat. It was uncommon to have bleeding codes from more than one category on the same day. For patients with multiple codes within a category, we created a ranked hierarchy of codes within category to aid in selecting a single code for each episode. Details for this algorithm are found in Appendix B.

Definition: Fatal Bleeding

For the outcome of death and its date, we used the VA Vital Status Mini-File. This dataset combines multiple sources of data, including the national death index, Medicare data, and VA data to determine a single best date of death for each VA patient. The Vital Status Mini-File is considered a reliable and authoritative source for dates of death among VA patients [10].

We defined fatal hemorrhage as a bleeding event followed by death within 30 days. However, we excluded certain categories of bleeding that were implausible causes of death, including epistaxis, hematuria, bladder wall hemorrhage, hemarthrosis, and any bleeding associated with internal or external hemorrhoids. Patients who died within 30 days of such events were not considered to have died because of the bleeding.

Definition: Critical Anatomic Site

Bleeding into a critical anatomic site was defined as major bleeding, because it would necessarily threaten life or limb. This included any type of intracranial hemorrhage, hemopericardium, hemoperitoneum, and any type of hemarthrosis (which would threaten limb function). We could not include retroperitoneal hemorrhage, intraspinal, intraocular, and intramuscular bleeding with compartment syndrome, which are equally serious, because no ICD-9-CM code uniquely identifies these conditions. Additionally, to a large extent we have likely captured these relatively uncommon intraspinal and intramuscular bleeding episodes using the all-purpose ICD-9-CM code "Hemorrhage NOS" (459.0). We also separately tabulated rates for intracranial hemorrhage,

a subset of critical-site bleeding defined by the ICD-9-CM codes 430, 431, 432.0, 432.1, and 432.9.

Definition: Transfusion

We identified all transfusions of packed red blood cells or whole blood that occurred within 30 days of a bleeding event. The number of units transfused was not available. Transfusions were identified from surgical codes 99.0, 99.03, or 99.04 (Blood Transfusion, Whole Blood Transfusion, and Packed Cell Transfusion) or CPT codes 36430, 36431, or 36440 (Blood Transfusion Service).

Definition: Primary/Principal Inpatient Diagnosis Code

In VA data, the "primary" diagnosis for each inpatient admission is the ICD-9-CM code for the condition that is most responsible for the patients' length of stay. In the CMS dataset, a "principal" code was identified as the diagnosis, condition, problem or other reason for the admission/encounter/visit shown in the medical record to be chiefly responsible for the services provided. We considered any ICD-9-CM code that occupied the primary or the principal position for an inpatient stay to represent a major hemorrhage.

Statistical Analyses

We considered any candidate event which fulfilled at least one of the four criteria discussed above (fatal event, critical anatomic site, transfusion, primary reason for a hospitalization) to represent a major hemorrhage. We also performed sensitivity analyses using an alternative, more restrictive definition that omitted the criterion "primary diagnosis code". We compared, in tabular form, the proportion of events retained under each definition, stratified by ICD-9-CM code. For these analyses, we allowed multiple events and did not censor.

For age-stratified rates of bleeding, all events were classified by patient's age as of Oct. 1, 2006, not age at time of event. Confidence intervals were obtained assuming events were Poisson-distributed. All analyses were performed using SAS version 9.2 (SAS Institute, Cary, NC). Drs. Rose and Jasuja and Mr. Reisman had full access to the study data and guarantee the accuracy and completeness of the results.

Results

Patients

Descriptive characteristics of the patients are reported in Table 1. The study sample primarily consisted of White males, with a median age of 70 years. Approximately 74% of the sample had been using warfarin for at least one year at the time of study inception. Patients in this study had a high burden of comorbid illness; for example, 31% had heart failure, 39% had diabetes, and 14% had chronic kidney disease. The burden of mental health conditions was also considerable: 23% of patients carried a diagnosis of depression, and 11% a diagnosis of alcohol abuse or dependence. Twenty-eight percent of patients were hospitalized at least once during the two-year study.

Inclusion of Candidate Events

Table 2 lists the bleeding ICD-9-CM codes for only those codes with at least 100 candidate events, and shows the number and rates for each of these bleeding event retained and the reason for their inclusion. A full version of this table, which also includes rarer event types, is presented in Supplementary Table 1 (Online Appendix). Among 71,338 unique events, 11,240 events (15.8%) were retained. Events that would seem on their face to be relatively severe were more often retained. For example, Diverticula of Colon with Hemorrhage (562.12), Esophageal Hemorrhage (530.82) and Hematemesis (578.0) were retained 46%, 43% and 42% of the time, respectively. Many candidate events, however, were contributed by event types that would only rarely have truly severe manifestations; these events were retained at much lower rates. For example, there were 30,100 episodes of Hematuria (representing 42% of candidate events), but only 4% of them qualified as major hemorrhage by our definition. Similarly, there were 5,927 episodes of Epistaxis, but only 6% were retained. Comparison of rates of inclusion and retention for our main definition and the more restrictive definition are presented in Supplementary Table 2 (Online Appendix).

Population Rates of Major Hemorrhage

We computed event rates by age strata for major hemorrhage, intracranial hemorrhage, and fatal hemorrhage for the entire population of 102,395 patients who received 158,511 patient-years of warfarin treatment from the VA (Table 3). Major hemorrhage occurred with an overall rate of 4.73 per 100 patient-years. The rate of intracranial hemorrhage, 1.29, represented 27% of all major hemorrhages, and the rate of fatal hemorrhage, 0.41, represented 9% of all major hemorrhages. There was an increasing rate of all 3 kinds of hemorrhage (any major, intracranial, and fatal) with increasing age. In particular, the rate of fatal hemorrhage increased sharply above age 70.

Comparison of the Present Study to other Major Studies

Table 4 presents a comparison of the rates of major bleeding reported in previous observational and randomized studies with the present study. The rates for major bleeding reported in observational

Table 2
Inclusion of candidate events by ICD-9-CM code. The total number of candidate events was 71,338, of which 11,240 were retained (15.8%). In this abbreviated version of the table, only event types with ≥100 candidate events are shown; the full version of the table, including rarer event types, can be found in the online appendix (Supplementary Table 1).

‡ Bleeding into a critical anatomic site was always included as a major hemorrhage.

cohorts such as ATRIA (0.91 per 100 person-years) and ACTION (1.90 per 100 person-years) were much lower than what we found in our study. The rates for major bleeding found in randomized clinical trials ranged from 2.2 per 100 person-years (ACTIVE W, 2006) to 3.4 percent per year (ROCKET-AF, 2011). Rates of bleeding from earlier studies (as reflected in the Linkins meta-analysis) tended to be higher (the cumulative rate of all included studies was 7.2 percent per year).

Discussion

The ability to perform surveillance for adverse events is a key foundation for any program of comparative effectiveness research or quality measurement and improvement. Major hemorrhage is an adverse event common to all types of anticoagulant therapy, and therefore the ability to identify major hemorrhage in real-time, using an automated approach, would be extremely attractive. In this study, we sought to develop a comprehensive definition for identifying major hemorrhagic events among warfarin patients in a large, automated database, in a setting where chart review would not be possible.

In our population of patients receiving warfarin therapy for varied indications from the VA, we found an overall rate of major hemorrhage of 4.73 events/100 patient-years. The rates of intracranial and fatal hemorrhage were 1.29 and 0.41 events/100 patient-years, respectively. These rates of warfarin-related bleeding are similar in magnitude to the rates observed in recent large randomized trials, such as ROCKET-AF, ARISTOTLE, SPORTIF-V and RE-LY, as well as the pooled results of earlier randomized and observational studies summarized in a key meta-analysis by Linkins, et al. [1]. However, our rates for major bleeding were much higher than those reported in observational cohorts such as ACTION, ATRIA and Euro Heart Survey; this is likely attributable to a much higher illness burden among VA patients. Taken together, these results suggest that our approach to identifying major hemorrhage in warfarin patients may achieve similar results to other methods that have been employed. In addition, we note that the risk of any major hemorrhage, intracranial hemorrhage, and fatal hemorrhage among this at-risk population all increased in our study with increasing age, with a generally monotonic trend. This also echoes the findings of earlier studies [20–22] and further suggests

Table 3
Population rates of major hemorrhage and subtypes of major hemorrhage by age category, among patients receiving warfarin therapy from the VA between 10/1/06-9/30/08.

Age at Start of Window	# Patients	Aggregate Time on Therapy (patient-years)	Rate of Hemorrhagic Events (per 100 patient-years with 95% C.I.)		
			Any Major	Intracranial*	Fatal
Total	102,395	158,511	4.73 (4.62 - 4.83)	1.29 (1.23 - 1.35)	0.41 (0.38 - 0.45)
Under 55	9,865	13,958	2.29 (2.04 - 2.55)	0.63 (0.51 - 0.78)	0.10 (0.05 - 0.17)
55 – 59	14,185	21,169	2.96 (2.73 - 3.20)	1.01 (0.88 - 1.15)	0.14 (0.09 - 0.20)
60 – 64	14,436	21,882	2.94 (2.72 - 3.18)	0.85 (0.74 - 0.99)	0.19 (0.13 - 0.25)
65 – 69	11,120	17,644	3.89 (3.60 - 4.19)	1.00 (0.86 - 1.16)	0.27 (0.20 - 0.35)
70 – 74	15,001	24,105	5.26 (4.97 - 5.55)	1.49 (1.34 - 1.65)	0.42 (0.34 - 0.51)
75 – 79	15,689	25,206	6.12 (5.82 - 6.43)	1.60 (1.45 - 1.77)	0.54 (0.46 - 0.64)
80 – 84	15,095	23,895	6.70 (6.37 - 7.03)	1.80 (1.63 - 1.98)	0.72 (0.62 - 0.84)
85+	7,004	10,652	7.56 (7.04 - 8.10)	1.76 (1.51 - 2.03)	1.09 (0.90 - 1.31)

Patients may experience >1 major hemorrhage during the study.

that our algorithm to identify warfarin-related major hemorrhage is working as intended.

The main limitation of this study is that we were not able to perform chart review to confirm cases of major hemorrhage, in large part because the merged VA-Medicare dataset we used would have required us to obtain data from every hospital in the United States. However, as discussed above, this study represents an important effort to find a rigorous and thoughtful approach to identifying warfarin-related major hemorrhage when a chart review is simply not possible. Our efforts borrowed heavily from previous studies that had used chart review as a gold standard [2–6]. However, no study involving chart review could have ever included a database of this size, because of the expense involved in reviewing so many charts. This study, therefore, represents an important effort to apply the results of previous (smaller) studies, which did involve chart review, to a new, larger platform, one which is ultimately necessary if automated databases are to be used for such important purposes as comparative effectiveness and quality assurance. Because Medicare data, which largely formed the basis of our study, is also the basis for so many other studies, our approach and our results may have wide applicability. However, since our at-risk population comprised of only patients on warfarin, findings from this study are only generalizable to patients on oral anticoagulant therapy such as warfarin and may not apply, for example, to patients receiving aspirin alone.

Our definition for major bleeding was actually fairly conservative, and it seems likely that we undercounted major bleeding if anything. The ISTH definition [7] includes a drop in hemoglobin level of 20 g L^{-1} to qualify an event as a major hemorrhage. We were unable to precisely characterize the time course of the hemoglobin level, particularly when using Medicare data (which does not include lab results). Therefore, hemoglobin levels were not used as a criterion for major hemorrhages in our study, and this likely resulted in considerable undercounting of events that otherwise would have qualified.

On the other hand, it is possible that our definition overcounted certain events; indeed, we cannot have avoided this entirely. In particular, our addition of a primary inpatient diagnosis code to the criteria for major hemorrhage represents an innovation, and is not contained within the original ISTH definition [7]. We considered this necessary as a way to compensate partially for our inability to establish major hemorrhage based on hemoglobin levels. In addition, this decision was supported by the finding of Arnason, et al. [2] that ICD-9 codes for hemorrhage have a 96% PPV when they are in the primary position for an inpatient stay. To us, this choice seemed like a logical way to capture at least some of the events that would have been included had we been able to track hemoglobin values. In addition, it can of course be argued that any bleeding that causes a hospitalization (or prolongs one) is, by definition, "major". Those who prefer to employ a definition more closely aligned to the original ISTH definition may wish to use our variant definition, which omitted this criterion (see Online Appendix for a comparison of the main and variant definitions). However, our main definition filtered more severe types of events to a lesser extent and filtered less severe sorts of events much more heavily. For example, "Diverticulosis of Colon with Hemorrhage" (562.13) was retained 47% of the time, while "Hematuria" (599.7) was retained only 4% of the time. In this respect, we consider our approach a success in differentiating between major and minor hemorrhagic events.

In conclusion, a definition of "warfarin-related major bleeding", modeled on similar parameters as the ISTH definition and applied to an automated dataset, allowed for computation of meaningful and comparable rates of hemorrhage. This method of extracting major hemorrhage may also prove useful with other automated datasets similar to our VA-Medicare merged dataset, for applications including comparative effectiveness, quality measurement, and quality improvement.

Conflict of Interest Statement

None.

Living with HIV: Responses to a Mantram Intervention Using the Critical Incident Research Method

Jeanne Kemppainen, PhD, RN,[1] Jill E. Bormann, PhD, RN,[2,3] Martha Shively, PhD, RN,[2,3] Ann Kelly, MS, APRN, BC,[2,3] Sheryl Becker, MS, RN,[2] Patricia Bone, BS, RN,[2,4] Wendy Belding, MA,[2,4] and Allen L. Gifford, MD[5]

Abstract

Objectives: The objective of this study was to identify and describe ways that a spiritually based intervention of silently repeating a mantram—sacred word or phrase—was used as a coping strategy for managing human immunodeficiency virus (HIV) disease.
Design: The design was a qualitative research method, the critical incident technique.
Settings/location: The study was conducted at an academically affiliated Veterans Affairs Hospital in southern California.
Subjects: The subjects were outpatient adults living with HIV ($n=32$) who were receiving care through HIV clinics, community agencies, and HIV providers.
Interventions: Subjects who participated in the intervention arm of a randomized controlled trial that tested the efficacy of a 5-weekly group mantram intervention were interviewed 2 months postintervention. Follow-up telephone interviews were specifically aimed at identifying instances of mantram use, and also participant perceptions of intervention usefulness or nonusefulness.
Outcome measures: The outcome measures comprised categorization and comparison of the types and frequency of incidents reported, describing ways that the intervention was "helpful" or "not helpful" in managing stressors of HIV disease.
Results: Participants reported a total of 185 incidents. Analysis and classification of the incidents resulted in eight mutually exclusive categories, including Increasing calm and/or peace, Mastering the technique, Changing my viewpoint, Increasing personal awareness, Adjusting behaviors, Managing physical symptoms, Increasing spirituality, and Enhancing relationships.
Conclusions: This study shows support for the benefits of the mantram intervention for adults with HIV. Additionally, the spiritually based mantram repetition intervention was found to be more helpful in providing a convenient, portable tool for managing a wide range of situations related to living with HIV disease.

Introduction

Although great strides have been made in the treatment of human immunodeficiency virus (HIV) disease and in extending both the quality and length of life, HIV/acquired immunodeficiency syndrome (AIDS) remains a stressful and demanding illness.[1] The psychologic and physical demands of coping with complex medication regimens, side-effects of treatment, symptom severity, as well as comorbid illnesses can be overwhelming and may influence health care behaviors such as medication adherence, substance use, sexual risk taking, or other behaviors that influence health outcomes.[1,2] In addition, persons living with HIV disease often experience psychosocial challenges such as depression, isolation, and traumatic life events that can impact the course of HIV disease progression.[2,3] Evidence suggests that stress may hasten HIV disease progression by increasing viral replication and suppressing the immune response.[4–6]

Intervention studies using combinations of cognitive and relaxation therapies in the era of highly active antiretroviral

therapy have shown improvements in psychologic quantitative measures in HIV-infected persons.[7] Limitations of these studies are that (1) they assessed multiple-component interventions (e.g., a variety of relaxation techniques and cognitive–behavioral strategies), making it difficult to conclude which ones accounted for changes in health status; (2) most were conducted on samples of gay and bisexual men, thus failing to study women and heterosexuals; and (3) most were pre-experimental or had a wait-list control group rather than a comparable control group.

Although research findings are not entirely consistent, there is some evidence that spirituality predicts slower HIV disease progression.[8,9] Patients who have endorsed a greater sense of spirituality after being diagnosed with HIV have shown a slower decline in CD4 cell counts and better control of viral load over 4 years.[8]

Recent attention has been directed toward developing spirituality-based interventions for managing stressors of chronic illness, including HIV/AIDS.[10–12] Practices such as prayer and meditation, for example, have been cited as commonly used coping strategies by persons living with HIV/AIDS.[13–15] More research on the healing aspects of spirituality is needed as new methods to measure spirituality are becoming refined.[16–19]

Objectives

In light of the huge impact of the psychologic burden experienced by persons living with HIV/AIDS, it is important to gain a broader understanding of the specific uses that a mantram-based, spiritual intervention has on the perceptions and behavioral actions of persons living with HIV disease. To provide a more comprehensive picture of the usefulness of a mantram intervention developed by Bormann and colleagues,[20] a qualitative component was added to the larger randomized controlled trial (RCT). Follow-up interviews were conducted with participants in the mantram arm of the original study at 2 months postintervention to enhance the quality and credibility of the quantitative findings.[21] The interviews were specifically aimed at determining how the skills learned from a mantram intervention played out in the real life of study participants. This analysis examined the qualitative interview findings. Specific objectives for this analysis included (1) identifying incidences of mantram use following participation in a spiritually based mantram intervention, and (2) identifying participant perceptions of intervention usefulness or nonusefulness.

Materials and Methods

Procedures

In the original RCT, Bormann and colleagues examined the efficacy of a group-based mantram intervention on HIV outcomes with a sample of HIV-infected adults receiving outpatient care through HIV clinics, community agencies, and HIV providers.[20] The study was conducted through the VA San Diego Health Care System and the University of California San Diego. Human subject approvals were obtained from university and VA hospital committees.

In the original RCT, participants were randomly assigned to either a mantram-based intervention or to an attention-matched education control group. Participants attended a series of 5 weekly 90-minute sessions, followed by 4 weekly automated phone calls from co-facilitators, and a final booster session in week 10. Sessions consisted of how to (1) choose and use a mantram, (2) practice slowing down one's thinking to help set health-related priorities, and (3) develop one-pointed attention for stress management. Participants were given *The Mantram Handbook*,[22] a list of mantrams to choose from and course manual with homework exercises. Weekly assignments included practicing mantram repetition at non-stressful times, such as each night before sleep or while waiting in lines. Other strategies taught were slowing down mentally and behaviorally, to make wiser choices, set priorities, and decrease hurried behavior, and one-pointed attention to increase concentration for repeating the mantram or engaging in one task at a time. For a more complete description of the intervention, see Bormann, 2006.[20] The qualitative data in this analysis were obtained through follow-up telephone interviews conducted at 2 months postintervention to assess the uses and sustainability of mantram practice.

Based on the findings of a larger RCT, it was anticipated that this spiritually based intervention would foster the continued use of positive coping behaviors in persons with HIV/AIDS.

Interviews

A qualitative research method, the critical incident technique,[23] was chosen for its ability to pinpoint specific behaviors and benefits of the mantram. This valid and reliable interviewing format is a very practical and efficient method for obtaining information quickly and in the participants' own words.[24] Critical incident interviews may be very brief, perhaps as short as 10–15 minutes. They are designed to pinpoint facts and eliminate personal opinion or generalizations.[23] They require only simple types of judgments and responses from the participants, and are used to increase knowledge about little-known phenomena, such as mantram repetition.

The critical incident technique has been applied in a variety of health care settings to examine patients' met and unmet psychologic needs, [25] predict patient perceptions of nurse behaviors,[26] and gather information about extended care nursing[27] and long-term care facilities.[28]

In the current study, critical incident interviews were conducted as follows. Participants were contacted 2 months after the final group session by a research nurse, trained in the critical incident interviewing method. Telephone audiotaped interviews were conducted on all participants, asking them to recall specific incidents of mantram use. Participants were asked to describe as many situations as could be remembered and to give examples of successful outcomes, as they defined it. Standard probes were used to obtain a more complete description of the context of the incident. The critical incident interviews lasted approximately 15 minutes and were transcribed for analysis. A critical incident expert was consulted prior to and during the study to guide the methods and analysis (e.g., taught the interviewer how to ask questions and assisted with data interpretation).

Data preparation and analysis

The data obtained through the critical incident interviews were analyzed through an inductive classification process developed by Flanagan.[23] This careful process enabled the

researchers to build a comprehensive picture of the behavioral dimensions of mantram use.[29]

First, the transcribed interview data were audited to ensure that each of the incidents included complete behavioral descriptions and also demonstrated a linkage between what the respondent did or did not do and the resulting outcome. The members of the research team and a doctorally prepared nurse with expertise in the critical incident research method made these judgments. Only 185 incidents out of 200 or 93% met Flanagan's criteria and were included in the analysis.

Incidents, which were judged to be nearly identical or very similar, were grouped together. Similar groupings were then combined to form subcategories of behaviors. Subcategories were sorted and grouped together to define more inclusive major categories of mantram use. Members of the research team and two doctoral-prepared nurses with expertise in HIV/AIDS and research methods independently re-sorted the incidents, and their disagreements were used to refine and determine the final set of eight mutually exclusive and exhaustive major behavioral categories.

As a check on the comprehensiveness of the classification system, 10% of the incidents were randomly selected using a table of random numbers and were independently categorized by 2 expert reviewers. The percent of inter-rater agreement was 95%.

Results

Subjects

Table 1 shows the demographic and severity of illness characteristics for the participants included in this analysis ($n=32$). The majority of the sample was male (78.1%) with a mean age of 44.1 years (standard deviation [SD] 6.7). Forty-three percent (43%) of the participants were nonwhite. The mean CD4 count for the sample was 517/mm^3 (SD 280.43), with an average time since acquiring an HIV diagnosis of 8.3 years (SD 5.96). At the time of the study, 23 of 32 participants (71%) were receiving highly active antiretroviral therapy. The majority of the respondents reported that they were never married or partnered (59.4%; $n=19$), while 81% ($n=70$) indicated that they completed some college. Sixty-nine percent (69%) ($n=22$) identified with a religious group. Approximately 41% of participants scored above the cutoff for depressive symptoms on the Clinical Epidemiology Study-Depression scale.

Table 1. Demographic Data ($N=32$)

Variable	*Range*	*Mean (yrs)*	*SD*	*Frequency*

Critical incident analysis

A total of 185 incidents describing mantram use behaviors were obtained from 32 participants who completed the mantram intervention. The analysis and classification of the incidents resulted in 8 mutually exclusive categories, and 16 subcategories.

Major categories of mantram use included the following: *Increasing calm and/or peace, Mastering the technique, Changing my viewpoint, Increasing personal awareness, Adjusting behaviors, Managing physical symptoms, Increasing spirituality, and Enhancing relationships.* A review of the incidents that were sorted into each category determined the definition. The taxonomy of major mantram repetition behaviors is presented in Table 2.

The largest category, *increasing calm and/or peace*, accounted for 36% of the total number of incidents. Two thirds of the incidents placed within this category ($n=42$; 64%) described behaviors where mantram repetition increased a sense of peace or calm in response to an identified stressor, including waiting for a doctor appointment, encountering a stressful situation while riding on public transportation, or being late for an appointment because "someone was late picking me up." As one of the participants stated:

Table 2. Categories of Mantram Repetition Behaviors (N=185 Incidents)

Major category	*Number of incidents*	*Percent*
I. Increasing calm and/or peace (66 incidents; 36%)		
1. Increasing calm and/or peace with an identified stressor	42	64%
2. Increasing calm and/or peace *without* an identified stressor	11	17%
3. Replacing anger with peace	11	17%
4. Calming others around me	2	3%
II. Mastering the technique (39 incidents; 21%)		
1. Practicing Mantram repetition	20	51%
2. Using one-pointed attention	16	41%
3. Renewing previous mantram training	3	8%
III. Changing my viewpoint (36 incidents; 19%)		
1. Changing perspective and "letting go of concern"	23	64%
2. Increasing patience	7	19%
3. Controlling thoughts	6	17%
IV. Increasing personal awareness (15 incidents; 8%)		
1. Becoming aware of emotional states	12	80%
1. Becoming aware of physical state	3	20%
V. Adjusting behaviors (14 incidents; 7.6%)		
1. Changing a specific behavior	12	86%
2. Slowing down	2	14%
VI. Managing symptoms (10 incidents; 5%)		
1. Inducing sleep	8	80%
2. Finding pain relief	1	10%
3. Breathing easier	1	10%
VII. Increasing spirituality (4 incidents; 2%)	4	100%
VIII. Enhancing relationships (1 incidents; 0.05%)	1	100%

> When I am really frustrated or in a line or something, I don't let that bother me. I just say my mantram, and before you know it, I am right up at the front of the line. It has really worked for me.

Mantram repetition was also used for managing emotions related to driving in heavy traffic or encountering "road rage." Many participants found that briefly repeating a mantram generated a sense of calm, and reduced negative feelings toward other drivers. Although Easwaran[22] did not endorse using mantram while driving, mantram repetition appeared to be more helpful than harmful. No one reported any accidents attributed to mantram repetition while driving. The following example describes a traffic-related incident:

> Instead of shouting or yelling or swearing at somebody in traffic, I just start using my mantram to bring myself off that cliff. I use it just about every time…. Instead of throwing words out the window, I can just sort of say it to myself….I don't drive away from the situation with my blood boiling, all mad and upset, because I realize that I keep myself down and don't let myself get to that hyped-up point.

Additional incidents placed into this category involved *increasing calm without an identified stressor* (n=11; 17%). As one participant stated:

> Sometimes when I get stressed out....like if I was having a really, really bad day…I deal with the anxiety and stress by using the mantram.

An additional 17% of the incidents in this category described the use of mantram repetition to replace anger with a sense of peace or calm. As one participant stated:

> The mantram, in itself, was very helpful. It helped out in a lot of different situations…being confronted by rude people, like in the public, and to keep from promoting violence, you know, just to back off and repeat it.

Two (2) additional incidents grouped within this major category describe the effectiveness of mantram repetition in calming others.

The second category, *mastering the technique,* reflected incidents where subjects practiced the primary skills of the mantram course intervention, including practicing mantram repetition (n=20; 51%), using one-pointed attention (n=16; 41%), and renewing previous mantram training (n=3; 8%).

The third category, *changing my viewpoint*, accounted for 16% of the total number of incidents. The majority of the incidents within this category (n=23; 77%) described circumstances where the study participants changed perspective about a circumstance or event. As 1 participant stated:

> I used to stress out about going to the doctor but don't do that anymore. I say my mantram instead. I had a colon test that I put off for a year and a half. I was so afraid thinking, "Oh my God, what if I have colon cancer?" And I scared myself so bad. I thought I'm going to get this done. And I called the doctor and I scheduled it. In the past, I would have been such a drama person about this and afraid that I had something before I went in.…I changed my whole thing of having a negative thing and going into a positive and not putting that much worth on it.

The fourth category, *increasing personal awareness,* included 15 (8%) incidents that described the linkages between mantram use and an increasing awareness of emotional and physical states. As 1 participant stated, "It taught me to feel how different my brain felt when I was calm so then I could sense that when I was getting angry."

Incidents that described behavior changes related to mantram repetition were placed in the fifth category. The following examples of changing behaviors include:

> When I get ready to eat, I turn the TV off and I just eat and just enjoy my meal. Instead of like eating and watching TV or listening to music, now I just relax and take time for myself.
>
> I am trying to be more patient with people that are not as quick as I need them to be at the moment or when I am talking to someone who is a little slower in understanding. I'm trying to also stop interrupting people and finish things for them.

A sixth category contained incidents that described the impact of mantram repetition on managing physical symptoms. Within this category, eight incidents described the use of mantram repetition as a sleep aid:

> It helps me to use the mantram instead of just lying in bed and tossing and turning. I can use my mantram and just repeat my mantram and I fall back asleep.…The next thing you know, it's the next morning.

One (1) participant described the successful use of mantram repetition to "ease breathing" during an episode of *Pneumocystis carinii* pneumonia (PCP), while a second participant reported using mantram repetition to ease physical pain. The two remaining categories included *increasing spirituality* ($n = 4$, 2%) and *enhancing relationships* ($n = 1$).

Perceptions of usefulness or nonusefulness of mantram program

Of the total number of reported incidents, the majority (99%) were positive reports of instances when mantram repetition enhanced the respondent's coping. Two (2) negative incidents associated with mantram use were reported, including the following:

> One of the things I was presented with was single task activity. I can't say that it was helpful and it was certainly contrary to everything I have ever done. I find it difficult to utilize that concept and I don't see how it can be used effectively.
> I learned the futility of trying to document the times and numbers of the mantra use. I thought it was distracting and counterproductive."

Discussion

This critical incident study represents a comprehensive effort to identify specific patterns of mantram use by persons living with HIV disease following participation in a spiritually based education program. This practical and efficient qualitative method allowed the researchers to gain a greater depth of understanding about the perceptions of study participants, as well as precise descriptions of behavioral outcomes of the mantram intervention. Participants reported using mantram repetition up to 2 months following the intervention, suggesting the sustainability of the intervention. An additional important finding is that the major categories of mantram use reflected the content of the educational program designed to teach this competency, as well as the findings of the larger RCT.

Eight (8) major categories of mantram use behaviors emerged from the critical incident interviews. The major categories from most to least frequent number of incidents included the following: *Increasing calm and/or peace, Mastering the technique, Changing my viewpoint, Increasing personal awareness, Adjusting behaviors, Managing physical symptoms, Increasing spirituality, and Enhancing relationships.* The fact that these major categories of mantram use were made up of multiple, similar behaviors lends credibility to their reports.[23,29] In addition, the reliability checks and the rigor of the critical incident technique suggest that the categories also have a consistent meaning to the study participants, as well as to the members of the research team who derived them.[29]

The largest category of mantram repetition behaviors, *Finding calm or peace,* reflected some findings that were not as clearly identified in the larger RCT. For example, results from the critical incident analysis revealed that study participants used mantram repetition to manage specific stressful situations and to decrease feelings of anxiety. In the quantitative measures, however, there were decreases of anxiety and perceived stress over time, but these results were found in both mantram and control groups, and could not be attributed to only the intervention. On the other hand, the qualitative critical incident data indicated that participants used mantram repetition to manage emotions other than stress, including anger and frustration. These findings are similar to the larger RCT,[20,30] where significant improvements were found in reducing anger, and these reductions were mediated by increased appraisal coping.

The second most frequent category of mantram repetition behaviors, *mastering the technique,* described incidents where study participants continued to practice strategies taught during the intervention. This finding further expands the quantitative outcome results of Bormann and colleagues,[20] who found significant relationships between frequency of mantram practice using wrist counters and quality of life, spiritual well-being, and subscales of meaning/purpose and faith/assurance. Although the frequency of mantram practice may have had a valuable, therapeutic effect on psychologic distress, this interpretation must be viewed with caution because participants who practiced mantram more frequently were self-selected.

The majority of the remaining categories directly reflect how the group-based mantram intervention was designed to promote increased metacognitive awareness to stressors as well as to strategies for evaluating cognitive and emotional responses to stressors. In the third most frequent category, *Changing my viewpoint,* participants reported that the use of mantram repetition led to changes in their primary appraisals of stressful events, as well as changes in their appraisals of methods for coping with those events. The critical incidents in the fourth most frequent behavioral category, *Increasing personal awareness,* indicated that mantram repetition cultivated increased metacognitive skills and heightened awareness of stressful events and to their own internal responses to stressors. A fifth category, *Adjusting behaviors,* reflected changes in their coping skills. Linkages were noted between the major categories, *Changing my viewpoint, Increasing personal awareness*, and *Adjusting behaviors* and the quantitative study findings from the RCT. In a secondary analysis performed on quantitative data from the original RCT, Bormann and Carrico[30] found significant increases in positive reappraisal coping in the mantram arm participants over the 5-week intervention period.

Analysis of the critical incident data also reflects consistency between the eighth category, *Increasing spirituality,* and the quantitative findings of the larger RCT. Bormann and colleagues[20,31] found that participants in the mantram arm of the RCT increased both spiritual faith/assurance and spiritual connectedness as well as significant correlations between frequency of mantram practice sessions and improvements in spiritual well-being subscales (i.e., meaning/peace and faith/assurance).

Although linkages were found between the many behavioral categories and the quantitative findings of the larger RCT, a difference was noted for the incidents in category six, *Managing symptoms.* A clear connection between the incidents in this category and the quantitative data in the larger RCT was not evident. The influence of spirituality on the management of physical symptoms, however, has received increased attention in the literature.[32–34] Wachholtz and Pargament[35] found spiritual meditation was related to greater decreases in both migraine headache frequency and severity compared to secular meditation. Coleman and colleagues[13,36] found that prayer was used as a self-care strategy for managing HIV-related symptoms, including depression, fatigue, and nausea. Wolf and Abell[37] found that repetition of the mantra compared to a placebo mantra or no-treatment control resulted in decreased depression and anxiety in adults.

Conclusions

Study findings support the integration of qualitative methods within a RCT to expand quantitative outcome results, and also to gain a broader understanding of how an intervention plays out in the real life of the study participants. In this study, mantram repetition was identified as a coping strategy for managing stressors associated with HIV disease. Participants applied mantram repetition to their lives, targeting areas of most bothersome distress. Study findings also contribute to a further refinement of the spiritually based intervention with veterans, and lay a foundation for use with broader populations.

ABSTRACT

We examined the effect of the quality of primary care-based chronic disease management (CDM) for alcohol and/or other drug (AOD) dependence on addiction outcomes. We assessed quality using (1) a visit frequency based measure and (2) a self-reported assessment measuring alignment with the chronic care model. The visit frequency based measure had no significant association with addiction outcomes. The self-reported measure of care—when care was at a CDM clinic—was associated with lower drug addiction severity. The self-reported assessment of care from any healthcare source (CDM clinic or elsewhere) was associated with lower alcohol addiction severity and abstinence. These findings suggest that high quality CDM for AOD dependence may improve addiction outcomes. Quality measures based upon alignment with the chronic care model may better capture features of effective CDM care than a visit frequency measure.

1. Introduction

Although alcohol and other drug (AOD) dependence is characterized as a chronic disease (McLellan, Lewis, & O'Brien, 2000), its treatment in the United States is too often episodic, poorly coordinated, and difficult to access (Friedmann, Lemon, Stein, & D'Aunno, 2003; Institute of Medicine, 2006). Access issues are due to several reasons including lack of insurance, inadequate supply of available treatments in close proximity, and confusing or strict program entry requirements (Cohen, Feinn, Arias, & Kranzler, 2007; Institute of Medicine, 2006). In addition, most patients with addictions have medical and/or psychiatric comorbidity (de Alba, Samet, & Saitz, 2004; Grant et al., 2004; Mertens, Lu, Parthasarathy, Moore, & Weisner, 2003). Care for conditions in these three spheres often occurs in separate locations and systems, a fact likely responsible in part for poor quality care (Samet, Friedmann, & Saitz, 2001).

There is growing interest in shifting addiction treatment from an "acute care framework" to one that is more suitable for patients with chronic disease (Institute of Medicine, 2006; McKay, 2009). Chronic disease management (CDM) models based on the principles of the chronic care model (Wagner, Austin, & Von Korff, 1996) may improve the quality of addiction care (Institute of Medicine, 2006; Saitz, Larson, LaBelle, Richardson, & Samet, 2008; Watkins, Pincus, Tanielian, & Klein, 2003). As with other chronic diseases such as depression, diabetes, and congestive heart failure (Blonde, 2000; Gilbody, Bower, Fletcher, Richards, & Sutton, 2006; McAlister, Lawson, Teo, & Armstrong, 2001; Neumeyer-Gromen, Lampert, Stark, & Kallischnigg, 2004), CDM for AOD dependence has the potential to improve addiction outcomes by providing patient-centered, longitudinal care to increase the receipt of effective treatments and provide self-management support (Wagner et al., 2001). Care may be delivered in a flexible manner with treatment intensity and modality responsive to fluctuations in disease severity and other patient needs. A multidisciplinary team can track and coordinate care with the goals of addressing a comprehensive set of needs (addiction, medical, psychiatric, and social) and re-engaging patients who drop out of care. However, despite the potential benefits of CDM for AOD dependence, few data are available about its effectiveness for people with AOD.

Interest in CDM for AOD dependence parallels a realignment of primary care settings to deliver longitudinal, coordinated care for a comprehensive set of health needs, known as the patient centered medical home (PCMH) (American Academy of Family Physicians, American Academy of Pediatrics, American College of Physicians, American Osteopathic Association, 2011). Increasingly, policy makers and others are recognizing the importance of addressing AOD dependence in primary care to potentially realize the benefits of the PCMH (Croghn & Brown, 2010). The National Committee for Quality

Assurance (NCQA) recently added a PCMH accreditation standard to target a mental health, behavioral, or substance abuse "condition" for quality improvement (NCQA, 2011). Although there is growing support to integrate care for AOD dependence in primary care (Substance Abuse and Mental Health Services Administration, 2012), it is not clear how AOD dependence care should be organized and delivered in the PCMH (Croghn & Brown, 2010). CDM for AOD shares many of the core tenets of the PCMH and may be an effective strategy for addressing AOD dependence.

Although there is evidence suggesting the efficacy of CDM for AOD dependence, little is known about whether the quality of CDM care should be considered, and if so, how it should be measured. The quality of addiction care has been measured by visit frequency and timing-based measures. The quality of CDM has been measured by self-reported validated scales. How the quality of CDM relates to addiction outcomes is unknown; however, we do know that when offered, most patients with AOD dependence are willing to engage with CDM care (Kim et al., 2011).

Therefore, the objective of the current study is to examine if higher quality CDM for AOD dependence is associated with better addiction outcomes (abstinence, addiction severity). We hypothesized that receipt of quality CDM care for AOD dependence is associated with abstinence and lower addiction severity which is the primary aim of this analysis. Because CDM care is structured to increase the receipt of effective treatments, the secondary objectives are to examine whether quality CDM care is associated with higher odds of specialty addiction treatment utilization, addiction pharmacotherapy, and mutual help group attendance. The rationale for examining the latter is that mutual help group attendance is consistent with two chronic care model principles, namely the importance of helping patients develop skills and confidence to manage their addiction (i.e., a self-management plan) and of promoting involvement with community support. Mutual help groups are also often thought to be important components of addiction treatment plans in the United States.

2. Methods

2.1. Study design

This is a secondary data analysis of data collected during the Addiction Health Evaluation and Disease management (AHEAD) study, a randomized clinical trial of access to a primary care-based CDM clinic for AOD dependence. Details of the study have been published (Kim et al., 2011). Briefly, eligible participants were adults with AOD dependence (Composite International Diagnostic Interview Short Form; Kessler, Andrews, Mroczek, Ustun, & Wittchen, 1998) and any recent (past 30-days) opioid, stimulant, or heavy alcohol use (i.e., >21 drinks in a week or at least 2 days of ≥5 drinks in a day for men; >14 drinks per week or at least 2 days of drinking ≥4 for drinks in a day for women) who were willing to establish or continue primary care at Boston Medical Center. Interest in addiction treatment and readiness to change were not required for study enrollment.

Recruitment occurred in several ways: screening in an inpatient detoxification unit, referrals from Boston Medical Center mostly from primary care clinics and the emergency department, and advertising to the general public in medical center public areas, in newspapers and on buses.

After completion of the baseline research interview, subjects were randomized to either have access to the AHEAD study the CDM clinic established for that purpose or usual care. All subjects, both intervention and controls, were referred to primary care at Boston Medical Center and were given access to short-term motivational enhancement therapy (MET). All subjects could choose to access medical, psychiatric, and addiction treatment services provided by the hospital or in the community.

For subjects randomized to attend the CDM clinic, research associates accompanied them to their first visit. Subjects were compensated for study procedures completed at study entry, which included the first visit to the CDM clinic for subjects randomized to it. Beyond the initial CDM clinic visit, subjects were neither required to attend nor compensated for additional CDM clinic visits though that clinic remained available to them. In-person research interviews were done at 3, 6, and 12 months after study enrollment. Research associates neither encouraged nor discouraged CDM clinic use.

2.2. Description of the AHEAD study CDM clinic

The AHEAD study CDM clinic was located in the primary care clinic at an urban hospital. Treatment goals were to engage patients in longitudinal addiction care, to facilitate access to community resources including specialty addiction care, to communicate with caregivers including primary care providers and to re-engage patients with care after relapse or loss to clinical follow-up (Saitz et al., 2008). The CDM system components in the clinic included: (1) multidisciplinary team composed of a nurse care manager, social worker, internist with addiction specific skills, and psychiatrist; (2) informal linkages to community addiction treatment; (3) a shared electronic medical record with primary care and other medical clinicians; (4) appointment reminders and proactive callbacks; and (5) availability for drop-in care.

The CDM clinic provided some services on-site and facilitated access to needed services provided elsewhere. Addiction specific components of care available in the CDM clinic included negotiation of treatment plans, MET, a primary care adaptation of relapse prevention counseling (Friedmann, Saitz, & Samet, 1998), addiction pharmacotherapy (buprenorphine, naltrexone, and/or acamprosate), and referral to methadone maintenance treatment, specialty addiction treatment, and mutual help groups. Psychiatric assessment and treatment as well as case management for concrete needs such as food, transportation, and housing were also available. Although the CDM clinic was co-located with a primary care practice, it provided short-term medical care but not primary care. Instead the nurse care manager facilitated access to primary care, reminded patients to attend or complete evaluations for medical problems with the primary care physician, and coordinated medical and addiction treatment. Although the CDM clinic provided a somewhat diverse set of services, all were focused on improving addictions. All of these services have been conceptualized as such (Saitz et al., 2008).

The initial addiction, medical, and psychosocial clinical assessment in the CDM clinic included feedback, preventive services, initiation of addiction, short-term mental health and medical care, and additional referrals as needed. While there were overall guidelines for care, treatment was individualized based upon a patient's needs, resources (e.g., insurance), and preferences. After the care plan was in place, the nurse care manager kept in contact with the patient to assess needs and help with relapse prevention, facilitate referrals and appointments, and encourage use of CDM services.

2.3. Measures

2.3.1. CDM quality measures

Our analytic models assessed the relationship between CDM quality and addiction outcomes. Three measures of CDM quality were used—a summary of each measure is presented in Table 1. The first quality measure, engagement with CDM clinic care, was based on the Washington Circle (WC) quality measure for outpatient addiction treatment engagement (Garnick et al., 2002). Because we were interested in evaluating care specifically from the CDM clinic, the WC engagement measure was adapted to only include CDM clinic visits rather than outpatient addiction treatment visits. Engagement with the CDM clinic care was defined as two or more visits to the CDM

Table 1
Description of measures of the quality of CDM care for AOD dependence.

Measures	Definition	Analytic sample	Exposure categories
Engagement[a]	At least two visits to the CDM clinic within 30 days of initiation of care (initiation = two visits within 14 days of study enrollment)	Subjects with any follow-up data (n=553)[b]	Engagement; No engagement; No access to the CDM clinic
PACIC-CDM clinic[c]	Measure of the degree that care delivered by the CDM clinic is aligned with core components of the chronic care model[c]	Subjects assigned access to the CDM clinic with 12-month follow-up data (n=249)[d]	PACIC-CDM clinic summary score (tertiles)
PACIC-any[e]	Measure of the degree that care for addictions delivered by any healthcare provider is aligned with core components of the chronic care model	Subjects who received any care for addictions from any healthcare provider since study enrollment with 12-month follow-up data (n=451)[f]	PACIC summary score (tertiles)

[a] Based upon the WC measure of treatment engagement.
[b] Alcohol and drug addiction severity analyses limited to subjects with alcohol dependence ("alcohol subsample"; n=409) and drug dependence ("drug subsample"; n=458), respectively.
[c] Patient Assessment of Chronic Illness Care (PACIC).
[d] Alcohol subsample: n=184 and drug subsample: n=208.
[e] Any care for AOD problems includes counseling, medication, groups or other treatments provided in any healthcare setting, such as detox, hospital, emergency room, or office by any healthcare provider, including doctors, nurses, social workers, or counselors.
[f] Alcohol subsample: n=320 and drug subsample: n=378.

clinic within 30 days of "initiation" of care [initiation was at least one visit within 14 days of the first ("index") CDM clinic visit] (Kim et al, 2011). This visit frequency-based utilization measure was determined prospectively using electronic medical records adapted for the clinic. Three exposure groups for the engagement analyses were developed: (1) subjects assigned (randomly to) access to the CDM clinic who engaged, (2) those assigned access to the CDM clinic who did not engage, and (3) those (randomly) assigned to not have access to the CDM clinic. The rationale for including this third group for comparison is that the specifications of the WC measure of engagement do not include any mention of access to services; patients who receive specified services qualify as having engaged, and those who do not (regardless of the reason) are categorized as not having engaged. Consistent with that approach we did not restrict analyses to those with access to the CDM clinic.

Both the second and third measures of CDM quality were assessed using the Patient Assessment of Chronic Illness Care (PACIC), a widely used 20-item patient-completed survey that measures the extent to which care is aligned with core features of the chronic care model (Table 2) (Glasgow et al., 2005). Higher scores indicate care with more core features of the chronic care model. Specifically, the second quality measure was an assessment of the extent to which care received from the CDM clinic contained core components of the chronic care model. This measure (PACIC-CDM clinic) was assessed with a subset of questions from the PACIC survey (to minimize repetitiveness and subject burden during the interview and to focus on concepts most relevant to the services provided by the CDM clinic while ensuring that at least one question was asked about each core component of the chronic care model (patient activation, delivery system design/decision support, goal setting/tailoring items, problem-solving/contextual issues, and proactive follow-up/coordination of care). Because the questionnaire asks specifically about care provided by the CDM clinic, it was only administered to subjects assigned to have access to the CDM clinic and recalled attending it.

The third quality measure was an assessment of the extent to which care from any healthcare source was aligned with the chronic care model using the PACIC questionnaire (the complete instrument). This quality measure (PACIC-any), unlike the PACIC-CDM clinic measure, was assessed for all subjects who received any care related to AOD dependence since study enrollment. Any care included "talking or counseling, medication, groups or other treatments" provided in any healthcare setting, such as "detox, hospital, emergency room, or office" by any "healthcare provider, including doctors, nurses, social workers, counselors or others."

Both PACIC measures were determined at a 12-month interview after study entry. Given the absence of well-established PACIC score cut-offs and to avoid an assumption of linearity, both PACIC-CDM clinic and PACIC-any scores were categorized based on tertiles of the distributions. Although the PACIC was developed to assess the CDM of medical conditions, questions in the PACIC ask about highly valued components of addiction care, such as shared decision making (Institute of Medicine, 2006), proactive follow-up (McKay, 2009), "encouragement to go to a specific group" (e.g., 12-step), and help with planning "to take care of my illness even in hard times" (e.g., relapse prevention counseling).

In sum, the first two quality measures, engagement with the CDM clinic and PACIC-CDM clinic, were an assessment of care provided by the CDM clinic, whereas the third quality measure, PACIC-any, reflected care provided by any healthcare provider, AHEAD study-related or otherwise.

2.3.2. Outcome measures

Outcomes were assessed during interviews at 3, 6 and 12 months. Abstinence, the primary outcome, was defined as no opioid or stimulant use, or heavy drinking (five drinks or more per day for men; four or more for drinks per day for women) in the past 30 days. Opioid and stimulant use were assessed by the substance use questions of the Addiction Severity Index (ASI) (McLellan et al., 1992) and heavy drinking by the 30-day timeline follow back (Sobell & Sobell, 1995) calendar method. Secondary outcomes included alcohol and drug addiction severity, assessed by the alcohol and drug composite scores of the ASI. Three past 3-month addiction treatment variables (dichotomous) were examined as potential intermediate outcomes of the receipt of quality CDM: (1) specialty addiction treatment defined as outpatient or inpatient addiction treatment excluding detoxification; (2) addiction pharmacotherapy defined as medication to prevent drinking or drug use, help cut-down, or quit, excluding medication for detoxification; and (3) any mutual help group attendance.

2.4. Analytic strategy

Descriptive statistics were used to portray the study sample at baseline. We examine the relationship between measures of CDM quality and each outcome of interest by fitting separate multivariable longitudinal regression models. Generalized estimating equation (GEE) logistic regression models were used to model binary outcomes (i.e., abstinence, utilization of any specialty addiction treatment, any addiction pharmacotherapy, and any mutual help group attendance). Because the distributions of alcohol and drug ASI scores were non-normal and a suitable transformation was not identified, each variable was categorized into multiple ordered categories. The alcohol ASI composite score cutpoints were: 0; >0 to 0.1; >0.1 to 0.2; >0.2 to 0.04; >0.4 to 0.6; and >0.6. The drug ASI composite score cutpoints were: 0; >0 to 0.1; >0.1 to 0.2; >0.2 to 0.3; and >0.3). The ordered categorical data were then analyzed using GEE proportional odds models. The

Table 2
Summary of item content for Patient Assessment of Chronic Illness Care (PACIC).[a]

Chronic care model core component	Description	PACIC survey question
Patient activation	Actions that solicit patient input and involvement in decision-making	1) Asked for my ideas when my healthcare provider made a treatment plan[b] 2) Given choices about treatment to think about[b] 3) Asked about problems with medications
Delivery system design, decision support	Actions that organize care and provide information for patients to enhance their understanding of care	4) Given written list of things to do to improve my health[b] 5) Satisfied that care was well-organized[b] 6) Shown how what I did to take care of my illness influenced my condition
Goal setting, tailoring items	Acquiring information for and setting of specific collaborative goals	7) Asked to talk about my goals in caring for my illness[b] 8) Helped to set specific goals to improve my eating or exercise 9) Given a copy of my treatment plan 10) Encouraged to go to a specific group or class to help you cope with your addiction 11) Asked questions, either directly or on a survey, about your health habits
Problem-solving, contextual issues	Considering potential barriers and the patient's social and cultural environment in making treatment plans	12) Sure that my doctor/nurse caring for my *addiction* thought about my values and my traditions when they recommended treatment[b] 13) Helped to make treatment plan that I could do in my daily life[b] 14) Helped to plan ahead so I could take care of my illness even in hard times 15) Asked how *addiction* affects my life.
Proactive follow-up, coordination of care	Arranging care that extends and reinforces office-based treatment and making proactive contact with patients to assess progress and coordinate care	16) Contacted after a visit to see how things were going 17) Encouraged to attend programs in the community that could help you 18) Referred to a dietician, health educator, or counselor 19) Told how visits with other types of doctors or health professionals helps my treatment 20) Asked how visits with other doctors or health professionals were going[b]

[a] PACIC is a 20-item instrument, response scores range from 1 to 5 with higher scores indicating care that is more consistent with the chronic care model. The summary score is the mean score of all individual survey items. The word "addiction" was used in place of "my illness".
[b] PACIC questions used to assess the quality of care from the CDM clinic based upon services provided in the CDM clinic.

odds of lower scores (i.e., better outcomes), were modeled for both cases. The GEE approach was used to account for the correlation from using repeated observations from the same subject over time. An independence working correlation was used and empirical standard errors from the GEE approach are reported for all analyses.

Different analytic samples were used based on the independent variables and outcomes analyzed. A summary of the criteria used to comprise the analytic samples is presented in Table 1. Subjects with at least one follow-up interview were eligible for all analyses. Analyses of alcohol and drug severity included only subjects with any alcohol dependence ($n=409$) and any drug dependence ($n=458$), respectively at study entry. There were additional criteria for the PACIC-CDM clinic and PACIC-any analyses. Both analyses included subjects who completed those interviews (done at 12-months). The PACIC-CDM clinic analyses, however, only included those who had been randomly assigned to have access to the CDM clinic and recalled attending it. Those without access to the CDM clinic were not included. Analyses of care provided by any health care source (PACIC-any) measure consisted of those who reported receipt of any care for AOD dependence since study enrollment with no distinction made to indicate whether subjects were in the intervention or control arms of the randomized study.

All regression models were fit with a single main independent variable of interest and the following covariates: age, sex, race/ethnicity, an indicator variable for time since enrollment (3, 6, or 12 months), homelessness (any night on the street or in a shelter, past 3 months), and moderate to severe depression [Patient Health Questionnaire (PHQ-9) score ≥ 10; Kroenke, Spitzer, & Williams, 2001]—the latter two were modeled as time-dependent variables. Alcohol and drug severity analyses also included baseline alcohol and drug severity, respectively. Prior to regression modeling, potential collinearity among covariates was assessed by calculating the correlation between all independent variables and covariates, and no pair of variables had a Spearman correlation >0.40. Due to the exploratory nature of the analyses, no adjustments were made for multiple comparisons. However, pair-wise comparisons were not made unless the global p-value for the CDM measure was statistically significant ($p<.05$). All statistical analyses were performed using SAS version 9.2 (SAS Institute, Inc., NC, USA).

3. Results

3.1. Sample characteristics

This study's analytic samples were derived from the AHEAD study randomized trial. Among the 655 eligible adults, 563 (87%) were randomized in the AHEAD intervention trial. Ninety-eight percent of those randomized completed at least one follow-up interview (89%, 87%, and 95% at 3, 6, and 12-month interviews, respectively). There was no significant difference between the proportion of the intervention and control groups interviewed at each follow-up.

Among the 563 subjects enrolled in the AHEAD intervention trial, 553 (98%) had at least one follow-up interview (analytic sample for the CDM clinic engagement analyses). Among the 270 subjects assigned access to the CDM clinic, 249 (92%) completed a 12-month follow-up interview, attended the clinic and recalled doing so comprising the analytic sample for PACIC-CDM clinic analyses. The analytic sample for the "any care" (PACIC-any) analyses was 451 (those who completed the 12-month interview [532] and reported receipt of care for AOD dependence from any healthcare source since study enrollment).

The analytic sample for the engagement analyses (Table 3) had the following characteristics: men (73%); non-white (53%); homeless (59%); had both alcohol and drug dependence (66%); a comorbid substance abuse-related medical condition (65%); and moderate to severe depression (84%). At baseline, a low percentage had past 3-month utilization of specialty treatment (34%) or addiction pharmacotherapy (6%), yet nearly half had mutual help group attendance. Approximately a quarter of the subjects with access to the CDM clinic met criteria for engagement (23%). Approximately a third of the sample was abstinent at follow-up (35%, 34%, and 43% at 3, 6, and 12-month interviews, respectively) (Table 4).

[g] Among subjects randomly assigned access to the CDM clinic, $n=270$.
[h] PACIC score range: 1–5 with higher scores indicating care with more core features of the chronic care model.
[i] Measure of the degree that care delivered by the CDM clinic is aligned with core components of the chronic care model.
[j] Measure of the degree that care for addictions delivered by any healthcare provider is aligned with core components of the chronic care model.

3.2. Multivariable regression results

No significant group differences were detected for the effect of engagement in CDM on abstinence or drug and alcohol addiction severity (Table 4).

Receipt of higher quality CDM from the clinic as reflected by higher PACIC-CDM scores was significantly associated with lower drug addiction severity (global p-value=.03) [adjusted odds ratio (AOR) 1.71; 95% confidence interval (CI) 1.13, 2.59, highest vs. middle tertile]. No significant associations were detected between PACIC-CDM clinic scores and abstinence or alcohol addiction severity.

Higher PACIC-any scores, reflecting the quality of care received anywhere, were associated with higher odds of abstinence (global p-value<.001) (AOR 1.99; 95% CI: 1.34, 2.95, highest vs. lowest tertile; AOR 1.75; 95% CI: 1.24, 2.48, highest vs. middle tertile) and lower alcohol severity (global p-value=.02) (AOR 1.68; 95% CI: 1.16, 2.45, highest vs. middle tertile). Higher PACIC-any scores appeared to be associated with lower drug addiction severity but the global association was not statistically significant ($p=.09$).

Upon examination of secondary outcomes, all measures of quality CDM care (Table 1) were significantly associated with specialty addiction treatment utilization (Table 5). Engagement was also associated with higher odds of addiction pharmacotherapy (AOR 3.55; 95% CI: 2.02, 6.25) but not with mutual help group attendance. Each PACIC measure, reflecting care from the CDM clinic (PACIC-CDM clinic) or any healthcare source (PACIC-any) was associated with higher odds of mutual help group attendance, but neither was significantly associated with utilization of addiction pharmacotherapy.

4. Discussion

To date, the most widely accepted measures of the quality of addiction care are based on visit frequency. In this sample of adults with AOD dependence, a measure of CDM care quality based on visit frequency—engagement—was not associated with abstinence or addiction severity despite being associated with receipt of specific addiction treatments (e.g., pharmacotherapies). However, a self-reported quality measure assessing alignment with the chronic care model was associated with several addiction outcomes. Specifically, those who received care from any healthcare source with core features of the chronic care model were more likely to be abstinent from heroin, cocaine, and heavy drinking and among those with alcohol dependence to have lower alcohol addiction severity. Those who received higher quality care specifically from the CDM clinic were more likely to have lower drug addiction severity (Table 6).

The lack of significant associations between CDM engagement and abstinence or addiction severity is notable. Engagement with CDM care as measured by visit frequency is likely a necessary minimum first step that can lead to receipt of known efficacious treatments; however in this cohort, adults with comorbidity and social ills (e.g., homelessness), it was not sufficient for improving addiction outcomes.

Findings were clearer and more consistent when the predictor of interest was the self-report quality measure of alignment with the chronic care model regardless of the source of care. Analyses examining care quality from any health care source are informative because individuals with AOD dependence often receive episodic acute care services (e.g., in detoxification units or emergency departments) rather than longitudinal comprehensive chronic care. Among patients with chronic medical conditions including diabetes mellitus, asthma, coronary artery disease, and chronic pain, higher PACIC scores

[a] Result of separate multivariable longitudinal regression models predicting abstinence (GEE logistic regression for engagement) and lower alcohol and drug addiction severity (GEE proportional odds model). All models include age, sex, race/ethnicity, time, homelessness, and depression (PHQ-9). Alcohol and drug addiction severity models also include baseline alcohol and drug addiction severity, respectively.

[b] Engagement defined as at least two visits to the CDM clinic within 30 days of CDM clinic initiation. Analytic samples consist of subjects with follow up data ($n=553$); alcohol and drug addiction severity analyses limited to subjects with alcohol dependence ("alcohol subsample") ($n=409$) and drug dependence ("drug subsample") ($n=458$), respectively.

[c] PACIC-CDM clinic defined as the degree that care delivered by the CDM clinic was aligned with core features of the chronic care model. Analytic samples consist of subjects randomized to have access to AHEAD CDM care with 12-month interview data ($n=249$); alcohol subsample ($n=184$) drug subsample ($n=208$). PACIC-CDM clinic score tertiles: highest 4.29–5, middle: 3.43–<4.29, lowest: 1–<3.43.

[d] Highest vs. middle PACIC-CDM clinic tertile predicting lower drug severity.

[e] PACIC-any defined as the degree that care delivered by any healthcare source is aligned with core features of the chronic care model. Analytic samples consist of subjects with 12-month interview data who received any care for alcohol or other drug dependence since study entry (n=451); alcohol subsample (n=320); drug subsample (n=378). PACIC-any tertiles: highest 3.70–5; middle: 2.95 –<3.70, lowest: 1–<2.95.

[f] Highest vs. middle PACIC-any tertile predicting abstinence AOR 95% CI: 1.75 (1.24, 2.48). Highest vs. lowest PACIC-any tertile predicting abstinence AOR 95% CI: 1.99 (1.34, 2.95).

[g] Highest vs. middle PACIC-any tertile predicting lower alcohol severity AOR 95% CI: 1.68 (1.16, 2.45).

(indicating care with more features of the chronic care model) were associated with more self-management behaviors (e.g., regular exercise; Schilinger, Wang, Handley, & Hammer, 2009) and higher quality of life (Schmittdiel et al., 2007). Our results suggest that receipt of care for AOD dependence that includes components of the chronic care model is also important for addiction treatment effectiveness.

Although the quality of CDM care from any health care source was significantly associated with abstinence and alcohol addiction severity, analyses of drug addiction severity did not quite achieve statistical significance. We did find, however, that drug addiction severity was significantly associated with the quality of care from the CDM clinic. It is possible that this finding was related to the way that services were organized in the CDM clinic. For example, the clinic provided some psychiatric services on-site and facilitated linkage to other psychiatric services. This may have been particularly helpful for those with drug dependence because of the higher mental health comorbidity rate for patients with drug dependence (Grant et al., 2004). In addition, since drug dependence is more difficult to treat without addiction pharmacotherapy, we postulated that greater access to addiction pharmacotherapy in the CDM clinic may have contributed to these findings. However, we did not find that the quality of care from the CDM clinic or from any source of addiction treatment was associated with higher odds of addiction pharmacotherapy receipt.

These differences should not be overstated and are only hypothesis-generating. Although there were differences in these analyses, overall, our main findings are that regardless of the source of care, the quality of CDM care matters and that a quality assessment based upon the content of care appears to have predictive validity but a visit-based, frequency measure does not. The fact that the results of

Results of separate multivariable logistic regression models for each outcome and each main independent variable. Specialty addiction treatment defined as outpatient or inpatient addiction treatment excluding detoxification; addiction pharmacotherapy as medication to prevent drinking or drug use, help cut-down, or quit (not for detoxification); and mutual help, 12-step (e.g., AA) groups.

All models include age, sex, race/ethnicity and the following time-varying covariates: homeless (Y/N), depression (PHQ-9), alcohol and drug severity, time since study enrollment (3, 6, or 12 months).

Analytic sample sizes: engagement with CDM clinic care=553, PACIC-CDM clinic=249, PACIC-any=451.

utilization analyses were the same for each PACIC measure, (i.e., significant associations for specialty addiction treatment and mutual help group attendance but not addiction pharmacotherapy) supports the finding that both PACIC measures assessed similar constructs regardless of the source of care. Both PACIC measures seem to be assessing something different than the engagement measure as indicated by the engagement association with addiction pharmacotherapy but not mutual help group attendance.

All quality measures were associated with higher odds of utilization of specialty addiction treatment. This is not insignificant because successful referrals to "off-site" addiction treatment providers with whom the CDM clinic did not have formal referral relationships can be particularly challenging (Gurewich, Sirkin, & Shepard, 2012) and linkage to outside resources is an important component of chronic care models (Wagner et al., 1996).

This study adds to the literature supporting the benefits of longitudinal, integrated care for patients with AOD dependence by showing that the quality of CDM can contribute to improved outcomes. (O'Toole et al. 2011) found that primary care with elements of the chronic care model customized for homeless patients, of whom 70% had alcohol abuse, was associated with better medical outcomes (blood pressure, glycemic control, and lipid levels). Alcohol use outcomes were not reported. Among patients in addiction treatment, (Chi, Parthasarathy, Mertens, & Weisneret 2011) found that continuing care, defined as having yearly primary care and specialty addiction and psychiatric care when needed, was associated with abstinence over a 9-year follow-up period. The current study contributes to this literature by examining addiction outcomes from a type of care that may facilitate receipt of primary, psychiatric, and specialty care that was also structured to provide self-management support and other elements of the chronic care model.

This study has several limitations. Due to the study's observational design, it is possible that patients who were abstinent (or had lower addiction severity) tended to rate treatment more favorably. However, we used prospectively collected data to assess addiction outcomes over a 12-month study follow up period adjusted for potential determinants of care (i.e., gender, race/ethnicity, homelessness, and depression). In addition, the PACIC is an instrument that assesses implementation of the chronic care model rather than simply patient satisfaction. Nonetheless we cannot exclude the possibility that unmeasured factors influenced which participants rated treatment with high PACIC scores and also influenced addiction outcomes. We did not have information about the type of addiction treatment participants were rating. However, the question of interest was not the specific treatment modality but rather receipt of care with core features of the chronic care model. Given that there are few data about CDM for AOD dependence, these findings serve as a "proof of concept" study. Future study should examine types of care that deliver high quality CDM.

Another limitation of this study is the method used to model exposure and outcome. Assessment of CDM quality was done at the 12-month study interview and addiction outcomes were measured prospectively at 3, 6, and 12-month interviews. Subjects may have rated care that was received after the addiction outcome was measured. Studies are needed to prospectively examine the receipt of care delivered before the assessment of addiction outcomes. Finally, generalizability is another consideration. The majority of participants were recruited from a detoxification unit and most participants had social and psychiatric co-morbidities such as homelessness and depression. This study's findings may not generalize to primary care patients seeking addiction treatment or individuals with less social and psychiatric comorbidity. On the other hand, it is precisely these sorts of populations who need and could potentially benefit from high quality integrated and coordinated care.

This study's strengths include prospective data collection and a high proportion assessed at follow-up. In addition to process measures of care such as receipt of addiction treatment and addiction pharmacotherapy, we examined outcomes with clear clinical significance (i.e., abstinence and severity). In addition, we used a measure based on the NCQA/HEDIS quality performance measure for addiction treatment engagement to define engagement with the particular treatment of interest in this study, CDM. In addition, this was an innovative analysis using a tool (PACIC) not often applied to addictions care that may be increasingly used to evaluate the quality of care consistent with CDM in the patient-centered medical home.

Given the need for improvement of the quality of care for patients with addictions, CDM shows some promise for improving patient receipt of effective treatments, thereby improving outcomes. These data support efforts to improve care for patients with addictions that integrate medical, mental health and addiction services, provide longitudinal coordinated care and care that pro-actively follows patients. These data also suggest that as such efforts become more common, attention will need to be paid to the quality of care—how it reflects key features of the chronic care model—to assure the effectiveness of primary care based CDM for AOD dependence.

In conclusion, this study provides empirical data that suggest that receipt of quality CDM for AOD dependence is associated with improved processes of care and better outcomes. Furthermore, our results suggest that widely used visit-based frequency measures may be inadequate for capturing characteristics of CDM that are associated with better outcomes, characteristics better captured by self-report measures of exposure to elements of chronic care management.

Acknowledgments

We presented an earlier version of the manuscript as an oral presentation at the Addiction Health Services Research Conference, Fairfax, VA on October 4, 2011.

Co-morbidity is the norm, not the exception: chronic respiratory diseases in chronic drug users

Individuals with chronic drug use disorders frequently have medical co-morbidities.[1,2] Mertens *et al.* documented the high prevalence of chronic medical conditions and its associated significant morbidity among insured patients in a specialty alcohol and drug treatment clinic.[3] Among alcohol or drug dependent patients on the opposite end of the socioeconomic spectrum in the USA – those without primary care who were entering residential detoxification – 45% reported having a chronic medical illness.[1] One third of a comparable group reported being in fair or poor health.[4] Thus, it is fair to say that co-morbidity, among the socioeconomic spectrum of chronic drug users in care, is the norm, not the exception.

Despite an expanding literature on medical co-morbidities among drug using populations, respiratory diseases have not been well-studied. The bulk of the literature on drug users and respiratory disease has focused on infectious complications of drug use, including bacterial pneumonia, septic pulmonary embolism, and tuberculosis (TB).[5,6] These medical conditions are acute or sub-acute (e.g. TB) episodic illnesses. Chronic, non-infectious respiratory diseases such as asthma and chronic obstructive pulmonary disease (COPD) among drug users have not been well-characterised. Studies demonstrating the effectiveness of disease management programmes for chronic medical conditions such as asthma typically exclude individuals with drug use.[7] However, a better understanding of the risks of chronic respiratory diseases would inform efforts to improve the medical assessment and treatment – both therapeutic and preventive – of patients who are also drug users. Such work would address a treatment gap for a population less likely to receive quality asthma care[7] and flu vaccination.[8]

In this issue of the *PCRJ*, Palmer *et al*. report on respiratory diseases in drug users.[9] Specifically, they performed a cross-sectional analysis of the association of chronic respiratory diseases and "drug misuse" using administrative data collected from general practices in Scotland. The authors found that drug users were more likely to have a diagnosis of chronic respiratory diseases (i.e. asthma, COPD, and "respiratory system disease") than a control group matched for age, gender, and economic status. Drug users were also more likely to be prescribed respiratory medications, primarily bronchodilators and inhaled corticosteroids. These associations did not appear to be fully attributable to the high prevalence of tobacco use, since these differences persisted with adjustment for tobacco use. This study's results are consistent with others in the literature,[1-4] and Palmer *et al*. substantively contribute to this literature by performing their analysis on a national database.[9] Additionally, the use of a control group matched on key socio-demographic variables strengthens the research design.

Nonetheless, interpretation of study findings requires consideration of study limitations. First, substance type was unknown in nearly three-quarters of cases (72%), making it difficult to assess what accounts for the relationship between drug use and respiratory disease. Second, chronic respiratory disease was defined as ever having a diagnosis of asthma, COPD, or "respiratory system disease" since birth; therefore it is unknown whether the respiratory disease predated the onset of drug use. Third, although the exact number of opioid users in the study is unknown, some portion of the drug "misuser" sample consisted of patients prescribed methadone for opioid dependence from general practices, which may have required frequent office visits; therefore, respiratory diseases may have been more likely to be detected given the increased surveillance among these patients.

Despite these caveats, the study raises useful questions and suggests pragmatic implications. As noted among other studies of drug users, tobacco use in this study's sample[9] was almost universal (90%). Although the findings may not have been fully attributable to tobacco use, tobacco is still the major driver responsible for respiratory disease in this population. From a clinical perspective, given that COPD is typically under-diagnosed and under-treated in primary care,[10] these findings, although not definitive, should raise awareness that individuals with drug addiction are at high risk of chronic respiratory diseases. From a research perspective, determining whether or not contributors other than tobacco exist would be of value, as it might enable medical teams pro-actively to direct attention to other useful evaluation and treatment.

Evidence of an increased risk of chronic respiratory diseases among drug users also enhances the case for the coordination of care between addiction treatment providers and those addressing these patients' chronic medical conditions.[11] Drug treatment is an opportunity for the patient not only to address drug use but also to consider the wider health consequences of drug use including respiratory illness and linking patients to medical care.[12,13] Raising the issue with the patient and making a plan to address this common diagnosis might serve not only to improve their health and quality of life but could build the rationale for the patient to make recovery a priority. Weisner *et al*. demonstrated improved addiction outcomes

with integrated addiction and medical treatment for those with chronic medical conditions.[14]

This examination of respiratory diseases among drug users[9] adds further strength to the premise that, given the frequency of overlapping drug use and medical co-morbidities, improvements in these health domains will likely require health professionals to be cognisant of both, in the quest to address either optimally.

The article by Gallagher *et al*.[1] in this issue of the *PCRJ* is of particular interest, not least because the authors studied 26 adolescents (aged 13 to 19 years) at risk for anaphylaxis and did *not* find the "rebel without a cause" mentality as the dominant reason why this age group is three to four times more likely to die than children because they take risks and have accidents.[2] The movie, "Rebel Without a Cause", starring James Dean, was released by Warner Bros on 27th October 1955, less than one month after the famous actor's fatal car crash. In this controversial movie of the time, Jim Stark (played by James Dean) is a rebellious 17-year-old teenager caught up in family discord who disobeys his parents, defies the local schoolboys, and confronts the differences and conflicts between generations.[3] One would think that teenagers susceptible to anaphylaxis would possess the James Dean-like rebellious personality, thereby accounting for the fact that adolescents with this disease are at increased risk of fatal outcomes.

However, just the opposite was found in this study. The majority of episodes of anaphylaxis, primarily from food allergies (in particular, peanuts and tree nuts) but also due to fish, shellfish, sesame seed, dairy, lentils, milk, egg, tomato and other fleshy fruits, legumes and insects, horse and idiopathic, "…did not result from stereotypically irresponsible behavior (such as alcohol misuse or deliberate exposure to known allergens)."[1] The authors found that most adolescents, as did their parents, took an active role in managing their risk of anaphylaxis. Some parents and adolescents emphasised the idea that

Depression and Anxiety Diagnoses Are Not Associated with Delayed Resolution of Abnormal Mammograms and Pap Tests Among Vulnerable Women

Andrea C. Kronman, MD, MSc[1], Karen M. Freund, MD, MPH[1], Tim Heeren, PhD[2], Kristine A. Beaver, MPH[1], Mary Flynn, BA, MS[1], and Tracy A. Battaglia, MD, MPH[1]

[1]Women's Health Unit, Section of General Internal Medicine, Department of Medicine, and Women's Health Interdisciplinary Research Center, Boston University School of Medicine, Boston, MA, USA; [2]Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA.

BACKGROUND: Delays in care after abnormal cancer screening contribute to disparities in cancer outcomes. Women with psychiatric disorders are less likely to receive cancer screening and may also have delays in diagnostic resolution after an abnormal screening test.

OBJECTIVE: To determine if depression and anxiety are associated with delays in resolution after abnormal mammograms and Pap tests in a vulnerable population of urban women.

DESIGN: We conducted retrospective chart reviews of electronic medical records to identify women who had a diagnosis of depression or anxiety in the year prior to the abnormal mammogram or Pap test. We used time-to-event analysis to analyze the outcome of time to resolution after abnormal cancer screening, and Cox proportional hazards regression modeling to control for confounding.

PARTICIPANTS: Women receiving care in six Boston-area community health centers 2004–2005: 523 with abnormal mammograms, 474 with abnormal Pap tests.

RESULTS: Of the women with abnormal mammogram and pap tests, 19% and 16%, respectively, had co-morbid depression. There was no difference in time to diagnostic resolution between depressed and not-depressed women for those with abnormal mammograms (aHR=0.9, 95 CI 0.7,1.1) or Pap tests (aHR=0.9, 95 CI 0.7,1.3).

CONCLUSIONS: An active diagnosis of depression and/or anxiety in the year prior to an abnormal mammogram or Pap test was not associated with a prolonged time to diagnostic resolution. Our findings imply that documented mood disorders do not identify an additional barrier to resolution after abnormal cancer screening in a vulnerable population of women.

BACKGROUND

Depression is associated with high overall mortality, [1] including increased breast cancer mortality [2]. The underlying mechanism explaining the relationship between depression and increased breast cancer mortality is unknown. A possible explanation is underuse of screening mammography, given that screening mammography reduces mortality, [3,4] and women with psychiatric disorders are less likely to receive standard preventive care,[5,6] including screening mammography.[7] Another possible explanation is delayed follow-up after an abnormality is detected on a screening test, since delayed diagnosis can reduce survival if cancer is diagnosed at a later stage. Vulnerable populations of women, as defined by low income or with racial/ethnic minority status, are less likely to receive standard preventive healthcare and therefore experience worse breast and cervical cancer outcomes. Previous studies showed less than 25% of these vulnerable women received adequate follow-up care after an abnormal cancer screening test.[8,9] In addition, the prevalence of depression is higher in vulnerable populations,[10–16] and twofold higher in women than men. National annual prevalence estimates for women range between 4 – 14%.[17,18]

Our previous work examined factors associated with delays in cancer care among a diverse population of women who received screening at urban community health centers (CHC).[19,20] We found the individual CHC site was a stronger predictor of timely resolution than race, ethnic group, language, insurance status, or age.[19,20] We then sought to examine additional patient characteristics that may identify a group of women who are particularly vulnerable to delayed resolution of abnormal cancer screening tests and might benefit from tailored interventions such as patient navigation. We hypothesized that depression would contribute to delays in

diagnostic resolution. In addition, since previous studies demonstrated that anxiety may result in more timely care,[21,22] we hypothesized that anxiety may decrease time to resolution, and modify an association between depression and time to diagnostic resolution. Thus, our objective is to determine if depression and anxiety are independent predictors of delays in care after abnormal mammograms and Pap tests in a vulnerable population of urban women.

METHODS

Study Design

This is a secondary analysis of data collected at baseline of the Boston Patient Navigation Research Program (PNRP), before a patient navigation intervention was implemented.[19] Boston PNRP partnered with six CHCs to collect retrospective medical record data for women who had abnormal mammograms or Pap tests. For this study, data were collected via chart review for psychiatric diagnoses, symptoms, and treatment for the 1-year period preceding the date of the abnormal cancer screening test.

Study Population

Eligible subjects in the baseline PNRP included adult women with an abnormal screening Pap test or mammogram performed between January 1, 2004 and December 30, 2005 at the 6 CHCs.[19] Eligible mammograms included Breast Imaging Reporting and Data System (BIRADS) scores indicating need for follow-up (BIRADS 0, 3, 4, and 5). Eligible Pap tests included cellular abnormalities indicating need for follow-up: atypical squamous cells of undetermined significance positive for human papillomavirus (ASCUS/HPV+), low-grade squamous intraepithelial lesion (LGSIL), and high-grade squamous intraepithelial lesion (HGSIL). All subjects with high-grade abnormalities were included (BIRADS 4, 5; HGSIL), and a random sample of low-grade abnormalities (BIRADS 0, 3; ASCUS/HPV+; LGSIL) to obtain approximately 100 women per site. At sites with fewer than 100 eligible cases, all eligible subjects were included. In order to prevent clustering of cases by CHC, a representative sample of equivalent numbers were selected from each center.

Data Sources

We previously described the details of how the data were retrieved from the EMR and registration databases of the six CHCs.[19] Socio-demographic and eligibility criteria were retrieved automatically, while clinical outcomes and psychiatric diagnosis and treatment data were abstracted manually by trained research staff.

Independent Variables of Interest

We categorized a subject as actively "depressed" if either of the following criteria was documented in the EMR during the 12 months preceding the abnormal test: 1) a new diagnosis of depression [ICD-9 diagnoses 311.x, 309.28, 309.0-309.1, 300.4] entered into the active problem list[1], or 2) depression diagnosis documented in the free-text "Assessment/Plan" section of office notes. By categorizing depression in this way, we ensured that depression was an active problem in the year prior to the abnormal cancer screening test. In order to further validate our definition of depression diagnosis, we abstracted depressive symptom data (depressed mood, sleep disorders, anxious feelings, fatigue, impaired concentration, appetite change, psychomotor change, social isolation, decreased interest, suicidality, hopelessness, other) from the EMR if documented as free-text in the "History of Present Illness" or "Review Of Systems" sections of provider notes, or listed in the Problem List during the specified time period. We categorized a subject as "anxious" if anxiety was documented either in the active problem list [ICD-9 diagnoses 300.0x, 300.2x] or in the free-text sections of office notes during the specified time period.

Covariate and Intervening Variables

We obtained anti-depressant medication data from the medication list in the EMR, and evidence that the patient received psychotherapy through the following indicia: presence of an office note from a therapist or psychiatrist, mention of therapy in the free text Assessment/Plan section, or referral to behavioral health from the Orders section. We then categorized subjects into one of four mutually exclusive categories based on depression treatment: 1) anti-depressants only, 2) psychotherapy only, 3) both anti-depressants and psychotherapy, or 4) no treatment. Other psychiatric diagnoses were abstracted from the Problem Lists in the EMR, including bipolar, psychoses, and substance abuse. We collapsed the race/ethnicity EMR data into four mutually exclusive categories: White, Black/African American, Hispanic/Latina, or Asian/Other. Because the age distribution is very different for women obtaining breast and cervical cancer screening (older women in the breast cancer screening group), we categorized different age categories for the two screening populations and subdivided them into three age groups that had clinical significance. We categorized primary language as English, Spanish or other. We created the following three mutually exclusive categories from the primary and secondary insurance data in the EMR: no health insurance, publicly financed health insurance (Medicare and/or Medicaid), or private health insurance.

Outcome Variables

Our primary outcome of interest was time (number of days) from index screening abnormality to diagnostic resolution. Subjects were followed for a maximum of one year. We defined d*iagnostic resolution* as either a definitive tissue diagnosis (biopsy with pathology report) or clinical evaluation (such as colposcopy) indicating no further need for evaluation. For subjects with LGSIL pathology, we considered the initial colposcopy with biopsy to be definitive, although surveillance is recommended. Similarly, for subjects with a recommended two-year surveillance for BIRADS three results, we considered diagnostic resolution as the next six-month mammogram, subtracting the six-month period for timely resolution in the

analysis[23]. Due to the long times to resolution and most of the cases resolving within 6 months, we censored this outcome at a maximum of 365 days.

Data Analysis

Women with abnormal mammograms were analyzed separately from women with abnormal Pap tests, because of marked differences between the groups in age, racial/ethnic distribution and characteristics of cancer screening test. Chi-square tests were used to compare the characteristics of depressed and not-depressed women and to compare the prevalence of depression across demographic subgroups. Next, we examined depressive symptom data in the depressed and not depressed groups to validate our definition of depression diagnosis. In the time-to-event analysis, we first compared time to resolution within 365 days between depressed and not-depressed women via the log-rank test. We then used Cox-proportional hazards modeling to predict timely resolution incorporating all of the covariates, and an interaction term for anxiety and depression. In the final models, we included only those categorical variables with a significant univariate Cox model p-value (< 0.05), excluding the interaction term because it was not significant. In secondary analyses, we modeled separate effects for depressed women with and without treatment, because treatment for depression may modify the effect of depression diagnosis. To determine if depression was associated with outcome for any subgroups of our population, we stratified our analyses by insurance, age and race/ethnicity. For women with abnormal Pap tests, the cumulative incidence curves with and without depression cross at about 120 days; therefore we modeled separate effects of depression for resolution before and after 120 days, using time-dependent indicators for depression in the Cox model. Analyses were conducted using SAS 9.1.[24] A two-sided p-value <0.05 was considered statistically significant for reporting associations.

RESULTS

Among 997 women, 523 had abnormal mammograms and 474 had abnormal Pap tests. Overall, 17% had depression and 8.5% had anxiety. Of the women with abnormal mammogram and Pap tests, 19% and 16%, respectively, had co-morbid depression. As expected, women with abnormal mammograms were older (96%>40 years old) compared to the women with abnormal Pap tests (70% between ages 18 – 30 years old). For both groups, depressed women were more likely to be on public insurance, and for women with abnormal mammograms, depressed women were less likely to be black. (Table 1) Depressed women in both study groups were more likely to have anxiety.

Depressive symptoms were statistically significantly more common among women defined as depressed compared to those who were not. The most common documented symptoms in the depressed group in decreasing frequency were: depressed mood (57% for both women with abnormal mammograms and Pap tests), sleep problems (41% and 38%), anxious feelings (33% and 15%), fatigue (32% and 18%), impaired concentration (21% and 14%), and changes in appetite (14% for either abnormal test). For depressed women with abnormal mammograms, 69% had some form of documented treatment (66% prescribed antidepressants), while 51% of depressed women with abnormal Pap tests had some treatment (45% prescribed antidepressants).

The median time to resolution was 27 days for women with abnormal mammograms, and 85 days for women with abnormal Pap tests. Figure 1 compares the time-to-diagnostic-resolution event analysis of women with and without depression diagnosis. In both of these screening groups, we note delays in diagnostic resolution, with less than half receiving a definitive diagnosis within 30 days after abnormal mammograms, and within 90 days after abnormal Pap tests. There was no difference in time to diagnostic resolution between those with and without depression diagnosis either for women with abnormal mammograms (Fig. 1a, p=0.22 from the log-rank test) or for women with abnormal Pap tests (Fig. 1b, p=0.53).

Tables 2a and b present the bivariate and multivariable findings from the Cox proportional hazard models predicting time to resolution for mammogram and Pap test abnormalities, respectively. In these analyses, a hazard ratio less than 1.0 indicates longer time to diagnostic resolution. When examining the whole study population, neither depression diagnosis nor anxiety was significantly associated with delayed diagnostic resolution for women with abnormal mammograms or abnormal Pap tests. Secondary analyses found no significant interaction between depression and anxiety for women with abnormal mammograms (p=0.64) or with abnormal Pap tests (p=0.16). The effects of depression remained non-significant when allowing for different effects in depressed women receiving treatment (aHR 0.8 (0.6, 1.1) for mammograms and aHR 1.0 (0.7, 1.4) for Pap tests), or not receiving treatment (aHR 1.0 (0.7, 1.5) for mammograms and aHR 0.8 (0.6 , 1.2) for Pap tests) for depression. Among women with abnormal Pap tests, there was no suggestion of a depression effect on time to resolution over the first 120 days of follow-up (aHR 1.0 (0.7, 1.4)); however, there was a non-significant trend toward slower resolution for depressed women after 120 days (aHR 0.6 (0.3, 1.1), p=0.096). We performed additional secondary stratified analyses in order to examine associations within subgroups of patient sociodemographics. Separate analyses by insurance status showed no depression effect for those with public or private insurance, but demonstrated a trend of delayed diagnostic resolution for those with no insurance (HR=0.3 (0.1 , 1.0) p=0.06 for mammograms and HR=0.5 (0.2 , 1.2) p=0.11 for Pap tests). There were no differences by race, ethnicity, or age.

DISCUSSION

To our knowledge, this is the first examination of the relationship between pre-existing depression with and without anxiety and time to diagnostic resolution of abnormal mammograms and Pap tests. In this vulnerable population seeking care at urban federally qualified community health centers, we found delays in diagnostic resolution after abnormal cancer screening. However, those with a depression diagnosis did not have increased delays compared to not-depressed women. In addition, there was no significant interaction between anxiety and depression.

Table 1. Characteristics of Depressed and Not Depressed With Abnormal Mammography and Pap Test Screening

Our findings suggest that for women with the lengthiest delays in diagnostic resolution (> 120 days), depression may contribute to diagnostic delays of abnormal Pap tests, but not abnormal mammograms. This may reflect differences in the populations themselves, as the populations are remarkably different in age, or differences in the perceived implications of delayed diagnostic resolution. For example, a delay of several months for an abnormal mammogram may be clinically more significant than several months of delayed resolution for abnormal Pap tests. However, our results contrast from studies of cancer screening tests reporting depression being associated with less screening mammography,[2,25] but not with fewer Pap tests.

Prior research found conflicting effects between the relationship of cancer screening behavior and depression. This may be due to depression frequently being confounded with anxiety, and the potential for anxiety having opposite effects on health outcomes. For example, a meta-analysis found that depressed patients were three times less likely to be adherent to treatment recommendations for a variety of illnesses, including breast cancer, but anxiety had little effect[6]. Patten and colleagues surveyed a large population, finding that a major depressive episode was not associated with receiving a screening mammogram in the subsequent year; however, co-existing anxiety was not accounted for in that analysis.[26] Additional analytical complexities are introduced by differential reporting and documentation of depressive and anxious symptoms. Frequently, depression and anxiety symptoms are under-documented.[27] Even if symptoms are documented, there remains an analytic challenge of determining if these symptoms reflect a stable psychological "trait" versus a temporary "state," and determining which is more important in determining future health behavior and outcomes. This distinction is of particular importance when studying the outcomes of follow-up care after abnormal cancer screening, as in this study, for the negative psychological states associated with receipt of an abnormal test could adversely affect the outcome of follow-up care.

In addition to the analytical difficulties, the relationship of depression and cancer screening behavior could vary by populations of women. For example, in our study population of ethnically diverse, economically disadvantaged women, who already have other socioeconomic barriers to reaching timely resolution after abnormal cancer screening,[28,29] our findings suggest that depression does not contribute to delays in diagnostic care, except perhaps for those who both are depressed and lack insurance. It is possible that depression does delay diagnostic resolution in women not socio-

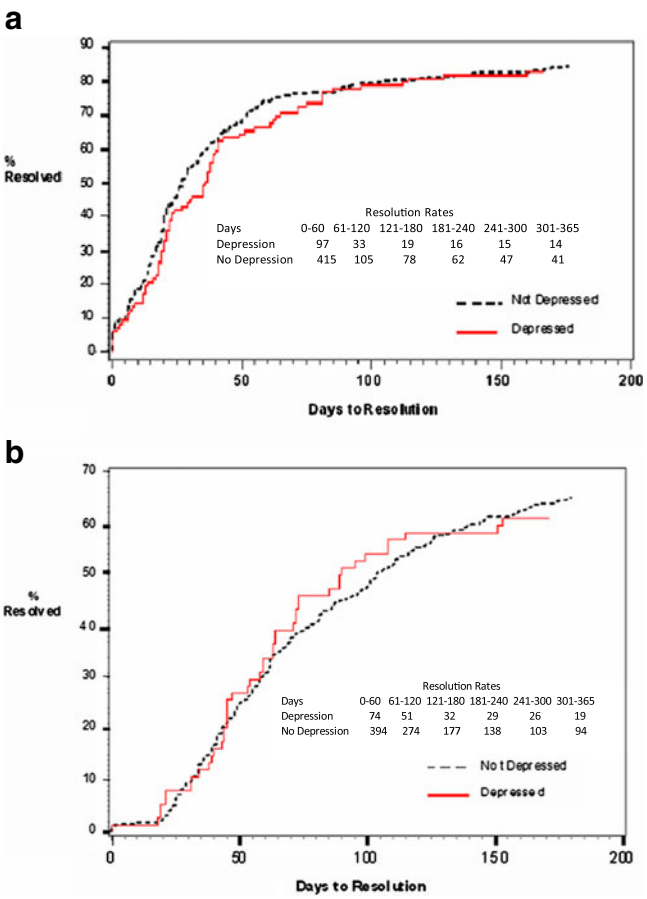

Figure 1. Time to event analysis comparison of depressed and not-depressed patients (a) Abnormal mammograms (b) Abnormal pap tests.

economically disadvantaged. Conversely, the women in our study were already engaged in the health care system, as having an abnormal cancer screening test was a mandatory inclusion criterion. If depression is a barrier to receiving screening mammography and/or Pap tests in a sub-population of women, they would not have been included in our study.

This study is limited by the relatively small sample size, limiting our power to detect statistical differences between the depressed and not-depressed groups. Using retrospective chart review to classify patients as depressed has the potential for misclassification bias in two ways, each biasing the results toward the null. First, it is possible that patients classified as "not-depressed" were truly depressed. In addition to known under-diagnosis of depression in primary care,[30] which may be differential in vulnerable populations[31] and those without insurance,[32] there may be under-documentation of it as well, since primary care providers are frequently not reimbursed if depression is the primary ICD-9 diagnosis. The accuracy of using administrative data or the EMR to determine depression diagnosis ranges from 58 – 83% depending on the contents of the EMR.[33,34] However, our 12 month depression prevalence was slightly higher than that previously reported for depression using survey tools, suggesting the possible extent to which under-diagnosis and under-reporting of depression were limited in our study.[15,35,36] Second, patients adequately treated for depression may be classified as "depressed" even though they are no longer experiencing symptoms. However, since almost all of our depressed patients had corresponding documented depressive symptoms, it is unlikely that a patient classified as depressed did not have depressive symptoms during the year preceding the abnormal cancer screening test. Although depression diagnosis documented in administrative data is more likely to correspond to severe and recurrent depression in patients,[37] we were not able to account for the clinical severity of depression or whether it was adequately treated. Finally, as our data was collected via retroactive chart review, there may be some residual confounding that we were not able to account for in our analyses.

This is the first examination of the relationship between pre-existing depression and time to diagnostic resolution of abnormal mammograms and Pap tests.[9] Previous studies focused on *screening* mammography and Pap tests. Our findings did not support the notion that pre-existing mood disorders documented in the EMR delays the time to resolution of abnormal cancer screening tests for vulnerable populations, although we did find a trend of delayed care in depressed women who were uninsured or took longer to resolve their Pap abnormalities. It is possible that the timing of depressive symptoms in relation to the time of being informed of abnormal cancer screening is a more informative predictor. Future studies should validate our results by using survey data to classify patients' depressive symptoms, their severity, and whether they reflect a stable psychological "trait" or temporary "state."

Our current findings are consistent with our previous work, in that individual characteristics of patients may be less important than system characteristics in determining the time to diagnostic resolution of abnormal mammograms or Pap tests in vulnerable women[19,20]. However, identifying which patients are most vulnerable may allow for more efficient allocation of resources, as patient-centered-medical-home models emerge and incorporate more elements of case management. Our findings imply that pre-screening the EMR for mood disorders may not be the most reliable approach to identify a group of patients at higher risk of delayed diagnostic resolution of abnormal cancer screening tests in a vulnerable population.

Table 2. Cox Proportional Hazards Analysis* Predicting Time to Resolution

	Univariate	Bivariate	Multivariate†	P
	HR (95% CI)	HR (95 % CI)	HR (95 % CI)	
Abnormal Mammograms N=538				
Depression	0.9 (0.7, 1.2)	0.9 (0.7, 1.2)	0.9 (0.7, 1.1)	0.31
Anxiety	0.9 (0.6, 1.2)	0.9 (0.6, 1.3)	1.0 (0.7, 1.4)	0.85
Abnormal Pap Tests N=415				
Depression	0.9 (0.7, 1.3)	0.96 (0.7, 1.3)	0.9 (0.7, 1.3)	0.73
Anxiety	0.9 (0.6, 1.3)	0.9 (0.6, 1.3)	1.1 (0.5, 1.1)	0.21

**Larger hazards ratios are associated with shorter time to resolution. p value is testing the HR from the multivariable model*

†Adjusted for individual community health center and degree of mammogram abnormality

‡Adjusted for individual community health center, race, language and insurance status. The cumulative incidence curves for women with and without depression cross at 120 days; therefore we modeled separate effects of depression for resolution within 120 days and after 120 days, using time-dependent indicators for depression in the Cox model

ABSTRACT

Purpose: Attributes of the organisational culture of residency training programmes may impact patient safety. Training environments are complex, composed of clinical teams, residency programmes, and clinical units. We examined the relationship between residents' perceptions of their training environment and disclosure of or apology for their worst error.

Method: Anonymous, self-administered surveys were distributed to Medicine and Surgery residents at Boston Medical Center in 2005. Surveys asked residents to describe their worst medical error, and to answer selected questions from validated surveys measuring elements of working environments that promote learning from error. Subscales measured the microenvironments of the clinical team, residency programme, and clinical unit. Univariate and bivariate statistical analyses examined relationships between trainee characteristics, their perceived learning environment(s), and their responses to the error.

Results: Out of 109 surveys distributed to residents, 99 surveys were returned (91% overall response rate), two incomplete surveys were excluded, leaving 97: 61% internal medicine, 39% surgery, 59% male residents. While 31% reported apologising for the situation associated with the error, only 17% reported disclosing the error to patients and/or family. More male residents disclosed the error than female residents ($p=0.04$). Surgery residents scored higher on the subscales of safety culture pertaining to the residency programme ($p=0.02$) and managerial commitment to safety ($p=0.05$). Our Medical Culture Summary score was positively associated with disclosure ($p=0.04$) and apology ($p=0.05$).

Conclusion: Factors in the learning environments of residents are associated with responses to medical errors. Organisational safety culture can be measured, and used to evaluate environmental attributes of clinical training that are associated with disclosure of, and apology for, medical error.

INTRODUCTION

Everyone makes mistakes. Over the past decade, the medical profession has started to apply a systems approach to patient safety, recognition that coordination of individual, team, and organisational forces are needed to promote patient safety. Analysis of the root causes of an error can prevent future errors by identifying and correcting problems.[1] However, in order to learn from mistakes and develop safer systems, errors must first be identified and reported.

Unfortunately, many errors are never reported. In one study, merely half of the house officers told their attending physicians about the most serious errors they committed.[2] Underreporting of adverse events is estimated to range from 50% to 96% annually.[1 3 4] Rather than dealing with mistakes constructively by reporting and learning from them, studies indicate that physicians typically respond to their mistakes defensively, blaming the system, other members of the healthcare team, or even the patient.[2 5–7] Possible explanations for underreporting medical errors include fear of litigation acting as a deterrent,[8–10] and the professional medical culture that limit an individual's willingness to discuss error.[5 11]

While elements of professional medical culture are hypothesised to lead to widespread underreporting of medical errors, few studies have elucidated and measured aspects of medical culture that are associated with a failure to disclose, particularly in the learning environments of clinical training programmes. In contrast to medical culture, non-medical industries such as aviation and nuclear safety have traditionally valued a professional 'culture of safety', which facilitates reporting of errors, so that individuals operating in groups within an organisation can learn how to prevent future errors.[12] Medical educators have recently attempted to incorporate system-based thinking into their curriculum, in order to incorporate aspects of a safety culture that, along with enquiry and trust, were previously lacking in

residency settings.[2 7 12] Although there is recognition of the need to create a learning culture of safety for residents,[13] measuring educational culture has proved to be a challenge. In addition to the complexities of quantitatively measuring an abstract concept of 'organisational culture',[14] residents train in multiple environments which are dynamic and divergent: their individual clinical teams (which often rotate), the academic residency training programme, and the clinical institution(s) (usually a hospital) each contributing to a trainee's overall sense of culture.

This study endeavours to measure a trainee's perception of their training environment as it relates to safety, and their response to committing an error. By collecting data on both these elements, we explore the relationship between the culture of the training environment and individual behaviour. Specifically, we hypothesised that house officers would be more likely to disclose and apologise for an error if they rate their clinical team as having an environment in which they can report errors without fear of punishment or rejection; rate their training programme as having positive attitudes about reporting and coping with errors in the workplace; and rate the hospital as having a high level of commitment to patient safety. Secondary aims of our study were to evaluate the association between individual characteristics of clinical trainees and, first, disclosure of a medical error, and second, apology for the error.

METHODS

Study design and survey administration

Anonymous, self-administered surveys were distributed to medicine and surgery residents at Boston Medical Center during educational conferences and department meetings in 2005. The distribution and retrieval procedures of the surveys ensured privacy and anonymity of the residents. The researchers (who were also attending physicians) were blinded as to which residents completed the survey, which ensured no conflict of interest for the researchers if asked to evaluate residents. The residents were assured that their privacy and anonymity would be protected, and that the researchers would remain blinded to their participation status. Specifically, the researchers approached a group of housestaff during an educational conference or meeting, explained the purpose of the survey, and then left the room and building. Residents who choose to participate completed the surveys and returned them in sealed envelopes to a box in the room. Those who chose not to participate returned blank surveys in sealed envelopes. At the end of each conference, a research assistant returned to the room to collect the box with the sealed envelopes. All participants received a $10 honorarium, whether or not they completed the survey. The survey, database, and protocol were de-identified. To further protect participants in the event of an accidental breach of anonymity, a certificate of confidentiality was obtained from the National Institutes of Health. The project was carefully reviewed and approved by the institutional review board.

Survey content

Our survey focused on three levels of environment that had the most face validity of microculture constructs within a resident's learning environment. Questions were selected from three validated surveys of organisational culture, adapted for this study to focus on the organisational environment of housestaff. Since the full survey instruments were deemed too high a respondent burden, the authors carefully considered and then selected items from each survey most relevant to the study. The microenvironment of the immediate clinical team was examined with five of seven questions from the Team Psychological Safety Survey, which assesses the belief that well intentioned actions will not lead to punishment or rejection by the team (see online appendix).[15] The macroenvironment of the residency programme was assessed with 10 of the 37 items from the Error Orientation Questionnaire; the items selected assess attitudes to errors and approaches to coping with errors in the workplace (see online appendix).[16] Perception of hospital management's commitment to patient safety on the clinical unit was assessed with four of 19 items from the Patient Safety Survey (see online appendix).[17] Responses were coded with six-point Likert scales, and summed to derive a total score for each survey. For all three scales (Team Psychological Safety, Residency Programme Error Orientation, and Managerial Safety Commitment), higher scores correlated with more positive aspects of culture. In relation to error, participants were asked to recall the circumstances of and share details regarding their most significant medical or surgical error using open-ended text. In a multiple choice format, participants were specifically asked about the following: consequences for the patient; consequences for the resident; if and to whom they disclosed the error; if they had apologised for the error; and perceived causes for the error. Responses to each question were constructed from the results of a previous survey of residents regarding medical error, conducted by Wu *et* al.[2] In addition, residents were asked to characterise their own level of distress from the error using a 10-point Likert scale.

Analysis

Univariate analysis was used to describe demographics, residency type, reporting rates (to colleagues and friends), apology and disclosure rates (to patients),

emotional responses of residents, types of mistakes, and consequences to and responses of both the residents and patients. Errors were classified from the written responses into one of the following categories: procedural, medical management, laboratory test follow-up, delayed diagnosis, or other/not classifiable. We used χ^2 to evaluate differences between categorical variables and Wilcoxon rank sum methods for the three organisational culture scales. In order to compare the subscales with each other, the raw score was converted to a scaled score, by dividing each raw score by the maximum possible score of each subscale, and multiplying by 33.3. We then calculated an overall Medical Culture Summary score, by summing the three scaled subscores, that is, each subscale contributes one-third of the overall Medical Culture Summary score.

RESULTS

Surveys were distributed to 109 residents and 99 surveys were returned, making an overall response rate of 91%. Two residents' surveys were excluded because they reported no mistake, leaving a final population of 97 residents, 59 (61%) from internal medicine residents and 38 (39%) from surgical residents. There were 57 (59%) male residents, of which 33 (58%) were internal medicine residents and 24 (42%) were surgical residents. Two surgical residents did not report their gender, and were excluded from analyses which included gender. The most significant medical or surgical error that was the focus of residents' responses typically occurred in an inpatient setting and during the first year of training (table 1).

Table 1 Characteristics of residents and setting where error occurred

	Total N=97 N (%)
Gender	
Men	57 (59)
Women	38 (39)
Unknown	2 (2)
Programme	
Medicine	59 (61)
Men	33 (56)
Surgery	38 (39)
Men	24 (63)
Training year	
First year	64 (66)
After first year	32 (33)
Unknown	1 (1)
Setting	
Ward	63 (65)
Ambulatory clinic	3 (3)
Operating room	5 (5)
Intensive care unit	22 (23)
Emergency department	4 (4)

Seventy-five per cent of the residents were extremely distressed by their mistake. While 41 (42%) did not provide an adequate description of their error to be classified, 26 (27%) were classified as medication related, 12 (12%) as procedural, 11 (11%) due to delayed diagnosis, and 9 (9%) due to inadequate follow-up to a laboratory test.

Although 20 (21%) of the involved patients had no reported consequences resulting from the errors, common consequences included delayed treatment for 23 (24%), delayed diagnosis for 22 (23%), prolonged hospital stay for 17 (18%), medical complications for 13 (13%), and death for 13 (13%) patients. The errors resulting in patient death were largely errors involving anticoagulants, potassium balance (either not checking blood work or inadequate management of blood potassium level), or insulin. There were no consequences for 60 (62%) of the residents due to the error, but 30 (30%) reported some form of reprimand, 16 (16%) presented the case at a morbidity and mortality conference (which was reported as a consequence), 6 (6%) reported their work and family life was affected, and 1 (1%) was named in a law suit. The most common attributions for the error reported by residents included being too busy (32, 33%) and inexperience (31, 32%). Many residents also attributed their error to having inadequate knowledge, hesitating before acting, or being too tired (table 2). While 30 (31%) reported apologising for the situation associated with the error, only 17 (18%) reported disclosing the error to patients and/or their family. Five residents both disclosed (29% of those who disclosed) and apologised (17% of those who apologised table 3).

Correlates of disclosure and apology

The disclosure rate was higher among surgery residents (24%) than internal medicine residents (14%), but this difference was not statistically significant (p=0.2). Of the residents who disclosed their error, 32 (33%) reported that it was unsupervised. Three (3%) residents reported being told by their attending not to discuss the error with the patient. Female internal medicine residents were significantly less likely to disclose their worst medical error to patients or their families than their male counterparts (p=0.03). In contrast, more female surgery residents, 7 (58%), apologised for their error compared with male surgery residents 7 (29%), though the difference did not reach statistical significance (p=0.1). Of the 13 errors that resulted in a patient's death, only 3 (23%) of the residents disclosed the error to the patient and/or the patient's family, but 6 (46%) residents apologised to the patient's family. More residents who made errors in medication management (8 of 26, 31%) disclosed their error than those who made

errors with procedures (3 of 12, 25%) or delayed diagnosis (2 of 11, 18%) (p=0.05).

Correlates of organisational culture measures

The Safety Culture Summary score was positively associated with disclosure of medical error to the patient and/or patient's family (p=0.04) and apology for the error (p=0.05). There was a trend of association between disclosure and higher scores on the subscales clinical Team Psychological Safety (p=0.07) and Residency Programme Error Orientation scales (p=0.07), but not for Managerial Safety Commitment (p=0.2). Report of apology to the patient and/or patient's family was not associated with the clinical Team Psychological Safety score (p=1.0) but was positively associated with scores on the Residency Programme Error Orientation (p=0.05) and Managerial Safety Commitment (p=0.01). There were no significant gender differences in scores for each of the subscales as well as the summary measure of safety culture. Surgery residents had higher scores on the Residency Programme Error Orientation (p=0.02) and Managerial Safety Commitment scales (p=0.05) compared with medicine residents, but there was no significant difference between programmes in the Safety Culture Summary score (table 4).

CONCLUSIONS

Only 17% of the residents we surveyed reported disclosing their most significant error to their patient and/or patient's family, and only 31% of the residents reported apologising for their most significant error. Our results suggest that factors in the learning environments of the clinical team and residency programme are associated with error disclosure and apology among residents. Individual factors, such as gender and type of error, also appear to be associated with error disclosure

Table 3 Individual factors associated with disclosure and apology, by gender* and programme

and apology, and more residents apologised for the error than disclosed it.

Our findings of discordance between apology and disclosure of medical error are consistent with previous studies exhibiting residents may be more willing to apologise for a bad outcome than to reveal that they played a role in causing the bad outcome, resulting in a 'partial disclosure'.[18 19] Collectively, these findings imply that factors that facilitate apologising for an error may differ from influences that facilitate disclosing an error. These findings are reflected in State laws that distinguish different components of conversations with patients about unanticipated outcomes: 'expression of sympathy' (apology), 'explanation' (disclosure), and 'admission of fault', which does not cleanly translate into either category.[20] Additional explanations for the discordance may include the social context in which the error occurred. For example, apologising for a systemic error that occurred would likely be easier than disclosing personal responsibility for an error, which could have greater legal and professional consequences.[19]

The relationships of gender to our outcome measures are complex. More male residents disclosed error (driven mostly by male internal medicine residents) while more women apologised (driven mostly by female surgical residents). With our small sample size, definitive conclusions about the interactions among gender, specialty and disclosure are difficult to ascertain from our data. Previous studies[2 9] have also demonstrated that individual attributes, such as gender and emotional response to the error, influence the reporting rate of the error. However, in contrast to our results, women in a previous study were *more* likely to discuss their errors with their patients and make constructive changes in their practice.[2] Although the female residents in our study were less likely to disclose their error, the female surgical residents were more likely to apologise, consistent with past reports of greater empathy among female physicians.[21] Our results suggest that there are barriers to disclosure in the learning environments of clinical trainees that affect men and women differently. Further research will be needed to elucidate which barriers to disclosure and apology affect genders differentially. For example, possible barriers to disclosure may be attitudinal— women may feel they have more to lose than men by disclosing in order to be professionally successful, or emotional— women may feel more of a sense of helplessness and loss of control once information is disclosed.

We found surgery residents to have higher scores on the residency programme's Error Orientation Scale and the clinical unit's Managerial Safety Commitment Scale than medicine residents, but not on the Safety Culture Summary score. This is consistent with a previous survey of residents, which found that presentations of errors causing adverse events occurred 18% of the time in internal medicine ground rounds compared with 42% in surgery.[22] The differences between these two fields are likely due to divergent regulatory and cultural factors. Historically, morbidity and mortality rounds have served as a forum where surgeons learn from poor outcomes and aspire to identify their errors,[23] but this tradition is weaker in medicine training programmes.[24] The Accreditation Council for Graduate Medical Education (ACGME) requires that surgery morbidity and mortality conferences present and discuss 'all deaths and complications that occur on a weekly basis'. Historically, there has been no similar requirement for internal medicine.[24] Without a specific requirement to do so, adverse events and errors occurring in the medicine service may not be generally discussed.[21]

Several medicine residencies have developed programmes to address the current ACGME competency on Systems Based Practice,[13] by teaching systems-based thinking using root cause analysis of medical errors,[25] which require residents to develop an awareness of working in multidisciplinary teams to enhance patient safety, and participate in identifying system errors and implementing potential solutions.[13] Several studies have demonstrated the benefits of such educational

interventions,[26–29] although to our knowledge, no study has attempted to measure changes in learning environment as a result of such interventions. Although such programmes are helpful, current ACGME guidelines do not require training programmes to address a thorough behavioural process of managing medical mistakes: accepting responsibility; discussing with colleagues; disclosing and apologising to patient; conducting an error analysis; and making changes in a practice setting designed to reduce future errors.[1 2 5 6 11 30]

The ability of residents to cope with medical error may be dependent on reassurance and learning opportunities provided by medical colleagues and supervisors.[26] Our findings would support this assertion, given the positive association between our derived Medical Culture Summary score and reporting of disclosure and apology. However the low frequency of disclosure and apology suggests that more work needs to be done within our training programmes to mitigate the negative effects of error to individuals, and gain potential benefits from more thorough processing of errors for individuals and the healthcare system.

There are several issues germane to housestaff and errors that are not addressed by our study. Some believe that an effective apology includes offering some form of reparation for the mistake.[31] We did not examine the issue of reparation. While the literature suggests that resident physicians who accept responsibility for their errors and discuss them are more likely to report other improvements in their medical practice,[2] we did not examine this phenomenon. Furthermore, while disclosure in a timely and appropriate manner may influence a patient's decision to pursue legal action,[1–3] we did not explore the relationship between our findings and legal action. In addition, though a doctor's emotional reaction to an error can last for years[32] and negative emotional responses are associated with increased odds of future self-perceived errors,[33] we did not evaluate emotional reactions or predict the future likelihood of error. Lastly, we did not directly examine the extent to which subjects were trained regarding coping with medical error, and hence could not determine if this training influenced their behaviour.

This study has several limitations. First, residents at only one academic medical centre were surveyed, so the results may not be generalisable. In addition, the residents were surveyed during 2004–2005, so it is possible that these results may no longer be accurate. During the past 6 years, the ACGME training requirements have increased their focus on systems-level thinking and training programmes have increasingly focused on reduction of error. However, the authors feel that the key findings of this study are relevant today. The rate of safety culture change is relatively slow, as demonstrated

by a recent hospital survey administered by the Agency for Healthcare Research and Quality: average composite change in safety culture to change 1% over 1–2 years.[20] An increased focus on reduction in error does not translate directly to increases in individual accountability, apology or disclosure of error. Second, the modest sample size, limits opportunity for multivariable analyses as well as statistical power to detect potential associations. Third, our survey directed residents to consider a single error. We did this to focus respondents' attention on the details of an event that they would remember clearly to gain insight into aspects of organisational culture. This specific error may not be representative of most errors. In addition, as most of these errors occurred during the residents' first year of training, the expectation for disclosure and apology may be different than for the other years of training. However, a prior study that included trainees at our institution suggested that the responsibility of delivering bad news often falls to junior members of the team, including first-year trainees and medical students.[34] Fourth, the scales of organisational culture we used have rarely been used in healthcare settings. As such, the clinical significance of our observed score differences are unclear.

Despite the limitations, we successfully adapted survey tools previously used in a business environment to measure aspects of the learning environment of clinical trainees which are associated with disclosure and apology for medical error. This instrument needs to be validated in other institutions before proving its value as a metric in residency programme safety culture. If validated, such an instrument could be a valuable tool to assess changes in learning environments. Measuring culture and providing such feedback to leadership and staff is one of the safe practices recommended by the National Quality Forum to promote patient safety and reduce medical error.[35]

Measuring culture change requires a multimodal approach, of which this instrument could make a valuable contribution.[36] Since the ability to measure medical culture, and changes to it, is immature,[37] our study provides baseline measurements to help move the field further along. Developing learning environment metrics will be valuable to other institutions and training programmes in the coming years, as incremental programmatic changes in systems-level thinking and disclosure of medical error continue to impact the learning environments of residents.

Our results suggest a need for training programmes to provide trainees with structured, meaningful ways to cope with errors to prevent negative emotional responses, as well as create learning environments that facilitate disclosure of errors. Attention may need to be paid to explicate potential gender-related differences. All this is particularly important if, as a profession, we are to instil proper values, attitudes and responses to the inevitable occurrence of error in the next generation of physicians. As residency programmes incorporate systems-level thinking into residency education for patient safety and error prevention, it is important not to neglect the humanistic and interpersonal consequences of error for providers and patients. In order to do so, we need to develop measurement tools for learning environments. Further research is needed to identify successful environmental attributes that promote disclosure and healthy processing of medical errors.

ORIGINAL ARTICLE

Does PEG Use Cause Dysphagia in Head and Neck Cancer Patients?

Received: 14 February 2011 / Accepted: 19 July 2011

Abstract Percutaneous endoscopic gastrostomy (PEG) use is common in patients who undergo radiotherapy (RT) for head and neck cancer to maintain weight and nutrition during treatment. However, the true effect of PEG use on weight maintenance and its potential impact on long-term dysphagia outcomes have not been adequately studied. This retrospective study looked at swallowing-related outcomes among patients who received prophylactic PEG vs. those who did not, and among patients who maintained oral diets vs. partial oral diets vs. those who were nil per os (NPO). Outcomes were assessed at the end of RT and at 3, 6, and 12 months post RT. A comprehensive review of patients' medical charts for a 6-year period yielded 59 subjects with complete data. Results showed no difference in long-term percent weight change between the prophylactic PEG patients vs. all others, or between patients who, during RT, had oral diets vs. partial oral diets vs. NPO. However, those who did not receive prophylactic PEGs and those who maintained an oral or a partial oral diet during RT had significantly better diet outcomes at all times post RT. Dependence on a PEG may lead to adverse swallowing ability in post-irradiated head and neck cancer patients possibly due to decreased use of the swallowing musculature.

Keywords Deglutition · Deglutition disorders · Head and neck cancer · Radiotherapy · PEG · Weight · Diet

Dysphagia is a well-known complication of radiotherapy (RT) for head and neck cancer (HNC). The incidence of dysphagia varies greatly by report, with figures ranging anywhere from 9 to 77% [1, 2]. These disparate figures are undoubtedly a result of multiple variables that may impact swallow function such as time after radiation treatment, stage of cancer, additional surgery or chemotherapy, patient characteristics, and response of the patient to the treatment. While instrumental procedures (i.e., fluoroscopy or fiberoptic endoscopic examination of swallowing [FEES]) can yield an objective diagnosis, more functional and more common indicators of a swallowing problem are weight loss, diet level, and the need for a feeding tube.

The need for a feeding tube in patients undergoing radiotherapy is a particularly interesting variable since it is viewed as both beneficial and detrimental for patients. In cancer clinics across the U.S., different institutional policies have prevailed. Some centers avoid placing a feeding tube unless the patient is showing signs of extreme weight loss or reported inability to swallow. Other centers place feeding tubes prophylactically in all patients (or those with advanced-stage cancer) before the RT regime even begins. Evidence for one policy over the other is lacking. Instead,

institutional precedent and anecdotal experience are more influential in guiding a physician in his recommendation.

Evidence for best practice in this area is scant. The American Head and Neck Cancer Society's guidelines regarding PEGs state that "Due to the location of their tumors and the mucosal effects of therapy, many patients with head and neck cancer are nutritionally compromised. If highly toxic therapy is planned, placement of a PEG tube prior to starting therapy enables patients to maintain nutrition during therapy and recover more quickly" [3]. These recommendations, which appear to favor prophylactic PEG placement, come from a consensus of practitioners who were selected by the Society and are not necessarily based on evidence from well-designed research studies.

In contrast to these guidelines, recent awareness of the significant dysphagia experienced by some patients after RT and the emphasis on swallowing rehabilitation have led some clinicians to believe that relying on a feeding tube during RT may adversely affect a patient's ultimate ability to swallow. This belief originates from the perception that if a person has a feeding tube during his course of RT, he will depend on it for nutrition and will stop taking anything by mouth because of pain, altered taste, and lack of appetite. While refraining from oral intake may be more comfortable for the patient, clinicians fear that the associated reduction in swallowing frequency may ultimately lead to muscle atrophy and augment the severity of radiation fibrosis in the throat. This belief is not based on strong research either, but it is suggested from one pilot study that showed some benefit to patients who exercised their swallowing muscles during RT [4].

The best evidence for guiding clinical practice comes from well-designed prospective or retrospective research studies. Ideally, patients who received a prophylactic PEG (placed before or during the first week of RT) would be compared to patients who received a therapeutic PEG (placed after the first week of RT) or to patients who never received a PEG and maintained a 100% oral diet. The outcome of interest would be swallowing status after a given period of time.

A literature search for all such studies published between January 1991 and January 2010 yielded only ten studies with acceptable evidence, including two prospective randomized control trials. Four studies compared prophylactic vs. therapeutic PEG placement [5–8], four studies compared prophylactic PEG to oral/no PEG patients [9, 10], and two studies compared prophylactic PEG to therapeutic PEG and to oral patients (or pooled therapeutic and oral patients) [11, 12]. None of these studies reported swallow status from an instrumental swallow examination; instead, they reported weight loss, use of a feeding tube, or patient/clinician report as surrogate indicators of swallow function.

Looking at *weight loss* as a possible measure of swallow function, the literature suggested that prophylactic PEG favors less weight loss over the course of RT treatment [5, 9, 10, 12–14]. Only one study, albeit a randomized clinical trial, found no significant difference in BMI change at the end of RT between patients who received prophylactic PEG vs. patients with therapeutic PEG or oral diets [11]. Reports of comparative weight loss for long-term outcomes were mixed. One study found no significant difference between the prophylactic PEG, therapeutic PEG, and 100% oral diet groups at 3 or 6 months post RT [14]. Two other studies found that prophylactic PEG patients fared better (lost less weight) than therapeutic PEG patients at 12 months post RT [7, 12].

Diet levels were not reviewed in any of the studies, but two studies did look at swallow function via clinician/patient rating scales. Chen et al. [14] found that significantly more patients who had been given a prophylactic PEG reported dysphagia at 3 and 6 months compared to patients who had 100% oral diets. Morton et al. [7] found that patients who had a PEG placed for longer durations, regardless of prophylactic or therapeutic nature, reported worse swallowing function at 12 months ($P < 0.01$).

In summary, there is a paucity of published evidence regarding dysphagia outcomes, and adequate guidelines for PEG placement are clearly lacking. In light of the preliminary results of Chen and Morton suggesting PEGs may detrimentally affect long-term dysphagia outcomes, the present study was undertaken to determine if PEG use influenced long-term swallow function in HNC patients who received radiotherapy at our institution. The first aim was to determine whether patients who received a prophylactic PEG had better or worse swallowing function, diet scores, or weight change outcomes than patients who did not receive a prophylactic PEG. The second aim of this study was to determine whether patients who used a feeding tube for all, some, or none of their nutrition fared differently in terms of eventual swallowing ability, diet level, and weight change. The results of the second question would hopefully cast light on the question of whether the act of eating and using the muscles involved in swallowing would impact long-term dysphagia outcomes.

Materials and Methods

A retrospective chart review was conducted of all head and neck cancer patients treated with RT from January 2003 to September 2008 at Boston University Medical Center. The chart reviews were performed by three authors (KVM, SEL, GPK) using the medical center electronic database and the clinical data warehouse. An initial search of various hospital databases revealed 880 patient records. After

excluding patients with ineligible cancer locations (e.g., esophagus, skin) or who did not fall within our eligibility window, a final list of 150 patients remained.

Patients were then excluded from analysis if there was incomplete outcome data at baseline, incomplete outcome data at more than one time point of interest, if they received only a partial dose of RT, or if they had persistence or recurrence of HNC at the time of outcome. Of the 150 medical records, there were 59 patients who met all inclusion and exclusion criteria, and for whom adequate data was available up to 1 year post RT. Approval from the Institutional Review Board of Boston University Medical Center was obtained prior to data collection.

Age, gender, location and stage of cancer, chemotherapy, and extent of surgery were recorded for each patient. Weight, diet level, and PEG status were noted at five time periods: start of RT, completion of RT, 3 months post RT, 6 months post RT, and 12 months post RT. Diet level at each time point was categorized by 6 diet levels listed in Table 1.

Objective instrumental evaluation of swallowing ability would have been an excellent indicator of function, but very few patients had formal swallow studies so this could not be considered. Accordingly, our primary outcomes of interest were percent weight loss and mean diet levels over time, both representing common surrogates of swallow function and dysphagia.

Percent weight loss, rather than absolute weight loss, was used to help account for vastly different body sizes. While weight at the *start of RT* was probably not the subject's usual weight, it was a good baseline from which change over time could be compared, especially to capture the effect of PEG use on weight during RT. However, *end of RT* was chosen as the baseline when recording *diet level* so that changes to this outcome would be a result of variables other than the acute effects of RT (such as pain). The end of RT represented a nadir in diet that was experienced by almost all patients, and any tumor-related dysphagia symptoms had been resolved. So this end-of-RT nadir served as a "normalized" starting point from which we could record changes in diet level over time between different groups of patients.

Table 1 Diet level categories

Diet level	Description
1	NPO
2	Partial PEG/partial oral
3	Liquid diet
4	Puree and wet soft foods
5	Edentulous or regular food with difficulty or requiring liquid wash
6	Regular diet with no alterations needed

Data Analysis

Two sets of analyses were conducted to determine the impact of PEG use on long-term diet level and weight change. All analyses used the same cohort of patients, although they were categorized differently depending on the question of interest.

The first set of analyses evaluated whether patients who received a prophylactic PEG (main independent variable) had different outcomes (%weight change and diet scores) than people who did not receive a prophylactic PEG. The second set of analyses assessed whether diet level at the end of RT for all patients (main independent variable) was associated with the two outcomes of interest. Outcomes of interest for both analyses were percent weight change and diet score at 3, 6, and 12 months after completion of RT.

For each of the above analyses, generalized linear mixed-effects models were used to evaluate the relationships of interest. The mixed-effects models were used to account for the correlation from using repeated observations on the same subject. Covariates considered were chemotherapy, stage of cancer, and major surgery. However, due to insufficient data in some cells, the results were adjusted only for surgery. Potential collinearity of covariates was confirmed by calculating the correlation between independent variables; no pair of variables had a Spearman correlation > 0.40. The association between diet status at baseline and diet scores at follow-up was evaluated in preliminary analyses using the nonparametric Kruskal–Wallis test at each time point, and the results were consistent with the parametric regression analyses. For the diet level analysis, the Tukey–Kramer method was used to identify significant pairwise differences across the different baseline diet groups. Analyses were performed using SAS software ver. 9.1 (SAS Institute, Cary, NC).

Results

Analysis 1: Prophylactic PEG vs. No/Therapeutic PEG

Table 2 summarizes patient descriptive characteristics in this analysis. Of the 59 patients in our cohort, 33 had a PEG placed at some time over the first year. The vast majority (27/33) of patients who had a PEG received it prophylactically (before or during the first week of RT). For this first set of analyses, these 27 patients were our "prophylactic PEG" cohort. Six of the 33 patients had a PEG placed therapeutically: 3 patients had a PEG placed during weeks

Table 2 Descriptive characteristics for prophylactic PEG vs. no/therapeutic PEG analysis

Characteristics	All patients ($n = 59$)	Prophylactic PEG ($n = 27$)	No PEG/therapeutic PEG ($n = 32$)

[d] Values in parentheses indicate percent of group that the adjacent number represents

2–6 of RT, 2 patients had it placed 6–8 months after RT completion, and 1 patient's date of PEG placement was not known. Our second cohort included these six therapeutic PEG patients as well as the 26 patients who never received a feeding tube.

Median duration of PEG use was 97 days or about 8 months (range = 61–2,049 days). Over the year, many patients had their PEG removed while a few had a PEG placed. The overall number of patients with a feeding tube was (1) 27/59 or 46% of all patients at the end of RT; (2) 21/59 or 36% at 3 months after the end of RT (20 were prophylactic); (3) 14/59 or 24% at 6 months (12 prophylactic); and (4) 9/59 or 15% at 12 months (7 were prophylactic).

There were 41 men and 18 women in the sample, with a mean age of 58.8 years. The most common sites for cancer were the oral cavity, oropharynx, and nasopharynx (78% in the prophylactic PEG group; 50% in the no/therapeutic PEG group). The majority of patients in both groups had advanced stage IV cancer and had chemotherapy added to their treatment, with a higher proportion in the prophylactic PEG group for each condition. Rates of minor, major, or no surgery were similar in both groups.

In order to determine whether the patients who received a prophylactic PEG had different outcomes over time than patients who did not receive a prophylactic PEG, percent weight loss and mean diet scores were analyzed over time. Table 3 summarizes these results.

Percent Weight Change

Analyses were performed using linear mixed-effects models adjusted for surgery. Percent weight loss between the two groups was analyzed from baseline at the start of RT to the end of RT, and 3, 6, and 12 months post RT. The differences were not statistically significant across time ($P = 0.19$).

Table 3 Adjusted mean differences in percent weight change and diet levels based on prophylactic PEG use (yes: $n = 27$, no: $n = 31$) at completion of RT

	% weight change		Diet level	
	Adjusted mean difference (95% CI)[a]	*P* value	Adjusted mean difference (95% CI)[a]	*P* value
Prophylactic PEG (yes vs. no)	−2.19 (−5.50, 1.12)	0.19	−1.11 (−1.78, −0.44)	0.002

[a] Adjusted for surgery and time since baseline

Change in Diet Level

Analyses explored whether prophylactic PEG placement affected diet status across time (from baseline at the end of RT to 3, 6, and 12 months after RT). In contrast to weight change results, the prophylactic PEG group had significantly worse diet outcomes than either the no PEG group or the therapeutic PEG group across time ($P = 0.002$).

In summary, these two analyses showed that prophylactic PEG placement by itself did not significantly influence long-term weight changes in head and neck cancer patients, but it did appear to affect diet level up to 1 year after RT. In order to probe these findings further, the next set of analyses were conducted.

Analysis II: Outcomes by Type of Nutritional Intake: 100% PEG Diet vs. Partial PEG/Partial Oral Diet vs. 100% Oral Diet

In this patient population, diet status and feeding tube status are not always analogous. This is because some patients who have a PEG still eat a full oral diet while others are partially or completely reliant on their feeding tubes. Since some people with PEGs had consistent oral diets, we speculated that PEG placement by itself may not be the most important factor influencing long-term diet outcomes. Instead, we wondered if PEG dependence, and hence less frequent use of swallowing musculature, may be more important in influencing long-term dysphagia.

Accordingly, in this second analysis we divided our 59 subjects into three cohorts based on each individual's diet level at the end of RT, regardless of PEG status. These three groups were (1) 100% NPO (nil per os) (diet level 1) representing very little swallowing muscle use, (2) partial PEG/partial oral (diet level 2) representing intermediate swallowing muscle use, and (3) 100% oral intake (diet levels 3–6) representing most swallowing muscle use. As in the first analysis, we analyzed percent weight loss and mean diet scores between groups at baseline and 3, 6, and 12 months after RT. Our hypothesis was that consistent eating and swallowing during RT would help preserve a patient's ability to swallow and thus lead to a more normal long-term diet.

Table 4 delineates descriptive characteristics in this second analysis. At the end of RT, 14 patients were 100% PEG dependent (forming group 1), 8 patients had a partial PEG and partial oral diet (forming group 2), and 37 patients had a 100% oral diet (forming group 3). Of the 37 patients who had a 100% oral diet, 9 had PEGs but were not using them. Overall, most patients reported only minor changes in diet prior to RT (average score was 4.8/6). By the end of RT, however, many subject's diet levels dropped dramatically, with the average diet score falling to 3.4/6 (liquid or puree/wet soft food).

Patients who relied partially or completely on their PEGs for nutrition all had advanced stage III or IV cancer, while 71% of patients who had a 100% oral diet had stage 3 or 4 cancer. Across all three groups, oral cavity, oropharynx, and nasopharynx cancers were most common, and minor surgery was a common adjuvant therapy. The distribution of major, minor, and no surgery was similar in all groups. The addition of chemo agents to the radiation therapy was common, ranging from 73 to 100%. Intensity-modulated radiation therapy (IMRT) and 3D/conventional radiation therapy techniques were equally represented among the groups.

Percent Weight Change

Percent weight change was recorded at the start of RT, the end of RT, and at 3, 6, and 12 months post RT. Figure 1 shows the mean change in weight over time in these three diet groups ($n = 59$). Longitudinal regression analyses adjusted for surgery revealed no significant difference in weight change across the three groups during the 1 year follow-up (see Table 5). Thus, the results were similar to the earlier analysis of weight change between prophylactic PEG users and all other patients.

Change in Diet Level

Since the data suggested that PEG placement or PEG use alone may not significantly affect weight change, a major question of interest was whether the subjects who were completely dependent on their feeding tubes (FTs) at the end of RT were able to advance their long-term diet levels

Table 4 Descriptive characteristics of total PEG vs. partial PEG vs. 100% oral groups at baseline (end of RT)

Characteristics	All patients ($n = 59$)	Group 1: all intake via PEG ($n = 14$)	Group 2: partial PEG/ partial oral ($n = 8$)	Group 3: 100% oral ($n = 37$)

as well as subjects who were partially dependent on their FTs or as well as those who had 100% oral diets. Using the same three groups defined by diet level at the end of RT, we analyzed mean group diet scores at 3, 6, and 12 months post RT. Preliminary Kruskal–Wallis tests were used to analyze these data (separately by time point), and indicated significant differences in mean diet score between the three groups at all time points ($P < 0.01$). Linear mixed-effects models were then used to evaluate differences in average diet score across all groups longitudinally after adjusting for surgery. Once again, there was a significant difference across all three groups (global $P < 0.001$).

The post-hoc Tukey–Kramer multiple-comparisons procedure showed that both the partial PEG/partial oral group and the 100% oral group had significantly higher mean diet scores than the 100% PEG group over time. There were no significant differences in mean diet scores between the partial PEG/partial oral group and the 100% oral group. Results of statistical analyses are presented in Table 5 and are represented graphically in Fig. 2.

Discussion

The motivation for the current study was the possibility that extended PEG use might hinder swallowing ability. Two indicators of adverse swallowing outcomes were investigated: percent weight loss and diet level. The results of this study showed that there was no significant difference in weight loss among all groups at any time after radiation therapy. It also found that patients who had PEGs placed prophylactically, or patients who relied totally on their PEGs for nutrition, had significantly worse diet outcomes than patients who did not receive prophylactic PEGs or who continued to eat orally despite receiving a PEG.

Two recent studies suggested that patients who have prophylactic PEGs or who use a PEG for an extended period of time experience adverse outcomes [7, 14]. However, this study is the first to present objective evidence that these patients may develop a more severe dysphagia than patients who do not receive prophylactic PEGs or who do not rely on a PEG for all their nutrition.

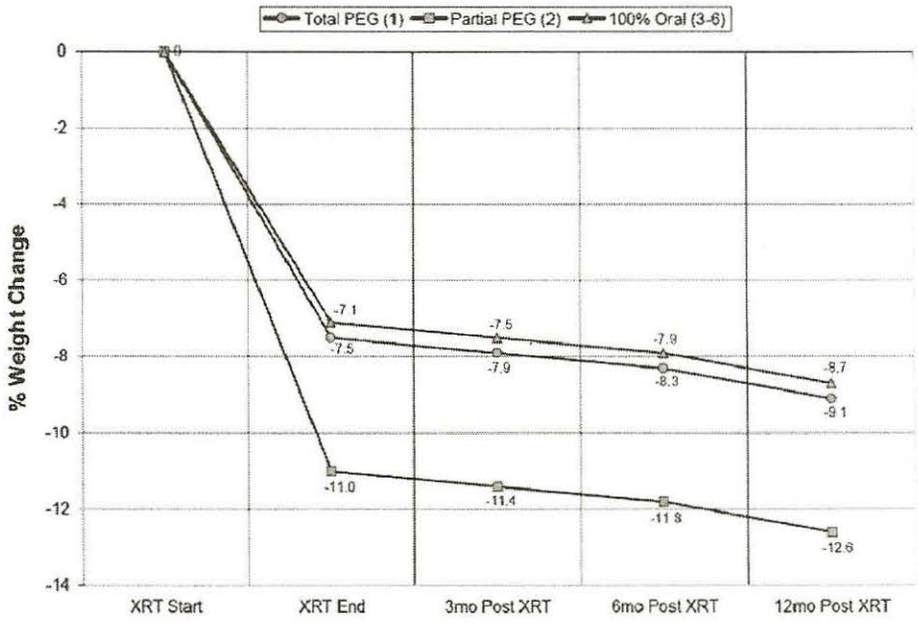

Fig. 1 Mean percent weight change of three groups from start of RT to 1 year post RT (unadjusted at RT start, adjusted for surgery at all other time points). Groups were categorized by diet level at completion of RT (baseline)

Table 5 Adjusted mean differences in percent weight change and diet levels based on diet level[a] at completion of RT

	% weight change		Diet level	
	Adjusted mean difference (95% CI)[b]	*P* value	Adjusted mean difference (95% CI)[b]	*P* value
Diet level[c]		0.27		<0.001
Group 2 vs. 1	−3.56 (−10.50, 3.37)		1.61 (0.53, 2.70)[d]	
Group 3 vs. 1	0.39 (−4.55, 5.33)		2.49 (1.73, 3.26)[d]	
Group 3 vs. 2	3.95 (−1.85, 9.76)		0.88 (−0.03, 1.79)

[d] Significantly different based on Tukey–Kramer method

Placing PEG tubes prophylactically before radiotherapy is a common practice in many institutions across the U.S. This study suggests that there may be real risks involved in this practice and it should be reanalyzed for its risk/benefit ratio. The median duration of PEG placement in the group studied here was 8 months, which agrees closely with the average duration of prophylactic PEG placement reported in the literature [15–17]. This is a substantial amount of time that a patient must endure an artificial means of feeding, not to mention the associated discomfort, stigma, and hindrance to social eating. The need for long-term PEG use follows a very difficult and traumatic cancer treatment and its associated morbidities and serves to exacerbate an already-decreased quality of life.

The most common reason for placing a PEG prophylactically is to maintain weight, hydration, and nutrition, especially during the painful weeks of radiotherapy which can make this treatment more endurable and in some instances safer. Surprisingly, the current study did not find a significant difference in percent weight change between prophylactic PEG and no/therapeutic PEG patients during RT, in contrast to several other published studies mentioned earlier [5, 9, 10, 12–14]. The current study also found no significant differences in weight loss between the prophylactic PEG and no/therapeutic PEG patients at any time point after RT. When the groups were reorganized into three groups according to diet level at the end of RT rather than the presence or the absence of a prophylactic feeding tube, we still found no significant differences in percent weight loss among the groups.

While long-term weight outcomes at 3, 6, or 12 months after RT are not often reported in the literature, the current findings were in agreement with the one other study that did investigate this outcome [14]. The reason for the discrepancy between findings from the current study and most of the literature is unclear. One may question whether

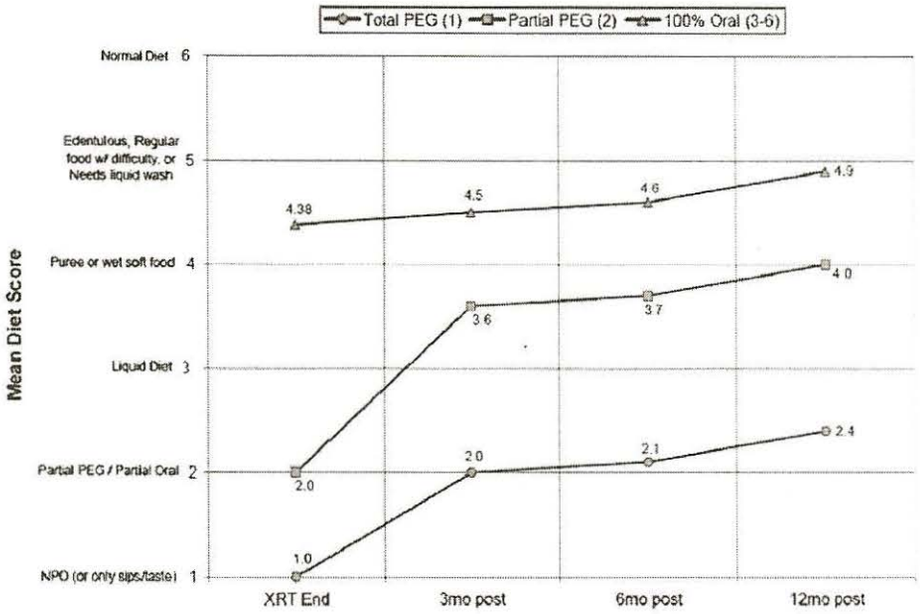

Fig. 2 Mean diet score over time in three groups defined by diet level at baseline (unadjusted at RT end, adjusted for surgery at all other time points)

confounding factors such as chemotherapy, stage of cancer, or any other patient or treatment variables could have accounted for our percent weight change results. It may be that the prophylactic PEG and the 100% PEG use groups had a greater share of these adverse factors that would have caused a significantly greater decrease in weight had they not received a prophylactic PEG and/or relied on their PEG. Such a conclusion would suggest that prophylactic PEGs and PEG reliance actually helped these patients minimize weight loss during RT as well as the other patients who did not have these other risk factors.

Table 2, which summarizes the patient demographics, does not support this hypothesis. The majority of patients in all groups had stage III/IV cancer (68% of those patients without prophylactic PEG) and received chemotherapy (74% of that same group). However, while the groups looked fairly similar demographically, they were not equally matched and the limited sample size precluded us from adjusting statistically for any confounding variable except surgery. Therefore, this question remains unsettled. A future study addressing this paradoxical issue would be extremely interesting and incredibly useful in guiding PEG placement policies.

Diet level was the other outcome investigated in this study. This is arguably the most functional and meaningful indicator of swallowing ability. Change in diet over the first year after RT has not been reported systematically in the literature, but it turned out to be very revealing in this study. When the patients were identified and grouped by the diet they were taking rather than whether they had a PEG, it became possible to study the effect on swallowing outcomes of eating and drinking orally versus depending on a PEG. The motivating question was whether consistent use of the swallowing musculature during and after RT determined long-term diet status. Would PEG reliance, perhaps coupled with radiation-induced fibrosis, translate into disuse atrophy significant enough to promote a chronic dysphagia?

This analysis found that (1) the 100% oral group had significantly higher mean diet scores than the 100% PEG group across time, (2) the partial PEG/partial oral group had significantly higher mean diet scores than the 100% PEG group across time, but (3) there were no significant differences in mean diet scores between the partial PEG/partial oral and 100% oral groups. These were surprising findings. First, we showed that patients who were 100% dependent on their PEGs for nutrition (and remained NPO) not only presented with worse diet outcomes over the first year compared to patients who consumed 100% of their diets orally, but also had worse diet outcomes than patients who had a PEG but continued to take some nutrition orally. Most of those 100% PEG users had their PEGs removed sometime over the course of the year, but their diet levels did not catch up to those of the other patients. In Fig. 2, it can be seen that the 100% PEG intake group (as defined by their diet status at end of RT) were on average consuming only an oral liquid diet at 6 and 12 months post RT, whereas the partial PEG and 100% oral groups were on average consuming several food consistencies. This very functional outcome is clearly meaningful to a person's daily life. Second, this analysis showed that patients who continued to take some nutrition orally, in spite of having a PEG, attained the same long-term diet outcomes as patients who never had a PEG. This suggests that continued oral intake during RT allows for continued use of the swallowing musculature, which in turn may prevent the

degree of dysphagia experienced by other patients who rely entirely on their PEGs.

The implications of this study are twofold. First, the community and the individual physician should reconsider recommending prophylactic PEG placement in patients who are likely to depend entirely on the PEG for nutrition unless it is absolutely necessary. There will always be patients who benefit from a PEG and they certainly should not be denied its convenience and ability to deliver much needed nutrition. Those patients probably consist of individuals who are severely malnourished, fragile, and have shown that they are not able to prevent a sharp and consistent weight loss.

Second, and perhaps more important, when a patient is given a PEG, this study suggests that they should be strongly encouraged to continue swallowing something orally on a regular basis. If the purpose is to prevent atrophy and loss of function of the swallowing musculature, it does not matter what the bolus is: the patient can simply sip water throughout the day. The point is to continue exercising and moving the muscles so that they do not become atrophied, stiff, and potentially locked in by fibrotic tissue.

This interpretation is still hypothetical and should be confirmed by larger studies that are able to control for all known confounders. A prospective randomized clinical trial would provide the best evidence, of course, and would mitigate the limitations of the current study. Since prophylactic PEG placement is still the standard of care in many institutions, an RCT could feasibly be carried out whereby all prophylactic PEG patients are assigned to one of two groups, where one remains NPO and the other takes some nutrition orally throughout the duration of their PEG use. A major improvement over the current study, and all others that have addressed this topic, would be to include formal swallow studies, a standardized diet score, and a QOL scale. The issue is too important to let the status quo stand unchallenged.

expenditure for Part A and B services for normal-weight beneficiaries was $6832, but expenditures were significantly less for overweight and obese beneficiaries ($5473 [$P<.001$] and $5790 [$P=.02$], respectively). Expenditures increased over time for all groups but appeared to increase more quickly in obese beneficiaries.

In regression analysis adjusting for demographic and economic covariates, expenditures increased by a mean of $122 per year ($P<.001$) for normal-weight beneficiaries, and increased significantly faster for overweight (excess increase of $108 per year [$P=.01$]) and obese beneficiaries (excess increase of $149 per year [$P=.001$]). Adjusting for chronic conditions accounted for differences in the trend across BMI groups. After adjusting for chronic conditions, interactions between overweight and time ($P=.71$) and obesity and time ($P=.98$) were no longer significant.

Comment. Although Medicare expenditures increased in all BMI groups over this period, expenditures increased significantly faster for overweight and obese Medicare beneficiaries. Increasing rates of weight-related chronic conditions over time appeared to account for this trend.

We found smaller obesity-related differences in expenditures than reported in previous research.[1,5,6] This may be due to differences in expenditure data (claims vs estimated expenditures), costs included (Medicare only vs total costs), or participant age range.

Our results suggest that projections related to the future costs of obesity should take into account changes in chronic health conditions among the obese older population as drivers of increased expenditures. If the parallel trends of increasing obesity and increasing numbers of chronic conditions continue, obesity-related Medicare spending may rise faster than projected based on prevalence of obesity alone.

Emergency Department Use by Primary Care Patients at a Safety-Net Hospital

In fee-for-service payment models, there are strong financial incentives for hospitals to tolerate high levels of emergency department (ED) use, including use by established primary care patients. Yet, as health care reform introduces global payment models, high levels of ED use will no longer be financially tenable. Understanding the magnitude of the problem of ED use by established primary care patients is crucial to redesigning primary care delivery and reimbursement in the United States. We had 2 objectives: (1) to characterize ED use at an urban safety-net hospital after the implementation of Massachusetts health reform, focusing on patients who had primary care providers (PCPs) and (2) to identify patterns of ED use that might inform the hospital-based primary care practices' transformation to a medical home, and eventually, to an accountable care organization.

Methods. Boston Medical Center (BMC) is an urban safety-net hospital with 8 primary care practices staffed by 105 PCPs. The practices predominantly serve a minority and low-income population. We identified patients who had 1 or more primary care visits from July 1, 2009, to July 1, 2010, and examined their ED use over this period. We defined frequent ED users as patients with 4 or more ED visits in the past year and occasional ED users as those with 1 to 3 ED visits in the past year. We

used an algorithm developed by Billings et al[1] to categorize each visit's principal *International Classification of Diseases, Ninth Revision, Clinical Modification* (*ICD-9-CM*) diagnosis and to determine the probability that a visit required ED care. Using a validation of this algorithm,[2] we defined visits as high severity if the probability that ED care was needed was 0.75 or higher for the visit's principal *ICD-9-CM* diagnosis. Similarly, we defined visits as low severity if the probability that ED care was needed was 0.25 or lower. Visits of indeterminate severity were defined as those with a probability higher than 0.25 and lower than 0.75. Visits classified as high severity have been found to have a strong association with future hospitalization or death.[3] We performed χ^2 tests and *t* tests to compare differences in demographics between persons with and without any ED use and with occasional vs frequent ED use. The Boston University Medical Campus institutional review board has approved this study as exempt.

Results. During the study period (2009-2010), 39 603 patients had 1 or more primary care visits. Most patients (65.4%) did not make any ED visits, while 11 787 (29.8%) were occasional ED users and 1928 were frequent ED users (4.9%) (**Table**). The 11 787 patients with occasional

ED use made 17 759 visits over the study period, while the 1928 patients with frequent ED use made 12 289 visits. Approximately half (49.8%) of all ED visits occurred on weekdays, while BMC primary care practices were open. Most ED visits were for low-severity conditions.

Comment. Emergency department use by primary care patients at an urban safety-net hospital was high, though most visits were of low severity. One possible reason for this is lack of access to primary care,[4] with few available appointments to see a PCP. While data on time to third next available appointment, a standard measure of primary care access,[5] are not available for the primary care practices during the study period, other practice metrics suggest that access may have been a problem. For example, missed primary care appointment rates were high, averaging 24.5%. High missed appointment rates are often correlated with long wait times to schedule appointments.[6] In addition, monthly telephone call statistics show that only between 72.4% and 88.1% of patient telephone calls were answered by the primary care call center over the study period. It is possible that patients called the practices with an urgent problem, did not have their telephone call answered promptly, and decided to seek care in the ED instead. Indeed, 13% of telephone calls were abandoned by patients over the study period (patients called and subsequently hung up while they were kept on hold). The fact that nearly half of all ED visits took place during the hours of primary care clinic operation further suggests that appointment availability may have been an issue. In addition, a sizable minority, roughly one-fifth, of primary care is provided by residents,[7] who have limited availability when they are not in clinic. It is also possible that Massachusetts health reform has affected access to primary care. As newly insured patients have entered primary care in large numbers, it is possible that access to primary care has worsened for other patients.

Massachusetts has been a bellwether for the implementation of health reform and will be a bellwether for the transformation of primary care, with the move away from fee-for-service payments and the introduction of global payments for health care. Overall ED volume has continued to increase in Massachusetts after health reform.[8] It is unclear if changes in primary care practice and payment will be sufficient to reduce high levels of ED use among patients at an urban safety-net hospital.

Proton Beam Therapy and Treatment for Localized Prostate Cancer: If You Build It, They Will Come

The number of treatment options for localized prostate cancer continues to expand, amidst growing concern regarding overdiagnosis and overtreatment of low-risk disease.[1-3] Treatment patterns, however, may be driven by availability of novel tech-

Intimate-Partner Violence — What Physicians Can Do

Jane M. Liebschutz, M.D., M.P.H., and Emily F. Rothman, Sc.D.

The U.S. Centers for Disease Control and Prevention (CDC) recently released a comprehensive report on the prevalence of sexual violence, stalking, and intimate-partner violence (IPV) in the United States.[1] The report relays the alarming findings that 35.6% of women in this country are raped, assaulted, or stalked by intimate partners at some point during their lives, and approximately 6% experience these events in any given year. Men are also at risk for IPV victimization: 28.5% report having been victimized at some time during their lifetime, and 5% report victimization within the past year. But the forms and consequences of IPV experienced by women and men are not the same. Women are more than twice as likely as men to experience sexual coercion in their intimate relationships (17% vs. 8%) and are twice as likely to experience severe forms of physical assault by an intimate partner, such as being choked, hit with a fist, or kicked (24.3% vs. 13.8%). The most striking differences relate to the consequences: very few men (5.2%) report ever being fearful of their intimate partners, in contrast to 28.8% of women, and women are almost four times as likely as men to be injured by a partner (14.8% vs. 4.0%).

The costs of IPV are burdensome, for the health care system and for society. A decade ago, the CDC estimated the cost of IPV to the United States to be $5.8 billion per year ($10.4 billion in 2012 dollars), and it's been estimated that the cost of providing health care to adult survivors of IPV ranges from $2.3 billion to $7.0 billion in the first year after the assault. The annual health care costs for women who are experiencing ongoing IPV are 42% higher than those for nonabused women. This finding is unsurprising, given the evidence that IPV victimization of women increases the risks of injury, gastrointestinal disorders, chronic pain, central nervous system symptoms (including fainting and seizures), hypertension, and gynecologic problems.[2]
