What can physicians do about IPV? All health care providers should be alert to aspects of patients' histories or symptoms that could suggest IPV and then should follow up with specific questions. According to the U.S. Preventive Services Task Force, screening asymptomatic female patients for IPV victimization may provide benefits, with minimal adverse effects.[3] As of August 2012, new guidelines under the Affordable Care Act require insurance coverage to include IPV screening and counseling as part of eight essential health services for women at no additional cost to the patient.[4] Therefore, at a minimum, all primary care physicians should now be screening female patients 12 years of age or older for IPV. Specialty professional organizations recommend that obstetricians and pediatricians also consider performing regular IPV screening. Numerous IPV screening instruments may be used to begin a dialogue with the patient; one of them (known as HITS) is shown in the table.[5] Another question that may be used to start a discussion about safety at home is simply, "Are you afraid of your partner or anyone else?"

There are several steps doctors should take when patients report potential IPV. First, clinicians should acknowledge the patient's admission of abuse: we advise thanking the patient for trusting the provider with the information and expressing concern about the patient's safety. Second, we suggest asking the patient if he or she would like to be connected to IPV advocacy services. If patients do want legal assistance, counseling, shelter, or other services, local domestic violence agencies affiliated with the state coalition are likely to be the most reliable resources (see box). Third, clinicians should offer the patient the National Domestic Vio-

The HITS Screening Tool for Domestic Violence.*

How Often Does Your Partner	Never	Rarely	Sometimes	Fairly Often	Frequently
Physically hurt you	1	2	3	4	5
Insult or talk down to you	1	2	3	4	5
Threaten you with harm	1	2	3	4	5
Scream or curse at you	1	2	3	4	5

* A total score of more than 10 is suggestive of intimate partner violence. This information, called R3, is available as a free Android or iPhone app. From Sherin et al.[5]

lence hotline number (see box); the hotline makes printed, pocket-size handouts (palm cards) available to providers who wish to distribute them to patients. Fourth, clinicians should consider whether child protective services are required. In many states, the abuse of one parent by another does not necessitate a report to child protective services, so it's up to the clinician to determine whether a report is warranted. Clinicians should consider inviting the patient to make the report directly in order to increase the likelihood that staff members at child protective services agencies will view the patient as able to maintain a safe household for the children. Fifth, they should screen the patient for coexisting depression, anxiety, and substance abuse. And they should use caution when prescribing sedatives, since the sedating action may diminish patients' physical or mental ability to defend themselves or deescalate tensions.

When patients screen negative for IPV but the provider nevertheless suspects that they're experiencing abuse, it's important that the provider not force disclosure. It's not critical that the patient acknowledge IPV victimization in order to benefit from the screening. Asking IPV-related questions signals to the patient that the provider is caring and concerned, trustworthy, and willing to discuss the topic during a future visit. Moreover, simply being asked the questions may prompt the patient to reconsider privately whether his or her relationship is healthy. And of course providers need not receive a positive screening response in order to provide universal education about IPV. Even if a patient screens negative, we would encourage the provider to state that many patients do experience IPV at some point and that there are many resources to help people who feel unsafe in their relationships. Handing palm cards with the national hotline number to all patients and encouraging them to take one for a friend if they wish, for example, may be an effective way of providing help to victims who don't feel comfortable disclosing their situations.

There are several ways in which providers can do unintentional harm to patients who are experiencing IPV. Asking no questions about IPV may signal that the provider is not a potential resource for the patient. But the manner in which IPV victimization is documented in patient records can have ramifications for child custody cases. Detailed information about best practices for IPV documentation is available from the national organization Futures without Violence (see box). In addition, providers should refrain from telling patients who are experiencing IPV what they must do (e.g., "you need to leave"). Only trained experts in IPV advocacy are qualified to help victims determine their own best course to safety. There is a potential for lethal and injurious harm, particularly when one partner attempts to leave the relationship. For this reason, actively ensuring that the link between the patient and an IPV advocacy agency is made successfully is the best practice. Finally, it's critically important that providers respect the confidentiality of patients who are experiencing IPV. Not only do victims face stigma and prejudice, but employers and insurers could potentially discriminate against them if their status became known.

IPV is now recognized as a substantial public health problem. Health care providers can play a critical role in helping to reduce and prevent IPV by screening and referring patients to appropriate resources, familiarizing themselves with best practices related to IPV documentation and victim response, and presenting themselves as caring and trustworthy allies for their patients who are experiencing abuse. Research has established that health care–based screenings and interventions for IPV can benefit patients,[3] and the Affordable Care Act ensures that preventive care will include these screenings for women and ado-

lescents. There is thus some cause for hope that we may curb the violence and play a role in creating safer homes and safer families nationwide.

Patients' perceptions of their "most" and "least" important medications: a retrospective cohort study

Amy Linsky[1,2,3,4,5*] and Steven R Simon[1,2,3,4,5]

Abstract

Background: Despite benefits of adherence, little is known about the degree to which patients will express their perceptions of medications as more or less important to take as prescribed. We determined the frequency with which Veteran patients would explicitly identify one of their medications as "most important" or "least important."

Findings: We conducted a retrospective cohort study of patients from ambulatory clinics at VA Boston from April 2010-July 2011. Patients answered two questions: "Which one of your medicines, if any, do you think is the most important? (if none, please write 'none')" and "Which one of your medicines, if any, do you think is the least important? (if none, please write 'none')." We determined the prevalence of response categories for each question. Our cohort of 104 patients was predominantly male (95%), with a mean of 9 medications (SD 5.7). Regarding their most important medication, 41 patients (39%) identified one specific medication; 26 (25%) selected more than one; 21 (20%) wrote "none"; and 16 (15%) did not answer the question. For their least important medication, 31 Veterans (30%) chose one specific medication; two (2%) chose more than one; 51 (49%) wrote "none"; and 20 (19%) did not directly answer the question.

Conclusions: Thirty-five percent of patients did not identify a most important medication, and 68% did not identify a least important medication. Better understanding of how patients prioritize medications and how best to elicit this information will improve patient-provider communication, which may in turn lead to better adherence.

Keywords: Communication, Adherence, Veterans, Quality of care, Patient safety

Findings

Background and objectives

Medication adherence may improve clinical outcomes, but approximately half of all prescriptions are not taken as prescribed [1-3]. Patient medication-taking behavior is influenced by many factors, including health literacy, socioeconomic status, perceived medication necessity, future health concerns and whether the drug provides symptom relief [4-6]. Further, patients' beliefs about their medications are dynamic and can fluctuate with changes in symptoms, competing health- and non-health-related demands and trust in the health care provider [5,7].

Patient non-adherence appears to imply that some degree of prioritization of medications is occurring, although not necessarily in an explicit manner. Moreover, it is unclear to what degree patients will express their perceptions of medications as more or less important to their treating health care provider and whether clinicians concur with patients' prioritization schemas. To begin to address these questions, we sought to determine the frequency with which Veteran patients would explicitly identify one of their medications as "most important" or "least important," as well as to characterize the medications selected.

Methods

We conducted a retrospective cohort study of a convenience sample of patients from ambulatory care clinics

at Veterans Affairs (VA) Boston Healthcare System from April 2010 until July 2011. Patients were former members of the United States military who sought and were eligible to receive care at the VA. Data were collected by fourth-year medical students, who were individually instructed on project processes as part of their Ambulatory Medicine Quality Improvement rotation. One student per month was assigned to the rotation. Immediately prior to a student-led clinical encounter, patients were given a printout of the electronic health record (EHR) listing of their medications and asked to answer two questions: "Which one of your medicines, if any, do you think is the most important? (if none, please write 'none')" and "Which one of your medicines, if any, do you think is the least important? (if none, please write 'none')." If needed, the student assisted the Veterans by reading the questions or writing their responses.

Because the data collection was intended as a quality improvement educational project, informed consent was not obtained. One of us (AL) entered all data into an Excel database, and we analyzed only the first chronologic encounter for each Veteran. Patient responses were entered exactly as written. Specific medications identified by patients were classified into medication classes using VA Drug Class Codes. Other data extracted from the EHR included patient sex, age at visit and number of actively prescribed medications.

Our two primary outcomes were patients' responses to the "most important" and "least important" questions. Responses to each question were categorized as one of four types: 1) One specific medication – the patient identified one medication only; 2) More than one medication – the patient reported more than one medication, chose medications to treat a diagnosis (e.g. "heart meds") or wrote "all"; 3) None – the patient wrote "none"; and 4) Did not answer the question – the patient left the response blank or wrote "n/a," "don't know," "uncertain" or "not sure."

We determined the prevalence of each primary outcome. Frequency counts identified the medication classes involved for responses where specific medications were chosen. Finally, we used chi-square tests to assess for associations between patient factors and choosing one specific medication as most or least important. All analyses were performed with SAS version 9.2 (SAS Institute, Inc) or Excel (Microsoft). Statistical significance was set at alpha < 0.05. This study protocol was approved by the Institutional Review Board of the VA Boston Healthcare System.

Results

Our study cohort of 104 Veterans was predominantly male (95%), and 59 (57%) were age 65 years or older (Table 1). Lists contained a mean of 9 medications (SD 5.7). Responding to the question about their most important medication, 41 patients (39%) identified one specific medication; 26 (25%) selected more than one; 21 (20%) wrote "none"; and 16 (15%) did not answer the question (Table 2). Answering the question about their least important medication, 31 Veterans (30%) chose one specific medication; two (2%) chose more than one; 51 (49%) wrote "none"; and 20 (19%) did not directly answer the question (Table 2).

There was no association between selecting one medication as most or least important and any of the available patient factors (data not shown). The most commonly cited most important medication classes were beta blockers (n = 8), angiotensin converting enzyme inhibitors (n = 7) and anticoagulants (n = 5). The most commonly cited least important medication classes were vitamins (n = 12), non-opioid analgesics (n = 4), antilipemic agents (n = 2) and antigout agents (n = 2). Full results of medications classes identified by patients as most important and least important are shown in Table 3.

Table 1 Baseline characteristics (n=104)

Patient characteristics	n (%)
Age 65 or older	59 (57)
Male	99 (95)
Total number of medications [mean (SD)]	9 (5.7)

*Care may have occurred previously or concurrently with present care at VA Boston.
†Medications dispensed from other VA facilities (i.e., remotely-dispensed), non-VA medications or documented as inpatient medications.

Table 2 Categories of responses to identification of most and least important medication

Response category	Most important n (%)	Least important n (%)
One specific medication	41 (39)	31 (30)
More than one medication*	26 (25)	2 (2)
More than one medication	5 (5)	0 (0)
Chose medications for a condition (did not name a specific medication)	11 (11)	1 (1)
More than one medication and chose it by condition	3 (3)	0 (0)
Wrote "all"	7 (7)	1 (1)
Wrote "None"	21 (20)	51 (49)
Did not answer the question*	16 (15)	20 (19)
Wrote "n/a"	4 (4)	5 (5)
Left it blank	10 (10)	11(11)
Wrote "don't know," "uncertain," or "not sure"	1 (1)	4 (4)
Wrote something undecipherable	1 (1)	0 (0)

*Subcategories sum to the total for their respective categories.

*Unit of analysis is medication. Results do not include responses for condition-related medications (i.e., "heart meds").

Discussion

Approximately one in three Veteran patients did not identify a most important medication, and more than two in three patients did not identify a least important medication. There are several possible reasons to explain this finding. Patients may not have understood the questions, leading them to choose medications to treat a particular condition – therefore not selecting a single medication – or simply to leave the response blank. Limited health literacy, reflected as poor understanding of their health conditions or of their medications and associated indications, may have contributed to low response rates [8-10]. Without full understanding of their medical problems, the potential consequences of untreated health conditions and the possible benefits and risks of medication for those conditions, some patients may have been unable to make an informed selection from their medication list. This notion highlights the importance of education and knowledge in enabling patients to maintain an active role in their health care decisions.

Another hypothesis for the observed pattern of responses is that the use of the word "important" may not accurately reflect the construct that we were attempting to measure. That is, patients may have perceived medications as important but may not have believed that they are of a necessity or benefit to their future health to warrant full adherence. Others have demonstrated that perceived adverse effects of medications often outweigh preventive benefits of medications [11]. Competing demands, such as financial or social obligations, may further outweigh patient perceptions of importance. Psychometric testing of the best way to assess patient prioritization of medications with reliability and validity will improve measurement in future studies.

Another possible explanation for our findings is that Veteran patients were in fact able to understand and identify a medication yet they were unwilling to share these beliefs with their providers. Patients discontinue prescriptions for a variety of reasons without informing their healthcare provider of this decision [12]. Improving communication between patients and providers can lead to better shared decision making and better adherence [2].

Our study results need to be interpreted in the context of several limitations. We analyzed a small convenience sample of patients from one site within a larger health care system, and the study participants' responses may not reflect the views of Veterans receiving care elsewhere or the perceptions of non-Veterans. Future research involving multiple settings and patient populations will enable better generalizability. We also had limited information on patients' comorbidities and other medications, restricting us from appraising patient

responses as concordant with clinician opinion. However, these answers still reflect what the patient perceived, and it is recognized that patient beliefs are associated with medication adherence [4]. Additionally, explicit discussions may enable providers to better reconcile known conflicts between what they believe is clinically best and what the patient perceives as important [13,14]. Finally, the training status of providers (i.e., medical students) theoretically could have influenced patients' willingness to divulge their prioritization.

In this study population where the mean number of medications was nine, higher than most commonly accepted definitions of polypharmacy [15], a minority of patients were able to express a medication as least important. Better understanding of how patients prioritize their medications and how best to elicit this information will improve patient-provider communication and perhaps lead to discontinuation of medications that both the patient and the clinician feel have less importance.

Screening

ABSTRACT

Background: An estimated 3.2 million persons are chronically infected with the hepatitis C virus (HCV) in the U.S. Effective treatment is available, but approximately 50% of patients are not aware that they are infected. Optimal testing strategies have not been described.
Methods: The Hepatitis C Assessment and Testing Project (HepCAT) was a serial cross-sectional evaluation of two community-based interventions designed to increase HCV testing in urban primary care clinics in comparison with a baseline period. The first intervention (risk-based screener) prompted physicians to order HCV tests based on the presence of HCV-related risks. The second intervention (birth cohort) prompted physicians to order HCV tests on all patients born within a high-prevalence birth cohort (1945–1964). The study was conducted at three primary care clinics in the Bronx, New York.
Results: Both interventions were associated with an increased proportion of patients tested for HCV from 6.0% at baseline to 13.1% during the risk-based screener period ($P < 0.001$) and 9.9% during the birth cohort period ($P < 0.001$).
Conclusions: Two simple clinical reminder interventions were associated with significantly increased HCV testing rates. Our findings suggest that HCV screening programs, using either a risk-based or birth cohort strategy, should be adopted in primary care settings so that HCV-infected patients may benefit from antiviral treatment.

1. Introduction

An estimated 3.2 million persons are chronically infected with the hepatitis C virus (HCV) in the U.S. Although the prevalence of HCV infection is estimated at 1.6% in the U.S. [1], urban clinic populations may have an HCV prevalence as high as 8% [2,3]. HCV infection causes approximately 40% of chronic liver disease [4] and the majority of cases of hepatocellular carcinoma [5], and we can expect that there will be up to a 4-fold increase in HCV-related deaths over the next 20 years [6–8]. Effective treatment is available for HCV which can lead to long-term remission of disease and decreased liver-related mortality rates, but approximately 50% of patients are not aware that they are infected [9,10]. Although the Institute of Medicine (IOM) has recommended increased HCV testing [11], optimal testing strategies have not been described [12].

The aim of this analysis is to evaluate two interventions designed to increase HCV testing for patients at risk for HCV infection and disease.

There are several potential screening strategies which may be used when designing HCV testing programs. The Centers for Disease Control and Prevention and other organizations have recommended HCV testing for persons with an increased risk of infection such as persons who inject drugs [4,13,14]. Risk-based approaches to testing may be efficient, because patients with identified risks such as injection drug use have a much higher prevalence of HCV infection (60–90%) [15] than the general population (1.6%) [1]. However, risk-based screening has been limited because primary care providers often do not ask patients about HCV risk factors, testing is rarely initiated based on physician-identified risks, and patients are often reticent to disclose stigmatized risk behaviors [16,17].

Another approach to HCV screening is to identify a group of patients at higher risk without asking about stigmatized risk behaviors. Americans born between 1945–1964 are more likely to be HCV-infected than those in other age groups [1], and we have established at the three study clinics that HCV infection is nearly 4 times more likely in this high-prevalence birth cohort compared to patients outside of this birth cohort [3]. Approximately 76% of HCV-infected Americans were born between 1945–1964, and Americans born between 1945 and 1964 have a anti-HCV prevalence as high as 4.3% [1]. Therefore, another strategy is to test all patients born between 1945 and 1964.

The Hepatitis C Assessment and Testing Project (HepCAT) was a prospective evaluation funded by CDC via AHRQ ACTION of two serial community-based interventions designed to increase rates of HCV testing of at-risk or high-prevalence patients in urban primary care clinics from rates seen during baseline testing (baseline period). The first intervention (risk-based screener intervention) prompted physicians with a clinical reminder sticker in the progress note to ask whether a patient had specific HCV-related risks and to order HCV tests based on the presence of these risks. The second intervention (birth cohort intervention) prompted physicians with a clinical reminder sticker in the progress note to order HCV tests on all patients born within a high-prevalence birth cohort (1945–1964). We hypothesized that both interventions would be associated with an increase in testing of patients for HCV.

2. Methods

2.1. Study design

The study was a serial cross-sectional evaluation of two community-based interventions. We evaluated HCV testing and positivity rates during a baseline and two subsequent intervention periods. We used electronic medical record (EMR) data to examine the associations of interventions with HCV testing rates overall and within at-risk sub-groups.

2.2. Study setting

The study was conducted at three community-based primary care (family medicine or internal medicine) clinics affiliated with Montefiore Medical Center, a university-affiliated teaching hospital. The three participating primary care clinics are large, urban clinics located in the Bronx, New York. Each year, 54,000 adults attend over 150,000 primary care visits to the three clinics. Physicians were 153 internal medicine and family medicine physicians, both attendings and residents. The clinic sites are located in economically depressed areas of the Bronx and serve patients with high rates of poverty and substance use. Reported prevalence of HCV infection is higher in New York City than the national estimate and the Bronx has a higher prevalence than NYC as a whole [18,19].

2.3. Study population

We examined data on all adult patients (at least 18 years of age) who had a primary care visit to one of three clinics during at least one of the three study periods. The three study periods included the baseline period (January 1, 2008–February 28, 2008), risk-based screener intervention period (November 24, 2008–March 6, 2008), and birth cohort intervention period (March 9, 2009–June 30, 2009). We excluded patients who had been previously tested for HCV at Montefiore Medical Center.

2.4. Description of the interventions

2.4.1. Components common to both interventions

Both the risk-based screener and birth cohort interventions included: (1) on-site educational sessions for primary care providers (PCPs) and staff – delivered prior to and during interventions; (2) regular communication between the research team and clinical leadership (by phone or email); and (3) environmental reminders (HepCAT buttons, pocket cards, and posters). In addition, project staff visited each clinic twice-weekly to place stickers on all progress notes, encourage adherence to screening protocols, and elicit feedback from clinic staff.

2.4.2. Risk-based screener intervention

The screener intervention included a risk-based screener sticker which was placed on top of each progress note (Supplementary Fig. S1). The screener prompted the physician to ask the patient nine questions related to HCV risk: behavioral risk factors (ever injected or snorted any drug); risk group associations (ever incarcerated or ever homeless); medical risk factors (transfusion or organ transplant before 1992, told by physician that patient had liver disease, long-term hemodialysis), and other risk factors (maternal hepatitis C). In addition, the physician was asked to indicate whether patients ever had an elevated ALT (defined as female $\geq$ 20 IU/L or male $\geq$ 31 IU/L) [20]. These risks were chosen based on CDC HCV testing recommendations, American Association for the Study of Liver Diseases (AASLD) guidelines and other associations reported in the literature [13,14,21]. Physicians were asked to complete the sticker at every patient visit unless previously completed, and to order an HCV antibody test if any risk was identified. Patients who were already HCV antibody positive or who had been tested within the last 12 months were not asked to be tested. Spanish translations of the sticker were available in every medical office, and laminated versions were placed in each provider's mailbox. PCPs were supplied with a script (English and Spanish) to help standardize and normalize the introduction of the screening questions. This phase was conducted from November 24, 2008 to March 6, 2009 (15 weeks).

2.4.3. Birth cohort intervention

During the birth cohort intervention, a birth cohort reminder sticker was placed on top of each progress note (Supplementary Fig. S2). The birth cohort reminder prompted PCPs to order HCV antibody tests for all patients born between 1945 and 1964 regardless of any other identified risk. The risk-based screener sticker was no longer placed on top of progress notes. Spanish translations of the birth cohort sticker and provider scripts (in both English and Spanish) were available in every provider office. This phase was conducted from March 9, 2009 to June 30, 2009 (16 weeks).

Table 1
Characteristics of study populations.

	Baseline ($n = 6591$)	Risk-based ($n = 8981$)	Birth-cohort ($n = 10{,}165$)	P-value
Age	48.3 ± 17.7	47.8 ± 17.7	47.4 ± 17.8	0.28
Male	1622 (24.6)	2330 (25.9)	2636 (25.9)	0.10
Race/ethnicity				0.06
White	330 (5.0)	389 (4.3)	442 (4.3)	
Black	2064 (31.3)	2733 (30.4)	3039 (30.0)	
Latino	3349 (50.8)	4734 (52.7)	5395 (53.0)	
Oth/unknown	848 (12.9)	1125 (12.5)	1289 (12.7)	
Insurance[a]				<0.001
Medicare	757 (11.5)	1029 (11.5)	1140 (11.2)	
Medicaid	3491 (53.0)	4609 (51.3)	5211 (51.3)	
Commercial	1596 (24.2)	2062 (23.0)	2404 (23.6)	
Self	740 (11.2)	1272 (14.2)	1391 (13.7)	
Diagnoses				
Substance abuse[b]	219 (3.3)	292 (3.3)	342 (3.4)	0.91
Alcohol abuse[c]	72 (1.1)	101 (1.1)	103 (1.0)	0.74
HIV[d]	148 (2.2)	167 (1.9)	174 (1.7)	0.04
STD[e]	154 (2.3)	244 (2.7)	303 (3.0)	0.04
Cirrhosis[f]	25 (0.4)	31 (0.3)	38 (0.4)	0.92
ESRD[g]	17 (0.3)	28 (0.3)	27 (0.3)	0.77
Psychiatric diagnosis[h]	918 (13.9)	1355 (15.1)	1608 (15.8)	0.004

Continuous variables reported as mean ± standard deviation, tested using Kruskal–Wallis test dichotomous variables reported as No. (%), tested using Chi-squared test.
[a] Column does not add to 100% because of missing values.
[b] ICD-9 or positive urine toxicology.
[c] ICD-9 for Etoh dependance or etoh liver disease or etoh level ≥ 80.
[d] ICD-9 or positive antibody test or Western blot.
[e] STD = sexually transmitted disease (not HIV): ICD-9 or positive GC or chlamydia PCR probe.
[f] ICD-9 code.
[g] ESR = end-stage renal disease: ICD-9 code or procedure code for hemodialysis.
[h] ICD-9 for affective, anxiety, schizophrenia, or psychosis.

2.5. Data extraction

We extracted demographic and clinical information dating back to March 1997, the year electronic records became available, including inpatient and outpatient ICD-9 diagnosis codes and laboratory testing results. The Institutional Review Boards of Boston University Medical Center and Montefiore Medical Center approved this study.

2.6. Outcome variables

In these analyses, we included only patients not previously tested for HCV. Patients were considered not to be previously tested for HCV if there was no HCV antibody test result in the EMR dating back to March 1997. The primary outcome was HCV antibody testing during each intervention period, and we also examined rates of HCV antibody positivity. HCV antibody testing was defined as an anti-hepatitis C virus antibody (anti-HCV) by ELISA performed either on the same date of the primary care visit or within 3 months of the initial primary care visit within the baseline or intervention periods. HCV antibody positivity (indicating past or current HCV infection) was defined as a positive anti-HCV test performed during that specified time period.

2.7. Other variables

We included the following sociodemographic variables. Age was dichotomized as within the high prevalence birth cohort (born between 1945 and 1964) vs. not within the cohort. Insurance status was categorized based on primary insurance: Medicare, Medicaid, Commercial, and Self/Uninsured. Race/ethnicity was collapsed into four categories: non-Hispanic White, non-Hispanic Black or African American, Latino or Hispanic, and other/unknown.

For at-risk sub-group analysis, we examined the variables below which were defined with ICD-9 codes and/or laboratory values. ICD-9 codes were classified using the Healthcare Cost and Utilisation Project of the Agency for Healthcare Research and Quality system [22]. Although a history of blood transfusion or organ transplant before 1992 is a known risk factor for HCV infection, the EMR did not have data on these risks, so the analysis does not include them. The following conditions were considered present if recorded at any time from March 1997 through the qualifying visit date.

Substance abuse. ICD-9 code for substance abuse/dependence or positive urine toxicology for amphetamines, barbiturates, cocaine, or methadone.

HIV. ICD-9 code for HIV infection or a positive antibody test confirmed by Western blot.

Sexually transmitted disease (STD). ICD-9 code indicating gonorrhea or chlamydia or positive gonorrhea or chlamydia PCR probe.

Alcohol abuse. ICD-9 code for alcohol abuse/dependence or alcohol-related liver disease, or a serum alcohol level ≥ 80 mg/dL.

HBV infection: positive serological test for anti-HBc.

Cirrhosis. ICD-9 code for cirrhosis.

End stage renal disease (ESRD). ICD-9 code for end-stage renal disease or procedure code for hemodialysis.

Psychiatric disease. ICD-9 code for affective disorder, anxiety disorder, schizophrenia, or psychosis.

ALT elevation. The highest ALT value reported from March 1997 through the clinic visit date for each subject was used. Elevated ALT was treated as a dichotomous variable and defined in two different ways: (1) >40 U/L (40 U/L is a commonly used upper limit of normal for all adults) [23] and (2) >19 U/L for females and >30 U/L for males (updated upper limits of normal) [20].

Any HCV risk. Any HCV risk was defined as having at least one of the following risks as defined above: substance abuse; HIV; STD; cirrhosis; ESRD, or elevated ALT (>40).

2.8. Statistical analysis

2.8.1. Proportion tested

Chi square and ANOVA tests were used to examine differences in demographic and clinical characteristics among the baseline period, risk-based screener period, and birth cohort period.

In each of the three periods, we determined the proportion of patients tested for anti-HCV. The proportions tested were calculated for predefined age categories and demographic characteristics, presence or absence of at-risk sub-groups, and the presence or absence of ALT elevation.

2.8.2. Comparison of intervention HCV testing rates with baseline testing rates

We compared the rates of HCV testing in the risk-based screener and birth cohort intervention periods with the baseline testing period, overall and within multiple subgroups by using chi square tests. We examined the odds of HCV testing for the risk-based screener and birth cohort intervention periods as compared with the baseline period, overall and within multiple subgroups using simple logistic regression models. To compare odds of HCV testing in each intervention period with the baseline period, we constructed multivariate models to adjust for age, sex, race/ethnicity, insurance status, substance use, alcohol abuse, HIV, STDs, cirrhosis, psychiatric diagnosis, and elevated ALT. To assess the influence of cross-contamination across periods, we performed multiple sensitivity analyses excluding patients who appeared in more than one period, and including only patients seen in more than one period, as well as all three periods.

STATA/IC software, version 10.0 (StataCorp, College Station, TX) was used for all data management and statistical analysis.

3. Results

3.1. Study population

The baseline cohort ($n = 6591$), the risk screener cohort ($n = 8981$), and the birth cohort ($n = 10{,}165$) included all adult patients (at least 18 years of age) who had not been tested for anti-HCV in the past (since 1997), and who made at least one primary care visit during the baseline, risk screener intervention, or birth cohort intervention periods respectively.

Demographic and clinical information for the overall study population are summarized in Table 1. The mean age was 47.8 years (SD = 17.7). The population was primarily female (74.4%), Latino (52.4%) or African American (30.4%), and Medicaid-insured (51.7%). Overall, 15.1% had a history of psychiatric disease, 3.3% had a history of substance abuse, and 1.9% had a history of HIV. The baseline period, risk-based screener period, and birth cohort period were similar with regard to most demographics and risks; slight differences were observed in rates of Latino patients, insurance status, HIV, STDs, and patients with psychiatric diagnoses.

3.2. HCV testing rates in each intervention period

Both intervention periods (Table 2) were associated with an increased proportion of patients tested for HCV from 6.0% at baseline to 13.1% in the risk screener phase ($P < 0.001$) and 9.9% in the birth cohort phase ($P < 0.001$). After adjustment, both interventions were associated with significantly increased odds of testing for HCV: aOR 2.37 (95% CI 2.10–2.67) for the risk-based screener period and aOR 1.70 (95% CI 1.50–1.92) for the birth-cohort period. To assess the influence of cross-contamination across periods, we performed sensitivity analyses excluding patients who appeared in more than one phase, and including only patients seen in more than one phase, as well as all three phases. In each sensitivity analysis, the results were similar to the primary analysis.

When the analysis was stratified by clinic, each clinic experienced a significant increase in the rate of HCV testing. In the clinic with the lowest baseline rate of testing, HCV testing increased almost four fold during the risk-based screener period (2.9% versus 11.3%, $P < 0.001$) and three fold during the birth cohort period (2.9% versus 8.7%, $P < 0.001$).

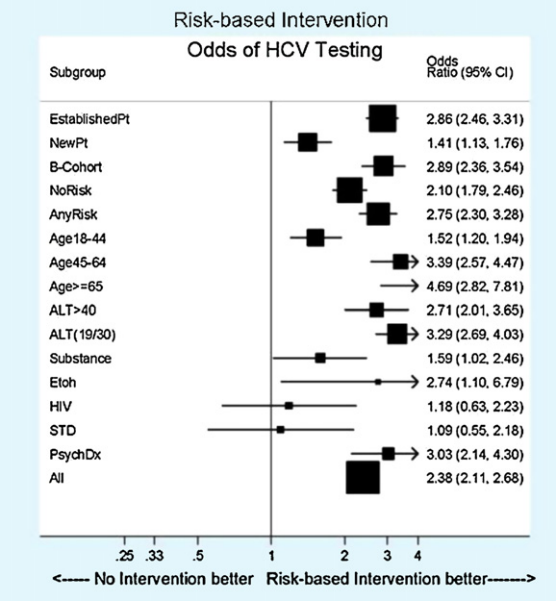

Fig. 1. Risk-based screener versus baseline forest plot.

3.3. Sub-group analysis

3.3.1. Risk-based screener intervention

Rates of anti-HCV screening increased in the following subgroups: patients with at least one risk (5.0–12.7%, $P < 0.001$), elevated ALT (5.7–14.1%, $P < 0.001$), HBV infection (1.6–8.5%, $P < 0.001$), 1945–1964 birth cohort (5.4–14.3%, $P < 0.001$), substance abuse or dependence (17.3–25.0%, $P = 0.04$), alcohol abuse or dependence (9.7–22.8%, $P = 0.02$), and psychiatric diagnosis (4.6–12.7%, $P < 0.001$). Rates of HCV testing significantly increased in all racial/ethnic groups and insurance sub-groups. There were significant increased adjusted odds of HCV testing in almost all sub-groups (Fig. 1).

3.3.2. Birth cohort intervention

Rates of anti-HCV screening increased in the following subgroups: patients with at least one risk (5.0–7.8%, $P < 0.001$), elevated ALT (5.7–8.1%, $P = 0.02$), previous HBV infection or vaccination (1.6–5.2%, $P = 0.02$), 1945–1964 birth cohort (5.4–13.2%, $P < 0.001$), and psychiatric diagnosis (4.6–8.7%, $P < 0.001$). Rates of HCV testing significantly increased in all racial and ethnic groups except Whites and in all insurance groups except those who were self-insured. There were significant increased adjusted odds of HCV testing in almost all sub-groups (Fig. 2).

3.4. Yield of HCV testing in each phase

Both interventions were associated with rates of anti-HCV-positivity that were more than three times the national prevalence of 1.6% [1]. The rate of anti-HCV-positivity was 5.3% in the risk-based screener period and 5.8% in the birth cohort period. Overall, 36 new anti-HCV+ patients (0.5% of all previously untested patients) were identified during the baseline period, 62 (0.7% of all previously untested patients) during the risk-based screener intervention period, and 59 (0.6% of all previously untested patients) during the birth cohort period, but the differences were not statistically significant.

Table 2
Proportion of patients tested.

	Baseline (n = 6591)	Risk-based (n = 8981)	Birth-cohort (n = 10,165)	Base/risk P-value	Base/birth P-value
All patients never tested – No.(%)	394 (6.0)	1179 (13.1)	1008 (9.9)	<0.001	<0.001

4. Discussion

We demonstrated that implementation of a clinical reminder sticker as the backbone of a multi-component intervention was associated with a significant increase of anti-HCV testing for a population of at-risk and high prevalence patients in three large urban primary care clinics. Both the risk-based screener and birth cohort interventions were associated with significantly increased rates of HCV testing overall, and among those with HCV-related risks. In the clinic with the lowest rate of baseline testing, there was a four-fold increase in rates of HCV testing with the risk-based screener strategy and a three-fold increase in testing with the birth cohort strategy. Both interventions were associated with a considerable yield of testing (over 5% HCV-positivity).

Several recent studies have demonstrated that risk-based HCV testing can identify most HCV-positive patients through asking about specific risks, but only one study, by Zuniga et al., was integrated within routine patient care (in Veterans Health Administration setting where HCV testing was mandated by a change in federal policy), and none were designed to demonstrate an increase of HCV testing in high-risk patients compared with baseline testing practises [1,2,24]. There are several studies which demonstrate interventions that increase HIV testing in real-world settings. An integrated package of quality improvement interventions utilizing decision support (a real-time, electronic clinical reminder to

identify patients at increased risk of HIV infection), academic detailing and audit feedback resulted in a doubling of HIV testing for a population of at-risk individuals who had not been previously tested at two large Veterans Health Administration health care systems [25]. Similarly, our risk-based screener intervention led to a more than doubling of anti-HCV testing in individuals with identified risks who had not been previously tested.

Identification of patients who have been infected with hepatitis C is the first step toward increasing the number of patients who initiate HCV treatment. Patients who achieve a sustained viral response (SVR) with therapy will have long-term remission of disease, and liver-related mortality rates comparable to the general population [26–28]. In patients with HCV-related cirrhosis, regression of cirrhosis may occur in patients who are treated, and regression is associated with decreased disease-related morbidity and improved survival [27]. Identification of HCV-infected patients is urgently needed as the prevalence of hepatitis C cirrhosis and hepatocellular carcinoma has increased over the past ten years, and will continue to increase through the next decade [28,29]. At the current low rates of treatment, only 14.5% of the projected 259,000 HCV-related deaths between 2002 and 2030 will be prevented [9,30–32]. Based on the estimates of Volk et al., if treatment rates were increased to 75% and new treatment options including direct-acting antiviral medications achieve SVR 75% of the time, we can expect that over half of liver-related deaths could be avoided [9,33–36].

Our study had several strengths. First, by utilizing the EMR to define subgroups of patients with HCV-related risks, we were able to test the associated outcomes of a clinic-wide intervention on the entire patient population visiting the clinic during a specified period of time. Second, we found that incorporating these interventions was effective even in clinics where physicians already demonstrated high rates of testing at baseline [3]. Lastly, our study may be generalizable to many other real-world settings in that our interventions did not require extensive technology and were not integrated within the electronic medical record [37].

There were several limitations to our study. First, because the overall duration of both interventions was only 31 weeks, it is unclear if either intervention is sustainable. Next, because we did not utilize a contemporaneous comparison group, we were not able to establish a causal link between the interventions and the increased HCV testing observed. Our findings may not be generalizable to clinical settings outside of urban settings such as suburban private practice environments. Lastly, the study was powered to evaluate for change in HCV testing, not HCV testing yield, so we were unable to examine for differences in yield between the study periods.

Future directions

Future studies could investigate the effect of combining our strategies by adding the birth cohort question to the risk-based screener. Risk-based screening will allow identification of younger patients who are less likely to have comorbidities and contraindications to HCV treatment, and have a better chance of SVR. Conversely, birth cohort screening will allow identification of older patients who are more likely to urgently need antiviral treatment to prevent decompensated cirrhosis, hepatocellular carcinoma and death. Future studies should focus on the sustainability of HCV testing strategies, as adherence to our risk-based screener decreased over time, and risk-based screening may be less sustainable in a busy primary care practice than a birth cohort strategy [38]. The national strategy for HIV testing moved from risk-based to universal testing to increase timely identification of HIV-infected patients, and to reduce stigma [39,40]. Similarly, a universal testing strategy for HCV testing involving a birth cohort strategy will likely increase timely identification of HCV-infected patients and reduce stigma. We must also investigate the potential important downstream benefits of HCV testing programs (vaccinations; reduction in alcohol use; antiviral treatment; and reductions in HCV-related morbidity and mortality) [9,41,42].

In summary, we have found that two simple clinical reminder interventions were associated with significantly increased HCV testing rates when compared with pre-intervention testing rates. Identification is the first step to facilitate treatment of chronic hepatitis C, and possibly prevent HCV-related morbidity and mortality. To respond to the Institute of Medicine's report calling for increasing HCV testing in high-risk populations [11], HCV screening programs using either a risk-based or birth cohort strategy should become integrated within primary care settings so that we may realize the potentially life-saving benefits of treatment, and move actively toward eradication of HCV infection in the United States.

Published online: 17 March 2012

Abstract To discuss and share knowledge about advances in the care of patients with thrombotic disorders, the Fourth International Symposium of Thrombosis and Anticoagulation was held in Salvador, Bahia, Brazil, from October 20–21, 2011. This scientific program was developed by clinicians for clinicians and was promoted by three major clinical research institutes: the Brazilian Clinical Research Institute, the Duke Clinical Research Institute of the Duke University School of Medicine, and Hospital do Coração Research Institute. Comprising 2 days of academic presentations and open discussion, the symposium had as its primary goal to educate, motivate, and inspire internists, cardiologists, hematologists, and other physicians by convening national and international visionaries,

Introduction

Venous and arterial thrombosis cause more than 50% of deaths in the developed world (http://www.cdc.gov/nchs/fastats/deaths.htm). Anticoagulants and antiplatelet drugs are the main tools used by physicians to prevent the formation of pathologic clots. During the first decade of the 21st century, dozens of clinical trials have been undertaken to evaluate promising new antithrombotic agents that offer the possibility of simpler treatment with either better efficacy, reduced toxicity, or both.

The Fourth International Symposium of Thrombosis and Anticoagulation was held in Salvador, Bahia, Brazil, from October 20–21, 2011; this congress offered its attendees the rare opportunity to network with each other while hearing about cutting-edge clinical research and discussing its implications for clinical practice with internationally recognized experts. This scientific program was developed for practicing clinicians in multiple specialties, and the meeting was endorsed by three major clinical research institutes: the Brazilian Clinical Research Institute, the Duke Clinical Research Institute of the Duke University School of Medicine, and Hospital do Coração Research Institute. It was also supported by the Brazilian Societies of Internal Medicine, Cardiology, Intensive Care Medicine, and Vascular Surgery, by the Latin American Group of Thrombosis and Hemostasis, and by the Anticoagulation Forum from the United States. The chairmen of the meeting were Dr. Renato D. Lopes and Dr. Richard C. Becker, both from Duke University School of Medicine and the Duke Clinical Research Institute, and Dr. David Garcia from the University of New Mexico.

After reading this summary of the symposium proceedings, we are confident the reader will agree that the symposium met its main goal: to educate, motivate, and inspire internists, cardiologists, hematologists, and other physicians to thoughtfully apply the best available evidence to the care of their patients with (or at risk for) thrombotic disease.

Platelet biology

Platelets are small cellular fragments devoid of a nucleus, derived from the megakaryocytes, with diameters ranging from 1.5 to 3.0 μm. In steady state, platelets assume a discoid shape that completely changes during activation. The half-life of platelets in circulation is approximately 8–12 days. Platelets contain large deposits of adenosine diphosphate (ADP) and adenosine triphosphate (ATP); thus, they have a high capacity for energy metabolism that is similar to that of smooth muscle cells. However, because platelets are devoid of a nucleus, they have limited ability for protein synthesis.

The main function of platelets is to ensure primary hemostasis. However, in several clinical scenarios (such as acute and chronic coronary syndromes and cerebrovascular diseases), platelets play a negative role and are considered the main elements responsible for the physiopathology of these serious diseases.

The platelet membrane is composed of proteins, carbohydrates, and lipids. Lipids represent 35% of the membrane composition and are anti-symmetrically arranged when the platelets are in steady state (not activated), with the negatively charged phospholipids arranged in the internal portion of the membrane. The external surface of the membrane is rich in receptors, among which are the glycoprotein complex (GP) Ib/V/IX that preferably binds von Willebrand factor (vWF); GP VI that strongly binds collagen; and GP IIb/IIIa that binds fibrinogen, allowing platelet aggregation. Also in the platelet membrane, proteins such as the p-selectin are expressed. These work as chemo-attractants for leukocytes.

Cytoplasmic organelles are also very important for platelet function. These include dense peroxisomes (responsible for lipid metabolism), mitochondria (oxidative metabolism), lysosomes (only released in response to very powerful stimulations; able to cause local injury), and dense granules and alpha granules. Dense granules contain calcium at high concentrations, as well as ADP, ATP, and serotonin. Alpha granules contain great variety of substances with pro-coagulant, mitogenic, and inflammatory functions (e.g., vWF, fibrinogen, cytokines, and platelet factor 4). The release of these granules varies according to platelet stimulation.

The platelet cytoskeleton is essentially undone and remodeled during platelet activation, changing from a discoid to a spherical shape. Also during platelet activation, phyllopods are formed. Contraction of the cytoskeleton contraction is one of the basic steps of platelet activation that allows secretion of dense and alpha granules.

Platelet function can be categorized into three actions: adhesion, activation, and aggregation. An initial trigger for platelet adhesion is vascular injury, with exposure of the subendothelial content (vWF and collagen). This vascular injury can be spontaneous or iatrogenic (e.g., during percutaneous coronary intervention [PCI]). Once vWF and collagen are exposed in the circulation, platelets initiate adhesion, through binding of the GP Ib/V/IX receptor to vWF and GP VI to collagen.

The degree of platelet activation depends on several vascular injury characteristics, such as: depth of the injury, vessel site, hematocrit level, flow speed at the site concerned, and vessel diameter. The activation process is initiated right after adhesion, and both continue to occur simultaneously. Four steps are fundamental during activation: mobilization of intracellular calcium (which works as the most powerful second messenger within the platelet); cytoskeleton contraction (with change in platelet shape); secretion of alpha and dense granules (with release of platelet agonists with autocrine and paracrine action; thus, enhancing the activation signal); and exposure of negatively charged phospholipids in the external portion of the membrane (with consequent activation of coagulation cascade and thrombin generation).

The more important platelet agonists are: thromboxane A2 (TP receptor), which stimulates initial activation and local vasoconstriction; ADP (acts on $P2Y_1$ and $P2Y_{12}$ receptors), which stimulates more stable activation; thrombin (acts on PAR 1 and 4 receptors), which primarily stimulates activation in pathological conditions and is considered the most powerful agonist; and collagen (GP Ib and GP VI), which stimulates activation.

Platelet aggregation is considered the final step in platelet response to injury and involves the conformational change of the GP IIb/IIIa receptor, which moves from a low-affinity steady state to a high-affinity activated state. The activated GP IIb/IIIa receptor binds fibrinogen, forming platelet-fibrinogen-platelet aggregates and a stable platelet plug.

Platelets interact directly with the coagulation system in many ways. The interaction can be physical, such as through exposure of negatively charged phospholipids on the external surface of the membrane, or chemical, through release of pro-coagulant granules. Platelets also interact similarly with inflammatory cells through exposure of p-selectin, leading to recruitment of leukocytes and exposure of the CD40 receptor from the surface of macrophages.

In short, platelets are important structures responsible for primary hemostasis, but play a negative role in several clinical scenarios. Platelet biology is very complex because platelets have to interact with other systems, including the coagulation cascade**.**

Measures of platelet function: are we ready to use them?

In the treatment of coronary disease, inhibition of platelet activation and aggregation is critical to the prevention of cardiovascular atherothrombotic outcomes. Clopidogrel, a $P2Y_{12}$ receptor antagonist, improves outcomes among patients with acute coronary syndrome (ACS) and after PCI. However, clopidogrel is a biologically inactive prodrug that requires several steps of metabolism for active effect. In part because of these activation steps, substantial inter-individual variability in pharmacodynamic response has been previously observed. Individual variation in response to antiplatelet therapies is in part predicated on intrinsic factors (such as genetic polymorphisms affecting absorption and/or metabolism of drug) and in part related to clinical factors such as patient non-compliance with therapies or drug–drug interactions.

There are several methods for assessment of platelet response to therapy. The current gold standard is light transmission platelet aggregometry, which involves introduction of a platelet agonist such as ADP with a light-based assay that ultimately assesses platelet aggregation. The requirement for high technical expertise, as well as substantial processing times to generate platelet-rich plasma, render this assay an unwieldy tool for clinical use. Point-of-care aggregation tests involving whole blood samples—such as the VerifyNow assay—employ the same principles in a cartridge-based fashion and have been validated against the gold standard. The vasodilator activated phosphorylation (VASP) assay measures intra-platelet phosphorylation in response to $P2Y_{12}$ receptor activation; higher VASP phosphorylation levels are observed with superior inhibition of the $P2Y_{12}$ receptor by agents such as clopidogrel. Yet, like light transmission aggregometry, this is a tool largely used for research purposes due to its technically demanding laboratory processes. Another platelet function testing modality, the multi-plate assay, examines the degree of platelet adhesion and aggregation on the sensors' surface by quantifying electrical resistance between the two central wires.

All of the above platelet function testing modalities have been shown to correlate with post-PCI outcomes. For VerifyNow, platelet reactivity unit levels > 235 are associated with increased risk of cardiovascular death, non-fatal myocardial infarction (MI), and stent thrombosis. The Do Platelet Function Assays Predict Clinical Outcomes in Clopidogrel-Pretreated Patients Undergoing Elective PCI study compared VerifyNow to traditional light transmission aggregometry and noted good correlation between these two tests in their ability to discriminate future thrombovascular outcomes. For VASP phosphorylation, low post-treatment response defined as platelet reactivity $> 50\%$ was associated with future risk of cardiovascular events. Similarly for the multi-plate assay, low responders were associated with a higher incidence of stent thrombosis.

The role of platelet function testing in tailoring therapy for individual patients remains to be elucidated. The multicenter Gauging Responsiveness With A VerifyNow

Assay—Impact on Thrombosis and Safety (GRAVITAS) trial focused on patients who had residual high-on treatment platelet reactivity measured by VerifyNow testing and randomized these patients to standard-dose clopidogrel (75 mg daily) versus higher-dose (150 mg daily). Unfortunately, no differences in clinical outcomes were noted between groups, which may in part be attributed to persistently high platelet reactivity even among the higher-dose group. While this study examined the impact of dose doubling, we look to studies such as the Double Randomization of a Monitoring Adjusted Antiplatelet Treatment Versus a Common Antiplatelet Treatment for DES Implantation, and a Interruption Versus Continuation of Double Antiplatelet Therapy (ARCTIC) trial, which will examine the role of tailored therapy using alternative agents, such as prasugrel or ticagrelor, that have been shown to provide more potent and consistent inhibition of platelet function.

One important question that has been raised is: what is the appropriate timing of platelet function testing? In a study by Campo et al., PCI patients had serial measurements at baseline and at one month. Among patients who were full responders at baseline, 4% became poor responders by 30 days; in contrast, among patients who were poor responders at baseline, 70% became full responders by one month. Further, patients who were poor responders both at baseline and at one month and those who were full responders at baseline but became poor responders at one month had worse ischemic outcomes by one year. These results suggest that the 30-day time point may be a more relevant time to test.

Another question is whether platelet function testing can be used to define a therapeutic window for antiplatelet therapies similar to the international normalized ratio (INR) for warfarin therapy. To date, the ability of existing platelet function tests to predict bleeding outcomes is limited. One modestly positive study by Sibbing et al. showed that bleeding was associated with an area under the curve $\leq$188 using multi-plate technology.

In summary, several testing modalities are currently available to assess on-treatment platelet response to antiplatelet therapies. While these tests provide important prognostic information for ischemic events, their potential for bleeding prediction appears limited. Platelet function testing may someday be helpful for therapeutic selection; however, further evidence is necessary.

Vitamin K antagonists: is this the beginning of the end?

For centuries, thrombosis has been recognized as a major pathological finding in many significant and often fatal clinical conditions. Parenteral anticoagulants, specifically unpurified heparin, led the way in the pharmacological treatment of thromboembolic diseases. Its main drawback was that it was not available for oral use. Shortly after, there came the anti-vitamin K oral anticoagulants—dicumarol and warfarin—which have been used widely since the 1950s for treatment and prevention of thromboembolic diseases, such as deep vein thrombosis (DVT) and pulmonary embolism (PE), and prevention of cerebral vascular embolism in conditions such as atrial fibrillation (AF), artificial cardiac valves, and ventricular thrombi.

Use of vitamin K antagonists was, from the very beginning, recognized as troublesome due to the very narrow therapeutic range of anticoagulation, which led to lack of protection when suboptimal and to hemorrhagic events when in excess of prescribed limits. Furthermore, many natural nutrients and medicines can interfere with the pharmacological action of vitamin K antagonists, requiring frequent monitoring of the anticoagulant status via repeated measurements of the prothrombin time. The INR (a standardized reporting method) must be maintained within a narrow therapeutic range to maximize the benefit of warfarin. Several observational studies and well-controlled trials have documented the challenges of long-term warfarin use. Among observational studies, the percent time in therapeutic range has ranged only from 50 to 55% and, in the controlled trials, from 58 to 65%.

All of these difficulties probably explain the under-use of oral vitamin K anticoagulants worldwide. The recent development of new oral anticoagulants with better pharmacological profiles and easier use has raised hopes that, in the near future, vitamin K antagonists will be replaced, assuming that the newer agents prove as successful in long-term surveillance as they have been demonstrated to be in relatively short-term trials.

New anticoagulants and new hematologic dilemmas

The development of novel anticoagulant medications has become a high priority for pharmaceutical companies. Enthusiasm for novel agents has resulted from the observation that about 50% of the population of the western world dies from either heart attack or stroke and that millions of people have AF, many of whom are inadequately treated using current oral anticoagulants. Additionally, our current armamentarium of anticoagulants (consisting predominantly of heparin, low-molecular-weight heparin [LMWH], oral vitamin K antagonists, and a selection of relatively infrequently used newer agents such as fondaparinux, hirudin, argatroban, and bivalirudin) are often perceived to be "old" and may have significant limitations that restrict their use. With the exception of the oral vitamin K antagonists, all of these medications are parenteral,

and many are expensive. Oral vitamin K antagonists are highly effective but have a slow onset and offset of action, large between-person variability in their dose requirements, are subject to food and drug interactions, and are complex to reverse. Despite these drawbacks, the oral vitamin K antagonists have been proven to reduce thromboembolism in a wide variety of settings, including patients with AF, mechanical heart valves, MI, and after orthopedic surgery. They are also effective for the secondary prevention of DVT, PE, and MI.

The "ideal" anticoagulant would be orally administered, have a rapid onset and offset of action, predictable pharmacokinetics and pharmacodynamics, a low propensity for food and drug interactions, be administered in fixed doses, be "reversible" in cases of bleeding, have a wide therapeutic window, and not require routine monitoring, but have a form of monitoring available should it be required. Oral vitamin K antagonists do not possess many of these characteristics.

Recent developments in the field of anticoagulants leave us at a crossroads; many clinicians are considering whether it is time to abandon the oral vitamin K antagonists. The rationale for reducing or eliminating use of oral vitamin K antagonists include eliminating the need for monitoring, having less variability in the dosing of the oral anticoagulant, and potentially reducing bleeding. However, eliminating oral vitamin K antagonists will be difficult. In some settings, they are the only proven therapy (e.g., patients with antiphospholipid antibody syndrome or those with mechanical heart valves). Additionally, oral vitamin K antagonists are inexpensive, they have 100% brand recognition internationally (thereby reducing the likelihood of medication errors), and the ability to monitor these drugs improves compliance. Finally, oral vitamin K antagonists can be rapidly reversed.

The development of novel anticoagulant medications has been facilitated by a comprehensive analysis of the coagulation cascade. Coagulation is initiated at sites of vascular injury when tissue factor binds with circulating activated factor VIIa. This complex converts factor X to factor Xa and factor IX to factor IXa. Factor Xa then acts in concert with factor Va to convert prothrombin to thrombin. Thrombin is the "engine" of coagulation. It converts fibrinogen to fibrin, facilitates a positive feedback loop leading to activation of coagulation, activates factor XIII, which cross-links fibrin stabilizing the clot, and has a number of other important roles in coagulation.

A clear understanding of the coagulation cascade has allowed the development of highly specific inhibitors of coagulation. Initially, these agents were developed using recombinant DNA technology modeled after naturally occurring anticoagulants. Perhaps the best example of this is the development of the hirudins, modeled after the anticoagulant present in the saliva of the medicinal leech. More recently, knowledge of the structure of the coagulation enzymes has allowed the development of molecules using computer-assisted design. These molecules are of low molecular weight, can be made orally bioavailable, and when carefully designed are highly specific to their enzyme target. Development of these agents has revolutionized the approach to anticoagulation.

Polypeptide drugs tested as inhibitors of coagulation include tissue factor pathway inhibitor, nematode anticoagulant peptide C2 (rNAPC2), active site-blocked factor VIIa, activated protein C, soluble thrombomodulin, and the hirudins. Low-molecular-weight inhibitors include rivaroxaban, apixaban, edoxaban, and dabigatran. Additional agents are under development.

In general, polypeptide drugs are falling out of favor, except for their use in acute situations such as ACS or in unstable patients with extensive thromboembolic disease. These drugs are used less and less frequently because of their high cost and need for parenteral administration. Furthermore, the effectiveness of many of these drugs has recently been questioned. For example, recombinant activated protein C was recently withdrawn from the worldwide market (http://www.hc-sc.gc.ca/ahc-asc/media/advisories-avis/_2011/2011_142-eng.php, accessed November 14, 2011). Some of these drugs (e.g., rNAPC2) are being studied for other indications, such as the treatment or prevention of cancer.

Recent research has focused on inhibition of factor Xa or thrombin, given their seminal roles in coagulation. Rivaroxaban, apixaban, and edoxaban are all highly active, orally bioavailable inhibitors of coagulation. Each has been extensively tested in diverse clinical situations, and each holds promise as a therapy for the prevention and treatment of both venous and arterial thrombosis. Dabigatran is the only thrombin inhibitor currently available; although it has reduced bioavailability, it has demonstrated its effectiveness as an agent for the prevention and treatment of thrombosis.

Novel agents should not be regarded as a panacea; although they address many of the perceived concerns with novel anticoagulants, they have their own limitations. These include cost, a lack of familiarity among the medical community (leading to the likelihood of medical error), a much less broad set of indications (given their development in a more restrictive regulatory environment), and a lack of antidotes or reversibility. Although there has been early work on the development of specific antidotes for both the direct Xa inhibitors and dabigatran, none of these agents has reached even early-phase clinical trials in patients with active bleeding.

Given the excitement surrounding novel anticoagulant medications, it is very likely that a great deal more research

describing their utility and toxicities will be undertaken in the coming years.

Antiplatelet agents under development

The evolution of antiplatelet therapy over the past decade has witnessed clear advances, with the development of increasingly potent and response-consistent $P2Y_{12}$ receptor antagonists, including prasugrel, and more recently ticagrelor, a non-thienopyridine agent that may also offer benefit through prolonged inhibition of adenosine re-uptake by erythrocytes. A wealth of information from phase three clinical trials highlights the broad potential of new-generation antiplatelet agents but also underscores the importance of patient selection, aspirin dosing, and uncommon yet potentially life-threatening hemorrhagic complications involving the gastrointestinal tract and brain. These adverse events serve as a reminder that platelets play an important role in hemostasis and the maintenance of vascular integrity, including the blood–brain barrier.

Future investigations will likely focus on strategies and technologies to optimize patient-centered therapies and platelet antagonists that attenuate thrombosis while preserving hemostatic potential and vascular reparative capacity.

Anticoagulation in ACS patients managed invasively: a time for change or a time of choice?

Earlier studies demonstrated that the use of enoxaparin in non–ST-segment elevation ACSs (NSTE ACS) patients managed conservatively reduced the rates of death or MI by approximately 20% both at 8 and 42 days compared with unfractionated heparin (UFH). More recent studies, however, indicated that an invasive strategy with early catheterization and angioplasty was associated with improved outcomes compared with a conservative approach. When enoxaparin was compared with UFH in the setting of an early invasive strategy, similar efficacy outcomes, regardless of anticoagulation therapy, were seen. In contrast, patients treated with enoxaparin had a significant 30% increase in severe bleeding as evaluated by the TIMI scale.

Recently, a great deal of evidence has suggested that bleeding is a major determinant of clinical outcomes in ACS patients. Both moderate and important bleeding are associated with worse outcomes after adjustment for potential confounders. In a pooled analysis of 26,452 patients with ACS, severe bleeding increased more than five times the odds of 30-day mortality or MI.

Drugs recently developed, such as factor Xa inhibitors and direct thrombin inhibitors, have an improved safety profile. In the Fifth Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS-5) trial, the indirect Xa inhibitor fondaparinux reduced major and minor bleeding by more than 50% in NSTE ACS patients. This resulted in a significant 11% reduction in mortality at six months. Similarly, the thrombin blocker bivalirudin reduced severe bleeding by almost 40% in ST-segment elevation MI patients, leading to a 30% reduction in all-cause mortality. This benefit extended to three years of follow-up.

The results of these trials indicate that safer anticoagulant drugs with similar efficacy profiles are currently available and that new treatment combinations may reduce mortality. Therefore, it is a time for change to the newer agents in ACS. At this point, it is very important that the guidelines and future studies focus on these new therapeutic options; clinicians can benefit from more evidence when choosing the best clinical setting for each particular agent.

Oral anticoagulants after ACS

Current guidelines recommend dual antiplatelet therapy after ACS, but the risk of recurrent ischemic events remains elevated in these patients. Meta-analyses of clinical trials on the addition of warfarin to aspirin after ACS indicate that this intervention is associated with a reduced rate of ischemic events at the cost of increased risk of major bleeding. Moreover, warfarin therapy requires frequent monitoring and is also associated with food and drug interactions. With the development of oral agents that directly inhibit thrombin or drugs that are direct inhibitors of factor Xa, a new opportunity for secondary prevention after ACS has emerged. These agents have predictable dose-dependent pharmacokinetics and pharmacodynamics and, therefore, do not require frequent monitoring. Some have also been shown to be effective and safe in the management of AF. Dabigatran, a direct inhibitor of thrombin, was compared with placebo on top of dual antiplatelet therapy in the Reduction by Dutasteride of Clinical Progression Events in Expectant Management (REDEEM) phase two trial in 1861 patients. The administration of newly developed direct factor Xa inhibitors on a background of single or dual antiplatelet therapy has also been evaluated by phase two trials. In the Rivaroxaban in Combination With Aspirin Alone or With Aspirin and a Thienopyridine in Patients With ACSs (ATLAS ACS TIMI-46) trial, different doses of rivaroxaban were compared with placebo in 3491 patients. Darexaban was also evaluated in the dose-ranging Study Evaluating Safety, Tolerability and Efficacy of YM150 in Subjects With ACSs (RUBY) trial with 1279 patients, and apixaban was evaluated in the Apixaban for Prevention of Acute Ischemic

Events (APPRAISE) dose-ranging trial with 1714 patients. The results of these phase two trials in patients after ACS are remarkably consistent, by showing a dose-dependent increase in major bleeding with little or no significant effect on the reduction of cardiovascular events. In agreement with these findings, a phase three trial, APPRAISE-2, with 7392 patients, was prematurely terminated because of an increase in major bleeding events with apixaban in the absence of a counterbalancing reduction in recurrent ischemic events.

The role of factor Xa inhibitors in the secondary prevention after ACS became even more complex after the results of the ATLAS-ACS 2 TIMI 51 trial, which evaluated more than 15,526 patients randomized to placebo or to two doses of rivaroxaban. Results of this highly anticipated trial demonstrated that ACS patients receiving standard therapy, including dual antiplatelet therapy, may benefit from the addition of the factor Xa inhibitor rivaroxaban, although at the cost of some additional bleeding complications. Both rivaroxaban doses reduced the primary end point of cardiovascular death/MI/stroke at the cost of increased bleeding rates. The 2.5-mg twice-daily dose had the better benefit/risk balance, due to lower bleeding risk, than the 5-mg twice-daily dose. Surprisingly, the lower dose of rivaroxaban resulted in a significant reduction in death from cardiovascular causes (2.7% vs. 4.1%, $P = 0.002$) and in all-cause mortality (2.9% vs. 4.5%, $P = 0.002$). These benefits were not observed in higher-dose rivaroxaban, and the difference between the two doses of rivaroxaban was significant. Rivaroxaban-treated patients experienced more major bleeding and intracranial hemorrhage than controls, but without a significant increase in fatal bleeding. It is possible that the addition of very-low-dose anticoagulation with rivaroxaban may represent a new treatment strategy in patients with a recent ACS. However, it is important to note that the ATLAS-ACS 2 trial had relatively small percentages of elderly patients, female patients, and patients with impaired renal function, suggesting that the results may not be entirely replicated with higher-risk patients in the real world.

In summary, as mentioned in the editorial by Matthew Roe and E. Magnus Ohman, "a new era of secondary prevention after an ACS has begun and will be characterized by the need to balance ischemic versus bleeding risks when selecting the type, number, and duration of antithrombotic therapies for individual patients."

New antiplatelet agents in ACS patients: how should we choose?

Treatment options for patients with ACS continue to expand. Most recently, two new potent oral inhibitors of the platelet $P2Y_{12}$ receptor, prasugrel and ticagrelor, were found in randomized clinical trials to be superior to clopidogrel in preventing death, MI, or stroke in patients presenting with ST-segment elevation MI and NSTE ACS and are now available for clinical use. However, their availability only adds to the complexity of treatment selection. Considering combinations of oral and intravenous (IV) antiplatelet agents, anticoagulants, and their use and timing relative to the use and timing of PCI, there are at least 144 different possible combinations for treatment of an individual patient. Given this complexity, a number of factors should be considered in selecting therapy.

First and foremost, the evidence supporting efficacy and safety of the agent must be considered. In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial, clopidogrel reduced the risk of death, MI, or stroke relative to aspirin alone by 20% with acceptable incremental bleeding. However, the CURE trial was conducted prior to the current era of invasive treatment for NSTE ACS and did not include ST-segment elevation MI patients. In addition, clopidogrel levels and platelet responsiveness to clopidogrel are highly variable across patients, in part related to polymorphisms in CPY2C19, an enzyme in the cytochrome P450 system responsible for converting clopidogrel from a pro-drug to its active form. Unfortunately, there is no evidence to date that increasing the dose of clopidogrel is effective in reducing clinical events in patients with reduced function polymorphisms of CYP2C19 or in reducing death, MI, or stroke in ST-segment elevation MI and NSTE ACS patients overall.

Like clopidogrel, prasugrel is a thienopyridine and administered as a pro-drug, but is more potent than clopidogrel in inhibiting platelet function with less variability in response across individuals. Additionally, prasugrel is less susceptible to the effects of CYP2C19 polymorphisms than clopidogrel.

Ticagrelor is a non-thienopyridine, reversible inhibitor of the $P1Y_{12}$ receptor that is more potent than clopidogrel and is administered as the active drug. Briefly, compared with clopidogrel in patients with both NSTE ACS and ST-segment elevation MI, prasugrel (administered after coronary anatomy was known and PCI was planned) and ticagrelor (administered as upstream therapy) reduced the risk of death, MI, or stroke by 19 and 16%, respectively, over treatment of approximately 12 months. Importantly, treatment with ticagrelor resulted in a significant 21% reduction in cardiovascular mortality. Efficacy results were consistent across major subgroups, with a possible enhanced benefit of prasugrel among diabetic patients and reductions in stent thrombosis with both agents. There was a significant treatment-by-region interaction in the Platelet Inhibition and Patient Outcomes (PLATO) trial, such that the point estimate for treatment effect favored clopidogrel

in North America. Subsequent analyses suggested that aspirin dose explained the majority of the difference in treatment response by region, and ticagrelor now carries a Food and Drug Administration (FDA) black box warning for use only with low-dose aspirin (<100 mg).

Although there was a higher rate of major bleeding with ticagrelor compared with clopidogrel, there was no increase in intracranial or life-threatening bleeding. However, prasugrel resulted in a 32% higher rate of major bleeding than clopidogrel, which included significant increases in life-threatening and fatal bleeding and an increase in intracranial hemorrhage in patients with prior transient ischemic attack or stroke. Net clinical benefit was also not favorable for prasugrel in patients over age 75 years and those with body weight <60 kg. Therefore, prasugrel has an FDA black box warning restricting use in these subgroups.

A practical consideration in selecting treatment is cost, particularly with the expectation that clopidogrel will become available in generic form in May 2012. Present pricing for consumers in the United States is approximately $200 per month for clopidogrel, $215 per month for prasugrel, and $260 per month for ticagrelor. Compliance is also a practical concern. Both clopidogrel and prasugrel were developed for once-daily dosing, but ticagrelor was developed to be given twice daily, which may affect compliance in some patients. Additionally, ticagrelor causes symptomatic dyspnea in some patients, which may lead to lower compliance.

Selection among the new antiplatelet agents and clopidogrel should consider local practice patterns, including such things as what agents are available in institutional formularies and in local pharmacies and how familiar physicians at the treating facility are with the properties of the agents and their potential benefits and risks. Finally, a systematic approach is recommended for oral antiplatelet treatment selection that considers these factors, as well as local interventional and referral patterns, and that simplifies the approach to selection of all antithrombotic therapy for treatment of ACS at an institution.

Bleeding and mortality in patients with ACS

Bleeding occurs commonly during the treatment of ACS, an observation that has been made in both clinical trials as well as in observational registries of community practice. However, the incidence of bleeding depends on the definition applied, and unfortunately varying definitions have been applied historically across trials. For example, in the TIMI trials, major bleeding is defined as fatal or life-threatening bleeding, intracranial hemorrhage, hemoglobin drop ≥5 g/dL, or hematocrit drop ≥15%. In contrast, the Acute Catheterization and Urgent Intervention Triage Strategy definition of major bleeding includes intracranial, retroperitoneal, intraocular, or access-site hemorrhage requiring surgical intervention, hematomas ≥5 cm in diameter, as well as more conservative hemoglobin drops depending on whether an overt source of bleeding is observed. The use of blood product transfusions has been variably incorporated into these definitions as well and contributes further to the variation and incidence of bleeding due to varying institutional thresholds for transfusion. The Bleeding Academic Research Consortium (BARC) assembled a working group to provide standardized bleeding definitions for cardiovascular clinical studies. This group acknowledged several challenges in creating a universal bleeding definition but proposed a consensus classification for bleeding evaluation or treatment. Type II bleeding includes clinically overt signs of bleeding that are actionable but do not meet criteria for other BARC bleeding. Type III is clinical, laboratory, and/or imaging evidence of bleeding with specific health care provider response. Type IV includes coronary artery bypass graft (CABG)-related bleeding, and Type V is defined as fatal bleeding.

Bleeding has important prognostic complications as it has been associated with an increased longitudinal risk of mortality. The severity of bleeding correlates with worse outcomes. Bleeding is costly, not only because it prolongs length of hospitalization, but also because it is associated with additional diagnostic and treatment interventions. Bleeding can also result in decreased use of evidence-based therapies. In a study of patients with ACS, patients who developed bleeding complications were less likely to be discharged on antiplatelet therapy such as aspirin and thienopyridine. Six months after a bleeding event, these patients remained less likely to receive these evidence-based therapies. Even nuisance bleeding is associated with a high rate of antithrombotic treatment discontinuation.

Bleeding also often leads to the transfusion of blood products. Tremendous variation in transfusion practices exists across health care organizations. However, a common theme is that older patients, female patients, and patients with renal insufficiency are more likely to receive transfusion therapy. Transfusion in the ACS setting has been independently associated with worse outcomes. Appropriate thresholds for transfusion have not been well established within the cardiovascular arena. The only randomized clinical trial on this topic was conducted by the Canadian Clinical Trials group in 1999, which randomized 838 critically ill patients to a liberal versus restrictive transfusion strategy. No difference in 30-day mortality was noted between transfusion strategies, although there was a suggestion of benefit for the more liberal strategy among patients with coronary disease.

There is increased focus on bleeding avoidance strategies. First and foremost would be the prediction of bleeding risk. The Can Rapid Risk Stratification of Unstable Angina Patients Suppress Adverse Outcomes with Early Implementation of the American College of Cardiology/American Heart Association Guidelines (CRUSADE) bleeding risk score was developed and validated in a cohort of patients with NSTE ACS, and it identified eight clinical factors that are associated with increased bleeding risk: female sex, prior history of diabetes, heart failure, peripheral vascular disease, or clinical and laboratory evidence of risk including lower creatinine clearance, higher heart rate on admission, lower systolic blood pressure on admission, and lower admission hematocrit. A key first step to bleeding avoidance is the appropriate dosing of antithrombotic therapies. Patients who are older or who have worsening renal function are particularly vulnerable to excess antithrombotic dosing. Appropriate dosing, particularly in these high-risk patients, may alleviate the relationship between these risk characteristics and increased bleeding risk. The use of safer antithrombotics may also be considered. Bivalirudin, for example, has been well studied in both the ST-elevation and NSTE ACS settings and has been shown to have efficacy comparable with the traditional combination of heparin and GP IIb/IIIa inhibitors but an enhanced safety profile with reduced bleeding risk. Arterial access for cardiac catheterization may also play a role in bleeding avoidance. The recent Radial Versus Femoral Access for Coronary Angiography and Intervention in Patients with Acute Coronary Syndromes (RIVAL) study compared clinical outcomes between patients who underwent radial versus femoral arterial access. Although the primary outcome of death, MI, stroke, and non-CABG-related major bleeding at 30 days was not significantly different between groups, secondary outcomes, including the occurrence of large hematomas or major vascular access site complications, were substantially reduced with radial access.

In summary, bleeding is an important event associated with increased mortality among patients with ACS, and bleeding avoidance should be prioritized while reducing ischemic risk with antiplatelet interventional therapies. Strategies that achieve this balance are associated with improved survival.

Thromboprophylaxis in critically ill patients

Critically ill patients have an increased risk of DVT due to their acute illness, procedures such as central venous catheterization, and immobility. Among patients in the intensive care unit (ICU), DVT is an important problem because thrombus propagation and embolization can lead to potentially fatal PE. The effects of thromboprophylaxis with LMWH compared with UFH on venous thromboembolism (VTE), bleeding, and other outcomes were uncertain in critically ill patients. To address this question, The Prophylaxis for Thromboembolism in Critical Care (PROTECT) trial (NCT00182143) was planned.

PROTECT was a randomized, stratified, concealed international trial comparing subcutaneous injection of UFH 5000 IU or the LMWH dalteparin 5000 IU once daily plus once-daily placebo for the duration of the ICU stay. The objectives of PROTECT were to examine, among medical-surgical critically ill patients, the effect of the LMWH versus heparin on the primary outcome of proximal leg DVT and the following secondary outcomes: DVT elsewhere, PE, any venous thromboembolism (DVT or PE), and the composite of VTE or death, bleeding, and heparin-induced thrombocytopenia. Patients were followed up to death or hospital discharge. Venous thromboembolism events were included after ICU discharge. All patients, families, clinicians, research personnel, outcome adjudicators, and the trial biostatistician were blinded to allocation. Data were analyzed according to the intention-to-treat principle.

The main results of the PROTECT trial suggested that there was no significant between-group difference in the rate of proximal leg DVT, which occurred in 96 of 1873 patients (5.1%) receiving dalteparin versus 109 of 1873 patients (5.8%) receiving UFH (hazard ratio in the dalteparin group, 0.92; 95% confidence interval [CI], 0.68–1.23; $P = 0.57$). The proportion of patients with pulmonary emboli (a key secondary outcome measure) was significantly lower with dalteparin (24 patients, 1.3%) than with UFH (43 patients, 2.3%) (hazard ratio, 0.51; 95% CI, 0.30–0.88; $P = 0.01$). There was no significant between-group difference in the rates of major bleeding (hazard ratio, 1.00; 95% CI, 0.75–1.34; $P = 0.98$) or death in the hospital (hazard ratio, 0.92; 95% CI, 0.80–1.05; $P = 0.21$).

Does aspirin have a role in venous thromboembolism prevention?

Patients undergoing orthopedic surgery are at high risk for VTE. Anticoagulant agents (e.g., LMWH or fondaparinux) significantly reduce the risk of VTE after orthopedic surgery, but the role of aspirin in VTE prevention has been controversial, in part because platelets are thought to be less important than fibrin in venous thrombosis. Guidelines published by the American Academy of Orthopedic Surgeons recommend aspirin as one of several acceptable VTE prevention strategies for the majority of patients undergoing major orthopedic procedures. In contrast, the eighth edition of the American College of Chest Physicians'

Evidence-based Guidelines on Antithrombotic Therapy strongly recommends that aspirin *not* be used for VTE prophylaxis.

A recent systematic review of all evidence relevant to aspirin suggests that aspirin is almost certainly more effective than placebo for the prevention of VTE following orthopedic surgery. The most important data come from two sources: a meta-analysis published by the Anti-Platelet Trialists' Coalition (APTC) in 1994 and the Pulmonary Embolism Prevention (PEP) study published in 1999. The APTC meta-analysis included data pooled from almost 9000 patients who had participated in VTE prevention trials following orthopedic surgery, as well as other clinical settings. Although the results indicated that, compared with placebo, aspirin reduced the rate of PE by more than 50%, the validity of the findings was questioned because many of the trials from which these data were abstracted had serious methodologic flaws (e.g., open-label design, sub-optimal DVT detection methods, non-uniform antiplatelet drugs and doses across studies).

The PEP trial was undertaken to address the fact that many physicians (especially non-surgeons) had rejected the APTC results. Over 17,000 patients in five countries were randomized to receive either aspirin 160 mg or placebo, started pre-operatively and continued for 35 days. The majority of patients underwent surgery to repair a hip fracture, but about one quarter of participants had an elective total hip arthroplasty. This well-designed, very large randomized trial with almost 100% follow-up for clinical end points found that aspirin reduced the risk of fatal and non-fatal PE; the relative effect was very similar to that seen for aspirin in the APTC meta-analysis. Based on data from PEP and APTC combined, it appears that, compared with placebo, aspirin could prevent 5–10 PEs per 1000 patients treated. Aspirin use following major orthopedic surgery would be expected to increase the number of patients who require transfusion by approximately 3–6 per 1000. Although a few direct comparisons between aspirin and anticoagulant agents in this setting have been published, the available evidence is too sparse and too inconsistent to draw definitive conclusions about the net clinical benefit (or harm) of anticoagulants versus aspirin in this setting. Pending further study, it seems reasonable to conclude that aspirin should have *some* role as a VTE prevention strategy after orthopedic surgery; without more data, however, we can expect ongoing disagreement about the patients for whom it would be most appropriate.

Should patients with cancer receive primary VTE prophylaxis?

The association between cancer and thromboembolic phenomena has been recognized since 1865. It was first described by Armand Trousseau (1801–1867) as a sign of occult pancreatic cancer, but there is wide variation in the relative risk of VTE in different cancers. The presence of an active cancer should be one of the leading risk factors recognized by physicians when assessing VTE risk during hospitalization. In the algorithm used for electronic alert to prevent VTE created by Kucher and colleagues, the presence of cancer carries a score of 3, while a score ≥ 4 reflects a high thrombotic risk. Some other scores evaluate the VTE risk in patients with cancer and on chemotherapy. The most important single message is that physicians should perform a systematic evaluation of each cancer patient, taking into account both factors linked to the patient (such as age, type and stage of the disease, previous history of VTE, known thrombophilia), as well as factors linked to the treatment (type of chemotherapy, hormonal therapy or an anti-angiogenic agent, such as thalidomide in association with corticosteroids, immobilization during hospitalization, and surgery).

VTE is one of the most frequent complications in cancer patients (4–20%). The risk of VTE is 3–5 times higher in cancer patients undergoing surgery than in those without cancer, and, as a consequence, among hospitalized cancer patients who die, one in every seven do so from PE. Also, when cancer patients develop a thrombotic event, they have a three-fold increased risk of recurrence, even years after the first VTE episode. Compared with similar patients without malignant disease, cancer patients have twice the incidence of bleeding during anticoagulant treatment. Furthermore, the development of VTE is independently associated with lower survival rates. At the same time, there is growing evidence that the use of anticoagulants lowers the risk of death; however, this hypothesis requires further research.

With regard to preventing thromboembolic disease in cancer patients, the patients who have been studied most often are those undergoing surgical intervention for their cancer. Low-dose UFH and LMWH are effective in preventing both DVT and fatal PE in general and in oncological surgical patients undergoing laparotomy. It has been demonstrated that cancer itself is a risk factor for the development of perioperative bleeding complications independent of pharmacological thromboprophylaxis type.

Cancer patients admitted to the hospital but not undergoing surgical intervention should be treated as other acutely ill hospitalized medical patients and provided with thromboprophylaxis when appropriate. The use of routine anticoagulation for patients with central venous catheters is no longer recommended. Although older studies suggested that the use of low-dose vitamin K antagonist or LMWH was associated with a benefit in reducing the frequency of thrombosis associated with central catheters, some more contemporary studies with the same agents fail to demonstrate a benefit.

At least three major guidelines for thromboprophylaxis in cancer patients have been published in recent years—the European Society for Medical Oncology, the American Society of Clinical Oncology, and the American College of Chest Physicians, 8th edition—and may help physicians in their clinical practices. Some of the key points about primary prophylaxis in cancer patients are as follows:

- LMWH, low-dose UFH, and vitamin K antagonist are not routinely indicated to prevent catheter-related thrombosis or during chemotherapy, if patients are ambulatory, except in multiple myeloma patients receiving thalidomide or lenalidomide or dexamethasone.
- Routine use of VTE prophylaxis with low-dose UFH or LMWH or fondaparinux in cancer patients undergoing medium and large surgical procedures is recommended.
- VTE prophylaxis should be maintained for at least 7–10 days and considered for up to 28 days in curative pelvic and abdominal cancer procedures.
- Routine use of prophylaxis should be considered in cancer patients hospitalized with an acute medical illness.

Managing anticoagulation in patients undergoing surgical procedures: diminishing bleeding and ischemic risks

Excessive bleeding leads to early instability and postoperative complications, and blood transfusion is clearly related to late mortality after cardiac surgery. Measures to prevent bleeding and avoid blood transfusion are very important to improve surgical outcomes. Preoperative anticoagulation and antiplatelet therapy comprise one of the six major risk factors for prediction of surgical bleeding.

Consequently, there are two situations in which coagulation status must be managed prior to surgical procedures to diminish bleeding and ischemic risk: in patients using an anticoagulation agent and in those receiving dual antiplatelet therapy. Aspirin is not a problem anymore. Although in the past it was recommended to cease aspirin use 3–5 days prior to surgery, this is no longer the case as guidelines now recommend that aspirin be administered prior to CABG because it has been shown to be related to better surgical outcomes. Thus, aspirin may be avoided only before special surgical procedures such as ophthalmic or intra-cerebral procedures.

Anticoagulants

Warfarin is by far the most widely used anticoagulant. In some regions, fenprocoumon is preferred because of its longer half-life. Newer agents, such as dabigatran, apixaban, and rivaroxaban, for example, have not yet been completely incorporated into the routine clinical armamentarium. Anticoagulants are mostly used for preventing arterial and pulmonary embolism in atrial fibrillation, for implanted mechanical valves, DVT, and PE. The main advantages of the newer anticoagulants are that they do not require monitoring and have a shorter half-life, which could facilitate management around the time of a surgical procedure. But there is very limited published evidence regarding those new drugs in surgery.

Warfarin might not be interrupted for low-risk endoscopic procedures. For patients at high risk for thrombosis who undergo procedures with low bleeding risk, it is recommended to stop use 3–5 days preoperatively. When the thrombosis risk is high and there is also high bleeding risk, it is recommended to stop warfarin 3–5 days preoperatively and monitor the INR. In the presence of an implanted mechanical heart valve, there is need to employ a bridge therapy prior to surgery, interrupting warfarin and introducing unfractionated or low-molecular-weight heparin until the moment of the procedure, and restarting warfarin the day after surgery. In this setting, a practical approach to perioperative anticoagulation would be: Discontinue warfarin 5 days preoperatively if INR is between 2 and 3 and for 6 days if INR is between 3 and 4.5. Observe that aging is associated with a slow resolution of anticoagulant effect.

Antiplatelet drugs

As already mentioned above, earlier guidelines recommended interruption of aspirin use some days prior to any operation. This is no longer true, especially in cardiac surgery, because with modern management, bleeding is seldom related to aspirin administration. Current guidelines do not recommend aspirin interruption, and the recently published American College of Cardiology/American Heart Association guideline for CABG surgery includes a Class I recommendation for the administration of aspirin in patients who are not taking it and who are undergoing CABG because it is related to better surgical outcomes.

Thienopyridines are related to postoperative bleeding and should be avoided or require specific management during the perioperative period. Because there are some different characteristics between the two most commonly used drugs of this class, they will be commented on separately below:

Clopidogrel

This is the most widely used ADP $P2Y_{12}$ inhibitor. Because its effect on platelets is irreversible, its use must be interrupted 5–7 days preoperatively, providing sufficient time for the platelet population to be renewed. The impact of exposure to clopidogrel in patients with ACS requiring coronary artery

bypass surgery was studied in a multicenter analysis for the end points of reoperation, major bleeding, and length of hospital stay. It was found that the adjusted risk for reoperation was 9.80 (95% CI: 2.18–43.95; $P = 0.01$) in the clopidogrel patient group. Interestingly, the management of patients undergoing CABG on clopidogrel seems to be improving, as bleeding and associated mortality have been reduced in recent reports as compared with the last two decades. There is variability in the patient's response to clopidogrel, due to genetic characteristics. For this reason, some would argue that there is a place for point-of-care testing to evaluate its action in the individual patient, although there is no formal recommendation for such testing. More studies to clarify the role of these tests in this setting are warranted.

Prasugrel

As with clopidogrel, this drug irreversibly binds the ADP $P2Y_{12}$ receptor. It has not been used as frequently as clopidogrel because it was more recently approved for clinical use. The Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction (TRITON–TIMI) found it to be rather efficacious despite a higher bleeding tendency in ACS. In patients receiving CABG, however, prasugrel was related to a 21.9% incidence of surgical bleeding, compared with 4.1% related to clopidogrel. It is reasonable to recommend stopping prasugrel for at least 7 days prior to CABG and to take special precautions to prevent perioperative bleeding.

Ticagrelor

This drug has some advantages over the above-mentioned thienopyridines because its effect is reversible and diminishes within 48 h, so that major surgical procedures can be done without fear of excessive bleeding. In the PLATO trial for ACS, ticagrelor was related to reduction of vascular death and MI but not stroke, compared with clopidogrel. There is little clinical evidence regarding the impact of ticagrelor on surgical outcomes. In a recently published analysis comparing ticagrelor with clopidogrel in the PLATO trial, among patients receiving CABG for whom ticagrelor/placebo was to be withheld for 24–72 h and clopidogrel/placebo for 5 days preoperatively, there was reduced cardiovascular and total death without an increase in major bleeding in the ticagrelor group.

Perioperative management in patients under dual antiplatelet therapy

As aspirin can be safely maintained during the surgical period, management is focused on the second antiplatelet drug. Taking clopidogrel as the paradigm drug and adjusting management for the others drugs, general measures can be summarized as below.

It is recommended as Class I in Society of Thoracic Surgeons (STS)/Society of Cardiovascular Anesthesiologists (SCA) guidelines to stop medications that inhibit the platelet $P2Y_{12}$ receptor before operation to decrease bleeding events. The timing of discontinuation depends on the pharmacodynamic half-life for each agent, as well as the potential lack of reversibility.

European Society of Cardiology/European Association for Cardio-Thoracic Surgery guidelines state that, for preoperative management of patients treated with dual antiplatelet therapy and considered for cardiac and non-cardiac surgery, one should proceed as follows: (1) emergent case: proceed to surgery; (2) semi-elective and urgent: "case-by-case" clinical decision; (3) elective: wait until completion of mandatory dual antiplatelet regimen. The decision-making process should balance the risk of thrombosis against the risk of bleeding, leading to continued use of aspirin + clopidogrel in low bleeding risk cases and continued use of aspirin but stopping of clopidogrel or even of both drugs in high bleeding risk cases.

The above-mentioned large meta-analysis on safety of clopidogrel being continued until CABG in ACS proposes an algorithm: (1) For stable elective CABG with no drug-eluting stent: stop clopidogrel for >5 days; (2) For stable elective CABG in the presence of drug-eluting stent implanted for <1 year: consider operating on clopidogrel or switch to IV tirofiban plus heparin as a bridge to surgery; (3) For non-elective CABG in emergent or urgent ACS: operate on clopidogrel, unless it is a reoperation, there is a bleeding disorder, or troponin is negative, favoring a multidisciplinary decision.

Lysine analogues, epsilon-aminocaproic acid, and tranexamic acid are very useful as they reduce total blood loss and decrease the need for blood transfusion during cardiac procedures and are indicated for blood conservation as Class I (Level A) in STS/SCA guidelines. Their effect is beneficial, even in routine CABG cases, for reducing postoperative thorax blood drainage. It might be advisable and is accepted in some centers for emergency ACS patients facing an intervention to avoid antiplatelet drugs until an anatomical coronary arteries diagnosis is obtained for deciding to proceed with a percutaneous intervention or surgery, or even excluding a non-coronary cause, such as aortic dissection, maintaining free use of aspirin and heparin.

Finally, some practical management tips based on surgical experience and previous literature are listed below:

- If possible, delay surgery for 3–5 days (clopidogrel or prasugrel) or 2–3 days (ticagrelor) if the patient is

relatively stable, balanced against severity and instability.
- If the patient is stable but the lesion is critical, give IV UFH until the effect of the antiplatelet drug wears off.
- No prophylactic preoperative transfusion of blood products.
- Do not stop heparin and give a full dose of heparin before bypass.
- Use tranexamic acid 10 mg/kg before surgical incision, plus 10 mg/kg on beginning of bypass.
- Generously use platelet transfusion after administration of protamine if diffuse bleeding, 0.2 units/kg.
- In the post-operative period, proceed to judicious surgical re-exploration, platelets infusion, and tranexamic acid when needed.
- Use reduced hemo-dilution under normothermia, modified ultrafiltration; minimize cardiopulmonary bypass circuits and priming.
- Employ good operative technique, including topical hemostasis, plus sealants or biological glues.
- Improve blood salvage methods and neutralize heparin with protamine on a titration basis.

Venous thromboembolism in heart failure patients: how should we manage this special population?

Venous thromboembolism and congestive heart failure (CHF) are among the most commonly encountered medical conditions, particularly in the elderly and hospitalized population. It is well recognized that CHF patients develop a hypercoagulable state that involves abnormalities in all three components of the Virchow's triad, which places these patients at an increased risk for VTE. Unfortunately, VTE has generally been regarded to be an end point of secondary importance in large, randomized CHF trials, and therefore, its actual incidence in this population has not been well studied.

Multiple autopsy studies have confirmed a very high prevalence of VTE in CHF patients. A case-controlled study has also shown that CHF is an important risk factor for VTE in ambulatory outpatients and that the risk progressively increases with worsening of the ejection fraction. Large, randomized CHF trials have suggested in retrospective analyses that the incidence of PE in mildly symptomatic ambulatory patients is probably low (<1%/year). On the other hand, hospitalized CHF patients with impaired mobility have an incidence of VTE as high as 21%, although most of the events are asymptomatic distal DVT. In a recent prospective study involving severe CHF patients admitted to a coronary care unit, PE was diagnosed in 9.1% during the hospitalization period, despite adequate prophylaxis in 70% of the cases. It is also important that PE patients with CHF have a higher mortality than those without CHF, and that PE is an independent predictor of death and rehospitalization in CHF patients.

The diagnosis of VTE in CHF patients is an increasingly frequent and challenging problem. There is a substantial overlap in symptoms and signs of both conditions, and some of the diagnostic tests for VTE do not perform as well in the heart failure population. D-dimer levels are already elevated in the majority of CHF patients; thus, its utility for suspected VTE in this population is severely compromised. Lung scintigraphy is often non-diagnostic, but computed tomography maintains its accuracy and is the preferred imaging test to evaluate suspected PE in CHF patients. The therapeutic options in CHF patients with VTE are the same and include the commonly used anticoagulants, fibrinolytics, and catheter or surgical embolectomy. Nonetheless, comorbidities, numerous medications, and renal dysfunction—all commonly seen in CHF patients—pose serious challenges to the management of patients with PE.

In summary, CHF is an important risk factor for VTE, with an incidence that varies widely from <1% to 20% depending on the severity of the disease and the clinical context. Both conditions negatively affect each other's prognosis, and therefore a high index of suspicion should be maintained in patients presenting with decompensated CHF. The preferred method for confirming and excluding the diagnosis of PE in the CHF population is the computed tomography scan. Treatment should be promptly initiated once the diagnosis is suspected, and careful attention should be paid to the choice, dosing, and management of antithrombotic therapy, as several physiologic abnormalities place these patients at a particularly high risk of bleeding complications.

Anticoagulation in atrial fibrillation: an important issue

Atrial fibrillation strokes are associated with a 30-day mortality of 24%. Warfarin has been shown to reduce the risk of stroke by 66%. Despite its proven efficacy, warfarin is underused in clinical practice. The dose response of warfarin is affected by age, sex, weight, liver function, dietary vitamin K, drugs, and pharmacogenomic factors. The narrow therapeutic window, coupled with a highly variable dose response, mandates frequent monitoring of the INR, which poses a barrier to warfarin's effectiveness in clinical practice. Several alternatives to warfarin have been evaluated in clinical trials. The first, dabigatran, is a direct oral thrombin inhibitor. Both rivaroxaban and apixaban inhibit factor Xa. All three of these agents reduced the risk of stroke (composite end point of ischemic and

hemorrhagic stroke) among patients with AF. The reduction in intracranial hemorrhage is unprecedented and is one of the most remarkable features of these drugs. Apixaban and the lower dose of dabigatran (110 mg) also reduced major extracranial bleeding compared with warfarin. These new oral anticoagulants are characterized by shorter half-lives compared with warfarin, do not require monitoring, and have fewer drug interactions. The degree of renal clearance is an important distinguishing feature of these drugs, as is the dosing frequency. Approximately 80% of dabigatran is eliminated by the kidneys, 66% of rivaroxaban (36% as unchanged drug), and 25% of apixaban. Both dabigatran and apixaban are dosed twice daily, and rivaroxaban is taken once daily.

Translating the efficacy of the novel anticoagulants from randomized trials into clinical practice will require heightened vigilance around medication adherence and changes in renal function. Creatinine clearance needs to be measured prior to initiation of these agents and then periodically throughout the duration of therapy. Although drug interactions are significantly less common with the new anticoagulants compared with warfarin, all are substrates of the P-glycoprotein (P-gp) transporter, so the potential for interaction with P-gp inhibitors and P-gp inducers exists. In addition, both apixaban and rivaroxaban are metabolized via CYP3A4. The short half-life and rapid onset of action obviate the need for perioperative bridging in most instances, but also highlight the importance of hemostasis prior to initiation following invasive procedures. The safety of these agents in combination with dual antiplatelet therapy warrants further study. In addition, data are needed regarding reversal of these anticoagulants in the setting of trauma, urgent surgery, and major hemorrhage. The ability to monitor the anticoagulant effect in select clinical situations remains a priority for real-world practice. The new oral anticoagulants represent a major advance in the prevention and treatment of thromboembolic disease. Current and planned studies will continue to inform their optimal use.

Stroke and bleeding in atrial fibrillation: how should we assess them?

The prevalence of AF in the United States is expanding rapidly. By 2050, estimates project that there will be over 5 million Americans with AF. Patients with both paroxysmal and persistent AF face elevated risks for stroke and systemic emboli. This risk can be successfully mitigated if patients are treated with chronic anticoagulation, yet use of such therapy can also cause serious bleeding events including intracranial hemorrhage and even death. Thus, selection of anticoagulant therapy should ideally be individualized, guided by a patient's specific risks for stroke with AF and bleeding with anticoagulation.

These risks can now be accurately estimated used several published risk prediction models. The $CHADS_2$ risk score uses a simple additive sum of five clinical features (CHF, hypertension, age $\geq$ 75 years, diabetes, and stroke [weighted = 2]) to stratify risk for stroke in AF. The $CHAD_2$-VASc score extends this simple risk score by adding in three additional risk factors: vascular disease, age 65–75 years, and sex = female). This modification provides for slightly more accurate risk estimation, particularly among lower-risks groups. Clinical trials have demonstrated that the benefits of warfarin therapy are linearly associated with patient risks. Based on these data, current U.S. and European guidelines recommend initiation of anticoagulation in all patients with moderate-to-high stroke risk.

The risks of bleeding with warfarin therapy are also associated with certain patient-related risk factors, which can be summated using published risk scores. These include the HAS-BLED, ATRIA, and HEMORR2HAGES bleeding risk scores. While these scores can stratify risk, the scores are often based on retrospective factors (such as labile INR results), thereby limiting their use in prospectively selecting a given patient for drug initiation. These bleeding scores also unfortunately demonstrate that many patient factors associated with stroke risk (including age, hypertension, and stroke) are also risk factors for bleeding. For example, the choices for anticoagulation therapy in older patients with multiple comorbidities will require a trade-off of high benefit and high risks.

The individualization of therapy does not end with these risk factors but is also determined, in part, by provider and system factors. For example, concomitant medications can also raise a patient's risk for bleeding. Specifically, combining use of aspirin and/or an ADP-inhibitor with warfarin can substantially raise a patient's risk for bleeding. Additionally, the effective and safe therapeutic window for warfarin therapy is narrow. Therefore, close patient monitoring and appropriate dose titration are needed to achieve optimal results. However, data indicate that this is rarely achieved in current U.S. clinical practice, where patients on warfarin are within the recommended therapeutic range less than 55% of the time. Newer anticoagulant therapies, including the direct thrombin inhibitor (dabigatran) and the new factor Xa inhibitors (apixaban and rivaroxaban), offer the promise of reducing anticoagulation-related bleeding risks, particularly the dreaded risk of intracranial hemorrhage. Yet, while these novel drugs may not require such careful therapeutic titration, patients must still closely and continuously adhere to instructions for the drugs to be safe and effective. These later points emphasize the importance of considering patient, provider, and system factors when

selecting AF treatment, as well as highlight future opportunities for quality improvement in AF care.

Triple therapy

Overlapping indications for antithrombotic therapy may lead to the need for "triple therapy," defined currently as aspirin, clopidogrel, and oral anticoagulation.

As the population ages, more patients will have both ACS and AF; accordingly triple therapy may be used more frequently. Prior studies have shown that, with more antithrombotic therapy, risk of bleeding increases. Many antiplatelet and anticoagulant drugs are part of the foundation for treatment of ACS and AF, making the decision about the right combination of these agents challenging. However, limited evidence is available to guide therapeutic decision-making about triple therapy. Registry information, subgroup analyses from clinical trials, and overviews of single-center experiences have been published, but no randomized trials evaluating different strategies of triple therapy have been completed.

Multiple guidelines and consensus statements from national societies provide recommendations for clinicians concerning the use of triple therapy. A simple flow diagram can be used by physicians to guide decisions about the need for dual antiplatelet therapy or triple therapy based on the assessment of patient bleeding and stroke risk. Five additional factors should be considered: (1) use of the lowest dose of antiplatelet therapy; (2) use of bare metal stents versus drug-eluting stents to minimize the duration of antiplatelet therapy; (3) optimal INR within a range of 2.0–2.5; (4) gastric protection with proton-pump inhibitors; and (5) minimization of the duration of triple therapy. It is also important to re-evaluate regularly the need for triple therapy. The risk of stent thrombosis will decrease over time, whereas bleeding risk will remain constant.

The ongoing What is the Optimal Antiplatelet and Anticoagulant Therapy in Patients with Oral Anticoagulation and Coronary Stenting (WOEST) trial is a prospective, multicenter, open-label randomized trial that aims to determine whether the combination of oral anticoagulants and clopidogrel 75 mg/d reduces the risk of bleeding and is not inferior to triple therapy (clopidogrel + oral anticoagulants + aspirin) with respect to the prevention of thrombotic complications. The primary outcome of the study will be the occurrence of bleeding up to 30 days and one year. Major adverse cardiac events will be the secondary outcomes. Sample size is 496, and the estimated study completion date is October 2011 (www.clinicaltrials.gov, NCT00769938).

The Triple Therapy in Patients on Oral Anticoagulation After Drug-Eluting Stent Implantation (ISAR-TRIPLE) study, an interventional, randomized, open-label trial, was designed to compare the six-week versus six-month clopidogrel treatment regimen in patients with concomitant aspirin and oral anticoagulants following drug-eluting stenting. The composite of death, MI, definite stent thrombosis, stroke, or major bleeding will be the primary outcome. The secondary outcomes will be the composite of cardiac death, MI, stent thrombosis, or ischemic stroke, as well as major bleeding complications. Estimated enrollment is 600, and the completion date is July 2012 (www.clinicaltrials.gov, NCT00776633). These two studies will also provide important insights about the use of triple therapy in clinical practice.

The optimal antithrombotic strategy for patients with ACS and AF who do or do not undergo PCI is still uncertain. Based on the available data, triple therapy offers the best protection against stroke and myocardial events but at the cost of increased bleeding. Currently, triple therapy defined as aspirin plus clopidogrel plus warfarin should be administered for the shortest period possible. Triple therapy may be redefined in the near future with new $P2Y_{12}$ inhibitors such as prasugrel and ticagrelor, newer antiplatelet agents such as PAR-1 inhibitors, other oral factor Xa inhibitors such as rivaroxaban or apixaban, and antithrombin agents such as dabigatran.

Recent data suggest that some new antithrombotic agents under development have significant potential to improve anticoagulant therapy. Their uptake and use will depend mostly on efficacy, safety, and cost relative to current medications. Moreover, a careful balance of antithrombotic efficacy and bleeding risk is now recognized as essential. Forecasting the death of vitamin K antagonists such as warfarin may be still premature, however. How to apply therapies, even when they have been shown to provide benefits in trials, will continue to be a major challenge in clinical practice. Finally, the optimal duration of triple therapy use and the population that may benefit the most from it also need to be defined.

How to manage anticoagulation in AF patients undergoing cardioversion

The reversion of an abnormal heart rhythm to its normal state was first described by Bernard Lown in 1961. The initial experience with cardioversion of ventricular and supra ventricular arrhythmias, including atrial fibrillation and atrial flutter, was furthered by several clinicians practicing at prominent institutions, who documented successes and potential complications, among them systemic embolism and stroke.

Guidelines for the management of AF and atrial flutter to include the peri-cardioversion period have been

formulated by national and international organizations and underscore the importance of anticoagulant therapy to minimize the risk of cardioembolic events that can be life-threatening or life-altering. While either IV or oral anticoagulants can be used as thromboprophylaxis for patients undergoing cardioversion, there are two fundamental tenets of effective therapy. First, a sufficient intensity of anticoagulation must be achieved at the time of the procedure. Second, a threshold level of anticoagulation must be maintained during a vulnerable period of varied duration after successful restoration of normal sinus rhythm.

The limitations of bleeding risk prediction rules in clinical practice

Clinicians prescribe anticoagulant therapy when they decide that the risks of such therapy (major bleeding) are outweighed by its benefits (thrombosis prevention). Estimating the benefits of anticoagulation is relatively straightforward, especially in patients with AF, where the widely accepted $CHADS_2$ score correlates well with annual stroke risk. To help clinicians determine the trade-offs associated with anticoagulation, several groups have derived prediction models that use patient characteristics to stratify an individual's annual risk for major bleeding. Although the development of these bleeding risk prediction models has helped clinicians by identifying factors (e.g., concomitant antiplatelet therapy, anemia, renal/hepatic failure, history of stroke) that are independently associated with an increased risk of warfarin-associated major bleeding, the models themselves are of limited value in clinical practice for a number of reasons. First, the majority of patients with AF stand to gain so much benefit (by reducing the risk of ischemic stroke) from warfarin that almost no calculated risk of bleeding should preclude a trial of anticoagulation. But even for the minority of AF patients whose absolute stroke risk reduction from warfarin is low (e.g., $CHADS_2$ score = 1), where these bleeding risk calculators seem more applicable, their use is impractical. All bleeding risk models estimate the annual likelihood that a patient will experience major bleeding. Unlike AF-related stroke (which is fatal or severely disabling more than 50% of the time), the "major bleeding" predicted by these models represent clinical events within a spectrum that includes both simple blood transfusion as well as fatal intracranial hemorrhage. Because warfarin-related major bleeding is fatal in fewer than 10% if cases, it is difficult to know how to weigh the information generated by a bleeding prediction model against the benefit of reducing the risk of ischemic stroke.

Even if the trade-offs were more straightforward, several of these bleeding risk scores are, unlike the $CHADS_2$ score, difficult to remember and/or calculate. In the case of the HAS-BLED score, we must know whether the patient has "labile INR values"—this is information that cannot be known to the clinicians who are trying to decide whether to initiate warfarin treatment. In the case of the model published by Shireman, the equation used to define bleeding risk is so complicated that the authors admit clinicians would be unable to commit it to memory. Other models are incomplete: the ATRIA bleeding risk score does not account for concomitant antiplatelet therapy, a factor known to increase the risk of warfarin-associated major hemorrhage more than two-fold. Finally, none of the new oral anticoagulants being studied (or recently approved) for stroke prevention in AF has been evaluated by these bleeding prediction models.

In summary, there is no doubt that the benefits of anticoagulant therapy must be balanced against the risk that they might cause major bleeding. That notwithstanding, for the reasons outlined above, the currently available bleeding risk scores/models have limited utility in everyday clinical practice.

Thromboprophylaxis for medical patients: should it be the default?

Medical thromboprophylaxis reduces the risk of DVT, PE, and fatal PE. There is excellent quality evidence that medical prophylaxis is under-prescribed, resulting in otherwise avoidable episodes of VTE. Use of medical prophylaxis has been endorsed by numerous peer organizations and is the focus of initiatives such as Required Organizational Practices of Accreditation Canada (http://www.accreditation.ca/uploadedFiles/ROP%20Handbook.pdf, accessed November 14, 2011).

However, it is clear that not all medical patients require thromboprophylaxis. Some patients have contraindications to anticoagulant therapy (such as those who have active bleeding and those with severe acquired or congenital bleeding disorders). Mechanical forms of prophylaxis (such as intermittent pneumatic compression devices or graduated compression stockings) might be used in such patients; however, their efficacy has never been tested in well-performed prospective studies. Extrapolating from other situations, mechanical prophylaxis reduces the risk of VTE but is associated with the potential for toxicity, including reduced mobilization, spread of infection, and skin ulceration. Mechanical forms of prophylaxis are also poorly tolerated by most medical patients.

More importantly, and the focus of recent evidence, is the observation that many patients in the hospital are at very low risk of VTE. When prophylaxis is administered to these patients, it results in the potential for toxicity

(bleeding and heparin-induced thrombocytopenia), as well as expense with little likelihood of benefit (because the background rate of VTE is sufficiently low so that it is unlikely to be lowered further by therapy).

There is no doubt that all patients admitted to the hospital should receive consideration for the administration of anticoagulant prophylaxis or mechanical prophylaxis. Adherence to this recommendation will be an enhanced by the use of preprinted orders, computerized prompting, and a multidisciplinary approach to care wherein multiple individuals take responsibility for ensuring the provision of optimal prophylaxis. When patients are considered to be at sufficiently low risk, then documentation of the rationale for non-administration of prophylaxis should be provided. This could take the form of a note in the chart or a specific notation in the computerized order entry system discussing why prophylaxis is not being administered.

Various authors have attempted to provide guidance for clinicians with respect to patient selection for prophylaxis. In a widely referenced paper, Dr. Charles Francis has proposed that a combination of age more than 40 years, anticipated limited mobility of three or more days, and at least one other risk factor provide sufficient likelihood of VTE to warrant prophylaxis. Conditions associated with increased risk include, but are not limited to, CHF, MI, stroke, inflammatory bowel disease, and a history of previous VTE, recent surgery, trauma or immobilization, obesity, central venous catheterization, known acquired or inherited thrombophilic states, and, potentially, estrogen therapy. Patients meeting three or more criteria should probably receive prophylaxis. In many hospitals, this will encompass nearly all patients; however, there remains a small subset of patients who do not meet criteria and who probably have a sufficiently low risk of VTE that the use of antithrombotic prophylaxis cannot be justified.

The case against routine prophylaxis was probably most compellingly made by Barbar and colleagues in a recently published paper. One thousand one hundred and eighty consecutive patients were followed after admission to an internal medicine service for the development of VTE over 90 days. A previously validated scoring system was used to assign patients to various risk classes for the development of VTE. Fully 711 patients were found to have a low risk of venous thromboembolism, of whom 659 (93%) did not receive any VTE prophylaxis. Among the 711 patients, there were two clinically apparent episodes of venous thrombi embolism, one occurring in the 659 patients who did not receive prophylaxis and one occurring in the 52 patients who did. These observations argue compellingly against the use of routine prophylaxis because the administration of routine heparin or LMWH to the 659 patients would have exposed them to the potential for toxicity without hope of further reducing the very low risk of VTE observed in this study. There is absolutely no doubt that bleeding rates would "swamp" the potential benefit of a reduction in the rate of VTE.

In summary, the administration of pharmacologic or mechanical thromboembolism prophylaxis is a critical consideration for all patients admitted to the hospital. Many patients harbor significant risks for venous thromboembolism, and all such patient should be treated with effective forms of pharmacologic prophylaxis. However, a significant proportion of patients will have a sufficiently low risk of VTE that the risks and costs of pharmacologic and mechanical prophylaxis cannot be justified; in such patients, documentation of the rationale for the omission of therapy is required, but venous thromboembolism prophylaxis should consist simply of aggressive mobilization and early discharge from the hospital.

Acknowledgments The Fourth International Symposium of Thrombosis and Anticoagulation (ISTA) was sponsored by unrestricted grants from AstraZeneca, Boehringer Ingelheim, Bristol-Myers Squibb, and Daiichi Sankyo. The symposium was organized by the Brazilian Clinical Research Institute, and the chairmen of the meeting thank Cecilia Jahnel, Fabio Villas Boas, and Jadelson Andrade for all of their assistance in organizing the event.

STATE-OF-THE-ART

Thermal protection of the newborn in resource-limited environments

K Lunze[1] and DH Hamer[2,3,4,5]

[1]Preventive Medicine, Department of Medicine, Boston University School of Medicine, Boston, MA, USA; [2]Center for Global Health and Development, Boston University, Boston, MA, USA; [3]Department of International Health, Boston University School of Public Health, Boston, MA, USA; [4]Section of Infectious Diseases, Department of Medicine, Boston University School of Medicine, Boston, MA, USA and [5]Zambia Centre for Applied Health Research and Development, Lusaka, Zambia

Appropriate thermal protection of the newborn prevents hypothermia and its associated burden of morbidity and mortality. Yet, current global birth practices tend to not adequately address this challenge. Here, we discuss the pathophysiology of hypothermia in the newborn, its prevention and therapeutic options with particular attention to resource-limited environments. Newborns are equipped with sophisticated mechanisms of body temperature regulation. Neonatal thermoregulation is a critical function for newborn survival, regulated in the hypothalamus and mediated by endocrine pathways. Hypothermia activates cellular metabolism through shivering and non-shivering thermogenesis. In newborns, optimal temperature ranges are narrow and thermoregulatory mechanisms easily overwhelmed, particularly in premature and low-birth weight infants. Hyperthermia most commonly is associated with dehydration and potentially sepsis. The lack of thermal protection promptly leads to hypothermia, which is associated with detrimental metabolic and other pathophysiological processes. Simple thermal protection strategies are feasible at community and institutional levels in resource-limited environments. Appropriate interventions include skin-to-skin care, breastfeeding and protective clothing or devices. Due to poor provider training and limited awareness of the problem, appropriate thermal care of the newborn is often neglected in many settings. Education and appropriate devices might foster improved hypothermia management through mothers, birth attendants and health care workers. Integration of relatively simple thermal protection interventions into existing mother and child health programs can effectively prevent newborn hypothermia even in resource-limited environments.

Keywords: newborn; neonatal; hypothermia; thermal protection

Introduction

The need for thermal newborn protection has long been known, as alluded to by Soranus of Ephesus (98 to 138 AD) in his four-volume treatise 'On Diseases on Women', which demonstrates the importance of keeping newborns warm.[1] The Bible provides probably the most well-known example of thermal protection of the newborn in Luke 2: 7, 'And she brought forth her firstborn son, and wrapped him in swaddling clothes, and laid him in a manger.'

Yet, in current times, the majority of the almost 4 million newborns globally who do not survive their first month of life[2] die of complications associated with hypothermia, such as prematurity and severe infections (mostly sepsis and pneumonia).[3] As two recent reviews have acknowledged, neonatal deaths related to hypothermia are relatively neglected, but considered easily preventable with attention to warmth, feeding and infection management.[4,5] This article focuses on the diagnosis of hypothermia and management of thermal protection of newborns in low-resource environments. We review mechanisms of neonatal thermoregulation, discuss the pathophysiology of newborn hypothermia and present simple strategies of thermal protection for the newborn.

Neonatal thermoregulation

The normal body temperature of a newborn infant is usually defined as ranging between 36.5 and 37.5 °C (97.7 to 99.5 °F).[6] A series of observational randomized trials starting in the late fifties[7,8] showed that keeping babies warm reduces mortality and morbidity, and spurred further research on the pathophysiology of thermoregulation in newborns. Thermoregulation is a biological priority for all homeothermic species.[9] Newborns, particularly preterm and low-birth weight (LBW) infants, have limited capacity for thermoregulation during the first weeks of life. The optimal environmental temperature is termed thermal neutral temperature, at which metabolic requirements of the organism are minimal.[10] Both a decreased and an increased core temperature increase the metabolic rate of newborns,[11] who have only very limited ability to maintain a normal temperature and easily become hypothermic or hyperthermic. Although hyperthermia also increases energy needs, hypothermia seems to carry a higher risk of complications.[12]

When the infant's body temperature decreases in response to sudden exposure to cold extrauterine environments, signals from peripheral and central thermoreceptors reach the hypothalamus through afferent pathways.[13] The resulting norepinephrine release then triggers nonshivering thermogenesis, or lipolysis of brown adipose tissue, which is the main homeothermic heat production mechanism in newborns. Heat production occurs through uncoupling ATP synthesis via the oxidation of fatty acids in the mitochondria, utilizing uncoupled protein.[14]

Afferent temperature information is processed in the hypothalamus. Thermoregulation requires an intact central nervous system,[15] and impaired thermoregulation, either hypo- or hyperthermia, can be indicators of central nervous system damage. The hypothalamus has a central role in regulating the autonomic, somatic and endocrine systems to maintain a normal body temperature. Decreasing body temperatures trigger a release of thyroid-stimulating hormone, which leads to an increase in thyroxine and consequently triiodothyronine. The resulting norepinephrine release causes vasoconstriction, glycolysis and uncoupling of mitochondrial oxidation in the brown adipose tissue, further generating heat production.[14] The latter process is ineffective in preterm infants, because it depends on the amount of brown fat as well as levels of the enzymes 5′/3′-monodeiodinase and thermogenin, which build up only later in fetal development.[13]

Shivering is not regularly involved in a newborn's reaction to cold stress.[16] Another mechanism of heat production is infant behavior:[10] the irritable baby prompts the mother to hold the baby, drying, cuddling and swaddling him or her, thus preventing heat loss.

Newborns are unable to maintain their body temperature on their own without thermal protection. Although a newborn's thermoregulation is as complex as in adults if not more sophisticated, as discussed above, their range of optimal or even tolerable body temperature is narrower. A newborn placed naked in an environment of 23 °C at birth suffers the same cold as does a naked adult at 0 °C.[17] Without thermal protection, human neonates are functionally poikilothermic, that is, they change their body temperature according to environmental temperatures. In newborns placed in a colder environment, core temperature decreases at a rate 0.2 to 1.0 °C per minute and finally may lead to death from cessation of metabolic activities.[10]

Pathophysiology of newborn hypothermia

The World Health Organization (WHO) defines neonatal hypothermia as a temperature below 36.5 °C (97.7 °F) and proposes the following classification:[17] Mild hypothermia, caused by cold stress, is classified as a body temperature range from 36 to 36.5 °C (96.8 to 97.7 °F) and is considered a cause for concern,[17] because the exposed infant begins to lose more heat than he or she can produce.[13] Moderate hypothermia is a body temperature from 32 to 36 °C (89.6 to 96.8 °F), indicating danger and requiring warming of the baby. According to the WHO classification, a body temperature of <32 °C (89.6 °F) is considered severe hypothermia, or cold injury, with a potentially grave outcome, and needs immediate skilled attention.

Heat loss occurs in several ways. The most common scenario is that of a wet baby who is not dried, and in whom evaporation of fluid from the skin leads to heat loss. Evaporation often occurs with amniotic fluids during the first minutes of life or with water after a baby is bathed. The energy loss is substantial: immediately at delivery, when the environmental temperature surrounding the baby drops from 37 °C in the maternal womb to the usually less warm air temperature, evaporative heat loss begins at a rate of 0.58 kcal ml^{-1} fluid evaporated.[10]

A baby placed naked on a cold surface loses heat through conduction. A newborn exposed to cool surrounding air or draughts will lose heat through convection. Radiation from cool objects next to the baby (for example, a cold wall) can also lower its body temperature. Unlike in adults, sweat secretion has little or no role in the thermoregulation of a newborn or preterm baby.[18]

As all data on hypothermia are from observational studies and prospective randomized trials without treating hypothermia are not permissive, the direction of causality for factors associated with hypothermia is not entirely clear.

Some argue that lowering body temperatures might increase metabolic processes to generate heat, which could lead to hypoglycemia and hypoxia in response to increasing energy demands.[13] As hypothermia and hypoglycemia both exacerbate hypoxia, this would reinforce a vicious circle[19] and could on one hand explain the mortality associated with hypothermia. However, studies have shown that hypothermia is not a risk factor for neonatal hypoglycemia in analyses adjusted for confounders such as LBW or anemia.[20] On the other hand, hypoglycemia is common among newborns in resource-limited settings[20] and, instead of being a consequence, could rather be a cause of hypothermia.

Similarly, with regard to the reported associations of hypothermia with infections and organ failure,[21,22] hypothermia might be either a consequence or a cause of severe infections. Clinically, hypothermia is an indicator for severe infections analogous to hyperthermia, or fever. In fact, neonatal hypothermia is associated in an unclear direction of causality with various pathologies such as surfactant inactivation, increased morbidity from infection, abnormal coagulation, delayed readjustment from the fetal to newborn circulation, hyaline membrane disease and intraventricular hemorrhage in LBW infants.[23]

In contrast, mild therapeutic hypothermia has emerged as a neuroprotective strategy in the treatment of hypoxic ischemic encephalopathy. Recent randomized controlled trials have shown that therapeutic hypothermia initiated within 6 h of birth reduces death and disability in these infants.[24] Induced under controlled clinical conditions, therapeutic hypothermia has been discussed as

being beneficial and outweighing the adverse effects in term newborns with hypoxic ischemic encephalopathy[25] and during or after cardiac surgery.[26]

Neonatal hyperthermia

Heat is transferred *in utero* via the placenta through umbilical arterial blood flow and via the uterus through amniotic fluid to the fetus.[14] At birth, fetal temperature is usually 0.5 to 1.0 °C higher than the mother's[27] and increases not only with elevated maternal temperatures due to prolonged labor, prolonged rupture of the membranes or other infectious etiologies (chorioamnionitis, urinary tract infection, and so on), but also with nulliparity and epidural analgesia.[28]

The most common cause of elevation of body temperature in the newborn is dehydration.[29] Rehydration is both therapeutic and diagnostic if the newborn improves. Elevated temperatures in the neonate rarely reflect intrauterine or perinatal infections. Among the 1 to 2.5% of newborns presenting with hyperthermia, <10% have culture-proven sepsis.[10] In septic newborns, temperature instability more frequently presents as hypothermia. The exact mechanisms that lead to fever in some septic neonates and normal body temperatures in others are ill understood. Infection is thought to produce fever mediated through cytokines such as interleukin1. Antipyretics are effective in reducing the temperature by modifying the central set-point of the hypothalamus. In hyperthermia due to environmental overheating, antipyretics are ineffective, and newborns are appropriately managed by reducing the environmental heat exposure.

Central malformations and intracranial hemorrhages, or congenital pathologies such as the Crisponi syndrome,[30] are rare causes of newborn hyperthermia.

Where thermoprotective devices are used, inappropriate incubation and exposure to radiant warmers are common causes of neonatal hyperthermia,[10] especially when makeshift apparatuses such as light bulbs, hot stones, and so on, are used. These are usually not designed and tested for safety and efficiency, and we discourage their use in favor of skin-to-skin care (SSC).

Management of newborn hypothermia

Qualitative inquiries into current thermal practices

Although lack of equipment is a problem for high-risk neonates in resource-poor settings, knowledge of hypothermia diagnosis and management is another concern. For example, only about half of 160 surveyed health care professionals in India could define neonatal hypothermia correctly or considered it a significant problem, and <20% knew how to correctly record a newborn's temperature.[31] A multinational study showed that knowledge on thermal control, especially concerning the physiology of thermoregulation and criteria for defining hypothermia, was insufficient and thermal control practices were frequently inadequate.[23]

Qualitative research on newborn care can help shed light on the beliefs and attitudes underlying potentially detrimental or harmful practices. Most published studies indicate that high-risk home delivery and newborn care practices that lead to heat loss, such as insufficient heating of the birthplace, placing of the uncovered newborn on the ground or other cold surfaces, delayed wrapping—partly with unclean clothes—and early bathing, remain common in resource-limited settings both in rural and urban areas, in facilities and during home births.[5,32,33]

Heating the birthplace is a critical issue for home births. Studies from Nepal reported that the birthplace was heated in only slightly over half of the settings,[34] often only after birth.[35] Wrapping the child prevents heat loss from evaporation, whereas bathing promotes heat loss. Less than half (46%) of the babies were wrapped within the first 10 min after birth, and almost all of them were bathed within 10 min (89%) or half an hour (96%) after birth.[34] In another study, only 64% of the babies were observed to be wrapped within half an hour after birth, and almost all were bathed within 6 h after birth.[35]

In a study from Tanzania, the practice of bathing newborns immediately after delivery was shown to be motivated by concerns about 'ritual pollution'.[36] In Ghana, early bathing was linked to reducing body odor in later life, shaping the baby's head, and helping the baby sleep and feel clean, and informants felt that changing bathing behaviors would be difficult, especially as babies are bathed early in facilities.[37] A study from Dhaka, Bangladesh, explained that babies are typically bathed soon after birth to purify them from the birth process.[38] Several studies, from Uganda,[39] Ghana[37] and India[40] suggested that in the absence of health facilities prepared to deliver essential newborn care, community members would accept thermoprotective practices such as SSC.

Clinical presentation

It has been estimated that prompt recognition of hypothermia and re-warming of hypothermic infants will avert up to 40% of neonatal deaths.[41] Newborn hypothermia presents with a combination of low core temperature and cold skin, pallor (acrocyanosis), tachypnea (respiratory distress), hypotonia, lethargy or irritability, poor feeding or vomiting. The non-specific clinical presentation and the complex process of thermoregulation discussed above imply a number of differential diagnoses such as infectious etiologies, respiratory distress syndrome, intraventricular hemorrhage or other central nervous causes, hypoglycemia, endocrine causes, or (maternal) drug side effects. Other factors potentially underlying hypothermia include prematurity, cardiovascular diseases and other congenital anomalies.

Diagnosis

Initial assessment should include a history of the baby's exposure to cold and whether the baby has been appropriately clothed and protected.[18] Although a rectal digital thermometer is used in many studies as standard method to measure a newborn's core temperature, this measurement site is associated not only with discomfort and disturbance to the newborn, but also with risks such as rectal perforation and vagal stimulation with resulting arrhythmias, bradycardia and apnea.[42]

The axilla is a less invasive, alternative site that provides reasonably accurate measurements. Mercury-in-glass, gallium-in-glass, digital thermometer, analogous electric thermometer, chemical thermometer and infrared thermometer are all accurate instrument options, with the latter being less hazardous and quicker than the former.[43] Most developed institutions use tympanic thermometers, which have recently shown to be a quick and accurate method to measure a newborn's body temperature,[44] whereas simple rectal thermometers are used in most resource-limited settings. WHO recommends frequent measurements, from every hour in a seriously ill baby, two to four times per day in a small or very small baby, to once daily in an infant progressing well.[18] However, due to their cost, thermometers are often not available in low-resource environments. Moreover, illiteracy and inability to read Arabic numbers have been a challenge to thermometer use.

In the absence of a measurement device, human touch of feet and abdomen has been used as a proxy for body temperature. Studies in India and Nepal have shown human touch to be reasonably reliable for the detection of hypothermia when health workers were trained for these investigations.[45–49] Mothers, however, seem to have a far lower sensitivity than health workers. Only 24% of mothers in India were able to correctly identify hypothermia.[50]

A device based on color indicators developed to detect hypothermia without the use of thermometers was previously found to accurately indicate hypothermia when used by health workers or mothers.[51,52] Its usefulness for some parts of the developing world and the feasibility for illiterate health workers to read the device have been debated.[53,54]

Therapeutic goals of thermal care

The therapeutic goal of thermal care is to keep the newborn in the thermoneutral zone, or thermal neutrality, the environmental temperature range in which the organism has least oxygen consumption.[9] No single environmental temperature is optimal for all babies. In general, the smaller and more premature a newborn is, the less its ability to regulate cold and heat. The optimal environmental temperature thus depends on the maturity (usually estimated by the gestational age) and age of the newborn. Weight, body temperature and skin perfusion as well as clothing of the infant and air humidity also factor in, so that the optimal environmental temperature can be hard to determine. It is narrow, especially in LBW or sick babies, and generally ranges from 32 to 36 °C.[55] It follows that a temperature appropriate for a healthy term baby can be too cold for a preterm infant (and, conversely, what is appropriate for the preterm infant can be too warm for the term baby). In general, most newborns at birth, if left wet and naked, cannot tolerate an environmental temperature of <32 °C. However, if the baby is immediately dried, put skin-to-skin with the mother and covered, the delivery room temperature can be as low as 25 to 28 °C.[17]

Prevention of newborn hypothermia

WHO recognizes maintaining a normal body temperature as a primary principle of newborn care and recommends thermal protection for all infants, with special attention for sick, premature, or small for gestational age infants, for example, <2.5 kg at birth or born before 37 weeks gestation.[18] Several methods can be used for warming the baby and maintaining the baby's body temperature (Table 1). The WHO proposes a 'warm chain', a set of 10 interlinked procedures carried out at birth and during the following hours and days. To be implemented in institutions and (in an abridged form) at home, the warm chain aims to minimize the risk of hypothermia in newborns, and includes warming the delivery room, immediate drying, SSC, early and exclusive breast-feeding, postponing bathing, appropriate clothing and bedding, placing mother and baby together, and in institutions warm transportation, warm resuscitation, and training and awareness raising.[17]

WHO recommends warming the delivery place in preparation for a birth (to at least 25 °C) and to keep the birthplace free from draughts. After delivery, it is crucial to devote some attention to the baby. The first and most substantial heat loss occurs through evaporation of amniotic fluid. Therefore, at birth, recommended first steps to prevent hypothermia are to immediately dry and cover the newborn, even before the cord is cut. While being dried, the baby should be on a warm surface, preferably the mother's chest or abdomen in skin-to-skin contact. The infant should then be clothed or covered, especially the head,[56] and kept in a warm environment, again usually best with the mother. Bathing should be delayed. Draughts, cold surfaces or nearby cold sources such as windows or walls should be avoided as they contribute to heat loss via convection and radiation.

Early breastfeeding, ideally within an hour after delivery, should be encouraged if possible and if not contraindicated. SSC with the mother, for LBW infants also known as kangaroo mother care, most of the time is appropriate to ensure thermal protection of the baby.[57] It requires minimal instructions and, when culturally accepted, can relatively easily be applied even in a community or home setting.[58]

Table 1 Management of hypothermia, modified from WHO 2003[18]

Method	*Selection and use*	*Advantages*	*Risks or disadvantages*	*Availability*
SSC by mother or other person	Management of stable babies with moderate hypothermia, and for hypothermia prevention	Mother can closely monitor other person can provide SSC	Not appropriate for critical conditions	Home and institutional
Kangaroo mother care with LBW babies	Management of stable LBW babies weighing 1.5–2.5 kg, and for hypothermia prevention	Mother can closely monitor. Usually effective to maintain normal body temperature	Mother might not be available. Not for very LBW	Home and institutional
Radiant warmer, water mattress	Management of sick babies weighing $\geqslant$2.5 kg. For initial assessment, treatment and procedures; for hypothermia prevention	Allows observation of baby. Allows for procedures to be performed	Hyperthermia, dehydration. Expensive to procure, requires electricity	Institutional
Incubator	Management of sick or at-risk babies. Continuous care for babies weighing $\leqslant$1.5 kg	Maintains constant temperature and humidity. Easy provision of oxygen. Allows observation of baby (can be naked)	Hyperthermia, dehydration; microbiological contamination. Expensive to procure, maintain, clean; requires electricity. Separation of mother and child	Institutional
Warm room	Recovering babies		Hypothermia. Uncomfortable for adults	Home and institutional
Other methods (water bottles, bricks, and so on)	For emergency situations only	Not recommended	Hypothermia. Hyperthermia, burns	Home and institutional Not recommended

Abbreviations: LBW, low birth weight; SSC, skin-to-skin care; WHO, World Health Organization.

Treatment of newborn hypothermia

According to current WHO guidelines for the treatment of cold babies, moderate hypothermia should be treated by SSC.[18] In severe hypothermia, rewarming the baby with an appropriate and available method in a health care facility setting is warranted, as close monitoring of vital signs including temperature and respiratory rate are essential parts of the management. Blood glucose should be controlled and hypoglycemia under 45 mg dl^{-1} (2.6 mmol l^{-1}) should be treated accordingly. When treating for sepsis, all IV fluids should be given warm. The infant can be discharged once a stable normal temperature is sustained and there are no other issues. Upon discharge, the mother should be counseled to prevent hypothermia at home as discussed above.

There is a relative scarcity of data documenting the effects of recommended thermal newborn care. A recent meta-analysis showed that SSC in conjunction with breastfeeding and recognition of danger signs substantially reduced neonatal mortality in hospital-born preterm babies (birth weight $<$2000 g) in hospital, and was highly effective in reducing severe morbidity, particularly from infection.[59] A study from Western India, in which 36.9% of hospitalized newborns were hypothermic, reported a decrease in this rate to 3.9% with kangaroo mother care.[60] However, in many countries there is resistance from health professionals, mothers and families related to local cultural practices.[61] Although evidence on the effectiveness of SSC in community-based settings is scarce,[40,62] it is estimated that SSC can avert up to 20% of newborn deaths.[63]

In the large Gadchiroli trial in India on home-based neonatal care assessing the outcome of sepsis management, case management included thermal protection of the newborn, and health care workers were given a thermometer, baby clothes and head cover, a blanket and a sleeping bag. Although the study included other interventions and was not specifically designed to prove a particular effect for hypothermia management, it showed a reduction in neonatal and infant mortality by nearly 50% among a malnourished, illiterate and rural study population.[64] A study from Nepal that found a high incidence of hypothermia suggests that simple interventions including immediate drying and another treatment (breast contact, radiant heater and mustard oil massage, or swaddling with an inner layer of plastic wrap) could lower the incidence of hypothermia 2 h after birth from 78 to 23% and 24 h after birth from 49 to 18%.[65] In Zambia, we recently showed that training traditional birth attendants in newborn care with special emphasis on resuscitation and simple thermal protection (wiping the newborn dry and wrapping the dried infant in a separate piece of cloth) along with an intervention to provide early treatment of possible sepsis reduced mortality rates at day 28 after birth by 45%.[66]

Low-cost, low-tech treatment of newborn hypothermia

The use of incubators for thermal protection of newborns has been reported for more than 150 years, since the Parisian obstetrician Jean Louis Paul Denucé in 1857 engineered his couveuse, a device

for the care of a premature infant. In 1878, his local colleague Stéphane Tarnier, using a modified warming chamber for the rearing of poultry, found a decrease in neonatal death rate from 66 to 38% among infants with birth weights <2000 g.[67]

Today, postnatal care devices (isolettes or infant warmers) combine the features of incubators and radiant warmer beds and have evolved with many features, including automated temperature and humidity regulations,[68] oxygen supplementation and light therapy.[11,69] Although beneficial in resource-replete settings,[70] utilization of their complex features requires electricity, concentrated oxygen supply, centralized suction and ongoing skilled maintenance. Priced at about US$15 000 to $36 000,[71] these devices are not affordable for most of the developing world. Simplified versions, such as water-filled mattresses or Indian made, low-cost radiant warmers are power-dependent and not appropriate for resource-limited settings. Polyethylene occlusive skin wrapping is a useful and effective method for delivery room management,[72] but mostly limited to immediate post-delivery care and protection during transport.

A number of postnatal care devices for resource-limited settings are currently in development, some including more sophisticated temperature and humidity regulations. Examples are the 'mkat,' 'Life Raft Incubator,' and 'Neo.nurture', projected to be priced between US $200 and US $625 per unit.[73] The 'Embrace Global', projected to be priced at a US $25 price, is a life vest style incubator in a 'sleeping bag' design.[74] The heat source is a pouch-containing phase change material, which keeps its temperature relatively constant over an extended period of time. The pouch is warmed electrically or by the user simply pouring hot water into a compartment, upon indication by a thermal strip. It can fully open to double as a heat mattress. With some models electricity independent, it can be used both at the institutional and community levels, and serve as visual reminders to mothers and other caretakers, birth attendants and health care workers. Devices such as these, although more costly than education alone, might thus foster improved hypothermia management by transporting a behavioral message to the end user, for example, promoting SSC. Distributed commercially or donated, they could help to raise awareness and enhance perception of the burden of newborn hypothermia.

Conclusions

Thermal protection of the newborn can relatively easily be achieved by warming of the delivery room, immediate drying, wrapping the infant after birth and keeping him or her in close contact with the mother, that is, kangaroo mother care or SSC, immediate and frequent exclusive breastfeeding, delaying of bathing until the infant is physiologically stable, and appropriate warm clothing. These behavior steps represent simple, low-cost measures, which should be integrated into holistic mother and child health packages.

Birth practices even in high-risk environments remain poor, so that interventions must primarily focus on participatory education about hygiene, infection prevention and management, as well as practices to avoid hypothermia. Low-cost, low-technology devices might be helpful in supporting and implementing these practices. Clinical effectiveness and implementation trials will have to investigate which intervention packages and messages for the thermal protection for newborns work best in a given environment, and how to optimally integrate them into existing maternal and newborn health programs.

Age of natural menopause and atrial fibrillation: The Framingham Heart Study

Jared W. Magnani, MD,[a,b] Carlee B. Moser, MA,[c] Joanne M. Murabito, MD, ScM,[a,d] Kerrie P. Nelson, PhD,[c] Joao D. Fontes, MD,[a] Steven A. Lubitz, MD, MPH,[e,f] Lisa M. Sullivan, PhD,[c] Patrick T. Ellinor, MD, PhD,[e,f] and Emelia J. Benjamin, MD, ScM[a,b,g,h] *Framingham, Boston, and Charlestown, MA*

Background Early menopausal age is associated with risk of cardiovascular events including myocardial infraction, stroke, and increased mortality. Relations between menopausal age and atrial fibrillation (AF) have not been investigated. We examined the association between menopausal age and AF.

Methods Framingham Heart Study women ≥60 years old without prevalent AF and natural menopause were followed up for 10 years or until incident AF. Menopausal age was modeled as a continuous variable and by categories (<45, 45-53, and >53 years). We used Cox proportional hazards regression to determine associations between menopausal age and AF risk.

Results In 1,809 Framingham women (2,662 person-examinations, mean baseline age 71.4 ± 7.6 years, menopausal age 49.8 ± 3.6 years), there were 273 unique participants with incident AF. We did not identify a significant association between the SD of menopausal age (3.6 years) and AF (hazard ratio [HR] per SD 0.94, 95% CI 0.83-1.06; $P = .29$). In a multivariable model with established risk factors for AF, menopausal age was not associated with incident AF (HR per SD 0.97, 95% CI 0.86-1.09; $P = .60$). Examining categorical menopausal age, earlier menopausal age (<45 years) was not significantly associated with increased AF risk compared with older menopausal age >53 years (HR 1.20, 95% CI 0.74-1.94; $P = .52$) or menopausal age 45 to 53 years (HR 1.38, 95% CI 0.93-2.04; $P = .11$).

Conclusion In our moderate-sized, community-based sample, we did not identify menopausal age as significantly increasing AF risk. However, future larger studies will need to examine whether there is a small effect of menopausal age on AF risk. (Am Heart J 2012;163:729-34.)

Younger age at menopause has been associated with increased risk of myocardial infarction, stroke, and mortality.[1,2] In the Nurse's Health Study, menopausal age <40 years and early menopause (age 40-44 years) were associated with up to 1.5- and 1.4-fold increased risk of cardiovascular events compared with menopause ≥55 years.[3] Conversely, older menopausal age (≥53 years) has been related to decreased mortality secondary to ischemic heart disease.[4] Prospective cohort studies have further related earlier age of menopause to increased risk for all-cause mortality.[2,5,6]

Given the association between menopausal age and cardiovascular events, we sought to examine the relation between age of menopause and atrial fibrillation (AF). Atrial fibrillation has profound social and medical burdens, increasing mortality and eliminating the survival advantage that women have over men.[7] Identifying risk factors for AF in women therefore has significant public health importance.[8] To our knowledge, the association between AF and age of menopause has had limited investigation. We considered that the myriad endocrinologic and vascular changes accompanying menopause would predispose women toward increased AF risk. We consequently hypothesized an increased risk of AF for women experiencing menopause at a younger age and, in particular, that cardiac events may mediate the increased risk for developing AF.

Methods

Study sample

The Framingham Heart Study is a longitudinal, community-based study designed to investigate cardiovascular disease and its risk factors.[9] Original cohort participants were enrolled in the Framingham Heart Study starting in 1948 and attend examinations every 2 years. Offspring cohort participation started in 1971 and consists of examinations every 4 to 8 years. To have 10-year follow-up, the present study used data from women attending the original cohort examination cycles 11 (1968-1971), 17 (1981-1984), and 23 (1992-1996), and offspring cohort examination cycles 1 (1971-1975), 3 (1983-1987), and 6 (1995-1998). Participants were included in the present analysis when they reached 60 years or older. Age 60 years was used as the minimum age because women were expected to have reached menopause by that age. Before exclusions, the sample was composed of 4,159 participant examinations. Participants were excluded if they had prevalent AF (n = 180), that is, been diagnosed with AF before study entry at 60 years of age; unreliable age of natural menopause secondary to oophorectomy with or without hysterectomy (n = 1,190); unknown age of menopause (n = 1); menopausal age <40 years (deemed premature ovarian failure,[10] n = 39); estrogen use before menstrual cessation (n = 17); or lacked complete data on key AF risk factors (n = 70).

We used cross-sectional pooling to construct the data set consistent with previous Framingham Heart Study analyses of AF,[11] such that study participants without incident AF included in the analysis were eligible to reenter the analysis for subsequent 10-year intervals. Study participants were followed up prospectively for incident AF for a maximum duration of 10 years after each baseline examination. Participants provided written informed consent at each examination. Study protocols and all examination cycles were approved by the institutional review board of the Boston University Medical Center.

Clinical assessments

Participants underwent a physician-administered medical interview, history, and examination at each Framingham Heart Study examination.[12] Body mass index was calculated from weight in kilograms divided by height in square meters and systolic blood pressure as the mean of 2 seated measurements obtained during a standardized examination. Hypertension treatment was established by self-report of prescribed medications. Heart murmurs of clinical significance were scored as at least grade 3 of 6 systolic or any diastolic murmur recorded by a Framingham Heart Study physician at the standardized examination. The electrocardiographic (ECG) PR interval was calculated from the 12-lead resting ECG as previously described.[13] Heart failure was adjudicated by 3 Framingham Heart Study physicians according to established major and minor criteria.[14] Covariates were selected for inclusion in the present analysis from a previously published AF risk prediction model.[11] Atrial fibrillation was determined by presence of AF or atrial flutter on ECG or Holter monitoring obtained at a Framingham Heart Study examination, external clinician visit, or during hospitalization, and all available outside visits to clinicians for cardiovascular diagnoses. Incident AF was adjudicated by at least 2 Framingham Heart Study cardiologists.

Age of menopause

Age of natural menopause was established by a standardized, physician-administered interview at each examination. Women were queried about their menstrual status, whether periods had stopped for 1 year or more; age periods stopped, cause, defined as natural, surgical or other; history of gynecologic surgery (hysterectomy and oophorectomy, including number of ovaries removed); and use of hormone-replacement therapies. *Natural menopause* was defined as the natural cessation of menses for ≥1 year. Menopausal age was categorized as age <45, 45 to 53, and >53 years after examining the distribution of menopausal age in a prior Framingham Heart Study analysis.[15] Women with a history of surgical cessation of menstrual periods were excluded because of lack of reliability of ascertaining menopausal age, consistent with prior Framingham Heart Study analyses of menopausal age as an exposure for cardiovascular outcomes.[16]

Statistical analyses

We summarized continuous variables with means, SDs, medians, and interquartile ranges and examined distributions graphically. Distributions of categorical variables were examined by frequency. Menopausal age was modeled as a continuous measure (in years) and using categories defined by age cutpoints: <45, 45 to 53, and >53 years. Atrial fibrillation incidence rates were determined by determining the number of events per menopausal age category per 1000 person-years. The association between the SD of menopausal age and incident AF was determined by Cox proportional hazards regression analysis with censoring at 10 years. Models were adjusted for risk factors associated with AF, including body mass index, systolic blood pressure, hypertension treatment, PR interval, significant murmur, and prevalent heart failure. Age was not included in the model because of its collinearity with age of menopause. Risk factors were measured for participants entering each 10-year risk assessment at the baseline examination. We then constructed cumulative incidence curves using menopausal age as a categorical variable. A 2-sided P value of <.05 was considered statistically significant, and all analyses were conducted using SAS version 9.1 (SAS Institute, Cary, NC).

The authors are solely responsible for the design and conduct of this study, the study analyses, and the drafting and editing of the manuscript, and its final contents.

Results

The study cohort consisted of 1,809 unique Framingham Heart Study participants with 2,662 examinations. The mean age was 71.4 ± 7.6 years, and the mean age at natural menopause was 49.8 ± 3.6 years (Table I). There were 273 incident AF events in follow-up. The unadjusted incidence rates per 1000 person-years were 15.8 in the menopausal age <45 years category, compared with 11.5 and 13.3 in the menopausal age 45 to 53 and >53 years categories (P = .24 between different age categories) (Table II).

When examining menopausal age as a continuous variable, we did not observe a statistically significant

Table I. Characteristics of 2,662* participant examinations included in the analysis

Variable†	Characteristic
Age (y)	71.4 ± 7.6
Age of menopause (y)	49.8 ± 3.6
Body mass index (kg/m^2)	25.9 ± 4.9
Systolic blood pressure (mm Hg)	142 ± 22
Hypertension treatment	447 (17)
PR interval duration (ms)	164 ± 25
Significant murmur‡	142 (5.3)
Heart failure	51 (1.9)

*The 2,662 baseline examinations correspond to pooled examinations from 1,809 unique individuals.
† Data are presented as mean ± SD, or n (%).
‡ Significant murmur defined as grade 3 of 6 systolic or any diastolic murmur.

Table II. Incidence of AF from 2,662* participant examinations in eligible Framingham Heart Study women

	Total events	Incidence rate per 1000 person-years (95% CI)
Menopausal age (y) by category		
Age <45 (n = 235)	28	15.8 (9.9-21.7)
Age 45-53 (n = 2246)	206	11.5 (9.9-13.1)
Age >53 (n = 366)	39	13.3 (9.1-17.5)
Total	273	12.1 (10.7-13.5)

*The 2,662 baseline examinations correspond to pooled examinations from 1,809 unique individuals.

association between menopausal age and risk of incident AF (P = .29). Similarly, when examining menopausal age categories, earlier menopausal age (<45) was not associated with increased AF risk compared with older menopausal age >53 years (P = .52) or when compared with menopausal age 45 to 53 years (P = .11). In multivariable analysis incorporating established risk factors for AF, age of menopause was not significantly associated with incident AF in the above analyses (Table III).

The cumulative incidence curves demonstrated no significant differences in incident AF across the 3 categories of menopausal age over 10-year follow-up (Figure 1). The log-rank test did not reach statistical significance as well (P = .24).

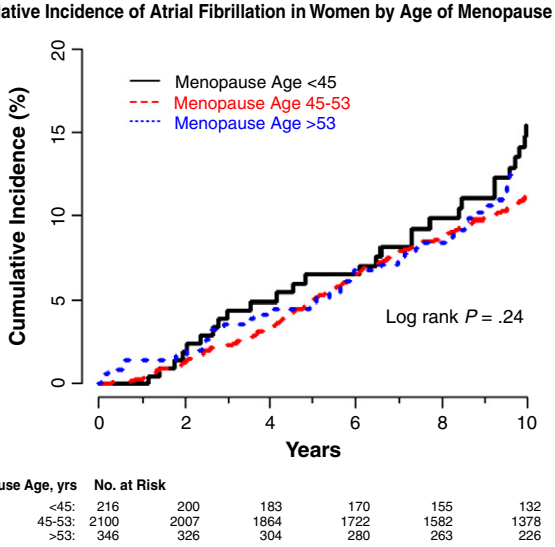
Following the above results, we conducted an analysis to determine the effect size that we were powered to detect. Assuming 80% power and given our number of observed AF events, we would have required a hazard ratio (HR) of 0.84 to observe a significant association between increasing menopausal age and decreased risk of incident AF. In contrast, our observed HR was 0.93.

Table III. Relation of age at menopause to 10-year risk of AF

Variable	HR	95% CI	P
Per SD of menopausal age			
Menopausal age	0.94	0.83-1.06	.29
Multivariable adjusted*	0.97	0.86-1.09	.60
Early menopause (<45) vs late menopause (>53)			
Menopausal age	1.20	0.74-1.94	.52
Multivariable adjusted	1.05	0.64-1.73	.84
Early menopause (<45) vs mid menopause (45-53)			
Menopausal age	1.38	0.93-2.04	.11
Multivariable adjusted	1.15	0.76-1.72	.51

The 2,662 baseline examinations correspond to pooled examinations from 1,809 unique individuals.
*The multivariable covariates are body mass index, hypertension, cardiac murmur, prevalent heart failure, and PR interval.

Figure 1



The figure shows the cumulative incidence of AF, stratified by 3 categories of menopausal age: age <45, age 45 to 53, and age >53 years. The log-rank test shows no significant difference between the 3 curves (P = .24).

Discussion

We hypothesized an association between menopausal age and 10-year risk of incident AF in a prospective, community-based cohort and, specifically, that decreased age of menopause would result in increased incident AF risk. Our hypothesis stemmed from the established association between earlier menopausal age and augmented risk for cardiovascular events.

A second rationale was the cardiovascular adaptation and remodeling by complex vascular and endocrinologic

pathways resulting from menopause.[17] Aging and cardiovascular adaptation after menopause are multifactorial processes that, in turn, yield an increased burden of clinical risk factors associated with AF. Hypertension increases in prevalence as women age,[18] is common across ethnic and racial groups,[19,20] and is a chief risk factor for AF in community-based studies.[21,22] Hypertension has been associated with increased left ventricular hypertrophy and mass in postmenopausal women[23] and increases risk for heart failure.[24] Both hypertension and heart failure are associated with AF.[25] Obesity has risen in prevalence in adults, and in the most recent National Health and Nutrition Examination Survey, 33.6% of women ≥60 years old had a mean body mass index of ≥30 kg/m^2.[26] Menopause results in redistribution of fat depots,[27] including epicardial fat,[28] which has been demonstrated as associated with increased risk for AF.[29] The interaction of such diverse anthropometric and clinical factors with AF risk in postmenopausal women merits continued investigation.

The final rationale for our hypothesis was the association between menopause and risk factors for AF. Inflammatory markers (eg, C-reactive protein) are associated with increased risk of cardiovascular events in women,[30-32] have been related to menopausal status,[33] and similarly have been associated with AF.[34] Postmenopausal hematologic changes include increased hematocrit, greater plasma viscosity, and higher fibrinogen levels, which may enhance risk for cardiovascular disease and AF[35]; in the Women's Health Study, fibrinogen has recently been associated with increased AF risk.[36]

Sex-specific differences in the incidence of AF and cardiac arrhythmias are well described,[37,38] and epidemiologic data have observed that AF is less prevalent in women than men.[39] Incident AF, in general, occurs at an older age in women than men.[21] Sex differences in atrial electrophysiology are demonstrated by decreased P wave indices—a noninvasive assessment of atrial electrophysiologic function—in women compared with men.[40] The study of sex-specific electrophysiologic differences from hormonal influences, specifically estrogen, is ongoing. Estrogen receptors have been studied in animal and human cardiac structures.[41,42] Mice receiving ovariectomies had decreased atrioventricular nodal conduction, as measured by PR and AH intervals, compared with those receiving estrogen or intact animals.[43] In human studies, there is age-associated methylation of the estrogen receptor gene alpha in atrial tissue, suggesting down-regulation of estrogen receptor expression.[44] Modeling of cellular differences in cardiac repolarization has demonstrated female cells having increased potential for arrhythmogenic early after depolarizations compared with male cells.[45]

Further studies are necessary to assess other cardiovascular markers (eg, natriuretic peptides, left atrial parameters, P wave indices), their association with menopausal age, and if they modify AF risk in postmenopausal women. Remaining questions concern estrogen exposure, receptor activity, and modification of atrial electrophysiology across the spectrum of menopause.

Our study has multiple strengths. It was conducted in a community-based cohort with routine examinations occurring every 2 to 8 years. Such frequent contact provided an opportunity for longitudinal assessments and facilitated the cross-sectional pooling used in this study. We included participants only ≥60 years old, thereby verifying that all participants had achieved menopause, and facilitated follow-up in older age when participants were at increased risk for incident AF. Participants with menopausal age <40 years were excluded because of concern for premature ovarian failure. In addition, the Framingham Heart Study's routine collection of varied medical and clinical records yielded the identification of incident AF.

The present study has several limitations. Framingham Heart Study participants were mostly older and primarily of European descent; the generalizability of our findings to younger women and other races and ethnicities is unknown, particularly given racial differences in AF incidence.[46,47] A chief limitation is our lack of power given our sample size and number of incident events. A larger cohort may have a greater number of events, thereby obtaining higher power and the ability to determine smaller risks between menopausal age and incident AF. In fact, we determined that our study would have required approximately 1,400 events in order for the HR of 0.93 to reach statistical significance. Furthermore, we did not examine postmenopausal hormone-replacement therapy and its potential effects on AF risk. Inclusion of hormone use will be essential for larger studies exploring the association between menopause and AF. Our results may further suffer from recall bias in reporting age of natural menopause. However, as we recorded age of menopause before the development of AF, such recall bias is unlikely to be biased by occurrence of AF. Such random misclassification would have biased our results toward the null. It is also possible that women had unrecognized episodes of paroxysmal AF, resulting in misclassification of outcome status. More extensive rhythm monitoring, challenging in a community-based study, would be necessary to capture paroxysmal AF.

To our knowledge, the present study is the first to examine the relation between menopausal age and incident AF. Although we did not observe a significant association between menopausal age and AF risk, studies in larger cohorts may have increased power to explore such a potential association. Atrial fibrillation carries tremendous social and medical burdens, and the number of older adults in the United States continues

to increase. Identification of novel risk factors will serve public health efforts by enhancing risk stratification and prevention initiatives.

Comparing Alcohol Screening Measures Among HIV-Infected and -Uninfected Men

Kathleen A. McGinnis, Amy C. Justice, Kevin L. Kraemer, Richard Saitz, Kendall J. Bryant, and David A. Fiellin

Background: Brief measures of unhealthy alcohol use have not been well validated among people with HIV. We compared the Alcohol Use Disorders Identification Test (AUDIT) to reference standards for unhealthy alcohol use based on 30-day Timeline Follow Back (TLFB) and Composite International Diagnostic Interview—Substance Abuse Module (CIDI-SAM), among 837 male HIV-infected and -uninfected patients in the Veterans Aging Cohort Study.

Methods: Three reference standards were (i) *Risky drinking*—based on TLFB >14 drinks over 7 consecutive days or >4 drinks on 1 day; (ii) *Alcohol dependence*—based on a CIDI-SAM diagnosis; and (iii) *Unhealthy alcohol use*—risky drinking or a CIDI-SAM diagnosis of abuse or dependence. Various cutoffs for the AUDIT, AUDIT-C, and heavy episodic drinking were compared with the reference standards.

Results: Mean age of patients was 52 years, 53% (444) were HIV-infected, and 53% (444) were African American. Among HIV-infected and -uninfected patients, the prevalence of risky drinking (14 vs. 12%, respectively), alcohol dependence (8 vs. 7%), and unhealthy alcohol use (22 vs. 20%) was similar. For risky drinking and alcohol dependence, multiple cutoffs of AUDIT, AUDIT-C, and heavy episodic drinking provided good sensitivity ($\geq$80%) and specificity ($\geq$90%). For unhealthy alcohol use, few cutoffs provided sensitivity $\geq$80%; however, many cutoffs provided good specificity. For all 3 alcohol screening measures, sensitivity improved when heavy episodic drinking was included with the cutoff. Sensitivity of measures for risky drinking and unhealthy alcohol use was lower in HIV-infected than in uninfected patients.

Conclusions: For identifying risky drinking, alcohol dependence, and unhealthy alcohol use, AUDIT-C performs as well as AUDIT and similarly in HIV-infected and -uninfected patients. Cutoffs should be based on the importance of specific operating characteristics for the intended research or clinical use. Incorporating heavy episodic drinking increased sensitivity for detecting alcohol dependence and unhealthy alcohol use.

Key Words: AUDIT, HIV, Veterans, Alcohol-Related Disorders, Mass Screening.

"UNHEALTHY ALCOHOL USE" includes any amount of drinking above "low risk" drinking and specifically includes risky drinking, alcohol abuse, and alcohol dependence (Bradley et al., 2009; Saitz, 2005). Unhealthy alcohol use is common in HIV-infected individuals and contributes to adverse health consequences (Conigliaro et al., 2003; Saitz, 2005). Alcohol consumption can influence HIV disease progression by impacting patients' adherence and response to antiretroviral treatment (Baum et al., 2010; Samet et al., 2006). Despite these findings, and the potential that even low levels of alcohol consumption may cause harm among those infected with HIV (Braithwaite and Bryant, 2010; Sullivan et al., 2011), there are no detailed studies comparing the operating characteristics of standard alcohol screening measures between HIV-infected and -uninfected individuals or validating the use of alcohol screening measures and identifying appropriate cutoffs to use for HIV-infected patients. This creates a problem for researchers and clinicians in deciding which measures should be used to identify and characterize unhealthy alcohol use among HIV-infected individuals.

To conduct meaningful research on alcohol use and related consequences in those with HIV infection and to identify patients who may benefit from counseling or pharmacologic interventions, researchers and clinicians need valid and feasible measures for identifying unhealthy alcohol

use. For instance, certain pharmacotherapies are indicated primarily for those who meet criteria for alcohol dependence. There are many instruments designed to identify those who may be at increased risk for unhealthy alcohol use, including brief screening measures such as the Alcohol Use Disorders Identification Test (AUDIT; Babor et al., 1989). More time-intensive methods such as the 30-day Timeline Follow Back (TLFB; Sobell et al., 1988a) and the Composite International Diagnostic Interview—Substance Abuse Module (CIDI-SAM; Compton, 1993) provide more definitive information about unhealthy alcohol use. Many prior studies have evaluated the use of the AUDIT for identifying various types of unhealthy alcohol use and have identified appropriate cutoffs to use in various populations (Babor et al., 1989; Bradley et al., 1998a,b; Gordon et al., 2001; Gual et al., 2002; Reinert and Allen, 2002; Rubinsky et al., 2010; Saunders et al., 1993; Schmidt et al., 1995) but not in an HIV-infected population.

The aim of this research was to determine the performance of various screening instruments and thresholds for 3 types of alcohol use in a large cohort of HIV-infected and -uninfected patients receiving primary care. The 3 drinking categories evaluated are (i) risky drinking (Fleming, 2004/2005), (ii) alcohol dependence (Diagnostic and Statistical Manual of Mental Disorders [DSM]), and (iii) unhealthy alcohol use (Saitz, 2005).

MATERIALS AND METHODS

Setting and Subjects

Subjects were male participants of the Veterans Aging Cohort Study (VACS), a prospective multisite observational study focused on the role of alcohol use on health in HIV-infected and -uninfected individuals (Justice et al., 2006a), funded by the National Institute on Alcohol Abuse and Alcoholism. VACS is an ongoing study conducted at 8 Veterans Affairs facilities (Atlanta, Georgia; Baltimore, Maryland; Bronx, New York; Houston, Texas; Los Angeles, California; New York City, New York; Pittsburgh, Pennsylvania; and Washington, District of Columbia). HIV-infected individuals are recruited from Infectious Disease clinics that provide primary medical care at the participating sites. All HIV-infected patients presenting to each participating site are eligible. Uninfected controls are recruited from the General Internal Medicine clinics at the same sites and are matched to the demographics of the HIV-infected subjects on 5-year age blocks, race/ethnicity, and gender. Subjects in this analysis are 837 male VACS participants enrolled from June 2002 to February 2004 who were part of a substudy designed to assess alcohol use and the validity of alcohol screening measures. VACS participants were asked to participate in the substudy if they had reported having at least 1 alcoholic drink in the past year. The study was approved by the Institutional Review Board of each site.

Measures of Alcohol Use Collected in VACS

The AUDIT was collected via self-administered paper survey at the 1-year follow-up (Babor et al., 1989). The CIDI-SAM and 30-day TLFB were administered via telephone interview shortly after the 1-year follow-up paper survey.

The CIDI-SAM operationalizes the diagnostic criteria of DSM-III, DSM-III-R, DSM-IV and International Classification of Diseases—10th Revision (ICD-10) psychoactive substance use disorders (Compton, 1993; Kessler et al., 1998). CIDI-SAM data were used to identify both lifetime and current (past 12 month) alcohol abuse and dependence disorders. The alcohol 30-day TLFB, a validated calendar-based method whereby subjects provide retrospective estimates of their daily drinking was used to collect information on alcohol consumption over the 30 days prior to the telephone interview. The TLFB has been evaluated in clinical and nonclinical populations and is validated when administered in person and by telephone (Maisto et al., 2009; Sobell and Sobell, 1992; Sobell et al., 1988a,b). The 10-item AUDIT (Babor et al., 1989; Gordon et al., 2001; Reinert and Allen, 2002; Saunders et al., 1993; Schmidt et al., 1995) was administered during the 1-year follow-up survey and includes the 3-item AUDIT-C, an instrument that consists of the 3 consumption items of the AUDIT (Bush et al., 1998; Dawson et al., 2005; Gual et al., 2002). The AUDIT-C has similar sensitivities and specificities for identifying unhealthy alcohol use to the AUDIT (Bradley et al., 1998a,b; Gual et al., 2002) yet is shorter.

We used the third item of the AUDIT, which asks: "How often do you have 6 or more drinks on 1 occasion?" with response options "never," "less than monthly," "monthly," "weekly," and "daily or almost daily" to identify patients with heavy episodic drinking. Those who indicated that they consumed 6 or more drinks (chose response option of "less than monthly" or more frequently) were classified as "ever" heavy episodic drinkers. Heavy episodic drinking has been associated with many adverse health effects including unintentional injuries, acute myocardial infarction, ischemic stroke, sexually transmitted diseases (Hansagi et al., 1995; Naimi et al., 2003; Raj et al., 2009), and among those with HIV, it has been associated with decreased medication adherence (Braithwaite et al., 2008). To determine whether we could improve the performance of the AUDIT and AUDIT-C measures with reference standard measures by incorporating the single heavy episodic drinking item from the AUDIT, we also created composite measures that were positive if the AUDIT measure was greater than a specified cutoff *or* if the person reported any heavy episodic drinking in the past year. These measures represent a broader spectrum of unhealthy alcohol use than do an AUDIT cutoff or heavy episodic drinking alone.

We used ICD-9 codes to identify subjects diagnosed with alcohol dependence. We also used ICD-9 codes to identify subjects with an alcohol-related diagnosis, which included ICD-9 codes reflecting alcohol abuse, alcohol dependence, or problems stemming from excessive alcohol consumption (e.g., alcoholic cirrhosis). The alcohol-related diagnosis ICD-9 codes used were based on the work of Piette and are listed on the VACS web site (www.vacohort.org) (Justice et al., 2006b; Piette et al., 1998). Patients were considered to have a diagnosis of alcohol dependence or an alcohol-related diagnosis if they had at least 1 inpatient or 2 outpatient alcohol-related ICD-9 codes ever and within the 12 months prior to and including the date of the follow-up telephone interview. Requiring at least 1 inpatient or 2 outpatient ICD-9 codes has been shown to improve the accuracy of these codes (Justice et al., 2006b).

Alcohol Reference Measures for Risky Drinking, Dependence, and Unhealthy Use

We used established reference standards ("gold standards") for risky drinking, alcohol dependence, and unhealthy alcohol use. The reference standard for *risky drinking* was based on the 30-day TLFB assessment of amounts that increase the risk for health consequences. We defined risky drinking as consuming >14 drinks over any consecutive 7-day period or >4 drinks in 1 day based on the guidelines recommended by the National Institute on Alcohol Abuse and Alcoholism to identify those at risk for alcohol-related problems (Fleming, 2004/2005). The reference standard for past year alcohol *dependence* was based on the CIDI-SAM diagnosis of dependence. We chose to use a dependence-only reference measure instead of dependence/abuse

because certain treatments and pharmacotherapies are indicated primarily for those who meet criteria for alcohol dependence. *Unhealthy alcohol use in the past year* was defined as having a CIDI-SAM diagnosis of alcohol abuse or dependence in the past year or meeting criteria for risky drinking based on TLFB interview.

Analysis

We describe demographic characteristics for the VACS participants who completed the CIDI-SAM. Using the 3 reference measures, we calculated sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), percent agreement, and kappa statistics for measures of alcohol use for both HIV-infected and -uninfected participants. We compared the following alcohol measures to the reference standard for risky drinking and unhealthy alcohol use: AUDIT, AUDIT-C, heavy episodic drinking, AUDIT or heavy episodic drinking, and AUDIT-C or heavy episodic drinking. For the unhealthy alcohol use reference standard, we also compared ICD-9 diagnosis of alcohol abuse or dependence in the past year. We compared those measures as well as the following measures to the reference standard for dependence: ICD-9 codes for alcohol diagnoses and an AUDIT dependence score (from items 4 to 6 of the AUDIT). The AUDIT and AUDIT-C cutoffs tested are based on prior research (Babor et al., 1989; Bradley et al., 1998b). Analyses were carried out using Stata 10.0 (College Station, TX).

RESULTS

Subject Characteristics

All subjects were men. Age and percentage with HIV were similar between the substudy sample (n = 837) and the entire VACS cohort (n = 6,467), although those in the analytic sample were more likely to be White than overall VACS participants (33 vs. 22%). Of the 837 in the analytic sample, half were HIV-infected, which is consistent with the study design target to recruit a similar number of HIV-infected and -uninfected patients. Race/ethnicity was similar between the HIV-infected and -uninfected participants with 53% African American, 8% Hispanic, 33% White, and 5% other. However, compared with uninfected subjects, HIV-infected were younger (average age, 50 vs. 54 years).

On the basis of the TLFB, 13% reported risky drinking amounts in the past 30 days. Seven percent of subjects met criteria for past year alcohol dependence based on the CIDI-SAM. On the basis of a combination of TLFB-determined risky amounts and CIDI-SAM-determined alcohol use disorders, 21% had unhealthy alcohol use. The prevalence of various levels of unhealthy use and alcohol measures is shown in Table 1, and there are no statistically significant differences in these alcohol measures between HIV-infected and -uninfected subjects.

Alcohol Screening Measures and Risky Drinking

For HIV-infected and -uninfected subjects, sensitivity was 80% or greater between the TLFB reference standard for risky drinking and the following measures and cutoffs: AUDIT 4+ (80 vs. 86%), AUDIT 5+ or heavy episodic drinking (83 vs. 84%), AUDIT 4+ or heavy episodic drinking (83 vs. 90%) AUDIT-C 3+ (83 vs. 90%), AUDIT-C 4+ or heavy episodic drinking (83 vs. 88%), and AUDIT-C 3+ or heavy episodic drinking (85 vs. 94%). Specificity was 90% or greater for AUDIT 8+ (92 vs. 94%), AUDIT 7+ (90 vs. 92%), AUDIT-C 6+ (96 vs. 95%), AUDIT-C 5+ (92 vs. 94%), heavy episodic drinking less than monthly (94 vs. 94%), and at least monthly heavy episodic drinking (98 vs. 97%) (Table 2). The kappa statistics for these comparisons ranged from 0.28 to 0.61, indicating fair to moderate agreement (Landis and Koch, 1977).

Alcohol Screening Measures and Alcohol Dependence

For HIV-infected and -uninfected subjects, sensitivity was 80% or greater between the CIDI-SAM reference standard, for alcohol dependence in past year, and the following measures and cutoffs: AUDIT 4+ (83 vs. 81%), AUDIT 8+ or heavy episodic drinking (83 vs. 78%), AUDIT 7+ or heavy episodic drinking (83 vs. 81%), AUDIT 6+ or heavy episodic

drinking (86 vs. 81%), AUDIT 5+ or heavy episodic drinking (86 vs. 81%), and AUDIT-C 3+ or heavy episodic drinking (77 vs. 81%). Specificity was 90% or greater for the following measures: alcohol-related ICD-9 diagnosis in past year (93 vs. 92%), ICD-9 diagnosis code for dependence in the past year (97 vs. 94%), AUDIT 20+ (99 vs. 98%), AUDIT 16+ (98 vs. 98%), AUDIT 8+ (92 vs. 91%), AUDIT-C 10+ (100 vs. 99%), AUDIT-C 8+ (98 vs. 95%), AUDIT-C 6+ (94 vs. 91%), heavy episodic drinking less than monthly (92 vs. 90%) heavy episodic drinking at least monthly (98 vs. 94%), and AUDIT Dependence Score 4+ (99 vs. 98%) (Table 3). Among HIV-uninfected, the kappa statistics are 0.06 and 0.10 for the alcohol-related ICD-9 diagnosis and dependence alone, respectively. Otherwise, kappa statistics ranged from 0.17 to 0.43 indicating slight to moderate agreement (Landis and Koch, 1977).

Alcohol Screening Measures and Unhealthy Alcohol Use

For HIV-infected and -uninfected subjects, sensitivity was 80% or greater between the reference standard for unhealthy alcohol use and the following measures and cutoffs: AUDIT-C 2+ (86 vs. 96%) and AUDIT-C 3+ or heavy episodic drinking (71 vs. 83%). Specificity was 90% or greater for AUDIT 8+ (95 vs. 96%), AUDIT 7+ (93 vs. 95%), AUDIT 6+ (91 vs. 93%), AUDIT-C 6+ (97 vs. 97%), AUDIT-C 5+ (94 vs. 96%), heavy episodic drinking less than monthly (96 vs. 95%), at least monthly heavy episodic drinking (99 vs. 98%), and alcohol-related ICD-9 diagnosis (94 vs. 92%) (Table 4). For the alcohol-related ICD-9 diagnosis, kappa statistics are 0.16 and 0.02 for HIV-infected and -uninfected respectively. Otherwise, kappa statistics range from 0.27 to 0.57 indicating fair to moderate agreement (Landis and Koch, 1977).

DISCUSSION

In this sample, the prevalence of various types of unhealthy alcohol use were similar among HIV-infected and -uninfected adults. Compared with the reference standards, the AUDIT-C can identify risky drinking and unhealthy alcohol use with over 80% sensitivity at the best-performing cutoffs among both HIV-infected and -uninfected patients. Using the AUDIT-C combined with any heavy episodic drinking in the past year (item 3 of the AUDIT-C) improves sensitivity for detecting both risky and unhealthy alcohol use compared with using the AUDIT-C alone. High specificity for risky drinking and unhealthy alcohol use can be obtained using various AUDIT-C cutoffs and even using the heavy episodic drinking single-item question alone. We note that sensitivity is higher for most cutoffs for risky drinking than for unhealthy alcohol use. We believe this is because alcohol abuse and dependence are included in the definition for unhealthy alcohol use, and they may be more difficult to detect with AUDIT-based measures than risky drinking alone. For both risky drinking and unhealthy alcohol use, many cutoffs provide moderate agreement or better based on the kappa statistics.

For identifying those with alcohol dependence, the AUDIT performs better than the AUDIT-C and combining heavy episodic drinking with the AUDIT cutoffs results in higher sensitivity. Using a cutoff of AUDIT 6+ or heavy episodic drinking resulted in sensitivity of 86% for HIV-infected and 81% for HIV-uninfected. High specificity for alcohol dependence can be obtained using high cutoffs for the AUDIT (20+ and 16+), the AUDIT-C (10+ and 8+), the AUDIT dependence score of 4+, and the ICD-9 code for dependence in the past year; however, sensitivity is low (14 to

31%). Many cutoffs provide fair agreement or better based on the kappa statistics.

Our findings are consistent with other studies that have reported on recommendations for AUDIT and AUDIT-C cutoffs for unhealthy alcohol use. The standard cutoffs recommended for AUDIT range from 5 or more to 8 or more, and those recommended for the AUDIT-C range from 3 or more to 6 or more for various types of unhealthy alcohol use (Bradley et al., 1998b; Bush et al., 1998; Gordon et al., 2001; Gual et al., 2002). Additionally, our finding that the AUDIT-C performs as well as the longer AUDIT for identifying those with risky drinking and unhealthy alcohol use is consistent with findings of other researchers (Bradley et al., 1998b, 2009; Gordon and Saitz, 2004; Gordon et al., 2001). We demonstrate that adding a heavy episodic drinking component improves sensitivity compared with AUDIT cutoffs alone without adding additional burden to the patients or survey respondents as this question is already included as part of the AUDIT.

We found that the prevalence of risky drinking is slightly higher in the HIV-infected subjects based on the TLFB, but the percentage of patients identified with risky drinking is slightly lower among the HIV-infected subjects based on the various cutoffs of AUDIT, AUDIT-C, and heavy episodic drinking. For risky drinking and unhealthy alcohol use, we are uncertain as to why sensitivity is lower among the HIV-infected compared with uninfected. One study reported that those with HIV used alcohol at lower usual levels but with greater variability compared with those who were HIV-uninfected (Braithwaite et al., 2008). Perhaps this difference in drinking patterns between HIV-infected and -uninfected provides some insight into the differences in sensitivity. More likely, however, there may be a social desirability bias causing the HIV-infected patients to underreport their alcohol consumption.

For alcohol dependence, agreement is particularly low for the ICD-9 codes for the HIV-uninfected (kappa $\leq$ 0.10) compared with the HIV-infected subjects (kappa = 0.23 to 0.26). Although we realize that alcohol-related diagnoses often are underreported, we are surprised to see a lower level of agreement among the HIV-uninfected subjects given that the prevalence of all alcohol measures including the ICD-9 measures are similar between the HIV-infected

CIDI-SAM, Composite International Diagnostic Interview-Substance Abuse Module; ICD-9; International Classification of Diseases, 9th revision; AUDIT, Alcohol Use Disorders Identification Test; HED, heavy episodic drinking; Sens, sensitivity; Spec, specificity; PPV, positive predictive value; NPV, negative predictive value; Agree, agreement; TLFB, Timeline Follow Back.

and -uninfected groups. Perhaps HIV-infected patients are screened more frequently or aggressively because of increased surveillance for the potential negative interactions of alcohol use with medications and/or other comorbidities, such as hepatitis C.

This study has several strengths. It uses a large U.S. multisite cohort of racially/ethnically diverse HIV-infected and -uninfected patients with multiple measures of alcohol use. Many studies have evaluated and identified the optimal cutoffs to use for the AUDIT and the AUDIT-C to identify risky drinking amounts, alcohol dependence, and the spectrum of unhealthy alcohol use. However, no other studies that we are aware of have evaluated these measures in an HIV-infected population. This study provides new information regarding the performance of commonly used screening and diagnostic instruments among HIV-infected subjects, an important population that is at higher risk for adverse outcomes from alcohol use. For many studies and clinical settings, it is important to have brief tools for evaluating alcohol use to help minimize participant burden and maximize time and resources, especially when one is attempting to collect information on a variety of behaviors. In clinical settings especially, patient assessments need to be brief because of patient and provider time constraints.

This study has several limitations. First, our study sample was restricted to Veterans receiving medical care and, because the majority of our cohort is men, we limited the analysis to men. Similar studies should be conducted on cohorts of HIV-infected and -uninfected women. The mean age of our study population is 52 years, and this should be considered when applying these findings to older or younger populations. For risky drinking, we compared the AUDIT, which captures data for the previous year, with the TLFB, which captures drinking information over the previous 30 days. On the basis of these differing time frames, we might expect to see lower prevalence of risky drinking identified by the TLFB, especially if we are incorporating heavy episodic drinking, which we expect to have reported more frequently over the past year in the AUDIT than in the past 30 days on the TLFB. How much prevalence differs would depend on how consistent drinking behavior was over time; furthermore, the AUDIT asks about typical drinking that is likely affected by recent (e.g., past month) behavior. In any case, sensitivity should not be impacted by the time frame discrepancy between measures because the screening test covers a longer time than the reference standard. However, specificity could be lower because of some individuals not meeting criteria for risky drinking over the past 30 days on the TLFB, but meeting risky drinking criteria based on AUDIT or AUDIT-C during the previous year.

Although our results demonstrate that agreement is similar between HIV-infected and -uninfected subjects for identifying participants on the spectrum of alcohol use, we cannot be sure that screening tests administered in person as 1 to 3 items as part of clinical care will perform the same as the screening tests asked as part of a research survey that is self-administered.

Despite these limitations, our findings have implications for the use of these screening measures in clinical practice and research. We cannot recommend a standard instrument or cutoff to use for all purposes, as the decision will depend on the purpose (e.g., screening) for each situation. However,

based on these findings, the optimal balance between sensitivity, specificity, and agreement is provided by the following instruments using the specified cutoffs for both general medical and HIV care settings: AUDIT-C 4+ or heavy episodic drinking for risky drinking; AUDIT 6+ or heavy episodic drinking for alcohol dependence; and AUDIT-C 3+ or heavy episodic for unhealthy alcohol use. Of note, for unhealthy alcohol use, few cutoffs provide sensitivity $\geq 80\%$; however, many cutoffs provide good specificity. For identifying alcohol dependence, the highly specific AUDIT dependence score and the ICD-9 diagnosis codes are not recommended when sensitivity is important, such as for screening measures by physicians. However, in the absence of other sources of alcohol data, ICD-9 codes can be useful where specificity is important and sensitivity is not (e.g., when evaluating costly and/or time-intensive interventions).

In summary, for both HIV-infected and -uninfected patients, briefer measures of alcohol use provide reasonable sensitivity and specificity for risky and unhealthy use compared with the longer more resource intensive measures. The incorporation of heavy episodic drinking from question 3 of the AUDIT with AUDIT and AUDIT-C cutoffs improves sensitivity for identifying risky drinking, alcohol dependence, and unhealthy alcohol use compared with using AUDIT and AUDIT-C cutoffs alone. For many research and clinical purposes, the briefer measures should be sufficient, at least for screening purposes, and then more time-intensive measures could be utilized to follow-up on positive screens. Cutoffs can be chosen to maximize sensitivity or specificity as appropriate to the clinical or research application. For alcohol dependence, the briefer measures may not be adequate for more than broad screening; a more intensive measure, such as the CIDI-SAM, may still be necessary when sensitivity is important. However, when specificity is important and sensitivity is not, brief tools can be used when identifying people with alcohol dependence.

Health Literacy and the Disenfranchised: The Importance of Collaboration Between Limited English Proficiency and Health Literacy Researchers

MICHAEL M. MCKEE

Family Medicine Research Programs, Department of Family Medicine, University of Rochester School of Medicine and Dentistry, Rochester, New York, USA

MICHAEL K. PAASCHE-ORLOW

Department of Medicine, Boston University School of Medicine, Boston, Massachusetts, USA

Inadequate health literacy and limited English proficiency are associated with poor health care access and outcomes. Despite what appears to be an interaction phenomenon—whereby the rate of inadequate health literacy is particularly high among limited English proficiency populations—researchers in health literacy and limited English proficiency rarely collaborate. As a result, few health literacy instruments and interventions have been developed or validated for smaller linguistic populations. Interventions to improve health outcomes for people with low health literacy and limited English proficiency show great potential to alleviate many of the health disparities currently experienced by some of the most disenfranchised individuals in our health care system, those from smaller linguistic minority groups, including Deaf American Sign Language users. It is critical for health literacy and limited English proficiency researchers to work together to understand how culture, language, literacy, education, and disabilities influence health disparities and health outcomes. It is important to ensure that research is collaborative and inclusive in order to broaden the reach of future interventions to smaller linguistic minority populations.

The health care system is struggling to care for an increasingly diverse patient population (National Center for Education Statistics, 2001; Smedley, Stith, & Nelson, 2003; U.S. Census Bureau, 2011). It is unfortunate that the details of this diversity, including language preference, literacy, and culture, have in general been examined independently. Few studies have concurrently explored health literacy and limited English proficiency (LEP). A recent PubMed search by the coauthors using the health

Michael M. McKee is currently supported by grant K01 HL103140-01 from the National Heart, Lung, and Blood Institute of the National Institutes of Health.

literacy and LEP as MeSH keywords generated 5,158 health literacy references and 595 LEP references, but only 36 overlapping references. The paucity of publications on this topic underscores the need for better collaboration between these fields.

More than 90 million Americans have inadequate health literacy (Nielsen-Bohlman, Panzer, & Kindig, 2004) and more than 24.5 million Americans experience LEP (U.S. Census Bureau, 2010), not accounting for people with LEP among the population of unauthorized or undocumented immigrants in the United States (Passel & Cohn, 2011). In addition, this estimate does not include approximately 500,000 Deaf American Sign Language (ASL) users (Harrington, 2004; Schick, 1988).

It is not well established what proportion of LEP individuals have inadequate health literacy, but overall it is thought to be higher than that of fluent English speakers (Berkman et al., 2004; Nielsen-Bohlman et al., 2004). Several populations at risk for LEP (no English spoken before starting school, Hispanic adults, and those with disabilities) are overrepresented among those with below basic prose literacy on the National Assessment of Adult Literacy (Baldi, 2009). However, more important than establishing a precise prevalence estimate of inadequate health literacy and LEP is to understand their health consequences. In isolation, both pose significant barriers to health care communication (Baker, Parker, Williams, & Clark, 1998; Fernandez et al., 2004; Graham, Jacobs, Kwan-Gett, & Cover, 2008; Paasche-Orlow & Wolf, 2007; Schillinger et al., 2003; Wilson et al., 2005). Together, the damaging effects of inadequate health literacy and LEP on health communication and outcomes are likely magnified (Sudore et al., 2009). This may be due to synergistic negative effects in phenomena such as socioeconomic position, access to care, access to information, as well as perceived and experienced discrimination (Egede, 2006).

Quality measures mandated by the Centers for Medicare and Medicaid Services heavily rely on improved patient communication and outcomes (Centers for Medicare & Medicaid Services, 2012). There is great interest among hospitals, managed care, and outpatient health centers to develop effective communication strategies to deal with diverse patient populations. Many of these approaches will require interventions to deal with the complexities of handling patient populations who experience LEP and inadequate health literacy. Unfortunately, the current research environment is poorly equipped to provide innovative approaches and interventions to increase the ability of a health consumer with LEP and inadequate health literacy to make appropriate health care decisions. Researchers must work together to understand how culture, language, literacy, education, and disabilities all play elemental roles in promulgating health disparities and health outcomes.

Benefits of Collaborative Research

Despite an increasing number of interventions designed to improve health knowledge, and disease management, few studies evaluate whether these interventions are reproducible in smaller language minority populations and among individuals with a range of health literacy (Sarkar et al., 2008; Schillinger et al., 2008). Many interventions intended to address LEP may also be appropriate for those with low health literacy as well as the converse. The hybridization of LEP and health literacy research would further enhance the ability to develop novel approaches and interventions that can potentially be interchangeable for diverse communication needs. Furthermore, health literacy research could greatly benefit from the infusion of transdisciplinary approaches provided in the fields of linguistics and cognitive science. LEP research

could gain from standardized measures and instruments available and emerging in health literacy research.

LEP research has demonstrated the benefits of language concordance and the use of interpreters including higher rates of appropriate health care visits, improved treatment adherence, and improved satisfaction (Graham et al., 2008; MacKinney, Walters, Bird, & Nattinger, 1995; McKee, Barnett, Block, & Pearson, 2011; Regenstein et al., 2008; Timmins, 2002). Interventions involving the use of community health workers, health coaches, language interpreters, and language-concordant providers are common approaches for LEP populations. However, it is unclear whether these interventions can improve health literacy among these populations. In addition, novel approaches for inadequate health literacy through the use of technology (e.g., virtual health coaches) have not yet been adequately examined in LEP populations. Health information technologies have promising potential to tailor health information to language and cultural needs and help people access to health materials in a variety of modalities when and where they may be needed (Munoz et al., 2009). Further research is needed to determine how this can be applied effectively for people with LEP and inadequate health literacy.

Populations Who May Benefit From Collaborative Research

Spanish-speaking populations, by virtue of their size, have garnered the majority of LEP and non–English health literacy research funding in the United States. Despite the fact that more than 376 languages are used in the United States, a review of the literature reveals very few of these studies extend beyond English and Spanish. Schillinger, Bindman, Wang, Stewart, and Piet (2004) demonstrated that even when accounting for language barriers, inadequate reading and health literacy were highly prevalent in one Latino population sample; only 55% of Hispanics have a high school diploma, and only 10% have a bachelor's degree (Schillinger et al., 2004). Inadequate health literacy may be even higher for smaller linguistic minority groups as a result of a paucity of accessible media and patient education.

Certain immigrant populations and Deaf ASL users live in relative isolation. These populations provide unique research challenges and opportunities because of reduced social interactions with the media and limited contact with allopathic norms, public health and prevention messaging, and health education. These groups experience poor patient–provider communication and frequently rely on inaccurate and inconsistent information from their social networks and the Internet (McKee et al., 2011; Valentine & Skelton, 2009; Vernon & Lynch, 2003).

Deaf ASL users, in particular, present a unique study population because they struggle with poor communication (i.e., due to hearing loss), language discordance, and possibly inadequate health literacy partly because of decreased opportunities to correct misinformation, and limited health surveillance (McKee et al., 2012). Deaf ASL users are considered an LEP population by the U.S. Department of Health and Human Services (U.S. Department of Health and Human Services, 2001); yet, they are rarely included in health literacy and LEP research studies. This is likely due to limited health and demographic information about Deaf ASL users, scarcity of adapted and validated research surveys and instruments in ASL, difficulty recruiting and accessing this population for research, inadequate supply of Deaf ASL proficient investigators, and concern about handling potential cognitive issues when present.

The exclusion of linguistic minorities is ultimately due to the fact that they are minorities. The research funding and the workforce are limited. Investigators want to have the largest possible impact and have research products that reach a critical mass. Although smaller language populations may be challenging to recruit and study, they are often most in need; work with such populations underscores a striking absence of health information accessible in languages beyond English and Spanish. Rudd and Anderson (2006) argued that existing health literacy interventions can be modified to apply to at-risk individuals and that environmental evaluations of health care systems to reduce literacy and language barriers could benefit a broad array of patients. The same approach to currently existing health literacy and LEP research tools and interventions can help identify critical steps needed to create greater inclusivity in research.

Future Implications

LEP and health literacy researchers should design research that advances knowledge regarding the intersection between these fields of inquiry. Approaches likely to promote this agenda include the following:

- Funding agencies should encourage collaboration between researchers through targeted requests for applications for research that incorporates both fields.
- Researchers should place special emphasis in developing tools and disseminating interventions that can be readily adapted and translated into languages for validation and use in other populations.
- Institutional review boards should give special consideration to smaller linguistic minority populations, including Deaf ASL users, to ensure that research is inclusive whenever possible.
- LEP and health literacy investigators should design research that implements novel strategies using information technology and other methods to lower communication barriers and bridge health care gaps more effectively and efficiently.
- Opportunities for collaboration and dissemination of innovative cross-disciplinary approaches, such as symposia and conferences with a special emphasis on bringing health literacy and LEP investigators together should be advanced.
- Academic institutions and research facilities should increase the number of researchers and staff from diverse backgrounds to improve recruitment of challenging-to-reach populations and provide greater social and cultural awareness necessary to establish rapport with targeted populations.

Conclusion

The fields of LEP and health literacy have largely functioned as separate silos of research, failing to address the needs of these unique and underserved populations in the U.S. health care system. It is clear that collaboration is needed between experts in these fields to help develop a variety of interventions and tools to assure the most vulnerable patients are not left behind. Without attention to the interaction between health literacy and LEP populations are at great risk for experiencing increasing health disparities.

Given that language and health literacy are integral to patients' ability to comprehend and act upon health recommendations, it is crucial to find ways to understand the joint effects of these phenomena. Researchers should view health literacy through

multicultural and multilingual lenses to help develop novel communication strategies and technologies that can be implemented in the increasing number of linguistic minority and LEP populations, including Deaf ASL users in the United States.

Discrepancy in Diagnosis and Treatment of Post-traumatic Stress Disorder (PTSD): Treatment for the Wrong Reason

Abstract

In primary care (PC), patients with post-traumatic stress disorder (PTSD) are often undiagnosed. To determine variables associated with treatment, this cross-sectional study assessed 592 adult patients for PTSD. Electronic medical record (EMR) review of the prior 12 months assessed mental health (MH) diagnoses and MH treatments [selective serotonin reuptake inhibitor (SSRI) and/or ≥1 visit with MH professional]. Of 133 adults with PTSD, half (49%; 66/133) received an SSRI (18%), a visit with MH professional (14%), or both (17%). Of those treated, 88% (58/66) had an EMR MH diagnosis, the majority (71%; 47/66) depression and (18%; 12/66) PTSD. The odds of receiving MH treatment were increased 8.2 times (95% CI 3.1–21.5) for patients with an EMR MH diagnosis. Nearly 50% of patients with PTSD received MH treatment, yet few had this diagnosis documented. Treatment was likely due to overlap in the management of PTSD and other mental illnesses.

Introduction

In primary care (PC) settings, patients with post-traumatic stress disorder (PTSD), are often not diagnosed; 2% to 11% with PTSD actually have the diagnosis noted in the medical record.[1,2] In addition, less than half of these patients with PTSD, or even fewer, actually receive treatment for PTSD.[3,4] To better address this condition in practice, more attention will likely need to be focused both on the recognition of PTSD and the treatment of PTSD when it is recognized.

Mental health (MH) treatment for PTSD includes pharmacotherapy and/or specialized MH counseling with structured cognitive behavioral therapy or psychotherapy.[5–9] Recent practice guidelines from the American Psychiatric Association recommend selective serotonin reuptake inhibitors (SSRIs) as first-line pharmacotherapy for patients with PTSD, given that they alleviate symptoms of PTSD, have few side effects, and also treat the comorbid depression, anxiety, and panic disorder that frequently co-occur with PTSD.[5,10] Few randomized trials have been completed to evaluate the efficacy of one type of treatment (i.e. pharmacotherapy vs. psychotherapy) over another; however, current guidelines state that, since pharmacotherapy has lower effectiveness for PTSD than MH counseling, it is prudent for prescribing clinicians to also refer patients for appropriate counseling.[6,7,10,11]

A literature review helped to identify some factors that are associated with recognition of mental illness and therefore with receipt of treatment for mental illness. First, more severe psychological distress increases the odds that a patient will be diagnosed with a MH disorder.[1,4,12] But little is known about whether this principle applies to PTSD in PC practice. It seems reasonable, however, to suspect that patients with more severe PTSD symptoms would be more likely to receive MH treatment.[1,4,11,12] Secondly, PC physicians are more likely to recognize depressive symptoms (and are more likely to mislabel patients with lone PTSD as having depression).[13] Thus it seems also likely that comorbid depression (with PTSD) might increase the likelihood of receiving MH treatment.[13] Finally, patient disclosure of trauma-associated symptoms to a medical professional seemed to also increase the likelihood of receiving MH treatment.[1,6,7,12–14]

To better understand factors associated with receipt of PTSD treatment by PC patients, a cross-sectional study of patients in PC was conducted assessing PTSD diagnosis and reviewing patients' medical records for MH diagnoses and PTSD treatments. Given the therapeutic overlap (i.e., SSRI pharmacotherapy) in the management of PTSD and depression, it was hypothesized that some patients with PTSD might receive MH treatment despite the fact that they are not recognized as having PTSD. In fact, it was thought that these patients might be mislabeled in the medical record

as having other MH diagnoses (especially depression) and thus receive PTSD treatment fortuitously due to this phenomenon of therapeutic overlap. It was also hypothesized that PTSD symptom severity and trauma-associated symptom disclosure would be associated with receipt of treatment for PTSD.

Methods

Study design

This secondary data analysis examines participants who met diagnostic criteria for current PTSD during a cross-sectional study completed at the PC clinics of an urban, safety-net, academic medical center.[2] This analysis had three key components. First, validated measures established the overall prevalence of interview-diagnosed PTSD, PTSD symptom severity, and depressive symptoms.[15] Second, participants' electronic medical records (EMRs) were reviewed for the presence of four MH diagnoses, SSRI prescriptions, and documentation of visits with MH professional in the prior year. Finally, logistic regression tested the associations between receipt of MH treatment and the hypothesized independent variables. A detailed description of study methods for recruitment and assessment can be found elsewhere; relevant methods are summarized below.[2] The Boston University Medical Center's Institutional Review and the HIPAA Privacy Review Boards approved the study. A Certificate of Confidentiality was obtained from the National Institutes of Health.

Recruitment and enrollment

From February 2003 to September 2004, adult patients awaiting PC appointments were approached and screened for eligibility by trained research assistants. Patients were eligible if they spoke English, were 18–65 years old, and had a scheduled appointment with a PC clinician. Of the 753 eligible patients, 607 (81%) enrolled in the study.[2] This analysis is limited to the 133 patients with a current (past 12 months) diagnosis of PTSD made using the Composite International Diagnostic Interview (CIDI) Version 2.1 PTSD Module.[16,17] Patients who participated in the study provided written informed consent, were compensated $10, and received safety referrals at the end of the interview.

Assessments and data

Interview assessments

Research assistants collected demographic data and administered a series of validated interview questionnaires. They administered CIDI to assess for current PTSD and the Patient Health Questionnaire-9 (PHQ-9) to measure depressive symptoms.[15–17] PTSD symptom severity was ascertained via the PTSD Checklist (PCL-C).[18,19] Participants were asked specifically whether they had ever disclosed that they suffered from trauma-associated symptoms to a medical professional, defined as a PC physician, MH professional/therapist, other physician, nurse, or social worker.

EMR data

All study subjects were patients at an academic medical center which maintains a comprehensive EMR. All outpatient encounters (PC clinical encounters and emergency department visits), inpatient discharge summaries, diagnoses, and prescriptions are documented in the EMR and are available for review. MH services are available at the same academic medical center and visits with

an MH professional are also documented in the EMR; however, restrictions do not allow for the specific contents of these visits (i.e., type of therapy performed) to be viewed. Using standardized data-collection forms, medical students and residents trained in chart abstraction, and supervised by an academic internist, reviewed each participant's EMR, starting from 12 months prior to the date of entry into the study. The EMR was reviewed for MH diagnoses and prior year MH treatments (prescription of an SSRI and/or greater than or equal to one visit with MH professional).[20,21] MH diagnoses included ICD-9-coded PTSD, depression, anxiety, and panic disorder in a patient's problem list and/or in a clinician's typed assessment from any given visit (excluding MH visits). With respect to visits with MH professional, the type of MH professional seen and the type of behavioral therapy received was not available for review. However, MH professional could enter MH diagnosis into a patient's problem list and/or prescribe an SSRI, both of which would appear in the EMR and be available for review for this study.

Main variables

The primary dependent variable was *receipt of MH treatment in the prior 12 months*. MH treatment was defined as receipt of either an SSRI prescription and/or greater than or equal to one visit with a MH professional, as these are treatments that could be effective for PTSD. There were four main independent variables of interest. *MH diagnoses in the EMR* included PTSD, depression, anxiety and/or panic disorder. *More severe PTSD symptoms* was a categorical variable indicating the highest quartile of the distribution of all participants' PCL-C scores.[19] *Comorbid depression* was defined as a PHQ-9 score of nine or greater, based on published scoring cutoffs from the PHQ-9 derived from studies correlating past two week depressive symptoms with a diagnosis of major or other depression.[15] *Disclosure of suffering from trauma-associated symptoms to a medical professional* was a dichotomous variable.[15,18,19] Covariates of interest included the sociodemographic factors age, sex, race (black vs. other), marital status, education level, employment status, and annual income. Insurance status was not included in the model as more than 99% of participants had coverage for the types of utilization studied via federal, state, or private insurance or through an uncompensated care pool ("free care").

Statistical analysis

Descriptive and bivariate analyses were conducted using *t*-tests for continuous data and the Chi-square (χ^2) test for categorical data. To determine factors associated with patients receiving MH treatment, logistic regression was tested for associations between the dependent variable, the main independent variables of interest, and potential confounding factors. The latter were selected if they had statistically significant associations with the outcome in bivariate analyses ($p<0.05$) or, in the cases of more severe PTSD symptoms and comorbid depression, due to prespecified hypotheses.

Results

Characteristics of patients with PTSD

Of the 133 participants (all with current PTSD by diagnostic interview), the mean age was 41 years (SD=11; ***Table 1). Eighty-two (62%) were female and 75 (56%) were black. Almost half had never been married, 40 (30%) had less than 12 years of education, and 83 (62%) were unemployed or on disability. Eighty-five (67%) participants earned less than $20,000 annually. The majority (71%) also had comorbid depression by diagnostic interview.

EMR documentation of mental illness

Table 1 describes the MH diagnoses in subjects' EMRs. The majority (88%) of participants who received MH treatment had at least one mental illness diagnosis documented in the EMR, most commonly depression (71%). For participants with research interview-diagnosed PTSD alone (N=39) and participants with research interview-diagnosed PTSD and comorbid depression (N=94), frequencies of EMR documentation of PTSD (10% vs. 11%, p=0.9) and depression (44% vs. 52%, p=0.4) were similar.

Receipt of MH treatment

Nearly half of the participants received MH treatment in the prior year: 23 (17%) had both an SSRI prescription and at least one visit with MH professional; 24 (18%) received only an SSRI prescription; and 19 (14%) had no SSRI medication but at least one visit with MH professional (mean number of visits was 4.5 with a range of 1–50; Fig. 1).

Predictors of receipt of MH treatment

In bivariate analyses, age and sex were not significantly different between those who received MH treatment compared to those who did not. Fewer black patients received MH treatment compared to all other racial groups combined, while more Caucasians and Hispanics did receive treatment. A significantly higher proportion of treated patients were unemployed or on disability.

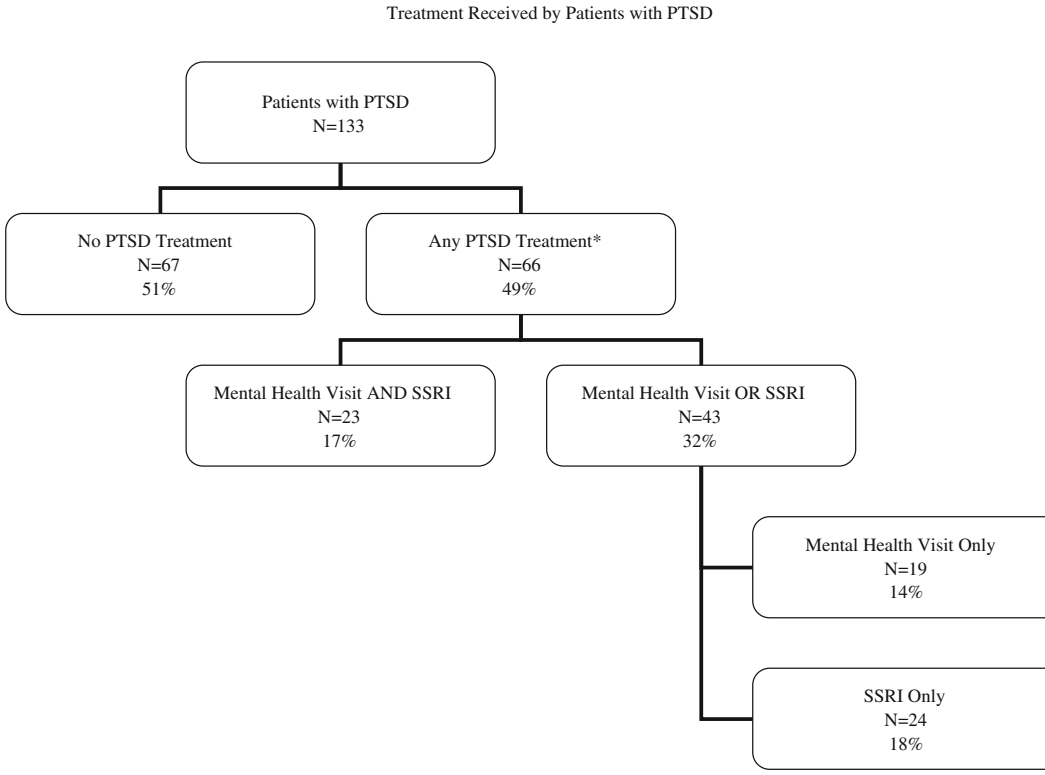

Figure 1

Treatment received by patients with PTSD. * Mean number of visits with MH professional is 4.5; standard deviation 7.6. Range 1–50

Among participants with more severe PTSD symptoms and those with comorbid depression as determined from the research interview, there was no statistically significant difference in the proportion that received MH treatment. Compared to untreated subjects, a higher proportion of treated ones reported that at some point they had disclosed suffering from trauma-associated symptoms to a medical professional. In addition, a significantly higher proportion of treated participants had a diagnosis of PTSD, depression, anxiety, and/or panic disorder in their EMR (Table 1).

In adjusted analyses, the odds of receiving MH treatment were increased 8.2 times (95% CI 3.1–21.5) for participants with an EMR MH diagnosis, even if the patient did not specifically have PTSD documented in the EMR. Disclosure of trauma-associated symptoms to a medical professional increased the adjusted odds of receiving MH treatment by 2.6 (95% CI 1.1–6.4). Being unemployed or on disability was also statistically significant (OR 2.7, 95% CI 1.1–6.7). Although attenuated in adjusted analyses, black patients were less likely to receive MH treatment. Race, as well as other factors hypothesized to be clinically relevant (more severe PTSD symptoms and comorbid depression as determined by the research interview), were not statistically significant in this analysis (Table 2).

Discussion

Among a sample of urban PC patients with PTSD, few patients had this diagnosis listed in their medical record. However, despite not having documented PTSD diagnoses, nearly 50% received MH treatment: either an SSRI and/or a visit with MH professional. In addition to a diagnosis of PTSD, any MH diagnosis (depression, anxiety, panic disorder) in the EMR, disclosure of trauma-associated symptoms to a medical professional, and being unemployed or on disability, were all associated with receipt of MH treatment.

Initially factors that might be associated with receipt of MH treatment were selected from the literature. The first two hypotheses were that having more severe PTSD symptoms and/or having comorbid depression (by research interview) would correlate positively with participants receiving MH treatment. These hypotheses were not supported in either bivariate or adjusted analyses. One potential explanation is that participants who received MH treatment may have improved as a result of the treatment and thus had less severe symptoms at the time of assessment for this cross-sectional study. Another plausible reason for these findings is the cross-sectional design of this study that, by definition, did not allow for prospective observations of participants over time.[14]

Table 2
Factors associated with receiving PTSD treatment[1]

Factor	Odds ratio[2]	95 % CI
EMR MH diagnoses	8.21	3.14.–21.52
Disclosure of trauma–associated symptoms	2.61	1.06–6.43
Unemployed/on disability vs. employed/student	2.68	1.08–6.65
Black race vs. others	0.42	0.18–1.02
Comorbid depression	0.52	0.18–1.49
More severe PTSD symptoms	1.32	0.50–3.51

[1]Adjusted odds ratio via logistic regression modeling including factors statistically significant in bivariate analysis

[2]As compared to patients who did not receive prior year PTSD treatment consisting of SSRI and/or visit with MH professional

Meredith et al.[22] found that lack of time and patient financial burden were the strongest barriers to diagnosis and treatment of PTSD among PC physicians, not doubt of the diagnosis. While prospectively Kessler et al.[14] demonstrated that while some patients with depression and anxiety are not recognized as suffering from mental illness at an initial consultation, over time, they are diagnosed and receive treatment.

The next hypothesis tested was that some patients with PTSD receive MH treatment despite the fact that they are not actually diagnosed as having PTSD, likely due to recognition of a comorbid mental illness or misdiagnosis of PTSD. In this sample, 29% of patients had lone PTSD and 71% had comorbid PTSD and depression by research interview. Interestingly, EMR documentation of PTSD was low among all patients (1 in 10). However, 50% of the sample had depression documentation in the EMR. Patients with both PTSD and depression were more frequently diagnosed as suffering from depression. Patients with lone PTSD (i.e., no depression) were commonly diagnosed incorrectly as suffering from depression. These data are consistent with the findings of Samson et al., who demonstrate that among PC patients with PTSD, it is the symptoms of depression or anxiety that are more likely to be recognized and treated.[13] It may be concluded that, in spite of not being appropriately diagnosed with PTSD, many patients receive some MH treatment simply due to therapeutic overlap in the management of common mental illnesses.[2,3,5,7,8] However, insufficiently treating patients with PTSD may result in partially treated PTSD and its associated comorbidities.[23–25]

While first-line pharmacotherapy for PTSD, depression, and anxiety/panic disorder is a SSRI, consensus statements recommend that patients with PTSD also have specialized MH counseling, with structured cognitive behavioral therapy (CBT) or psychotherapy, as part of a comprehensive treatment plan.[5–10] This contrasts to depression, for which monotherapy with antidepressants is recognized by current guidelines as an effective first-line treatment for patients with mild, moderate, or even severe major depression.[26,27] In clinical trials of patients with PTSD, CBT is superior to SSRI treatment, with 50% of patients achieving remission with lone CBT versus 30% with lone SSRI treatment.[11] Thus consensus guidelines suggest that PC patients with PTSD ought to be referred for psychological treatment.[8,9] In this study, it is likely that most participants who received a visit with MH professional did not receive CBT or other specific psychotherapy, as the mean number of visits (4.5) was fewer than the number of visits typically necessary for CBT in studies of PTSD (9–12 sessions).[28]

Ultimately, there is a significant benefit to focused PTSD treatment, as incomplete treatment leads to suboptimal outcomes. Patients with partially treated PTSD (termed Partial PTSD), although less symptomatic than those who meet criteria for full PTSD, still suffer from clinically meaningful symptoms and are at increased risk for suicide.[3,23–25,29–33] In addition, patients with untreated anxiety disorders, including PTSD, more frequently utilize healthcare and generate substantial direct and indirect costs.[34] The United States Preventive Services Task Force currently does not offer any recommendations on screening for PTSD.[35] Until formal guidelines are available and more physicians are proficient in diagnosing PTSD, the findings of this study suggest that physicians consider inquiry about trauma-associated symptoms for those with anxiety or depressive symptoms, or those in high prevalence populations (e.g., returning military or past substance dependence) to facilitate identification of PTSD and thus referral to appropriate treatment.[36] Prospective trials are needed to establish the evidence base for routine inquiry.

Another finding merits discussion. Being unemployed or on disability was also significantly associated with receipt of MH treatment. Patients with PTSD (and anxiety disorders) as well as more significant impairment (i.e., are on disability) more frequently utilize healthcare.[3,4] Perhaps it is this increase in utilization which, as Kessler et al.[14] suggests, ultimately leads to the accurate diagnosis of PTSD. Once diagnosed, patients with PTSD who are unemployed or disabled, may also be more available to partake in treatment compared to their employed counterparts.[14]

Although the relationship was attenuated when adjusted for other factors, blacks were less likely to be diagnosed with PTSD and less likely to receive MH treatment. Perhaps the fact that cultural differences exist in the experience of psychological trauma can partially explain this phenomenon.[37] Others studies show similar findings and posit that a patient's race may actually affect a physician's awareness of mental illness.[38] Further investigation into this phenomenon is needed in order to develop interventions to reduce this disparity.

Perhaps physicians are hesitant to assign a diagnosis of PTSD for fear that the stigma of a MH diagnosis may exacerbate the symptoms of mental illness or lead to discrimination.[39] However, studies have shown, and physicians should be counseled, that there is a therapeutic benefit for patients in the accurate recognition of mental illness.[12] Ormel et al. examined recognition of mental illness by general practitioners in the Netherlands. In addition to the fact that patients recognized as having mental illness were more likely to be treated, compared to those who were not recognized, recognition on its own had positive effects on patient psychopathology and social functioning.[12] Ormel suggests that the key elements present in the process of mental illness recognition, acknowledgement, re-interpretation, and social support, form the therapeutic basis for these positive results.[12]

This study has several limitations. The study was conducted at an urban, academic safety-net hospital, with the majority of participants unemployed, or on disability, and earning less than $20,000 annually. This may seem to make the results less generalizable to other practice settings. However, there are numerous similar practice settings in US cities. Furthermore, historically studies examining patients with mental illness in other PC settings similarly demonstrate that those with mental illness have higher rates of disability affecting both social and occupational functioning.[40,41] The cross-sectional study design does not allow for patients to be followed over time. This does limit the types of inferences one can make. For example, during the interview, patients were asked whether they have ever disclosed to a medical professional that they suffer from trauma-associated symptoms. For those patients who both answered affirmatively and also received MH treatment, one cannot assume this disclosure was made prior to receiving treatment. Although prior research shows that a known history of trauma is highly correlated with receipt of MH treatment, the temporal relationship in this study is not known and one cannot assume causality.[7] Another aspect of the study design, the EMR review, provided some limitations. There was no data on the length or content of treatment that patients received, nor whether patients were adherent to their treatments. In addition, it is not known whether some patients received MH treatment prior to the year before the study interview. Such information might have captured additional treatments for PTSD, however it is also not known whether patients had a diagnosis of PTSD more than a year prior to the study interview. Thus the added value of such information is unclear (this study examined utilization during the time period that coincides with the diagnostic information available). The EMR did not allow for the capture of information on patients who may have been offered, yet refused, MH treatment. In addition, it is not known if any participants sought MH treatment outside of the study facility. Given that a large percentage were unemployed or on disability and earned less than $20,000 annually, it was speculated that they were less likely to utilize MH services outside of the safety-net hospital. Finally, as there was no access to the content of visits with MH professionals, it was not possible to evaluate the type of therapy that may have been received. However, using validated measures to assess for PTSD at the time of entry into the study allowed for the study of patients with current mental illness and to evaluate the types of treatment they received while they had a documented diagnosis. Most importantly, these data provide new insight into factors that impact whether or not a PC patient with PTSD receives MH treatment, and demonstrate the need for further research examining both patient and physician related barriers to PTSD diagnosis and treatment.

Implications for Behavioral Health

Among urban, safety-net hospital PC patients with current PTSD, half received some sort of MH treatment in the prior year, defined as a SSRI and/or a visit with MH professional. However, rather than a diagnosis of PTSD in their EMRs, many patients were identified as suffering from depression, anxiety, and/or panic disorder. Thus it appears as though treatment was often fortuitously received due to therapeutic overlap in the management of PTSD and other common mental illnesses (specifically depression). Encouraging PC patients to disclose if they suffer from trauma-associated symptoms may improve PC identification and treatment of PTSD. Future research, focused on strategies to reduce patient and physician barriers to disclosing trauma and aimed at improving the diagnosis and treatment of PTSD in PC, is essential to advancing the delivery of MH treatment to those suffering from this disabling condition.

Abstract

Objective. No evidence-based methods exist to identify prescription drug use disorder (PDUD) in primary care (PC) patients prescribed controlled substances. Aberrant drug-related behaviors (ADRBs) are suggested as a proxy. Our objective was to determine whether ADRBs documented in electronic medical records (EMRs) of patients prescribed opioids and benzodiazepines could serve as a proxy for identifying PDUD.

Design. A cross-sectional study of PC patients at an urban, academic medical center.

Subjects. Two hundred sixty-four English-speaking patients (ages 18–60) with chronic pain (≥3 months), receiving ≥1 opioid analgesic or benzodiazepine prescription in the past year, were recruited during outpatient PC visits.

Outcome Measures. Composite International Diagnostic Interview defined *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) diagnoses of past year PDUD and no disorder. EMRs were reviewed for 15 prespecified ADRBs (e.g., early refill, stolen medications) in the year before and after study entry. Fisher's exact test compared

frequencies of each ADRB between participants with and without PDUD.

Results. Sixty-one participants (23%) met DSM-IV PDUD criteria and 203 (77%) had no disorder; 85% had one or more ADRB documented. Few differences in frequencies of individual behaviors were noted between groups, with only "appearing intoxicated or high" documented more frequently among participants with PDUD (N = 10, 16%) vs no disorder (N = 8, 4%), $P = 0.002$. The only common ADRB, "emergency visit for pain," did not discriminate between those with and without the disorder (82% PDUD vs 78% no disorder, $P = 0.6$).

Conclusions. EMR documentation of ADRBs is common among PC patients prescribed opioids or benzodiazepines, but unsystematic clinician documentation does not identify PDUDs. Evidence-based approaches are needed.

Key Words. Prescription Drug Use Disorder; Diagnosis; Aberrant Drug-Related Behaviors; Primary Care; Chronic Pain

Introduction

Chronic pain is a common presenting problem in the primary care (PC) setting; approximately 22% of PC patients report chronic pain [1]. Over the past two decades, opioid prescribing for chronic noncancer pain has dramatically increased, accompanied by rising rates of opioid misuse, unintentional overdose, and legal prosecution of physicians [2–6]. Benzodiazepine prescribing has similarly become a topic for debate, not only due to risks for medication abuse and diversion but also because of the association of benzodiazepines to opioid-related deaths [7]. Given that PC physicians (PCPs) provide the vast majority of psychoactive substances nationally [8], they must take great care in the decision to prescribe these medications and monitor for side effects to avoid such negative outcomes. In addition, PCPs must assess for risk of prescription drug use disorder (PDUD), defined as abuse of or dependence on prescription opioids and prescription benzodiazepines and/or any illicit substance and/or alcohol dependence while receiving opioid and/or benzodiazepine pharmacotherapy [9,10]. One suggested method of monitoring patients prescribed opioids and benzodiazepines is assessing for aberrant drug-related behaviors (ADRBs) [9].

Experts in pain medicine define ADRBs as behaviors suggesting out of control use of medications, one hallmark of addiction. Examples of such behaviors include insisting on a medication by name, claiming non-narcotic medications "do not work," buying medications off the street, making frequent emergency visits for pain medications, asking for an early refill, and spending extensive time discussing medications [11]. ADRBs may also include taking a medication in a manner not prescribed—e.g., taking someone else's medication, unsanctioned dose escalations, multiple prescription locations, or different providers writing prescriptions [11]. Finally, in addition to behaviors that are suggestive of a patient taking medication in an out of control manner, some behaviors suggest medication diversion, the transfer of legally obtained drugs into illegal channels—where patients exchange or sell their prescription drugs to someone else [4,12]. It is worth noting that when ADRBs do occur, there can be multiple possible explanations for the behavior and hence consideration of a differential diagnosis of their etiology is appropriate, with PDUD being one of several plausible explanations [13].

Currently, experts recommend monitoring patients prescribed chronic opioids for ADRBs based on the assumption that ADRBs indicate medication misuse, diversion, or addiction [14–19]. However, the evidence supporting this assumption is very limited: studies using ADRBs have relied on physician recall and/or documentation of ADRBs in a patient's chart as a proxy for PDUD [20–23]. In order to establish an evidence base for the use of ADRBs as a proxy for PDUD in patients with chronic pain prescribed opioids and benzodiazepines, we compared chart documentation of ADRBs with a systematically obtained patient diagnosis of PDUD.

Methods

Study Design

This was a cross-sectional study of PC patients with chronic pain who were recruited from the PC clinics of an urban, academic, safety-net medical center [24,25]. Safety-net hospitals in the United States care for poor and vulnerable populations who may be uninsured or underinsured and include disproportionate numbers of underrepresented minorities [26]. We collected data from participants by an in-person interview with a trained member of the research team and by a subsequent electronic medical record (EMR) review for abstraction of prescription opioid and benzodiazepine data to assess entry criteria, as well as to identify any documentation of 15 prespecified behaviors considered by experts to be concerning for addictive disease [10,11]. Further specific details of study methods have been published previously [24,25].

Setting

Research interviewers recruited patients waiting for scheduled PC visits. Interviewers were physicians, master-level professionals, college graduates, and college students who underwent 60+ hours of interview training. All participants were approached in the waiting rooms of the hospital-based PC practice [25].

Recruitment and Enrollment

Of the 833 (40.0%) patients eligible for the study based on explicit criteria, i.e., were 18–60 years of age, spoke English, endorsed pain of at least 3-month duration, reported use of any analgesic medication, including over

the counter or prescription, in the prior month, and had a scheduled PC appointment, 589 patients (70.7%) agreed to participate. Informed consent was obtained from eligible patients, and participants were compensated $10 for the one time interview. The Boston University Medical Center Institutional Review Board approved the study.

All EMR entries from 12 months prior to study entry were reviewed looking for documentation of any opioid or benzodiazepine prescription; a comprehensive list of all included medications has been previously published [24,25]. Standardized chart abstraction forms were used. EMRs were comprehensive including notes from all clinic visits, all emergency department records, all inpatient discharge summaries, phone calls, and an institutionalprescription database. This data analysis was based on the 264 (44.8%) study participants who were prescribed an opioid pain reliever and/or a benzodiazepine in the 12 months prior to their interview.

Measures and Key Variables

Independent Variable: PDUD

PDUD was defined as per DSM-IV diagnostic criteria for current (past year) abuse of or dependence on prescription opioids and prescription benzodiazepines [10]. Also included in this definition was any illicit substance and/or alcohol dependence while receiving opioid and/or benzodiazepine pharmacotherapy. During the interview portion, participants were assessed using the Composite International Diagnostic Interview (CIDI) v.2.1 module on Drug Disorders to diagnose drug use disorders [27]. Criteria for drug abuse included social, physical, or legal consequences from use. The criteria for drug dependence included compulsive use, health consequences, and physical dependence (i.e., tolerance or withdrawal). Physical dependence alone did not suffice to meet the diagnosis. The CIDI short form was used to measure current alcohol dependence; current alcohol abuse and past alcohol use disorders were not measured in order to reduce respondent time burden [27]. Thus, participants with PDUD may have a lone prescription opioid and/or benzodiazepine disorder, a lone substance use disorder (SUD) (an illicit drug disorder and/or past year alcohol dependence) while receiving prescription opioids and/or benzodiazepines, or a comorbid prescription opioid and/or benzodiazepine disorder along with another SUD (i.e., comorbid illicit drug disorder and/or past year alcohol dependence) [27].

While it may be questioned whether a lone SUD while receiving prescription opioids and/or benzodiazepines truly constitutes PDUD, this is a definition that has been used clinically and also suggested by experts in pain and addiction [10,28,29]. However, this was taken into account and a sensitivity analysis was conducted, in which those with a lone other SUD while prescribed an opioid and/or benzodiazepine were analyzed as a unique group. As this analysis yielded similar results, for simplicity the data presented are from a two-group analysis comparing those with PDUD as defined above to those with no disorder. Nicotine dependence was not included in the variable SUD.

Dependent Variable: ADRBs

Two years of EMR data were reviewed for each participant in order to assess ADRBs, records from 12 months prior to and poststudy entry, looking for documentation of 12 prespecified behaviors. These behaviors were recognized in the published literature as signs of potential addiction or diversion in patients prescribed controlled substances [11]. While our list of behaviors was based on the work of Portenoy and meant to represent the concepts he first put forward, our nomenclature was slightly modified. Standardized chart abstraction forms were used.

Statistical Analysis

Using Fisher's exact test, frequencies of each ADRB and cumulative numbers of ADRBs were compared between participants with PDUD and no disorder.

Results

The demographic characteristics of the 264 participants, stratified by the presence or absence of PDUD, are presented in Table 1. Twenty-three percent (61/264) of study participants met criteria for current PDUD. We found few demographic differences between the two groups (i.e., age, gender, race, and education). Characteristics included mean age of mid-40s, majority African American, and over two-thirds with 12 or more years of education. At least 50% of each group, with and without PDUD, were receiving disability payments and over 95% of each group had severely disabling pain [30]. However, participants with PDUD were more likely to have the following characteristics: posttraumatic stress disorder (PTSD), depression, smoker, past time in jail, and a family history of substance abuse (Table 2).

Among patients receiving prescriptions for opioids in the prior 12 months, 15% received the equivalent of 20 tablets of 5 mg oxycodone in ≤2 fills, 12.6% received 21–60 tablets in ≤3 fills, 22.7% received 61–150 tablets in ≤3 fills, and 49.6% received >150 tablets or >3 fills of any amount (e.g., four prescriptions of 20 tablets each). The majority of those in the last category received >6 fills. Of those receiving benzodiazepines in the prior 12 months in one or more prescriptions (N = 66), 17% received less than 30 pills, 15% received 30–100 pills, 15% received 101–200 pills, and 41% received >200 pills. Eight patients (12%) received benzodiazepine prescriptions from outside psychiatrists, for which specific pill counts and fills were unavailable.

Of the 15 behaviors assessed, only "appearing intoxicated or high" was documented more frequently in the EMRs of participants with PDUD (N = 10, 16%) vs no disorder (N = 8, 4%), $P = 0.002$. However, the frequency was low and this behavior was present in the charts of those with no disorder (Table 2). Indeed most participants in both groups

Table 1 Demographic characteristics of PC participants with chronic pain and analgesic medication use stratified by prescription drug use disorder (PDUD) (N = 264)

Variable		PDUD N = 61 (23%)	No Disorder N = 203 (77%)	*P* Value
Mean age (year)		45.9	47.3	0.24
Female gender		49%	58%	0.24
Race	African American	54%	60%	0.26
	Hispanic	13%	9%	
	White	28%	20%	
	Other	5%	11%

Ever in jail		71%	33%	<0.001
Family substance abuse		74%	48%	<0.001

PC = primary care; PTSD = posttraumatic stress disorder.

had at least one ADRB (85%, *P* = 1.0). With respect to the remaining 14 behaviors, the frequency of any one documented behavior was not significantly different among patients with PDUD and with no disorder. An urgent visit for pain was the most common aberrant behavior, but frequency did not differ between the two groups (PDUD vs no PDUD—82% vs 78%, *P* = 0.6). Early refill was present in about 15% of both groups of patients. The remaining behaviors were present in 15% or less of participants. With respect to cumulative behaviors, patients with PDUD do not have significantly more documented ADRBs in their EMR (Figure 1). Rather, having one or two behaviors in the chart was common; over 80% of the patients with and without PDUD had at least one behavior in their chart and almost 40% in both groups had two ADRBs.

Discussion

By using patients' EMRs and research interviews, this study investigated whether ADRBs documented in patients' charts reflected a diagnosis of PDUD. If documented ADRBs were indeed viable indicators of PDUD, then the EMR abstractions would have revealed significant differences in patients' charts; patients with a diagnosis of PDUD would have had more ADRBs documented in their medical charts than those with no diagnosis. The data reveal no differences; ADRBs as noted in routine PC practice do not identify patients with PDUDs. Despite the thoughtful clinical insight that went into the development of these recommended "clinical pearls," empirically they do not yield the desired outcome, identification of patients that should be of great concern to the clinician. However, the negative results of this study nevertheless do provide insight about physician recording in the EMR and suggest that relying on nonsystematic documentation to identify addiction or diversion is not useful.

Table 2 Frequency of aberrant drug-related behaviors stratified by prescription drug use disorder (PDUD) (N = 264)

Behavior	PDUD N = 61 N (%)	No Disorder N = 203 N (%)	*P* Value
Appears intoxicated/high	10 (16%)	8 (4%)	0.002
Use someone else's medication	3 (5%)	8 (4%)	0.8
Bought medication off the street	3 (5%)	3 (2%)	0.1
Extensive time discussing medication	3 (5%)	9 (4%)	1.0
Involvement in an accident	3 (5%)	29 (14%)	0.07
Number of prescription locations	3 (5%)	4 (2%)	0.2
Insists non-narcotics do not work	1 (2%)	8 (4%)	0.7
Try to get scripts from other MDs	1 (2%)	3 (2%)	1.0
Urgent visit for pain	50 (82%)	159 (78%)	0.6
Early refill	9 (15%)	29 (14%)	1.0
Urgent visit for narcotic pain medications	9 (15%)	14 (7%)	0.06
Insists on medication by name	7 (12%)	22 (11%)	0.8
Lost medication	5 (8%)	11 (5%)	0.5
Increase dose without authorization	4 (7%)	12 (6%)	0.6
Reports stolen medication	3 (5%)	3 (2%)	0.1

MD = medical doctor.

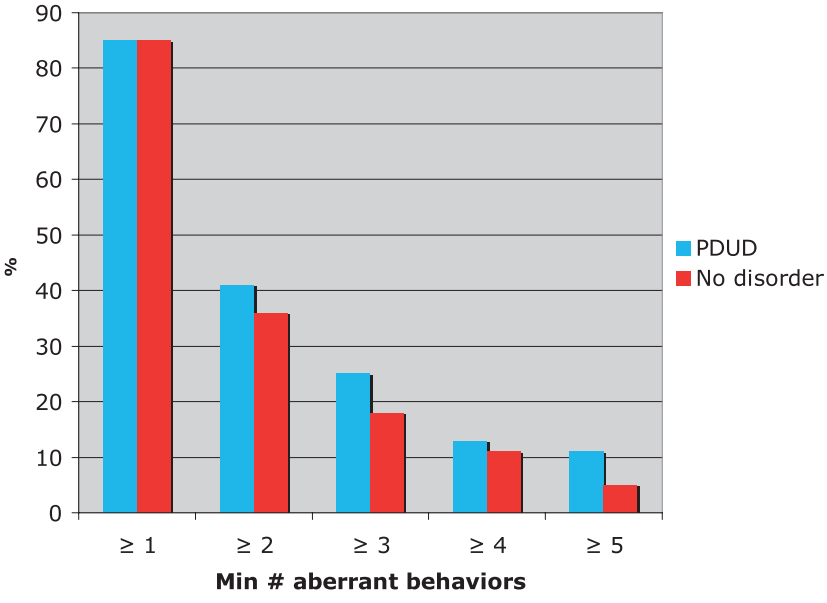

Figure 1 Cumulative aberrant drug-related behaviors among participants with prescription drug use disorder (PDUD) and no disorder. No results were statistically significant.

Clinicians prescribing opioids for patients with chronic pain are aware that some degree of ADRBs may occur during the course of treatment. Accordingly, the provider should be aware that there is a differential diagnosis for ADRBs, of which PDUD is only one potential explanation [31]. Included in this differential is pain that is not adequately controlled, leading patients to increase their dose of medication without authorization and the subsequent need for an early refill [31]. For example, randomized controlled trials have demonstrated that opioid analgesia is not consistently effective; thus, patients with uncontrolled pain may take additional medication in an effort to find relief [32,33]. In addition, some patients with adequately controlled pain may hoard medications, fearful of a time when the pain may suddenly worsen [11,34]. This too can lead to early refills and even use of multiple prescription locations. Finally, a pain flare can send a patient to the emergency department in an effort to find relief. Thus, patients without PDUD can also plausibly have ADRBs documented in their charts. This study found that this is in fact the case, and these events do occur at a comparable frequency as ADRBs in patients with and without PDUD. The presence of these behaviors in those *without* PDUDs has been referred to as a pseudoaddiction, in which the aberrant behaviors will resolve once the pain is adequately treated [13]. It is clear that the patients in this study did not have adequately controlled pain, as over 95% of both groups of patients had severely disabling pain. Perhaps if the pain were better treated, then a true difference in documented ADRBs would exist between the groups. Alternatively, as suggested by Portenoy and McCarberg and Passik, perhaps many of the behaviors considered to be concerning are really more benign and not truly associated with addiction or diversion [11,31].

One documented behavior warrants a deeper investigation. From the 15 ADRBs examined, only appearing intoxicated or high was documented more frequently in the EMRs of patients with PDUD. Any time a clinician suspects a patient of being intoxicated or high, further evaluation is warranted. Recently published guidelines offer clinicians a framework for safely initiating and continuing to prescribe opioids [9]. It is suggested that at every clinical visit, the patient is assessed for any risks associated with the opioids as well as any benefits received from the medication. Prescribing ought to continue when the benefits of a medication outweigh its potential risks, thus ensuring an ethically equitable distribution of benefits and burdens [35]. If a patient seems to be intoxicated or high, concern arises that the potential risks to the patient, as well as society, outweigh any benefits. In this situation, titration off of the opioid or benzodiazepine combined with the provision of adjunctive therapy for pain and/or anxiety, as well as referral to substance abuse treatment and/or psychiatry, is likely most appropriate [36].

The other 14 ADRBs were not significantly different between the groups. As this study examined documented behaviors, the negative results suggest that relying on unsystematic physician documentation is not useful for identifying patients with PDUD. Rather, in order to determine if ADRBs can be useful to monitor patients for PDUDs, a reasonable next step would be to assess implementation of standardized clinical assessment tools into clinical practice.

Although it may appear that ADRBs are not useful in detecting PDUD, the nonsystematic collection of ADRBs may be the problem rather than the ADRBs themselves [37]. Validated tools have been studied to predict misuse of substances while being prescribed opioid analgesia for chronic noncancer pain [9]. For example, the Screener and Opioid Assessment for Patients with Pain™ is a tool to help risk-stratify patients at the

initiation of opioid therapy [20]. The results provide an idea of how closely a patient ought to be monitored during treatment [20]. In addition, the Current Opioid Misuse Measure (COMM) provides a means for ongoing risk estimation via standardized assessment of aberrant behaviors [38]. The present authors have studied the COMM and caution that clinical assessment tools may perform differently in distinct patient populations, as the sensitivity and specificity of some tools may vary with the prevalence of disease [24]. As this study demonstrates, ADRBs as recorded in a patient's EMR are not associated with PDUD. Thus, caution should always be utilized when monitoring any patient for the development of PDUD, even when standardized assessment tools are in place. As Butler et al. stress, the purpose of these tools is not to serve as the basis for punitive measures [38]. Rather, they are to help clinicians have a means for consistent patient assessment and to limit the need to rely on haphazard documentation.

Finally, the results demonstrate that patients with PDUD were more likely to suffer from PTSD and/or depression, to be current smokers, to have ever been in jail, and to have a family history of substance abuse. The present authors have previously explored these clinical risk factors for PDUD [25]. In addition, as previously reported, over 30% of patients without PDUD also suffered from comorbid mental illness, smoked, had been in jail, and had a family history of substance abuse [25]. Clearly, there is a significant burden of comorbid mental illness in patients with chronic pain, offering further support of the need for an interdisciplinary approach to the management of chronic pain [36].

This study has limitations. All participants with PDUD may not have been properly identified through inadequacy of the study instruments or through inaccurate reporting on the part of study participants. This would lead to misclassification bias, in which patients with PDUD are inappropriately labeled as having no disorder, serving to bias the results toward the null hypothesis [39]. In addition, tolerance to and withdrawal from opioids and benzodiazepines can be a naturally occurring phenomenon but are nonetheless included in the diagnostic interview for PDUD [10]. This would serve to bias results away from the null hypothesis. Finally, the CIDI does not assess for drug diversion, a specific risk related to prescription opioids and benzodiazepines [5,12,40]. Even with its acknowledged limitations, the CIDI has been used widely and is considered to be a well-validated diagnostic instrument [27]. The sample size was small and included only 61 patients with PDUD. Even if a larger sample size revealed statistically different findings, individual ADRBs would likely have little predictive value in diagnosing PDUD, as the majority of patients without a substance disorder also demonstrated each of the behaviors. Two years worth of chart entries were reviewed for each study participant, thus providing data to examine cumulative numbers of behaviors exhibited, which were not significant. However, when we looked at a combined number of behaviors, we did not stratify them and look at a hierarchy of more severe behaviors. Overall, the results contribute to the recognition of the potential limitations of documented ADRBs and suggest a need to utilize a standardized approach to patient assessment as a potentially more informative way to gain clinical insight from ADRBs.

Conclusion

Among PC patients with chronic pain receiving prescription opioids and/or benzodiazepines, having at least one ADRB documented in the EMR is almost universal. In addition, frequencies of most individual behaviors are similar among those with and without PDUD. Reliance on nonsystematic documentation of ADRBs to identify PDUD in PC patients with chronic pain may not be useful. Based on these findings, physicians and researchers should be cautious before using documented ADRBs in the EMR as a proxy for PDUD. Prospective studies, in which ADRBs are systematically assessed, are needed. Only then can we determine the true significance of these behaviors.

Abstract

Background Hypertension is more prevalent and clinically severe among African–Americans than whites. Several health behaviors influence blood pressure (BP) control, but effective, accessible, culturally sensitive interventions that target multiple behaviors are lacking.

Purpose We evaluated a culturally adapted, automated telephone system to help hypertensive, urban African–American adults improve their adherence to their antihypertensive medication regimen and to evidence-based guidelines for dietary behavior and physical activity.

Methods We randomized 337 hypertensive primary care patients to an 8-month automated, multi-behavior intervention or to an education-only control. Medication adherence, diet, physical activity, and BP were assessed at baseline and every 4 months for 1 year. Data were analyzed using longitudinal modeling.

Results The intervention was associated with improvements in a measure of overall diet quality (+3.5 points, $p<0.03$) and in energy expenditure (+80 kcal/day, $p<0.03$). A decrease in systolic BP between groups was not statistically significant (−2.3 mmHg, $p=0.25$).

Conclusions Given their convenience, scalability, and ability to deliver tailored messages, automated telecommunications systems can promote self-management of diet and energy balance in urban African–Americans.

Introduction

In the USA, the prevalence of hypertension is significantly higher among African–Americans compared to Whites. Although the majority of US Blacks who have hypertension receive medical care and antihypertensive medication, only 58% of them achieve adequate blood pressure control [1].

Multiple well-designed studies have shown that lifestyle interventions delivered in-person can improve adherence to antihypertensive medication regimens, to regular physical activity, to a healthful diet, and to weight control recommendations—all of which can reduce elevated blood pressure [2–4]. Nonetheless, these programs are not suitable

for use on a public health scale for reasons including their high cost of personnel, facilities, and materials and the burden on participants to attend multiple counseling sessions in the face of other life priorities. Minority groups of low socioeconomic status (SES) may encounter additional barriers including logistical obstacles (e.g., unreliable transportation), cost considerations, and cultural incongruence of intervention content or delivery [5, 6].

The current public health challenge is to design and implement health programs that can be delivered easily to the millions of patients with hypertension in a practical, low-cost manner. Tailoring these programs to the needs, barriers, and ethno-cultural characteristics of specific populations can help maximize their impact [7].

Studies from our group and others have shown that computer-based, telephone intervention systems can be efficacious in changing patients' health-related behaviors, including medication adherence for hypertensive patients [8], physical activity [9, 10], and dietary behaviors [11]. However, most of these have targeted single rather than multiple behaviors, and few have been culturally adapted. The purpose of this study was to evaluate an automated, culturally adapted, multi-behavior intervention that can be used on a public health scale to promote hypertension self-management in urban African–Americans of low socioeconomic status. The primary study hypothesis was that the intervention group would experience greater improvements in these behaviors than the control group. Our secondary hypothesis was that mean blood pressure (BP) would decrease more in the intervention than control group.

Methods

We conducted a two-armed randomized controlled trial (intervention vs. usual care control) of a novel automated telephone counseling system designed to promote three health-related behaviors that affect blood pressure control: (a) adhering to the antihypertensive medication regimen, (b) following the dietary approaches to stop hypertension (DASH) diet [2], and (c) engaging in regular physical activity [12].

Participants were drawn from the adult primary care practices of a large, urban safety-net hospital and from four affiliated community health centers. Inclusion criteria were as follows: (a) African–American by self-report; (b) a diagnosis of hypertension on the active problem list of the patient's medical chart; (c) a current prescription for ≥1 antihypertensive medications; (d) ≥1 primary care office visits in the previous 2 months; (e) two elevated clinic BP readings in the previous 6 months (systolic blood pressure ≥140 mmHg and/or diastolic blood pressure ≥90 mmHg among non-diabetic patients, and ≥130/80 among diabetic patients); and (f) age ≥35 years. Patients were ineligible if they were pregnant, or had a medical condition that precluded moderate exercise or for which the DASH diet was contraindicated. Patients were also excluded if they scored 7 out of 7 on a modified version of the 8-item Morisky Medication Adherence Scale, indicating high baseline medication adherence [13], had a terminal illness, psychiatric or cognitive disorder, or no access to a telephone.

Potentially eligible patients were identified by searching the electronic medical records of the participating clinical sites for patients who met the inclusion criteria (a–f) above. Primary care providers were then asked to review lists of their potentially eligible patients and remove those with any exclusion. The remaining patients were sent a letter on behalf of their primary care provider that described the study and were asked to return a postage-paid postcard if they did not want to be contacted by study staff. Those who did not opt-out were contacted by phone, the study was explained to them, and they were screened for eligibility. All participants provided informed consent. Based on power analyses and projected attrition, we sought to randomize 360 patients expecting 300 to complete the 8-month study assessment thus providing sufficient power to analyze the three primary behavioral outcomes.

Intervention: Telephone-Linked Care for Hypertension in African–Americans

The intervention was a totally automated, computer-based, interactive telephone counseling system called Telephone-Linked-Care, designed to monitor, educate, and counsel African–American adults with hypertension and to provide summary data regularly to the patient's primary care provider [8–10]. The intervention incorporated principles of social cognitive theory [14], the transtheoretical model of behavioral change [15], and motivational interviewing [16], and was tailored to the user's values. Content was also adapted to cultural characteristics of culturally African–American adults (i.e., not Caribbean–American, Black–Hispanic, etc.). This group-level cultural adaptation was guided by a conceptual framework targeting "surface" and "deep" structural domains, and by ethnic mapping [17] in focus groups of potential users. S*urface structure* adaptation involves matching intervention materials and messages to observable, "superficial" characteristics of a target population including familiar or preferred people, places, language, music, food, locations, and clothing. In this study, surface adaptation included using pre-recorded speech from African–American voice professionals to deliver the automated telephone counseling messages. *Deep structure* can be viewed as the underlying rationale for surface structure preferences. It denotes the cultural values, social, historical, and psychological forces that influence how a given health behavior is viewed by the target population. For example, inviting an African–American adult

to join a neighborhood walking group may have greater deep structure appeal than suggesting he/she walk alone due to the cultural priority of community well-being observed in African–American subgroups [18].

In ethnic mapping, we presented focus group members with foods, activities, and health recommendations and asked to rate them on a continuum from "Mostly a black thing" (e.g., dancing) to "Mostly a white thing" (e.g., skiing, yoga) and we included material in automated telephone scripts, accordingly. These scripts were then pre-tested by potential users of the system and their feedback was incorporated. New script elements emerged from focus group material related to topics such as dance as an effective method to combine fun and healthy exercise, and using low-cost community resources, home-based exercise, or mall-walking to achieve a safe place to exercise. Another new element addressed concerns over "sweating out" one's hairdo as a barrier to exercise:

> "Some hairstyles can get messed when you sweat or swim in a pool. It's nice to look good, but it's also important to be healthy. Consider a low-maintenance style that will look good on you and hold up well with an active lifestyle, like a short natural cut or braids. Ask your hairstylist's opinion the next time you visit. And remember—regular exercise can help you look good too."

The automated telephone intervention delivered one call per week for 32 weeks. The first three calls introduced the three targeted behaviors and their role in BP control, and described the system. Subsequent calls were arranged as modules on medication adherence, physical activity, and diet, and were delivered in the order chosen by the participant. Each call consisted of (a) an introduction, (b) a section for reporting health information collected on study-issued home measurement devices (pedometers, sphygmomanometers, weight scales), and (c) theory-based interactive education and counseling on the targeted behavior.

The physical activity module consisted of 12 calls to increase levels of moderate-or-greater intensity physical activity and was adapted from our previously evaluated automated telephone systems to promote physical activity [9, 10]. The diet module consisted of nine calls—one overview call and two calls for each of four topics: fruits and vegetables, fiber, sodium, and fat. The content of these calls was designed to promote the DASH diet [2]. The medication adherence module consisted of eight calls and was adapted from a successful prototype from our group [8]. Study staff monitored participant use of the system and contacted those who did not call to assist or re-engage them with the system. In addition, participants and their primary care providers received printouts of the participant's progress in each health behavior. These were sent at the beginning and end of each of the three behavioral modules and were designed to reinforce the intervention.

Randomization Groups

Patients who screened eligible by telephone attended an in-home study visit for the purpose of health education, baseline assessments, and randomization. At this visit, participants received a 75-page resource manual that described hypertension, listed dietary recommendations, heart healthy food recipes, and local resources for exercise, and provided information to support antihypertensive medication adherence. They received a 20-min education session based on the content of this manual, and were given a pedometer and a digital weight scale (Healthometer, model # HDR900KD01). Participants completed baseline study assessments and were then randomized to the automated, telephone-linked behavioral intervention plus standard primary medical care, or to the control condition of standard primary medical care alone. Randomization was accomplished using a random number generator to assign subjects to one of the two groups. Neither participants nor research assistants knew the group assignment until after baseline assessments were complete. After group assignment was revealed, intervention group members received a digital home BP monitor (Omron, model # HEM711AC), were trained to use it, and were trained to use the automated telephone system.

Assessments

Assessments were completed by trained research assistants at the participant's home except for a handful done in the study office for logistical reasons. The three primary study outcomes were change in (a) diet quality, (b) leisure time physical activity of moderate-or-greater intensity, and (c) adherence to the antihypertensive medication regimen from baseline to the end of the 8-month intervention period. The secondary outcome was change in BP. All outcomes were assessed at baseline (randomization), 4, 8 (end-of-intervention), and 12 months. Other assessments included weight, height, psychosocial characteristics, and users' perceptions of the automated telephone system (see Table 1 for a list of demographic, medical, and social characteristics assessed, and for information about how they were measured and categorized).

Physical activity outcomes were assessed with the interviewer-administered 7-day physical activity recall [19]. The main physical activity outcomes were (a) minutes per week of moderate-or-greater intensity physical activity, (b) total energy expenditure per day (kcal/day) [20], and (c) whether the participant met the joint Centers of Disease Control and Prevention—American College of Sports Medicine recommendation of at least 150 min of moderate-or-greater physical activity per week [12]. In order to validate self-reported physical activity, 48 participants were randomly selected to wear an accelerometer (CSA Actigraph,

[g] Scores correspond to a 7th–8th grade reading level

model # W7164LS) for 3 days before the baseline and 8-month assessments.

Diet outcomes were assessed with the picture-sort Food Frequency Questionnaire [21]. Five diet outcomes were derived and were analyzed as continuous variables and as categorical variables denoting whether or not the participant reported consuming recommended levels. The outcomes and their categorical cut-offs are as follows [22]: (a) percent of total calories derived from fat (≤30%); (b) percent of total calories derived from saturated fat (≤7%); (c) grams of fiber (≥25 g/day); (d) servings of fruit and vegetables (F&V ≥5 servings); and (e) milligrams of sodium (NA ≤2,400 mg/day).

A composite diet quality score was constructed that combined the five diet outcomes using an approach similar to that used in previous research [11]. Each diet outcome variable was converted into a score from 0 to 100, with higher scores indicating healthier dietary intake. Participants received a score of 100 if they met or exceeded the dietary recommendations described above for total fat, saturated fat, and fiber. However, for fruit and vegetables and sodium intake, a score of 100 points was based on stricter DASH diet recommendations [2]: ≥10 fruit and vegetable servings/day and ≤1,500 mg NA/day. As there are no published criteria to anchor the unhealthy end of the five component dietary outcome scales listed above, we assigned a score of zero to values ≥95th percentile for fat and sodium intake in baseline data, and ≤5th percentile for fiber and F&V. These values were 50.5% of calories from total fat, 16.9% of calories from saturated fat, 9.2 g/day of fiber, 1.5 servings/day of F&V, and 7,663 mg NA/day. This approach captured most of the variation in the sample and reduced the effect of outliers. Next, scores between 0 and 100 were set using a linear transformation (e.g., a value halfway between the criteria for 0 and 100 would receive a score of 50). The overall Diet Quality Score was set as the

mean of these five component scores and, therefore, also had a possible range of 0–100.

Medication adherence was assessed using a 7-item version of the 8-item Morisky Medication Adherence Scale [13]. Scores could range from 0 to 7, with higher scores indicating better adherence.

BP was measured with the Welch Allyn Spot Vital Signs Monitor (Model # 4020-00) by trained research assistants during each home visit using a research protocol similar to other studies [23]. These BP monitors were calibrated at the beginning of the study and annually thereafter. Participants were instructed to sit quietly for 5 min before each reading. At the first home visit a reading was taken in each arm, and the arm with the highest blood pressure was chosen for all subsequent readings. At each visit, three readings were taken in the designated arm and the mean of the last two was used for analysis. Systolic (SBP) and diastolic blood pressure (DBP) were analyzed as continuous outcome variables in separate statistical models. Each was also analyzed as the dichotomous variable ("high" or "controlled") according to national guidelines [24]. Specifically, among non-diabetic participants SBP values ≥140 mmHg and DBP values ≥90 mmHg were considered "high". The corresponding BP cut-off for diabetic participants was 130/80 mmHg. We examined another dichotomous BP outcome that considered BP "controlled" when both the SBP and DBP values were below the recommended cut-off, and "high" when one or both of these values exceeded its cut-off.

Data Analysis

The distributions of the primary outcome variables were examined and adjustments were made to normalize the data when appropriate. For diet outcomes, we eliminated as unreliable all Food Frequency Questionnaire results where the total caloric intake appeared unrealistically low (<800 cal/day) or high (>6,000 cal/day). Consequently, 15 (1.3%) were eliminated for low values and 30 (2.6%) for high values. Results from the remaining sample across the five dietary behaviors were normally distributed except for a few high outliers. These remaining outliers were capped at three standard deviations from the mean, which affected only 32 (0.6%) of the 5,705 total observations.

The distribution of minutes of moderate-or-greater physical activity had a large positive skew; therefore, log-transformed values were used in analyses. Non-transformed means are presented for ease of interpretation. At baseline, the distribution of total energy expenditure (kcal/day) and medication adherence scores were approximately normal.

Preliminary analyses found a higher rate of drop out in the intervention group than among controls, and our primary outcome analyses used an intent-to-treat approach to minimize this potential bias [25]. Missing data were imputed using the last value carried forward. For cases where data were available at time points before and after the missing value, the mean of these two values was used. Results of analyses that considered only participants who were assessed at the 8-month, end-of-intervention time point (i.e., the available-cases analyses) were similar to results from the intent-to-treat analyses.

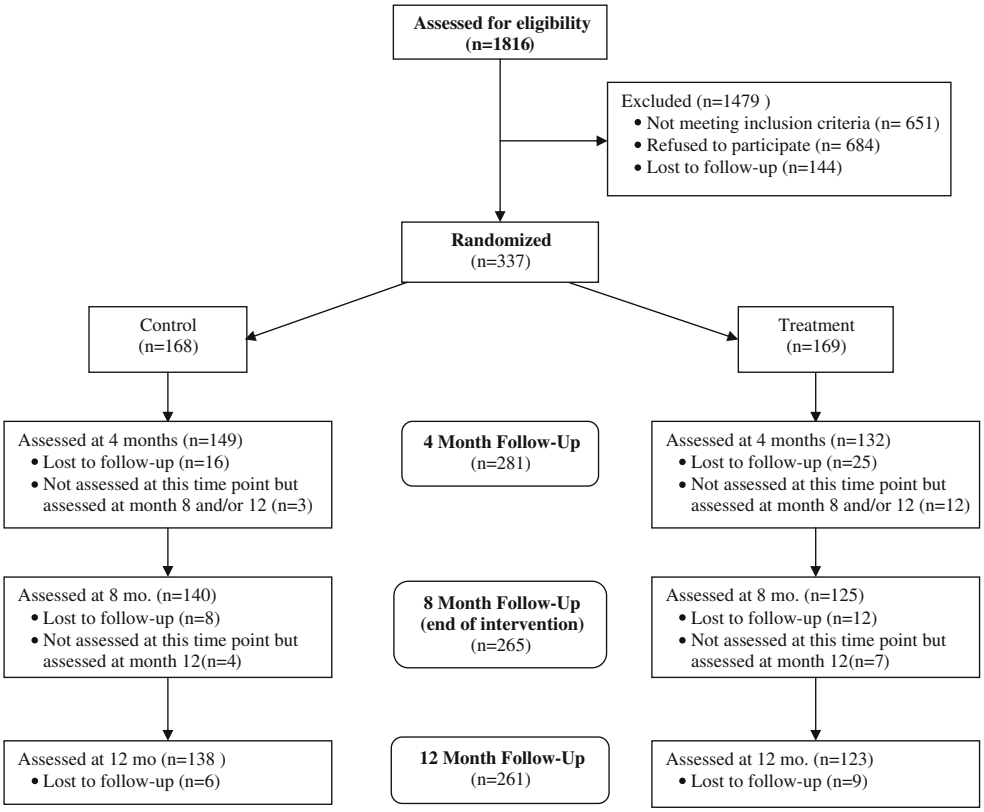
The two study groups were compared on demographic and outcome variables at baseline using t tests for continuous characteristics and chi-square tests for categorical characteristics. Regression models for longitudinal data were used to analyze the effect of randomization group on the change in primary outcomes from baseline to each of the three follow-up assessment time points (i.e., 4, 8, and 12 months). As we hypothesized that intervention effects would be greatest at the end of the intervention, our primary focus was on changes in outcome through the 8-month assessment. Variables on which the groups differed significantly at baseline (e.g., stroke history) or that were likely to independently affect the outcome were included as covariates in each analysis. These included gender, age, perceived financial well-being, education, diabetic status, and stroke history for all analyses (see Table 1). Other covariates were included for particular outcomes as appropriate (e.g., season for physical activity and diet outcomes). Random effects linear regression models were used for continuous outcome measures. Generalized estimating equations logistic regression models were used for categorical outcomes. SAS version 9 was used for all analysis. Dose–response analyses were conducted for participants randomized to the treatment group by calculating the Pearson correlation between the number of completed automated telephone calls and outcomes at 8 months. Analyses were repeated separately for the subset of patients with type 2 diabetes.

Results

Study Participants

Participant recruitment and follow-up occurred from October 2003 to July 2007. Figure 1 displays the flow of potentially eligible participants through the study. Of the 1,816 individuals who were contacted by phone and invited to participate in the study, 684 (35.8%) refused to participate, 651 (37.7%) did not meet eligibility criteria, and 144 (7.9%) were lost to follow-up before the baseline assessment. Of those not meeting eligibility requirements, 161 (24.7%) were excluded because of a perfect medication adherence score on the 7-item Morisky Medication Adherence Scale at the eligibility screening telephone call. The remaining 337 (18.6%) were confirmed to be eligible and were randomized. Table 1 displays sample characteristics at baseline. Of those

Fig. 1 Consort diagram



randomized, 70% were female, 35% had a live-in partner and 37% reported a diagnosis of type 2 diabetes. Of the 99% who reported health insurance, 79% had Medicare/Medicaid or state-subsidized coverage. The sample's SES status was low: 84% had an annual income <$30,000, 27% worked full time, and the average duration of education was 12.2 years. Mean medication adherence was low in both groups, but almost 20% of participants had an adherence score of six or greater at baseline indicating higher adherence [13]. Intervention group participants reported more moderate-or-greater physical activity per week than controls (162.4 min. vs. 126.3 min., $p=0.04$), and a greater percentage of the intervention group met national moderate-or-greater physical activity recommendations (38.5% vs. 26.2%, $p<0.02$). In addition, more intervention group participants than controls reported a history of stroke (11.2% vs. 4.2%, $p<0.02$).

Participant Attrition

By the 8-month assessment, 61 (18.1%) of the 337 randomized participants had become lost to follow-up resulting in a sample size of 276. Sixty-seven percent ($n=41$) of these had dropped out by the 4-month visit. The dropout rate was higher in the intervention group than in the control group (21.9% vs. 14.3%, $p=0.07$), and all of these differential dropouts occurred by the 4-month assessment. We compared dropouts to completers on the characteristics displayed in Table 1 and found that participants who dropped out by the 8-month assessment were more likely to be male (44.3% vs. 26.4% of completers, $p=0.006$). Those who met recommendations for physical activity at baseline dropped out at the same rate across groups, but those who did not meet the recommendation dropped out at twice the rate from the intervention group as from the control group (25.0% vs. 12.1%, $p=0.01$). Lastly, we examined if those who dropped out from the intervention group were different from control group dropouts on other factors. The only significant difference was the control group dropouts were more likely to be diabetic than intervention group dropouts (50% vs. 22.2%, $p=0.03$).

Use of the Automated Telephone System

Overall use of the automated telephone system was modest: 26 (15.4%) did not call the system at all, and 8 (4.5%) connected with it but did not complete a call. The mean number of completed automated telephone calls was 9.0 of the 32 planned calls, and for those who completed at least one call the mean number of completed calls was 11.4. Eight percent of the intervention group completed at least 80% of the 32 planned calls. Participants with diabetes completed 24% more calls than non-diabetic participants (10.8 vs. 8.2, $p=0.08$). Use of the three modules was nearly identical. Among intervention group members, 75 (44.4%) completed at least one diet module call. For medication adherence and physical activity the numbers were 75 (44.4%) and 77 (45.6%), respectively. Participants completed a mean

of 5.03 of 9 diet calls (56%), 5.85 of 12 physical activity calls (49%), and 5.05 of 8 medication adherence calls (63%). Their choice of which module to do first was equally distributed across modules.

We examined whether any of the following 11 patient characteristics predicted patterns of system use: age, gender, income, perceived financial well-being, education, health literacy, number of medications, presence of diabetes or stroke, total number of comorbidities, employment status, presence of a live-in partner, and number of household occupants. We found that none of these variables significantly predicted whether or not an individual used the system. Among intervention group participants who completed at least one automated telephone call, age (r=0.22, p=0.009) and greater perceived financial well-being (r=0.17, p=0.05) correlated positively with the number of calls made. In a multiple linear regression model containing all 11 patient characteristics, only perceived financial well-being (p=0.02) was an independent predictor of number of completed automated telephone calls.

Multivariable Analysis of Outcome Measures

Table 2 presents the change in adjusted means and proportions from baseline to the 8-month (end of intervention) assessment for the primary and secondary outcome variables by study group. No significant intervention effects were observed at the 4- and 12-month assessments. Adjusted group means for continuous outcome variables across all four assessment time points are graphically presented in Fig. 2.

Dietary Outcomes

At the 8-month assessment, there was a significant improvement of 3.5 points (or 0.25 SD, p<0.03) in the overall diet quality score in the intervention group vs. controls. Among the five diet component subgroups, fiber intake improved significantly in the intervention group vs. controls (relative improvement of 2.29 g/day, p<0.02). Favorable changes were also observed for other diet components, but none of these reached statistical significance.

Physical Activity

Actigraph readings from the subsample at baseline and at 8 months correlated with self-reported leisure time moderate-or-greater physical activity (r=0.33, p<0.05), thus providing objective validation of the 7-Day Physical Activity Recall questionnaire data. There was no significant difference between groups in leisure time moderate-or-greater physical activity or in the percentage meeting the recommended

Table 2 Change in the primary and secondary outcomes from baseline to the end of the intervention period (month 8) within and between groups

Variables	Within-group change scores from baseline to the end of intervention		Difference in change scores between groups
	Automated telephone intervention (n=169)	Control (n=168)	
Primary outcomes[d]			
Overall diet quality score	2.8	−0.74	3.54*
MOD+PA[a] (min/week)	−3.44	2.77	−6.21
>150 min/week MOD+PA (%)	−2	5	7
Total energy expenditure (kcal/day)	43.8	−36.2	80.0*
Medication Adherence Score[b]	0.45	0.26	0.19
Secondary outcomes[d]			
Systolic blood pressure (mmHg)	−2.06	0.25	−2.31
Achieved control[c] (%)	0.7	1.9	−1.2
Diastolic blood pressure (mmHg)	−1.28	−0.1	−1.18
Achieved control[c] (%)	6.4	5.1	1.3
Achieved control of both systolic and diastolic blood pressure (%)	5.8	5.0	0.8

*p<0.05

[b] From the 7-item version of the 8-item Morisky Medication Adherence Scale [13]

[c] Systolic blood pressure control defined as <140 mmHg (<130 mmHg if diabetic). Diastolic blood pressure control defined as <90 mmHg (<80 mmHg if diabetic)

[d] Means and proportions are adjusted for covariates used in the specific regression model (see text)

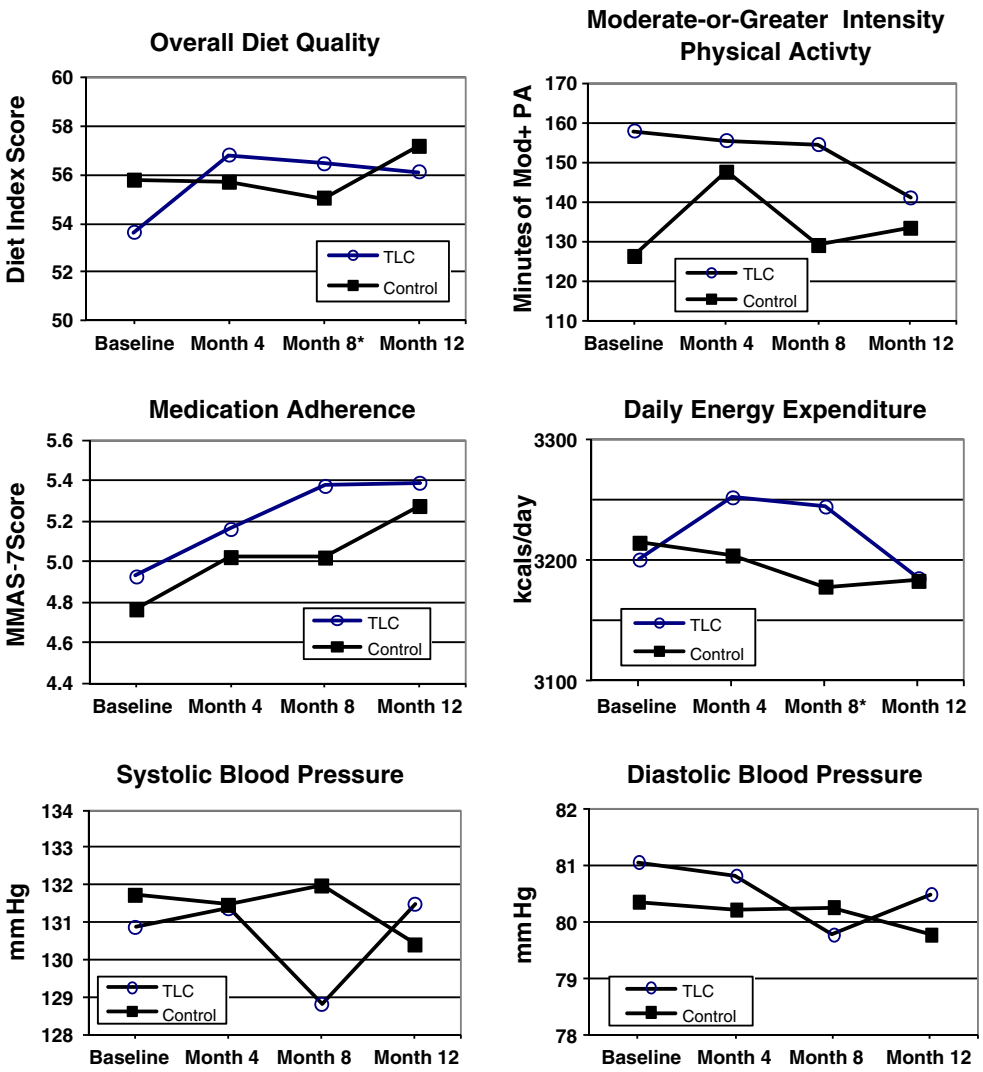

Fig. 2 Primary and secondary outcomes across all time points. *Asterisks* difference between groups in change in outcome from baseline to 8 months significant at $p<0.05$. *TLC* telephone-linked-care, the name of the automated telephone intervention

150 min/week, but there was a significant increase in energy expenditure of 80 kcal/day in the intervention group vs. controls at the 8-month assessment ($p=0.02$). This finding was primarily due to a relative increase in work-related activity in the intervention group.

Medication Adherence

Although the treatment group's adjusted 7-item Morisky Medication Adherence Scale scores improved by 0.19 points relative to controls, this change was not statistically significant ($p=0.25$) in the intent-to-treat analysis. When this analysis was done on available cases, the relative change was larger, at 0.35 points ($p=0.08$).

Blood Pressure

When analyzed as continuous variables, the largest decrease in both SBP and DBP in the intervention group vs. the control group occurred at the 8-month assessment (-2.3 mmHg, and -1.2 mmHg, respectively); however, neither difference was statistically significant. Similarly, there was no statistical difference between groups in the proportion who achieved control of SBP, DBP, or both.

Diabetics

Though there were no pre-specified hypotheses for diabetic participants, we examined intervention effects in this subgroup both because the automated telephone intervention contained material tailored specifically for diabetics with hypertension, and because BP control is especially important in this population. In the intervention group, participants who reported type 2 diabetes used the automated telephone system more and had a lower attrition rate than those without diabetes. Among all diabetics, the intervention was associated with greater absolute improvements in most primary and secondary outcomes relative to controls than for non-

diabetics, but the differences were not statistically significant given the small subgroup size (n=127). For example, in the full sample there was no appreciable effect on minutes of moderate-or-greater physical activity, but among diabetics there was an increase of 37 min/week in the intervention group vs. controls at 8 months (p<0.18). Similarly, among diabetics mean SBP decreased by 6.21 mmHg and DBP 1.51 mmHg in the intervention group vs. controls (p=0.1 and p=0.43, respectively).

Dose Response

There was a dose–response relationship between the number of completed diet calls and improvement in the overall diet quality score (r=0.31, p=0.008). There were no significant dose–response relationships for the other outcomes.

Acceptability of the Automated Telephone System

At the 8-month assessment, participants who completed at least one intervention call were surveyed on their experience with the automated system [26]. Responses to key summary questions were on a scale from 1 to 5 with 5 being the most favorable rating. The mean score for the question "How satisfied were you with the automated telephone system?" was 3.7. For "How helpful did you find the system?" it was 4.1, and for "How helpful did you find the information the system provided?" it was 4.2. The most frequent reasons reported for missing or skipping automated calls were participant related such as not being home when the system called (77%), being too busy (56%), or having major life disruptions (36%). By contrast, system-related reasons for missed calls were reported less often. Examples include "The system wasn't right for me" (16%), and participants having problems accessing the system (14%). Several baseline participant characteristics correlated with users' opinions of the automated telephone system. Those with lower educational attainment rated it as more enjoyable, helpful, useful, friendly, personal, and informative (r=0.19–0.29, p=0.002–0.02). After controlling for educational attainment, the system was rated as more flexible by users with lower vs. higher perceived financial well-being (r=0.19, p=0.04).

Discussion

The intervention was associated with statistically significant improvements in the primary outcomes of overall diet quality and energy expenditure, and with modest improvements in BP that were not statistically significant (Fig. 2). For all outcomes, positive effects did not persist 4 months after the intervention had ended. There was a dose–response effect on diet quality in the intervention group. Diabetic subjects in the intervention group had a significantly lower dropout rate than non-diabetics. They also tended towards greater use of the intervention and greater improvements in most outcomes than non-diabetics though these differences were not statistically significant.

In prior studies from our group, single automated telephone interventions targeting physical activity, diet, or medication adherence alone were each found effective [8, 9, 11]. Although the current intervention combined content from these successful single-behavior prototypes, the observed effects were smaller overall. This difference may relate to differences in the study sample (e.g., proactive recruitment in this study versus volunteer-based in our prior studies) and study protocols (greater participant burden and attrition due to the need to assess multiple behaviors vs. a single behavior). It may also reflect fundamental differences in adherence caused by the effort and complexity of making more than one lifestyle change [27]. Nevertheless, a recent meta-analysis found that computer-tailored interventions targeting up to three health behaviors can be as effective as those targeting only one [28].

With respect to multi-behavior interventions, a further consideration is the relative impact of delivering each module sequentially vs. simultaneously. The scant literature on this issue is mixed. In one study comparing simultaneous and sequential interventions among 289 blacks with hypertension, there was evidence that the simultaneous approaches were superior for sodium reduction and smoking cessation [29]. In contrast, findings from another trial among 315 female smokers supported a sequential over a simultaneous approach to multiple behavior changes including diet, exercise, and smoking cessation [30]. In our study we delivered each module sequentially, but required all participants to check and report their home blood pressure readings throughout follow-up. A subsample also chose to measure and report their weight regularly. Such longitudinal self-monitoring constituted a "simultaneous" intervention that spanned the three behavioral modules and may have helped participants form connections between the content of each module.

In this study, maximal intervention effects were seen at 8 months for several outcomes despite the fact that each behavioral module lasted only 2–3 months. This suggests that subsequent modules may have reinforced positive changes initiated during earlier modules, even though each module targeted a different behavior. This phenomenon is akin to the "co-variation" of effects described in other multi-behavior interventions where improvements in a targeted health behavior are associated with improvements in other targeted or even non-targeted behaviors [31]. Indeed, the first three automated calls were designed not only to introduce the three behavioral modules, but also to emphasize the complementary role of each behavior in blood pressure control. Making these explicit connections

between the three behavioral modules early may have enabled mutual reinforcement of behavioral messages later on. More research is needed to elucidate how messages targeting one behavior can be used to reinforce messages targeting other behaviors in multi-behavior change interventions whether modules are delivered sequentially or simultaneously.

What is clear from the literature and from our results is that positive behavioral changes decay toward baseline levels once the intervention is withdrawn [32]. A more intensive intervention or booster sessions following an intervention can slow this decay [32]. An advantage of automated counseling systems such as the one we report here is that they can be easily modified to deliver a more intensive intervention (i.e., to increase content and contact frequency), and to help maintain positive behavior change by providing booster contacts after the primary intervention ends. In retrospect, providing intermittent reinforcement of positive behavior changes throughout the intervention may have maintained or increased earlier improvements and been more effective.

The low overall rates of system use in this study likely limited intervention effects. Factors such as lower income and educational attainment and the presence of social–environmental obstacles have been shown to predict lower subject participation in research studies [5, 6]. There was little socio-demographic variation in our study sample and no baseline characteristic predicted system use vs. non-use, but participants who reported greater perceived financial hardship used the system less often than those who felt more financially secure. This is despite the fact that those with greater perceived financial hardship actually rated the system as *more* flexible than subjects who felt more financially secure. This suggests that those who experience greater financial stress and its attendant life disruptions may particularly appreciate the flexibility and accessibility of computerized health promotion systems such as ours. Even though their life circumstances may make it difficult for them to fully utilize these systems, it is conceivable that their engagement in more rigid, traditional, face-to-face programs would be even lower. Similarly, we found that participants with lower educational attainment rated the system more favorably than more educated users in the areas of information content, applicability, and in their overall experience. Efforts were made to develop an intervention that was acceptable to a wide range of literacy levels. The system's ability to identify and address the user's knowledge gaps and to allow users to repeat conversations within modules may have enhanced its appeal among participants with less formal education. Further qualitative work is needed to identify barriers to engagement in automated behavior change programs.

Several additional issues may have reduced observed intervention effects. First, baseline values for several outcomes were unexpectedly high, which made it more difficult to achieve substantial improvements in the intervention group on these outcomes. Despite selection criteria designed to create a sample with uncontrolled BP and low adherence to self-care recommendations, mean baseline BP was only 131/81; 36% and 37% met recommendations for fruit and vegetable intake, respectively; and 32% met recommended guidelines for physical activity. In fact, 47% more participants in the intervention group met physical activity guidelines than in the control group (38.5% vs. 26.3%). This chance occurrence meant that a greater proportion of intervention group participants were advised to maintain rather than increase their levels of physical activity, and that downward regression to the mean for physical activity was more likely in this group. Additionally, since participants with low baseline physical activity were twice as likely to drop out of the intervention group than were control participants, the potential impact of upward regression to the mean was decreased in intent to treat analysis, also reducing physical-activity-related intervention effects.

The limited impact of the intervention on our three behavioral outcomes made it especially difficult to see an intervention effect on BP—a secondary outcome of this study—especially in the context of limited power. In our sample, there was less than 80% power to detect a difference in SBP of 7 mmHg between the experimental groups. The relationship between behavior change and resulting physiologic change is complex and depends on both the magnitude and duration of the observed behavioral changes. Further, BP reductions achieved by multi-behavior interventions are typically smaller than the sum of the reductions observed for their components when deployed alone. For example, the Trials of Hypertension Prevention Phase II study [27] showed an intervention combining weight loss and sodium restriction was associated with a smaller reduction in diastolic BP vs. controls at 6 months (−2.8 mmHg, $p<0.001$) than the sum of the two component interventions when deployed singly (−2.7 mmHg for weight loss alone, $p<0.001$, −1.6 for sodium alone, $p<0.001$). In the PREMIER trial [4], adding the original DASH diet to an "established" regimen consisting of weight loss, limited sodium and alcohol intake, and increased physical activity did not significantly reduce systolic BP further (−0.6 mmHg vs. "established", $p=0.43$).

Conclusion

This study is the first to evaluate a culturally adapted, computer-based telephone counseling system for African–Americans that targets three health-related behaviors for the self-management of hypertension. It was associated with modest improvements in several study outcomes, but

effects were hampered by high baseline attainment of goal levels for several principal study outcomes and by low system use. Nevertheless, computerized technologies like this one provide an opportunity to deliver behavior change programs on a public health scale at relatively low cost, and to tailor health messages to both ethnic/racial group and individual-level characteristics. Although our automated system was developed using input from African–Americans in Boston, it was designed to address obstacles that are likely to pose barriers to a broader segment of urban African–American of low socioeconomic status as well. As such, our results can be generalized to other urban settings in the USA. In addition, the content of the intervention can be further culturally adapted to reflect the cultural themes of specific African–American communities. More research is needed to better understand what combination of system features and user characteristics may lead to improved hypertension self-management among urban African–Americans of low SES.

Acknowledgments This study was funded by a grant from the National Heart, Lung, and Blood Institute (R01 HL69395). We would like to thank Kenneth Resnicow, PhD for his assistance in conceptualizing and designing this study; Lisa Marks, Adena Cohen-Barak, and Julia Gefter for their dedication to seeing this project through; and Amy Bachand, PhD for her assistance with the accelerometer data analysis.

Conflict of interest Dr. Friedman has stock ownership and a consulting agreement with InfoMedics, the company that owns commercial rights to the TLC technology used in the computerized intervention. He is also a member of its Board of Directors. None of the other authors has any potential conflicts of interest to disclose.

Health Literacy and 30-Day Postdischarge Hospital Utilization

SUZANNE E. MITCHELL, EKATERINA SADIKOVA, AND BRIAN W. JACK

Department of Family Medicine, Boston University School of Medicine/Boston Medical Center, Boston, Massachusetts, USA

MICHAEL K. PAASCHE-ORLOW

Section of General Internal Medicine, Boston University School of Medicine/Boston Medical Center, Boston, Massachusetts, USA

Low health literacy is associated with higher mortality, higher rates of hospitalization, and poor self-management skills for chronic disease. Early, unplanned hospital reutilization after discharge is a common and costly occurrence in U.S. hospitals. Still, few studies have examined the relation between health literacy and 30-day hospital reutilization rates. The authors examined the association between health literacy and 30-day reutilization of hospital services (readmission or return to the emergency department) in an urban safety net hospital, and conducted a secondary analysis of data from the control arm subjects of the Project RED and the RED-LIT trials. Health literacy was measured using the REALM tool. The primary outcome was rate of 30-day reutilization. The authors used multivariate Poisson regression analysis to control for potential confounding. Of the 703 subjects, 20% had low health literacy, 29% had marginal health literacy, and 51% had adequate health literacy. Sixty-two percent of subjects had a 12th-grade education or less. Subjects with low health literacy were more likely to be insured by Medicaid ($p < .001$); Black non-Hispanic ($p < .001$); unemployed, disabled, or retired ($p < .001$); low income ($p < .001$); and less educated (high school education or less, $p < .001$). The fully adjusted incidence rate ratio for low health literacy compared with adequate health literacy was 1.46 (CI [1.04, 2.05]). Low health literacy is a significant, independent, and modifiable risk factor for 30-day hospital reutilization after discharge. Interventions designed to reduce early, unplanned, hospital utilization after discharge should include activities to mitigate the effect of patients' low health literacy.

Nearly 20% of Medicare patients are readmitted to the hospital within 30 days of discharge (Jenks, Williams, & Coleman, 2009). Known predictors of early readmission include the following: lower socioeconomic status (Weissman, Stern, & Epstein, 1994), history of prior hospitalization (Van Walraven, Mamdani, Fang, & Austin, 2004) and advanced age (Cho, Lee, Arozullah, & Crittenden, 2008; Marcantonio et al., 1999),

This work was supported by the Agency for Health Research and Policy 1K08HS019771-01 (Dr. Mitchell). The authors acknowledge Ms. Jessica Martin for her support in data preparation.

length of stay greater than 7 days (Krumholz et al., 1997), a high burden of comorbid illnesses (based on Charlson score; Librero, Peiro, & Ordinana, 1999), and specific diagnoses (e.g., depression, congestive heart failure, chronic obstructive pulmonary disease, myocardial infarction; Krumholz et al., 1997; Mitchell et al., 2010; Parashar et al., 2006; Wong et al., 2008). Meanwhile, a streamlined discharge process designed to enhance patient safety during care transitions can reduce 30-day postdischarge hospital utilization as much as 30% (Jack et al., 2009). The 30-day rehospitalization rate has emerged as an important indicator of hospital quality, particularly because the Centers for Medicare and Medicaid Services introduced a series of new reimbursement policies that include decreasing payments to hospitals with high rates of rehospitalization and bundled payment schemes in which accountable care organizations will be paid less for subsequent hospital utilization within 30 days. Thus, there is great interest in identifying modifiable risk factors for rehospitalization that could be used to refine intervention models and lead to improvements in quality of care, patient outcomes, and cost savings.

Low health literacy has been linked to poor health outcomes, particularly for patients with chronic conditions such as diabetes, asthma, cancer, depression (Lincoln et al., 2006), HIV/AIDS (Kalichman & Rompa, 2000), and heart failure (Peterson et al., 2011). *Health literacy*, defined as the degree to which individuals have the capacity to obtain, process, and understand health information, skills, and services needed to make informed health decisions and take informed actions, affects many Americans (Paasche-Orlow, 2011; U.S. Department of Health and Human Services, 2000). An estimated 26% of the U.S. population has low health literacy, and an additional 20% has marginal health literacy (Paasche-Orlow et al., 2005). Health literacy barriers are often associated with greater risk of hospitalization (Baker, Parker, Williams, & Clark, 1998), higher rates of self-reported poor health status (Baker, Parker, Williams, Clark, & Nurss, 1997) decreased knowledge of one's medical condition, poor medication recall, nonadherence to treatment plans, poor self-care behaviors (Evangelista et al., 2010), and increased all-cause mortality (Wolf, Feinglass, Thompson, & Baker, 2010). Patients with low health literacy also are more likely to report unsatisfactory patient–doctor communication at the time of discharge, suggesting that some physicians may be insensitive or unaware when their patients are having difficulties comprehending discharge instructions (Kripilani et al., 2010). Although several of these factors have been linked to an increased risk for 30-day rehospitalization, very limited evidence has been presented to demonstrate the independent association between low health literacy and hospital reutilization within 30 days of discharge.

This study examined the relation between health literacy and hospital reutilization within 30 days of discharge at the Boston Medical Center. The Boston Medical Center is the largest safety net hospital in New England, providing a spectrum of medical services to an urban, socially and economically diverse population. We hypothesized that low health literacy would be an independent risk factor for early unplanned hospital reutilization after discharge for general medical patients (i.e., adult patients admitted for acute general medical conditions such as pneumonia, unstable angina, pancreatitis, acute renal failure).

Method

We conducted a secondary analysis of the Project RED (Re-Engineered Discharge) and RED-Lit clinical trial data sets (clinicaltrials.gov identifier: NCT00252057) to assess the association between health literacy and the rate of subsequent 30-day hospital reutilization. The original Project RED included 738 participants and

RED-Lit included 802 participants. All Project RED studies enrolled English-speaking patients 18 years or older who were admitted to a general medical unit at the Boston Medical Center. Study subjects were required to have telephone access and be able to convey an understanding of study procedures and other consent elements in English. Participants were excluded if their admission was planned, they were on suicide watch, transferred from another health facility or were deaf or blind. Outcome data was not used in the secondary analysis if participants withdrew consent, died during the index admission, or were not discharged to the community. The combined sample included 1,540 patients from the control and intervention arms with complete information for the primary independent variable of interest—health literacy—and the outcome variable—30-day hospital utilization. We used a final sample of 703 patients identified from the control arms of each of these trials. Subjects from the intervention groups were excluded to eliminate effect modification introduced by exposure to the intervention.

Key Outcome Variables

The primary outcome variable for this analysis was a combined count measure of emergency department and hospital utilization events by a patient within a 30-day period after the index discharge. We also examined the emergency department revisit and hospital readmission count outcomes separately for the purposes of identifying factors associated with these distinct events. The number of utilizations ranged from 0 to 15; however, we top-coded to a count of 8 to avoid undue influence of outliers. We collected outcome data using the Boston Medical Center electronic medical record or participant self-report obtained by phone interview after 30 days. Both reutilizations of the Boston Medical Center and other hospitals and emergency departments were included.

Primary Independent Variable

We measured health Literacy using the Rapid Estimate of Adult Literacy in Medicine (REALM), which is a 66-item validated word recognition test (Davis et al., 1993). The REALM assigns a grade level of literacy, with scores of 0–18 corresponding to literacy of third grade or below, 19–44 to 4th–6th grade, 45–60 to 7th–8th grade, and 61–66 to 9th grade or above. For the purposes of our analysis, the two categories of lowest literacy were combined because of the distribution of scores. We administered the REALM in person to study participants.

Statistical Analysis

Descriptive Statistics

We performed bivariate analyses to assess the unadjusted relation between demographic and clinical characteristics and the three REALM categories of health literacy. The crosstabs reflect the results of chi-square tests. We then conducted Poisson regressions for all three outcome variables (combined reutilization, rehospitalization and return to the emergency department) to control for potential confounding. Predictors were included into the multivariable Poisson regressions on the basis of their effect on the association between health literacy and the outcomes, as well as the significance of their independent associations with the outcomes. Predictors were chosen from: age, gender,

marital status, income, insurance, employment, education, race, having a primary care physician, being homeless in the 6 months before the index admission, evidence of depressive symptoms, frequent utilizer status, length of stay, and medical comorbidity.

Adjusted Charlson Score for Comorbidity

Because of differences in the methods used to calculate Charlson scores between the RED and RED lit trials, we calculated a correction factor using a linear transformation procedure to adjust for the inconsistency in the distributions of Charlson scores for the combined analytic dataset. Charlson scores for the RED Lit II sample were calculated in a manner that accounted for comorbid conditions using all available records. For Project RED and RED Lit I, this process did not include outpatient record review. To derive a comparable Charlson score for the complete dataset, we calculated a z-score for each RED-lit II participant's observed score using the mean and standard deviation for the RED-lit II sample. Adjusted Charlson scores were then calculated for RED and RED-lit I (using the mean and standard deviation of this sample) to correspond to the *z* scores from the more comprehensively calculated sample.

Adjustment for Confounding

We constructed multivariable Poisson regression models using thorough backwards selection processes for each of the three outcome variables. We included certain variables (e.g., race, education, insurance) into the models because of their established relations with the variables of interest. We used SAS 9.1 to conduct the analysis with two-sided tests with $p < .05$ to judge significance.

Results

Of the 703 subjects, 138 (20%) patients had low health literacy (≤6th grade or REALM score of 0–18), 207 (29%) had marginal health literacy (7th to 8th grade or REALM score of 19–44) and 358 (51%) had adequate health literacy (≥9th grade or REALM score of 45–60). Study participants' mean age was 49.2 years of age, which did not differ by REALM score (see Table 1). Patients with low health literacy were more likely to be insured by Medicaid ($p < .001$); Black ($p < .01$), unemployed, disabled, or retired ($p < .001$); low income (<$40,000/year, $p < .001$); and less educated (high school education or less, $p < .001$). Of subjects, 29% ($n = 206$) were frequent utilizers, defined as two or more admissions in 6 months before index admission. The mean length of stay for the index admission was 2.8 days and did not differ significantly by REALM score. The mean Charlson Comorbidity Index score was 0.6, with a majority of the sample reporting a score of 0. There was no relation between comorbidity and health literacy.

The unadjusted 30-day postdischarge hospital reutilization incidence rate ratio for subjects with low health literacy compared to subjects with adequate health literacy was 1.76 (95% CI [1.21, 2.55]). After adjusting for potential confounding using a multivariate Poisson regression analysis—which included education, gender, marital status, income, race, affiliation with primary care provider, homelessness, depression, frequent utilizer status, age, length of stay, and the Charlson Comorbidity Index—we found that patients with low health literacy are 1.46 times (95% CI [1.04, 2.05]) more likely than patients with adequate health literacy to return to the hospital or emergency department within 30 days. Frequent utilizers were 2.04 times more likely

than nonutilizers (incidence rate ratio = 2.04 [1.58, 2.62] $p < .0001$) and those who were homeless in the 6 months before their index admission were 1.54 times more likely than those who were not homeless (incidence rate ratio = 1.54 [1.14,2.08] $p = .0053$; see Table 2) to return to the hospital or emergency department. Female gender (incidence rate ratio = 0.75 [0.58, 0.96] $p = .02$) and Black race (incidence rate ratio = 0.73 [0.55, 0.98] $p = .04$) were both associated with lower risk for early hospital reutilization. In subanalyses of the outcome variable, we used multivariate Poisson regression to examine incidence rate ratios for emergency department visits and hospital readmissions separately. We found that, compared with patients with adequate health literacy, low health literacy patients were 1.71 times more likely to be readmitted to the emergency department ($p < .05$) and 1.67 (95% CI [0.98, 2.83], $p < .06$, times more likely to be readmitted into the hospital within 30 days of index admission.

Discussion

Concern about 30-day unplanned hospital reutilization is warranted as these events correlate with higher morbidity, mortality, and costs and is being used as a marker of the quality of hospital care (Ashton, Del Junco, Souchek, Wray, & Mansyur, 1997). Our study suggests that patients with low health literacy are more likely than patients with adequate health literacy to return to the hospital or emergency department within 30 days of discharge. These results were robust and health literacy remained an independent predictor of hospital utilization within 30 days of discharge after adjusting for a range of potential confounding phenomena, including education level. This study adds to growing evidence demonstrating the negative consequences of limited health literacy on patients' health and well-being (Davis & Wolf, 2004). It also establishes a link between health literacy and the process of care transitions, which has emerged as a centerpiece of efforts to improve quality and decrease cost.

There are several potential reasons as to why patients with low health literacy may return to the hospital soon after their discharge relative to those with higher health literacy levels. Health literacy may prevent patients from understanding their discharge instructions—including proper comprehension of their diagnosis and the treatment regimen (Anonymous, 2009; Williams et al., 1995). Williams and colleagues who showed that patients with low health literacy misread medication dosing (23.6% incorrect) and appointment slips (39.6% incorrect) in a survey of hospitalized patients while those with adequate literacy did well on these tasks. Patients may also have difficulty managing self-care instructions after hospital discharge, such as understanding symptoms of medication side effects and how to mitigate such phenomena, appreciating early signs of disease exacerbation and responding appropriately, and accessing and utilizing routine and urgent outpatient services. These issues may all contribute to how health literacy is related to returning to the hospital.

Our results bring attention to the need for interventions designed to decrease the rate of unplanned hospital reutilization to focus on health literacy. Such interventions can augment the level of patient and family education and guidance that is provided. Agency for Healthcare Research and Quality offers an evidence-based toolkit to address health literacy titled, "Health Literacy Universal Precautions Toolkit." The toolkit notably addresses four strategies for overcoming health literacy barriers. These include the following: (a) using easily understood spoken communication, (b) modifying written communication, (c) teaching self-management and empowerment, and (d) bolstering patient's support systems. Agency for Healthcare Research and

Quality's approach advocates for creating an environment in which patients of all health literacy levels can thrive. Some of these methods include the following: drawing pictures, using plain (nonmedical) language, and using the teachback approach (Brach et al., 2012; Koh et al., 2012; Weiss, 2003).

Limitations

Major strengths of the present study are the reasonably large dataset and the broad range of covariates available for analyses. However, several limitations should be noted. First, this study was conducted using data from clinical trials implemented at a single safety net hospital; therefore, results may not be generalizable to other patient populations. Further, reutilization events outside of the Boston Medical Center were collected by subject self-report but were not independently confirmed. However, we were able to confirm 91% of all events by medical record review. Last, although we attempted to account for known confounders, other factors may also exist and could remain unaddressed.

Conclusion

Our study suggests that low literacy is significantly associated with a higher rate of 30-day postdischarge hospital utilization. Patient health literacy plays an influential role in health outcomes and low health literacy can be a significant barrier to patients' safe transitions from hospital to home. Future directions include interventions to improve patient education for care transitions, reduce the health literacy burden of the discharge process, and remove unnecessary complexity from critical self-care tasks.

Abstract

Aim: To analyze alcohol use, clinical data and laboratory parameters that may affect FIB-4, an index for measuring liver fibrosis, in HCV-monoinfected and HCV/HIV-coinfected drug users.

Patients and Methods: Patients admitted for substance abuse treatment between 1994 and 2006 were studied. Socio-demographic data, alcohol and drug use characteristics and clinical variables were obtained through hospital records. Blood samples for biochemistry, liver function tests, CD4 cell count, and serology of HIV and HCV infection were collected at admission. Multivariate linear regression was used to analyze the predictors of FIB-4 increase.

Results: A total of 472 (83% M, 17% F) patients were eligible. The median age at admission was 31 years (Interquartile range (IQR) 27–35 years), and the median duration of drug use was 10 years (IQR 5.5–15 years). Unhealthy drinking (>50 grams/day) was reported in 32% of the patients. The FIB-4 scores were significantly greater in the HCV/HIV-coinfected patients (1.14, IQR 0.76–1.87) than in the HCV-monoinfected patients (0.75, IQR 0.56–1.11) ($p<0.001$). In the multivariate analysis, unhealthy drinking ($p=0.034$), lower total cholesterol ($p=0.042$), serum albumin ($p<0.001$), higher GGT ($p<0.001$) and a longer duration of addiction ($p=0.005$) were independently associated with higher FIB-4 scores in the HCV-monoinfected drug users. The effect of unhealthy drinking on FIB-4 scores disappeared in the HCV/HIV-coinfected patients, whereas lower serum albumin ($p<0.001$), a lower CD4 cell count ($p=0.006$), higher total bilirubin ($p<0.001$) and a longer drug addiction duration ($p<0.001$) were significantly associated with higher FIB-4 values.

Conclusions: Unhealthy alcohol use in the HCV-monoinfected patients and HIV-related immunodeficiency in the HCV/HIV-coinfected patients are important risk factors associated with liver fibrosis in the respective populations

Introduction

Liver fibrosis is the main predictor of whether chronic hepatitis C will progress to cirrhosis and end-stage liver disease [1]. Because the complications of liver disease mainly occur in patients with advanced-stage fibrosis, assessing chronic hepatitis C early is essential when evaluating at-risk patients [2]. In Western countries, more than 50% of new HCV infections are associated with drug abuse. However, this particular population also has lower rates of clinical assessment and chronic hepatitis C treatment. Given the likelihood of new and more effective treatments, drug abusers with chronic hepatitis C would benefit from simple, non-invasive measurements of liver fibrosis.

The cofactors associated with chronic hepatitis C progression differ among studies; alcohol abuse, male gender, age at infection, body mass index, and coinfection with human immunodeficiency virus infection (HIV) and Hepatitis B virus infection (HBV) have been related to more rapid disease progression [1–5]. In HCV/HIV-coinfected individuals, CD4 cell counts below 200 cells/μL have been associated with liver fibrosis progression [6]. In parallel, highly active antiretroviral therapy (HAART) has been shown to reduce liver-related deaths [7,8].

In HIV-negative patients, it is well established that alcohol abuse and HCV infection have a synergistic effect on liver fibrosis. However, there are conflicting results regarding the independent effect of alcohol on liver damage in HCV/HIV-coinfected patients [6,9,10].

Liver biopsy is the gold standard for assessing fibrosis [11]. However, assessing liver disease through an invasive procedure is unlikely in patients with substance abuse [12]. Furthermore, eligibility for chronic hepatitis C treatment in this population is low compared with eligibility in other populations [13,14]. To

a certain extent, the evolution of liver disease in drug abusers parallels the natural history of chronic hepatitis C.

Several non-invasive markers of liver fibrosis have been proposed as alternatives to liver biopsy. Some of these markers reflect the modified extracellular matrix turnover that occurs during fibrogenesis [15,16], whereas others reflect alterations in hepatic function [17,18]. FIB-4 was initially described in 2006 [18], and since then, it has been proposed as reliable marker of fibrosis in both HCV-monoinfected and HCV/HIV-coinfected individuals [18,19]. FIB-4 correlates well with liver biopsy in patients with and without advanced fibrosis [20,21]. Moreover, non-invasive markers of liver fibrosis have been proposed as predictors of all-cause and liver-related mortality [22,23].

Although abuse of alcohol and illegal drugs is frequent in patients with HIV infection and HCV infection, it is unclear how non-invasive liver fibrosis tests may reflect disease progression. In this study, we hypothesize that certain clinical and laboratory characteristics may influence a simple index of fibrosis and that the cofactors associated with elevated FIB-4 scores may differ between HCV-monoinfected patients and HCV/HIV-coinfected patients. Hence, the primary objective of the study was to characterize the putative differences in risk factors for elevated liver function biomarkers between HCV-monoinfected and HCV/HIV-coinfected patients.

Patients and Methods

Study Population

This was a cross-sectional study of patients admitted for substance abuse treatment between 1994 and 2006. The demographic and drug use characteristics were recorded through a structured questionnaire administered by a physician the day of admission. Questions related to drug and alcohol abuse included: (i) the main drug of abuse (type of drug, age at first use, duration of drug use and route of administration), (ii) poly-drug use (yes/no) (iii) alcohol consumption: do you regularly drink alcohol? (yes/no); if yes, do you drink 5 or more standard drinks per day?. A standard drink unit contains 12–14 grams of alcohol and unhealthy alcohol consumption was defined as a daily alcohol intake $\geq$50 grams (g) [24,25] in the 6-month period prior to admission. All participants gave written informed consent. The methods used in this study complied with the ethical standards for medical research and principles of good clinical practice defined by the World Medical Association's Declaration of Helsinki. The study was approved by the Ethics Committee of the Hospital Universitari Germans Trias i Pujol.

Routine laboratory parameters, including liver function tests and serology for HIV infection and HCV infection, were analyzed at admission. Other characteristics of admission for substance abuse treatment have been described elsewhere [26].

The liver function tests and biochemical parameters were assessed using an Olympus 5200 Multichannel chemistry analyzer. The procedure, which remained the same throughout the study, was based on the reference method recommended by the International Federation of Clinical Chemistry.

HIV infection was identified by an enzyme-linked immunosorbent assay. Repeatedly reactive samples were confirmed by the Western immunoblot technique.

HCV infection was assessed prior to or during admission by a second- or later-generation enzyme immunoassay (Ortho Diagnostics, Raritan, NJ). The positive samples were confirmed by either a recombinant immunoblot assay (RIBA HCV 2 SIA, Chiron Corporation, Emeryville, CA) or a qualitative/quantitative assay (COBAS AMPLICOR, Roche Diagnostic Systems, Branchburg, NJ).

Outcome

The primary outcome was the FIB-4 score, which was calculated as

$$FIB4 = \frac{Age[years] \times AST[U/L]}{Platelet[10^9/L] \times \sqrt{ALT[U/L]}}$$

FIB-4 scores lower than 1.45 indicate lack of liver fibrosis with a negative predictive value of 90% and a sensitivity of 70% [18]. FIB-4 scores greater than 3.25 indicate significant liver fibrosis with a positive predictive value of 65% and a specificity of 97% [18].

Statistical Analysis

All of the analyses were conducted separately for the HCV-monoinfected (N = 228) and the HCV/HIV-coinfected (N = 244) individuals. We used medians and interquartile ranges (IQRs) to describe the quantitative variables and absolute frequencies and percentages to describe the qualitative variables.

The distribution of FIB-4 score was strongly skewed to the right (i.e., there were several very high values); we therefore normalized it for analysis purposes using a logarithmic transformation.

We used multiple linear regression models to determine the FIB-4 predictive values of the variables. There were three types of predictors: (1) binary, which included sex, alcohol use, and HBsAg; (2) continuous on a natural (additive) scale, which included body mass index (BMI), CD4 cell count, total cholesterol, alkaline phosphatase, and duration of drug use; and (3) continuous on a logarithmic (multiplicative) scale, which included total bilirubin, serum albumin, and GGT. The decision to analyze a variable using a logarithmic scale was based on the need to reduce the undue influence of high values in predictors with strong right skewness.

The interpretation of the regression coefficients differed among the three types of predictors. Specifically, the regression coefficients of the binary variables represented the percentage FIB-4 difference between those with and without the condition; the regression coefficients of the additive continuous variables represented the percentage FIB-4 difference associated with an unitary increase or decrease in the variables, and the regression coefficients of the multiplicative continuous variables represented the percentage FIB-4 difference associated with an increment or decrement in the variables.

The intercept represented the expected FIB-4 score in an individual with zero values for all of the predictors.

The test results were considered to be statistically significant if the resulting P-*value* was $<.05$. The statistical analysis was performed using the SPSS software, version 15.0.1 (SPSS, Chicago, IL, USA).

Results

Patients were eligible for this study if they had chronic HCV infection (N = 544). Patients with aminotransferase levels 10 times greater than the upper limit of the normal range (N = 5,1.0%), patients who had received HCV antiviral therapy (N = 6,1.1%) and patients with antecedent of decompensated liver cirrhosis (N = 10,1.8%) were excluded. In addition, patients with an HCV-RNA level below the limit of detection (<50 IU/mL) were

excluded (N = 9, 1.7%). Finally, patients with outlier laboratory values and those with incomplete data for calculating FIB-4 score were also excluded (N = 42, 7.7%). After these exclusions, the study population consisted of 472 patients and 244 patients (52%) were coinfected with HIV. Table 1 shows the descriptive statistics at admission for the entire group and for the HCV-monoinfected (N = 228) and HCV/HIV-coinfected (N = 244) subgroups. Overall, 17% of the patients were women, the median age at admission was 31 years (IQR 27–35 years), the median BMI was 22 kg/m^2, the median duration of drug use was 10 years, and unhealthy drinking was reported in 32% of the patients. In addition to decreased CD4 cell counts, the HCV/HIV-coinfected patients had a longer median drug use duration, an increased frequency of unhealthy alcohol intake, lower levels of total cholesterol, higher levels of GGT and a higher prevalence of HBsAg than those infected with HCV only. The median AST and ALT levels and platelet counts were 35 U/L, 47 U/L, and 180 × 10^9/L, respectively.

Thirty-one percent of the HIV-positive patients were receiving antiretroviral therapy at admission, and 48% had never received antiretroviral therapy.

The median FIB-4 score at admission was 0.93 (IQR 0.65–1.46); it was significantly higher in the HCV/HIV-coinfected patients (1.14, IQR 0.76–1.87) than in the HCV-monoinfected patients (0.75, IQR 0.56–1.11). Figure 1 shows the distribution of the FIB-4 scores in the two groups on both natural and logarithmic scales. As can be seen in the bottom panels of Figure 1, the log-transformed FIB-4 scores approximately followed a normal distribution, rendering normally based methods appropriate for the analysis.

Regression Analysis of FIB-4 (Log Scale)

We conducted univariate regressions of the variables shown in Table 1 against the log-transformed FIB-4 scores; only the variables that define FIB-4 were not used in the univariate regressions. The two columns with univariate headings in Table 2 show the results of the univariate analyses separately for the monoinfected and coinfected patients.

In the univariate models for the HCV-monoinfected patients, unhealthy alcohol use, higher BMI, longer duration of drug use, lower cholesterol, higher bilirubin, lower albumin, and higher GGT were significantly associated ($p<0.05$) with higher FIB-4 scores. In the coinfected patients, higher FIB-4 scores were found to be significantly associated ($p<0.05$) with a longer drug use duration, lower cholesterol, higher alkaline phosphatase, lower CD4 cell count, higher bilirubin, lower albumin, and higher GGT.

For each group, the variables that showed significant relationships in the univariate analyses were used in a multivariate model. In the multivariate model for the HCV-monoinfected patients, unhealthy alcohol use ($p = 0.034$), longer drug use duration ($p = 0.005$), lower cholesterol ($p = 0.042$), lower albumin ($p<0.001$), and higher GGT ($p = 0.001$) continued to be significantly associated with higher FIB-4 scores.

In the coinfected patients, longer drug use duration ($p<0.001$), lower CD4 cell count ($p = 0.007$), higher bilirubin ($p<0.001$), and lower albumin ($p<0.001$) were significantly associated with higher FIB-4 scores.

Longer drug use duration and lower albumin levels were significantly associated with increased FIB-4 scores in both groups. By contrast, unhealthy alcohol use was strongly predictive of high FIB-4 scores only in the HCV-monoinfected group; similarly, high

*p value for the comparison between HCV-monoinfected and HCV/HIV-coinfected patients; p values correspond to χ square test in categorical variables and t test for differences of mean values in continuous variables.

doi:10.1371/journal.pone.0046810.t001

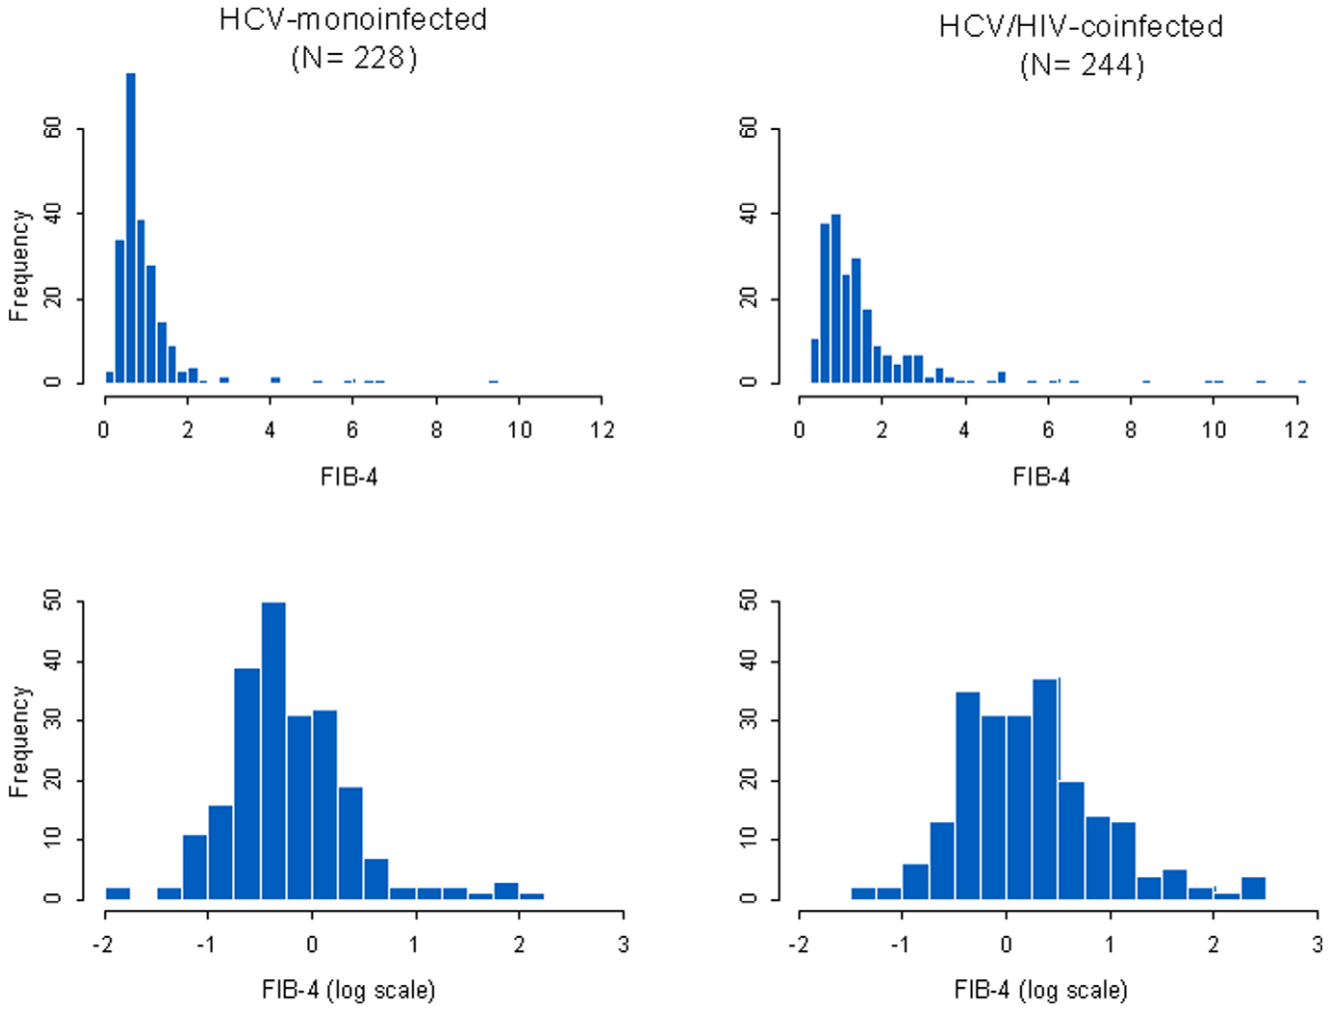

Figure 1. Distribution of FIB-4 score and log FIB-4 score according to HCV-monoinfection and HCV/HIV-coinfection.
doi:10.1371/journal.pone.0046810.g001

total bilirubin levels were associated with higher FIB-4 scores only in the coinfected patients.

Although the primary aim of the study was the characterization of the variables that were associated with FIB-4 increase in HCV-monoinfected and HCV/HIV-coinfected, the intercepts of the multivariate models provide a means of comparing a hypothetical HCV-monoinfected individual with a hypothetical HCV/HIV-coinfected individual, assuming that both have 900 CD4 cells/μL and that all of the other variables are equal. The slightly increased FIB-4 intercept value (0.778 in the monoinfected and 0.875 in the coinfected patients) was not statistically significant ($p = 0.218$). However, for each decline of 100 CD4 cells/μL among the coinfected patients, there was a significant FIB-4 increase of 3.6% ($p = 0.007$) (Table 2).

To further characterize the differential effect of unhealthy alcohol use on FIB-4 scores, Figure 2 shows the distributions of the FIB-4 scores in the four groups by alcohol consumption and HIV coinfection. Figure 2 shows box plots that are graphically enhanced to show the 2.5^{th}, 5^{th}, 10^{th}, 25^{th}, 50^{th}, 75^{th}, 90^{th}, 95^{th} and 97.5^{th} percentiles of the FIB-4 distribution. It is clear from Figure 2 that the primary difference was between the non-drinking HCV-monoinfected patients and the other three groups. In particular, the increased FIB-4 score due to unhealthy alcohol use among the HCV-monoinfected patients was similar to the effect of HIV-related immunodeficiency among the non-drinkers. The additional increase in FIB-4 among the coinfected individuals with unhealthy alcohol use was small and not significant ($p = 0.695$).

Discussion

Individuals with histories of drug use account for the majority of new hepatitis C infections in Western countries. This population is at risk for liver fibrosis, and a number of disease progression cofactors highlight the relevance of medical assessment. Evaluating liver fibrosis via non-invasive tests early in the course of drug addiction may increase the proportion of patients who are eligible for treatment. This study of young adults with chronic hepatitis C shows that the factors associated with higher FIB-4 scores clearly differed between the HCV-monoinfected and HCV/HIV-coinfected individuals.

The main contribution of the study is related to the fact that unhealthy alcohol use had a differential effect on FIB-4 values if patients have hepatitis C alone or HCV/HIV coinfection. Unhealthy alcohol drinking has been regarded as a major contributor to the progression of liver disease in the setting of chronic hepatitis C [27] and, a synergistic effect between HCV and alcohol has been proposed [28]. However, even though

*Expected value of FIB-4 for individuals with predictors at BMI = 22 kg/m^2, no alcohol consumption, total cholesterol = 155 mg/100 mL, Total bilirubin = 0.4 mg/dL, albumin = 39 g/L, GGT = 38 U/L, and duration of IDU = 10 years.
**Expected value of FIB-4 for individuals with predictors at CD4 = 900 cells/μL, total cholesterol = 155 mg/100 mL, total bilirubin = 0.4 mg/dL, albumin = 39 g/L, Alkaline Phosphatase = 70 U/L, GGT = 38 U/L, and duration of IDU = 10 years.
doi:10.1371/journal.pone.0046810.t002

alcohol use is among the cofactors related with liver fibrosis in coinfection in studies with liver biopsy [6,29], the present and other studies that have used non- invasive methods to estimate fibrosis [9,10], does not detect an additional effect of alcohol drinking on the FIB-4 of HCV/HIV-coinfected patients.

In coinfected patients with unhealthy alcohol consumption, the FIB-4 does not reflect the negative impact of alcohol intake on liver fibrosis. Therefore, clinicians may not be able to assess the impact of ethanol nor can advise the patient on the risk of disease progression. On the contrary, unhealthy alcohol use is reflected in

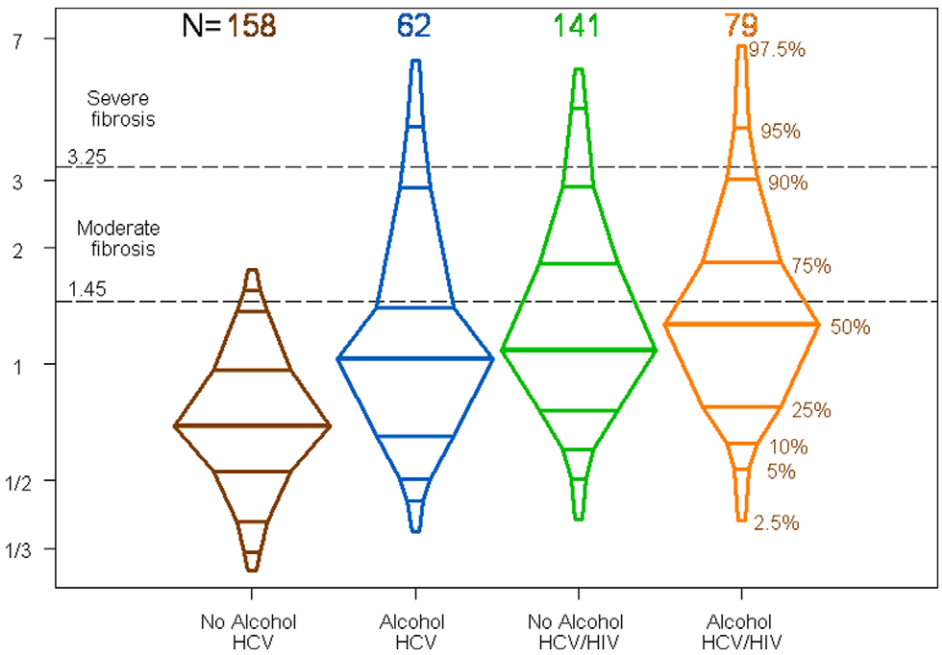

Figure 2. Distribution of FIB-4 scores according to unhealthy alcohol use in HCV-monoinfected and HCV/HIV-coinfected patients.
doi:10.1371/journal.pone.0046810.g002

the FIB-4 of the monoinfected patients thus making possible preventive interventions to reduce harm.

Unhealthy alcohol use in the HCV-monoinfected patients and HIV-related immunodeficiency in the HCV/HIV-coinfected patients are the most important cofactors associated with fibrosis progression in the respective populations. In addition, we found that drug use duration and serum albumin were correlated with the FIB-4 scores of both the monoinfected and coinfected patients, whereas unhealthy alcohol use, GGT and total cholesterol were associated with higher FIB-4 scores only in the monoinfected patients. The effect of HIV-related immunodeficiency in the coinfected patients was strong (an increase of 3.5% in the FIB-4 score for every 100 CD4 cells/μL decrease). Furthermore, we did not observe differing FIB-4 values between the HCV-monoinfected and coinfected individuals with CD4 cell counts above 900 cells/μL. This observation suggests that FIB-4 elevation is associated with immunoactivation and the resulting decrease of CD4 cell counts in HCV/HIV-coinfected drug users.

The relationship between HIV-related immunodeficiency and liver fibrosis progression has been described in coinfected patients [6,29,30]; in fact, treating HIV/AIDS with HAART has been shown to reverse the effect of HIV-related immunodeficiency in patients with chronic hepatitis C [7,26,29,31].

In this study, decreased serum albumin and increased total bilirubin were associated with elevated FIB-4 scores. This finding may facilitate identifying a subpopulation of patients at increased risk for cirrhosis. It is well known that albumin and bilirubin are key components of the Child-Turcotte-Pugh score that clinicians use to assess decompensated liver cirrhosis.

In individuals with history of injection drug use, the duration of injection use is a surrogate for the duration of HCV infection [32]. As expected, the duration of drug addiction in this study was related to increased FIB-4 scores.

It has been reported that HCV infection itself lowers both low-density lipoprotein (LDL) and total cholesterol and that patients treated for chronic hepatitis C had larger increases in LDL and total cholesterol from baseline [33]. Interestingly, the current study did not find a significant association between cholesterol levels and FIB-4 scores among the HCV/HIV-coinfected patients.

This study has a number of limitations that should be mentioned. First, the alcohol intake assessment was limited to one categorical variable (>50 g/day, ≤50 g/day in the 6-month period before admission), and there was no information on the history and complications of alcohol consumption. In previous studies, however, recent alcohol consumption has been treated as a dichotomous variable using a threshold of 40–50 grams of ethanol per day or using the definition of heavy alcohol intake provided by the US National Institute on Alcohol Abuse and Alcoholism (NIAAA) [6,9,10]. Second, we used a single measurement of laboratory parameters to calculate the FIB-4 scores which precluded examining the evolution of fibrosis over time. Furthermore, nearly half of the patients had normal aminotransferases values, as has been previously described for IDUs [34]; despite the lack of correlation between liver enzyme alterations and liver damage, it is possible that FIB-4 scores are affected by normal liver enzymes [20]. Third, the HAART status of the HIV-positive patients was represented by a qualitative covariate, which hindered an analysis of the effect of antiretroviral treatment on FIB-4.

In summary, this study shows that unhealthy alcohol use strongly influence FIB-4 in HCV- monoinfected patients, whereas in the context of HCV/HIV coinfection, HIV-related immune depression exerts a major negative role on FIB-4 results, with no significant worsening by alcohol intake.

Author Contributions

Conceived and designed the experiments: RM AM. Performed the experiments: RM JT DF. Analyzed the data: AM AS SPH EM. Contributed reagents/materials/analysis tools: AS. Wrote the paper: RM AM DF.

Background—Genetic determinants of peripheral arterial disease (PAD) remain largely unknown. To identify genetic variants associated with the ankle-brachial index (ABI), a noninvasive measure of PAD, we conducted a meta-analysis of genome-wide association study data from 21 population-based cohorts.

Methods and Results—Continuous ABI and PAD (ABI ≤0.9) phenotypes adjusted for age and sex were examined. Each study conducted genotyping and imputed data to the ≈2.5 million single nucleotide polymorphisms (SNPs) in HapMap. Linear and logistic regression models were used to test each SNP for association with ABI and PAD using additive genetic models. Study-specific data were combined using fixed effects inverse variance weighted meta-analyses. There were a total of 41 692 participants of European ancestry (≈60% women, mean ABI 1.02 to 1.19), including 3409 participants with PAD and with genome-wide association study data available. In the discovery meta-analysis, rs10757269 on chromosome 9 near *CDKN2B* had the strongest association with ABI ($\beta=-0.006$, $P=2.46\times10^{-8}$). We sought replication of the 6 strongest SNP associations in 5 population-based studies and 3 clinical samples (n=16 717). The association for rs10757269 strengthened in the combined discovery and replication analysis ($P=2.65\times10^{-9}$). No other SNP associations for ABI or PAD achieved genome-wide significance. However, 2 previously reported candidate genes for PAD and 1 SNP associated with coronary artery disease were associated with ABI: *DAB21P* (rs13290547, $P=3.6\times10^{-5}$), *CYBA* (rs3794624, $P=6.3\times10^{-5}$), and rs1122608 (*LDLR*, $P=0.0026$).

Conclusions—Genome-wide association studies in more than 40 000 individuals identified 1 genome wide significant association on chromosome 9p21 with ABI. Two candidate genes for PAD and 1 SNP for coronary artery disease are associated with ABI. **(*Circ Cardiovasc Genet*. 2012;5:100-112.)**

Key Words: cohort study ■ genetic association ■ genome-wide association study ■ meta-analysis ■ peripheral vascular disease

Peripheral arterial disease (PAD) affects approximately 27 million people in Europe and North America,[1] and is associated with increased risk for myocardial infarction, stroke, and mortality.[2–6] Measurement of ankle and arm blood pressures with a Doppler device and calculation of the ankle-brachial index (ABI) is a simple and reliable method to detect PAD. An ABI ≤0.90 is indicative of definite PAD.[7] In previous work, the Ankle-Brachial Index Collaboration demonstrated a reverse J-shaped relationship of ABI with mortality and coronary events, with a low risk ABI ranging from 1.11 to 1.40.[8]

Clinical Perspective on p 112

Little is known about genetic susceptibility to PAD, but familial aggregation and heritability estimates suggest a significant genetic component.[9–13] A study of 112 biological candidate genes identified only 2 single nucleotide polymorphisms (SNPs) in *NOS3* significantly associated with ABI.[14] The candidate gene approach to identify novel genetic variants for PAD has been limited by modest study sample size, relatively small number of genes examined, and lack of replication in independent samples.[13]

Genome-wide association studies (GWAS) have led successfully to the discovery of novel genetic variants for several common diseases, including coronary artery disease (CAD).[15] The association between genetic variants on chromosome 9p21 and CAD has demonstrated replication,[16,17] persistent association across race or ethnicity,[18] and association with other vascular diseases.[19–21] Notably, GWAS of subclinical atherosclerosis phenotypes, such as intima-medial thickness or ABI, are sparse. Therefore, we conducted a meta-analysis of GWAS findings for ABI within an international consortium of 21 population-based cohort studies that included 41 692 participants of European ancestry, among whom 3409 participants had PAD (ABI ≤0.90). We conducted replication analyses of our strongest findings in over 16 000 individuals from population-based cohort studies and clinically based samples of PAD. We hypothesized that this approach would lead to the unbiased identification of genetic variants associated with ABI. Further, we hypothesized that some genetic variants for ABI would be identical to those reported to be associated with CAD or its risk factors given shared underlying biological pathways, while some genetic variants would be associated uniquely with PAD.

Methods

Discovery Studies

Our analyses were conducted within the international Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium,[22] and included 4 of the 5 original CHARGE cohorts: Atherosclerosis Risk in Communities Study (ARIC, n=7630), the Cardiovascular Health Study (CHS, n=3193), the Framingham Heart Study (FHS, n=3572), and the Rotterdam Study (RS-I, n=5169 and RS-II, n=1642). Ten additional population-based cohorts joined the collaboration for analysis of ABI phenotypes: the Family Heart Study (FamHS, n=1736), Genetic Epidemiology Network of Arteriopathy Study (GENOA, n=991), Gutenberg Heart Study (GHS, n=3122), Health, Aging, and Body Composition (Health ABC, n=1564), the Invecchiare in Chianti Study (InCHIANTI, n=1130), Cooperative Health Research in the Region of Augsburg (KORA F3, n=1581 and KORA F4, n=1407), Netherlands Study of Anxiety and Depression (NESDA, n=1612), Nijmegen Biomedical Study (NBS, n=544), and the Study of Health in Pomerania (SHIP, n=543). A further 6 studies derived from population isolates also were available for the analyses: Amish Study (Amish, n=1183), Croatia-Vis (n=897), Croatia-Korcula (n=851), Croatia-Split (n=499), Erasmus Rucphen Family Study (ERF, n=2133), and the Orkney Complex Disease Study (ORCADES, n=693). For all studies participating in the meta-analyses, each participant self-identified as European or European-American and provided written informed consent, and the Institutional Review Board at the parent institution for each respective cohort approved the study protocols. More detailed study-specific information is provided in the online-only Data Supplement Methods.

Ankle-Brachial Index Phenotypes

Ankle and brachial blood pressure measurements for each participating study were obtained from the baseline examination or the first examination in which the measurement was obtained. Details on the ABI protocol used and the calculation performed in each study are provided in online-only Data Supplement Table I. To calculate the ABI for each leg, the systolic blood pressure at each ankle was divided by the systolic blood pressure in the arm. If the systolic blood pressure was measured in both arms, the higher arm reading was used in the ABI calculation. If replicate readings were obtained, the mean of the 2 measurements for each limb was used to calculate the ABI, with the exception of InCHIANTI, which used the higher of the 2 readings of each measurement set to calculate the ABI. The lower of the ABIs from the 2 legs was used for analysis. In ARIC and FamHS, the ABI was measured in only 1 leg, chosen at random. Participants with an ABI >1.40 were excluded because this high ABI may represent medial sclerosis, fibrocalcific disease secondary to diabetes mellitus, or other causes of noncompressible vessels.

To maximize the sample size and the power to detect genetic variants with modest effects, and to examine the entire range of ABI values given the recent evidence of increased cardiovascular disease risk associated with ABI values up to 1.1,[8] we examined the continuous range of ABI <1.40. As a secondary analysis to provide a clinical phenotype, we defined PAD as ABI ≤0.90 and conducted a case (ABI ≤0.9)/control; ABI >0.90 and <1.40) comparison analysis.

Genotyping and Imputation

Different genotyping platforms were used by the 21 studies (online-only Data Supplement Table II). Each study imputed the genotype "dosage" (0 to 2) for the expected number of alleles for ≈2.5 million Phase II HapMap CEU SNPs for each participant using currently available imputation methods.[23] CHS used BIMBAM (available at http://stephenslab.uchicago.edu/software.html),[24] GHS, InCHIANTI, NESDA, and SHIP used IMPUTE,[25] and all other cohorts used MACH (http://www.sph.umich.edu/csg/abecasis/MaCH/).

Statistical Analysis

We devised a GWAS analysis plan for the ABI and PAD phenotypes that each study independently implemented. Sex-specific and age-adjusted residuals of ABI were created from linear regression models and used as phenotypes in the analysis. No transformation of the ABI measure was performed before analysis. In FHS, residuals also were obtained separately in the original and offspring cohorts. Multi-site studies (ARIC, CHS, and FamHS) additionally adjusted for field study site. Each SNP was tested for association with ABI in additive genetic models using linear regression. The Amish Study, FamHS, FHS, and GENOA cohorts used linear mixed effects models to account for familial correlations. Croatia-Vis, Croatia-Korcula, Croatia-Split, ERF, and ORCADES used the "mmscore" function of the GenABEL package for R statistical software for the association test under an additive model. This score test for a family-based association takes into account pedigree structure and allows unbiased estimations of SNP allelic effect when relatedness is present between examinees. Logistic regression adjusting for age and sex was used to test each SNP for association with the PAD phenotype. The FamHS,

FHS, and GENOA cohorts used generalized estimating equations clustering on family to account for family correlations.

A genome-wide meta-analysis using a fixed effects approach with inverse variance weighting was then conducted in METAL[26] [www.sph.umich.edu/csg/abecasis/metal] for 2 669 158 SNPs in the meta-analysis, excluding the population isolates (2 670 732 SNPs including the population isolates) that met imputation and quality control criteria (online-only Data Supplement Table II). Before meta-analysis, genomic control was applied to each study. The association of ABI per each additional risk allele was quantified by the regression slope (β), its standard error [SE(β)], and the corresponding probability value. We calculated a meta-analysis odds ratio for each of the most significant SNP associations for PAD. The meta-analysis odds ratio estimates the increase in odds of PAD for each additional copy of the risk allele of the SNP. SNP associations were considered to be significant on a genome-wide level at $P<5\times10^{8}$.[27,28] Standardized gene and SNP annotations were created using a PERL script.[29] We also tested for heterogeneity of study specific regression parameters using Cochran Q statistic. Because of concerns about heterogeneity, we conducted analyses of nonisolate studies and of the full group of studies. We selected SNPs for replication using results from the meta-analysis, excluding the population isolates, because the available replication samples did not include isolates. We excluded SNP association results if the total meta-analysis sample was less than 20 000 and if the average minor allele frequency of the SNP was <5%.

Replication

We sought to replicate independent SNP associations for ABI that attained genome-wide significance (1 region), SNPs with suggestive associations (5 regions, $P<10^{-5}$), and bioinformatics data supporting the signal. The bioinformatic analyses are described in detail in the online-only Data Supplement Material. In addition, we sought to replicate 1 SNP associated with both ABI and PAD at $P<10^{-4}$. The replication studies included 5 population-based studies and 3 clinically-based studies, including a total of over 16 000 participants: the Bruneck Study (n=786), the Copenhagen City Heart Study (CCHS, n=5330), the Multi-Ethnic Study of Atherosclerosis (MESA, n=2611), the National Health and Nutrition Examination Surveys (NHANES 1999–2002, n=2335), Prevention of Renal and Vascular End-stage disease (PREVEND, n=3691) cohort, Cardiovascular Disease in Intermittent Claudication (CAVASIC, n=443) Study, Genetic Determinants of Peripheral Arterial Disease (GenePAD, n=850), and the Linz Peripheral Arterial Disease (LIPAD, n=671) Study. Each collaborating study was provided with a SNP list and a detailed analysis plan. MESA and PREVEND used *in silico* genotyping (online-only Data Supplement Table II), and the remaining studies genotyped the SNPs using Taqman assays or Sequenom. Relative excess heterozygosity analysis demonstrated that all genotyped SNPs were compatible with Hardy-Weinberg equilibrium at the nominal 5% test-level (online-only Data Supplement Table III).[30]

Examination of Candidate Genes Associated With Peripheral Artery Disease and Coronary Artery Disease/Myocardial Infarction

We selected candidate genes for ABI or PAD from the published literature using PubMed search terms "([ankle-brachial index] OR [peripheral arterial disease]) AND polymorphism." Association studies with at least 100 cases and 100 controls were included regardless of whether the original study results were positive or negative. Using the discovery meta-analysis results for ABI, we then identified the most strongly associated SNPs based on probability values within the gene region ±100 kb upstream or downstream of the candidate gene. Because of the high correlation of imputed genotypes, the effective number of loci were calculated for each gene region[31] using the genotype scores from the KORA F4 Study (online-only Data Supplement Methods). Bonferroni correction of probability values then was applied in each region using the effective number of loci. Subsequently, false discovery rates (FDR) were calculated using these corrected probability values, accounting for the number of gene regions examined (online-only Data Supplement Methods). Lastly, we examined the association with ABI of 30 SNPs strongly associated with CAD in recent GWAS.[32–34] Our ABI discovery meta-analysis did not include 2 of the 30 SNPs (rs17465637 and rs3798220), and we were unable to identify proxy SNPs available in our data. Using the probability values for the 28 SNPs in our discovery meta-analysis, we then calculated the FDR for each CAD SNP, accounting for the 28 regions examined.

Results

Study Sample

The study sample included 41 692 participants of European ancestry (56% women, 6256 from population isolates) with ABI data and genome-wide genotyping. Participant characteristics at the time of ABI measurement for each cohort are provided in online-only Data Supplement Table IV. Across the studies the mean age ranged from 41.8 years to 73.8 years, the mean ABI ranged from 1.02 to 1.19, and 8.2% (n=3409) had PAD (ABI <0.9). Characteristics of the replication samples were similar to the discovery set (online-only Data Supplement Table V).

ABI-SNP Associations

We conducted a meta-analysis with (n=41 692) and without (n=35 434) the population isolates (online-only Data Supplement Figures I and II, QQ-plots and Manhattan plots, and study-specific lambdas ranged from 0.997 to 1.044). Our primary meta-analysis excluded studies from population isolates because of concern for study heterogeneity and the lack of availability of replication samples from isolates. The strongest SNP association for ABI was rs10757269 on chromosome 9 near *CDKN2B* ($\beta=-0.006$, $P=2.46\times10^{-8}$, P for heterogeneity=0.23, Table 1; meta-analysis results, including the population isolates, online-only Data Supplement Table VII). Among the 96 SNP associations for ABI with $P<10^{-5}$, 79 were located in the chromosome 9p21 region (online-only Data Supplement Table VI). The ABI SNP rs10757269 is in strong linkage disequilibrium (LD), with several SNPs in the region previously reported to be associated with CAD or myocardial infarction ($r^2>0.8$), but this ABI SNP is not in LD with SNPs previously associated with the type 2 diabetes mellitus (Figure 1). We repeated the meta-analysis to examine the association between ABI and rs10757269, first adjusting for CAD and then excluding individuals with CAD among the nonisolate studies. The association remained but was no longer genome-wide significant (adjusting for CAD: $P=5.56\times10^{-6}$; excluding CAD: $P=3.79\times10^{-5}$). Next, we sought to replicate the association between rs10757269 and ABI in both population-based and clinically-based samples (n=16 717). The magnitude and direction of the association in the replication studies was similar to the discovery set ($\beta=-0.0035$, $P=0.0176$), providing evidence of replication. In the combined stage 2 discovery plus replication meta-analysis, the ABI-rs10757269 association became stronger ($P=2.65\times10^{-9}$). The study-specific estimates of effect for the discovery studies, population isolates, replication studies, and overall discovery plus replication meta-analyses are presented in Figure 2. Two studies among the population isolates (the Amish Study and Croatia-Split) had effect estimates in the

opposite direction to the other studies. None of the other SNP associations for ABI achieved genome-wide significance. The significance of the associations for the additional SNPs chosen for replication diminished in the discovery plus replication meta-analysis (Table 1, online-only Data Supplement Table VII).

PAD-SNP Associations

None of the SNP associations for the PAD phenotype (defined by an ABI ≤0.9) achieved genome-wide significance (Table 2; for meta-analysis results including population isolates see online-only Data Supplement Table VIII). The strongest association was found for rs6584389 on chromosome 10 near the *PAX2* gene (odds ratio 1.17, 95% confidence interval 1.10, 1.25, $P=2.34\times10^{-6}$). Of note, the chromosome 9 SNP rs10757269 association with PAD was in a direction consistent with the ABI association but did not achieve statistical significance (Table 1, $\beta=0.0849$, $P=0.004$, increasing the odds of PAD).

Overlap in SNP Associations for ABI and PAD

While the directions of effect for the ABI SNPs in Table 1 were consistent with the PAD association result (lower ABI, increased odds of PAD), there was little overlap in the top associations for the 2 phenotypes. Only 3 regions marked by SNPs in or near *IDE* (10q23–q25), *DAB21P* (9q33.2), and *GRAMD1C* (3q13.31), in addition to the chromosome 9p21 region, showed association with both ABI and PAD at the $P<10^{-4}$ level (online-only Data Supplement Table IX). SNP rs7100623 in *IDE* demonstrated the strongest novel association with both ABI ($\beta=-0.005$, $P=1.89\times10^{-5}$) and PAD ($\beta=0.139$, $P=8.39\times10^{-5}$) at $P<10^{-4}$; however, the association probability value was not significant in the replication stage, and diminished in the combined discovery plus replication meta-analysis.

Examination of PAD Candidate Genes

Among the 55 candidate genes or regions previously tested for association with ABI or PAD, 8 regions showed nominally significant probability values ($P<0.05$) after correction

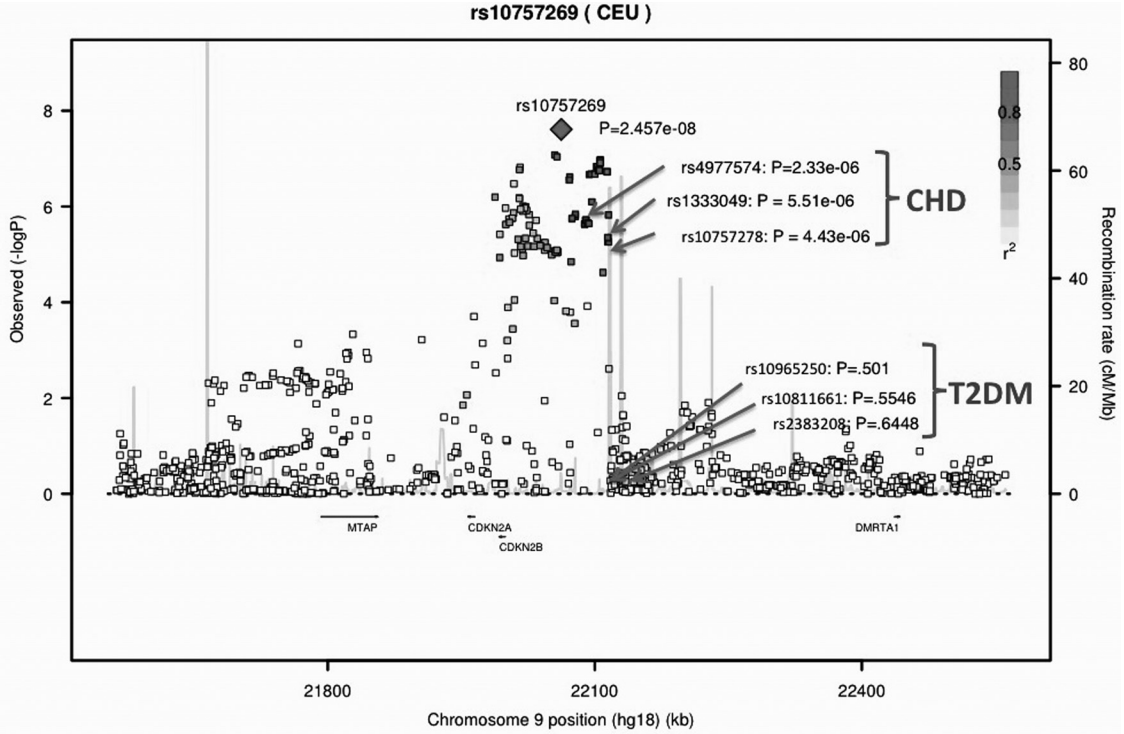

Figure 1. Genomic context of the genome-wide significant signal at chromosome 9p21 plotted against the $-\log_{10} P$ values. r^2 is between the top signal (rs10757269) and each SNP is shown. SNPs previously reported from genome-wide association studies (GWAS) to be associated with coronary artery disease (CHD, arrows), type 2 diabetes (T2DM, arrows), and *P* value for association with ankle-brachial index are shown. Chromosome positions are based on build hg18.

for the number of effective loci for each gene region. After accounting for the number of regions examined using a false discovery rate (FDR <0.10), we found evidence of association between ABI and *CYBA* (rs3794624, uncorrected $P=6.3\times10^{-5}$, corrected $P=0.0036$, FDR=0.0665) and *DAB21P* (rs13290547, uncorrected $P=3.6\times10^{-5}$, corrected $P=0.0035$, FDR=0.0665), in addition to the chromosome 9p21 locus (rs1333049) reported to be associated with ABI (Table 3).[35] We found no evidence of association between ABI and any of the other candidate genes previously tested for association with ABI or PAD (online-only Data Supplement Table X).

Examination of Coronary Artery Disease/ Myocardial Infarction Candidate Genes

Among the 30 SNPs previously reported by GWAS to be associated with CAD or myocardial infarction, 28 SNPs were available in our discovery meta-analysis of ABI, and 2 of these SNPs demonstrated an association (FDR <0.10) with ABI, including rs4977574 near *CDKN2B* ($P=2.33\times10^{-6}$) and rs1122608 in *LDLR* ($P=0.0026$) (Table 3, online-only Data Supplement Table XI).

Discussion

Our GWAS meta-analysis for ABI conducted in more than 40 000 adults of European ancestry has several notable findings. First, we identified and replicated 1 genome-wide significant association between a SNP in the chromosome 9p21 region and ABI. No other ABI-SNP associations achieved genome-wide significance. Second, in our discovery sample, over 3000 adults had PAD (ABI ≤0.9); however, none of the SNP associations were significant. Third, the directions of effect were consistent across the 2 phenotypes for the most significant ABI SNPs (lower ABI, increased odds of PAD): however, we observed minimal overlap in the top SNP associations for ABI and PAD. Finally, the effect size for the 9p21 SNP was modest. The association itself is, however, intriguing, and may provide insights into the biological mechanisms contributing to generalized atherosclerosis.

Chromosome 9p21 Locus and Atherosclerosis Susceptibility

Common genetic variants in the 9p21 locus are associated strongly with myocardial infarction and CAD,[17,33,36] and confer risk for other atherosclerotic diseases including stroke,[19] cerebral and abdominal aortic aneurysm,[20,21] and clinically diagnosed PAD; however, the relation with PAD was diminished when coronary artery disease cases were excluded.[20] SNP associations at the 9p21 locus with subclinical measures of atherosclerosis have been conflicting. Initially, no association was observed with carotid intima-medial thickness or flow mediated dilation in young or older adults;[37,38] however, more recent reports demonstrate an association with the development and progression of carotid atherosclerosis[39] and with the suggestion of a stronger effect in men.[40] To further investigate the ABI-9p21 SNP association noted in this study, we conducted the meta-analysis after adjusting for CAD and after exclusion of individuals with CAD. Not surprisingly, the association persisted but was no

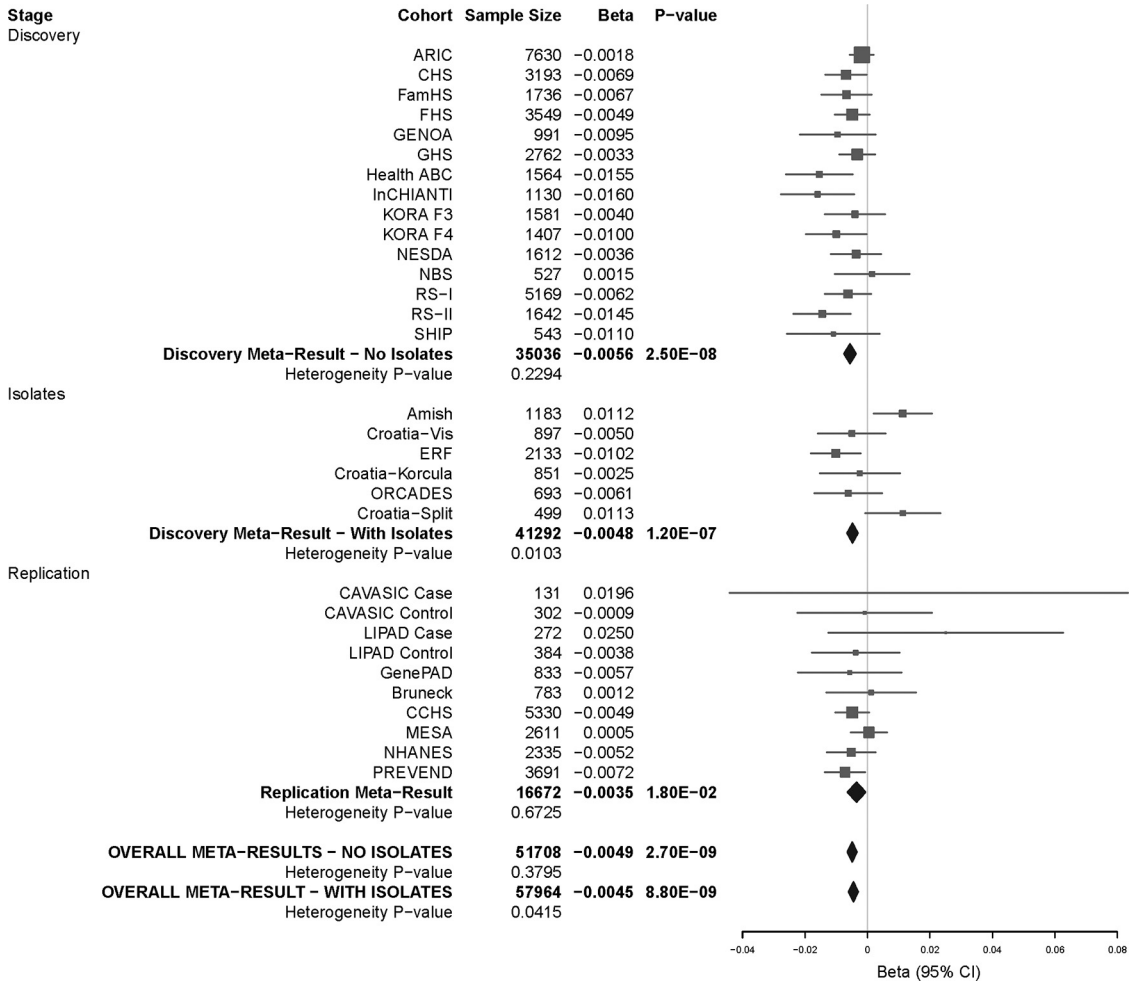

Figure 2. Ankle-brachial index-chromosome 9p21 (rs10757269) association: study-specific estimates of effect for the discovery studies, population isolates, replication studies, and overall discovery and replication meta-analyses.

longer genome-wide significant. Both CAD and PAD are manifestations of underlying atherosclerosis, and nearly two thirds of individuals with PAD have coexisting coronary or cerebrovascular disease.[41] One previous report conducted in 3 studies of older adults identified an association between a variant at 9p21 and lower ABI, as well as an increased risk for PAD.[35] The primary effect of the chromosome 9p21 region may be on the atherosclerotic process itself, and there are likely to be many other factors, both genetic and environmental, that determine whether it manifests as CAD, PAD, or another clinical atherosclerotic phenotype. The primary biological mechanism underlying the association with ABI is unknown but appears to be independent of 2 major PAD risk factors, diabetes and smoking, as the ABI SNP in the 9p21 region we identified is not in linkage disequilibrium with the SNPs in the region associated with diabetes risk[42,43] or smoking-related behaviors.[44] The mechanism may be related to modulation of platelet reactivity,[45] atheroma formation, plaque instability, thrombosis, or biological processes not yet identified.[46] The SNP associated with ABI is nearest to

**P* value from Discovery GWAS of ABI. Chr indicates chromosome.

†Candidate genes for PAD were selected for testing with ABI if an association study with at least 100 cases and 100 controls was available in the literature, independent of whether the study was positive or negative. Genes for CAD were considered only for testing with ABI if they were identified by recent GWAS to be genome-wide significantly associated with CAD. The table shows only the genes which showed an experiment-wise significant association with ABI after correction for multiple testing. The entire list of genes can be seen in online-only Data Supplement Table X and XI for PAD and CAD genes, respectively.

‡Due to the high correlation of imputed genotype scores, the effective number of loci was calculated for each PAD gene region (31) using the genotype scores from the KORA F4 Study. Bonferroni correction of *P* values then was applied in each region using this number. Furthermore, the corrected *P* value thresholds of significance for 28 CAD loci (tested in online-only Data Supplement Table XI, $\alpha=0.05/28$, 1.85×10^{-3}) and 55 PAD loci (tested in online-only Data Supplement Table X, $\alpha=0.05$/effective number of loci) were calculated. We also calculated a false discovery rate (FDR) using the corrected *P* values accounting for the number of gene regions examined. An FDR <0.10 defined evidence of a significant association.

CDKN2B, a well recognized tumor-suppressor gene that encodes a cyclin-dependent kinase inhibitor and is involved in regulation of the cell cycle. *CDKN2B* is abundantly expressed in human atherosclerotic lesions,[47] and animal models suggest that altered *CDKN2A/B* expression results in abnormal regulation of vascular cell proliferation.[48] Functional studies reveal a long noncoding RNA at this locus named ANRIL, and a mouse model has confirmed the essential role of ANRIL in regulation of *CDKN2B* expression through a cis-acting mechanism.[49,50] ANRIL is implicated in proliferation and senescence.

PAD Candidate Genes

We performed a literature search to identify all candidate gene regions previously investigated for association with PAD or ABI, irrespective of whether the association was reported to be positive or negative. This approach revealed 2 further associated gene regions: *DAB2IP* and *CYBA*. *DAB2IP* rs13290547 was not only associated with ABI, but also with PAD ($P=3.62\times10^{-5}$ and 2.2×10^{-5}, respectively; online-only Data Supplement Table X). The *DAB2IP* gene encodes an inhibitor that is involved in the regulation of cell survival and proliferation. One variant in the *DAB2IP* gene (rs70254486) recently has been detected in a GWAS of abdominal aortic aneurysm.[51] That study also detected an association with PAD as a secondary end point in 3690 cases versus 12 271 controls ($P=3.9\text{x}10^{-5}$). The same SNP showed an association with CVD within a meta-analysis of case control studies.[52] The *CYBA* gene is involved in NADPH oxidase regulation, which contributes to oxidative stress and plays a key role in the pathophysiology of coronary disease. Only 1 report investigated a SNP (rs4673) in this gene for association with PAD among 324 cases and 295 controls, but did not find an association.[53] Our study found an association of rs3794624 ($r^2=0.5$ with rs4673) with continuous ABI, which may indicate that the earlier study likely lacked power to find this association. None of the other gene regions had sufficient evidence for association with continuous ABI in our meta-analysis. Another very wide-reaching approach designed to systematically examine a large number of genes related to intermediate phenotypes of atherosclerosis, such as blood pressure regulation, lipoprotein metabolism, inflammation, oxidative stress, vascular wall biology, obesity, and diabetes, found only eNOS to be significantly associated with ABI.[14] This gene could not be confirmed by our candidate gene examination.

Coronary Candidate Genes

Besides the chromosome 9 locus, 1 other SNP reported to be associated with coronary disease in recent GWAS also showed an association with ABI in our study; rs1122608 in *LDLR*. The *LDLR* gene plays an important role in cholesterol homeostasis, and mutations at this gene have been shown to influence LDL cholesterol levels and the subsequent risk for coronary disease.[54] The association of *LDLR* gene with ABI in our study is a confirmation of the shared biological pathways underlying both subclinical and clinically apparent disease.

Strengths/Limitations

Our meta-analysis represents the largest collaborative effort to date to identify genome-wide SNP associations for variation in ABI and PAD (ABI ≤0.90), and our findings suggest the absence of common variants with large effects on ABI. Use of ABI as our primary phenotype has major advantages of detecting asymptomatic PAD, as the ABI is an objective measurement, whereas clinical PAD requires subjective symptoms of exertional leg discomfort and mobility of the individual. However, several limitations of our meta-analysis merit comment. The blood pressure measurement protocol and ABI calculation was heterogeneous across participating studies. While protocols were standardized within each study,

the studies were not designed to be fully standardized and comparable across studies (online-only Data Supplement Table I). This phenotype heterogeneity may have impacted our ability to detect associations. Furthermore, for many studies, information about a previous revascularization intervention was not available. This lack of data may have resulted in the misclassification of some of the most affected persons by placing them into an ABI range of unaffected individuals and consequently reducing our power to detect true associations. Our sample was restricted to individuals of European ancestry, and thus our findings cannot yet be generalized to individuals of other race or ethnic groups. Furthermore, some PAD susceptibility variants may be race or ethnic specific and only can be uncovered through the study of non-Europeans. For example, African-Americans have a higher prevalence of PAD that cannot be attributed to traditional or novel risk factors.[55] This observation raises the hypothesis that polymorphisms unique to African-Americans partially may be responsible for the higher prevalence of PAD.[55] We did not evaluate gene by environment interactions, which may be especially relevant for cigarette smoking, a strong risk factor for PAD,[56] and a factor known to interact with other genes to modulate atherosclerosis.[57]

Conclusions

In conclusion, a common variant near the *CDKN2B* gene in the chromosome 9p21 locus is associated with a lower ABI. PAD represents a diffuse form of atherosclerosis associated with increased risk for death and incident CVD events. Thus, the identification of genetic variants associated with ABI may provide an important opportunity not only to unravel the biological basis of PAD, but also to improve our understanding of the causes of the variation in degree of atherosclerosis from 1 arterial bed to another. Additional studies are warranted to identify the causal variants in the 9p21 locus and to characterize their functional significance. The search for genes influencing predilection to PAD remains elusive, and alternative approaches are warranted.

Sources of Funding

The Amish Study was supported by grants R01 088119, R01 AR046838, U01 HL72515, and R01 AG18728, the University of Maryland General Clinical Research Center, Grant M01 RR 16500, Mid-Atlantic Nutrition Obesity Research Center Grant P30 DK072488, General Clinical Research Centers Program, National Center for Research Resources (NCRR), and the Baltimore Veterans Administration Geriatric Research and Education Clinical Center (GRECC). Dr. Montasser was supported by AG000219. ARIC is carried out as a collaborative study supported by NHLBI contracts (HHSN268201100005C, HHSN268201100006C, HHSN268201100007C, HHSN268201100008C, HHSN268201100009C, HHSN268201100010C, HHSN268201100011C, and HHSN268201100012C), R01HL087641, R01HL59367, and R01HL086694; National Human Genome Research Institute contract U01HG004402; and NIH contract HHSN268200625226C and infrastructure support UL1RR025005. CHS research was supported by NHLBI contracts N01-HC-85239, N01-HC-85079 through N01-HC-85086; N01-HC-35129, N01 HC-15103, N01 HC-55222, N01-HC-75150, N01-HC-45133, and NHLBI grants HL080295, HL075366, HL087652, HL105756, with additional contribution from NINDS. Additional support was provided through AG-023629, AG-15928, AG-20098, and AG-027058 from the NIA. DNA handling and genotyping was supported in part by National Center for Research Resources grant M01-RR00425 and National Institute of Diabetes and Digestive and Kidney Diseases grant DK063491. The Family Heart Study GWAS was funded by grant HL08770002, and the work was supported by NHLBI contract numbers R01HL08770003I, and R01DK06833603 and R01DK07568101 from NIDDK. This work was partially supported by the National Heart, Lung and Blood Institute's Framingham Heart Study (Contract No. N01-HC-25195) and its contract with Affymetrix, Inc, for genotyping services (Contract No. N02-HL-6-4278). A portion of this research used the Linux Cluster for Genetic Analysis (LinGA-II) funded by the Robert Dawson Evans Endowment of the Department of Medicine at Boston University School of Medicine and Boston Medical Center. "Genetic Epidemiology Network of Arteriopathy (GENOA) study is supported by the NIH, grant number 5R01HL087660." The Gutenberg Heart Study is funded through Rheinland-Pfalz ("Stiftung Rheinland Pfalz für Innovation," contract number AZ 961-386261/733), the research programs "Wissen schafft Zukunft" and "Schwerpunkt Vaskuläre Prävention" of the Johannes Gutenberg-University of Mainz and its contract with Boehringer Ingelheim and PHILIPS Medical Systems, including an unrestricted grant for the Gutenberg Heart Study. This research also was supported by the National Genome Network "NGFNplus" (contract number project A3 01GS0833 and 01GS0831), by the Federal Ministry of Education and Research, Germany. Health ABC was supported by NIA contracts N01AG62101, N01AG62103, and N01AG62106. The GWAS was funded by NIA grant 1R01AG032098-01A1 to Wake Forest University Health Sciences, and genotyping services were provided by the Center for Inherited Disease Research (CIDR). CIDR is fully funded through a federal contract from the National Institutes of Health to The Johns Hopkins University, contract number HHSN268200782096C. The InCHIANTI study baseline (1998–2000) was supported as a "targeted project"(ICS110.1/RF97.71) by the Italian Ministry of Health and in part by the NIA (Contracts: 263 MD 9164 and 263 MD 821336); the InCHIANTI Follow-up 1 (2001–2003) was funded by NIA (Contracts: N.1-AG-1-1 and N.1-AG-1-2111; the InCHIANTI Follow-ups 2 and 3 studies (2004–2010) were funded by NIA (Contract: N01-AG-5-0002), supported in part by the NIA Intramural research program. A portion of the support was through a R and D contract with MedStar Health Research Institute. KORA F3 and KORA F4 were partially funded by the "Genomics of Lipid-associated Disorders-GOLD" of the "Austrian Genome Research Programme GEN-AU" and by the Austrian Heart Fund to F. Kronenberg and by the Austrian National Bank (Project-Nr. 13662) to Barbara Kollerits. The MONICA/KORA Augsburg cohort study was financed by the Helmholtz Zentrum München and the German National Genome Research Net NGFN2 and NGFNplus (H.-E. Wichmann 01GS0823). NESDA was supported by the Geestkracht program of ZonMW [grant 10-000-1002]; matching funds from universities and mental health care institutes involved in NESDA (GGZ Buitenamstel-Geestgronden, Rivierduinen, University Medical Center Groningen, GGZ 25 Lentis, GGZ Friesland, GGZ Drenthe). Genotyping was funded by the Genetic Association Information Network (GAIN) of the Foundation for the US NIH, and analysis was supported by grants from GAIN and the NIMH (MH081802). NBS support was obtained from RUNMC. The measurement of ABI was supported by Grant 2003B057 of the Netherlands Heart Foundation. This work was sponsored by the Stichting Nationale Computerfaciliteiten (National Computing Facilities Foundation, NCF) for the use of supercomputer facilities, with financial support from the Nederlandse Organisatie voor Wetenschappelijk Onderzoek (Netherlands Organization for Scientific Research, NWO). The Rotterdam GWA study was funded by the Netherlands Organisation of Scientific Research NWO Investments (nr. 175.010.2005.011, 911-03-012), the Research Institute for Diseases in the Elderly (014-93-015; RIDE2), the Netherlands Genomics Initiative (NGI)/Netherlands Consortium for Healthy Aging (NCHA) project nr. 050-060-810. Dr Jacqueline Witteman is supported by Netherlands Organization for Scientific Research (NOW) grant (vici, 918-76-619).

Abbas Dehghan is supported by Erasmus University Rotterdam (EUR) fellowship. The Rotterdam Study is funded by Erasmus Medical Center and Erasmus University, Rotterdam, Netherlands Organization for the Health Research and Development (ZonMw), the Research Institute for Diseases in the Elderly (RIDE), the Ministry of Education, Culture and Science, the Ministry for Health, Welfare and Sports, the European Commission (DG XII), and the Municipality of Rotterdam. SHIP is funded by the Federal Ministry of Education and Research (grants no. 01ZZ9603, 01ZZ0103, and 01ZZ0403), the Ministry of Cultural Affairs, as well as the Social Ministry of the Federal State of Mecklenburg-West Pomerania. Genome-wide data have been supported by the Federal Ministry of Education and Research (grant no. 03ZIK012) and a joint grant from Siemens Healthcare, Erlangen, Germany, and the Federal State of Mecklenburg-West Pomerania. CROATIA Studies (Croatia-Vis, Croatia-Korcula, and Croatia-Split) were supported by grants from the Medical Research Council UK and Ministry of Science, Education and Sport of the Republic of Croatia (No. 108-1080315-0302), and CROATIA-Vis by the European Union framework program 6 European Special Populations Research Network (EUROSPAN) project (contract LSHG-CT-2006-018947). The genotyping for the ERF study was supported by EUROSPAN (European Special Populations Research Network) and the European Commission FP6 STRP grant (018947; LSHG-CT-2006-01947). The ERF study was further supported by grants from the Netherlands Organisation for Scientific Research, Erasmus MC, the Centre for Medical Systems Biology (CMSB), and the Netherlands Brain Foundation (HersenStichting Nederland). ORCADES was supported by the Chief Scientist Office of the Scottish Government, the Royal Society, and the European Union framework program 6 EUROSPAN project (contract no. LSHG-CT-2006-018947). DNA extractions were performed at the Wellcome Trust Clinical Research Facility in Edinburgh. The Bruneck Study was supported by the Pustertaler Verein zur Prävention von Herz- und Hirngefaesserkrankungen, Gesundheitsbezirk Bruneck, and the Assessorat fuer Gesundheit, Province of Bolzano, Italy. The Copenhagen City Heart Study was supported by a Specific Targeted Research Project grant from the European Union, Sixth Framework Programme Priority (FP-2005-LIFESCIHEALTH-6) contract 037631, the Danish Medical Research Council (Copenhagen), the Research Fund at Rigshospitalet, Copenhagen University Hospital (Copenhagen), Chief Physician Johan Boserup and Lise Boserup's Fund (Copenhagen), Ingeborg and Leo Dannin's Grant (Copenhagen), and Henry Hansen's and Wife's Grant (Copenhagen). Genotyping was supported by a grant from the Austrian Heart Fund. National Health and Nutrition Examination Surveys (NHANES) are supported by the Centers for Disease Control and Prevention. The Vanderbilt University Center for Human Genetics Research, Computational Genomics Core, provided computational or analytical support for this work. MESA and the MESA SHARe project are conducted and supported by the NHLBI in collaboration with MESA investigators. Support is provided by grants and contracts N01 HC-95159, N01-HC-95160, N01-HC-95161, N01-HC-95162, N01-HC-95163, N01-HC-95164, N01-HC-95165, N01-HC-95166, N01-HC-95167, N01-HC-95168, N01-HC-95169 and RR-024156. "Funding for SHARe genotyping was provided by NHLBI Contract N02-HL-6-4278." The PREVEND study is supported by the Dutch Kidney Foundation (Grant E033), EU project grant GENECURE (FP-6 LSHM CT 2006 037697), and NWO VENI (grant number 916.76.170). The CAVASIC study was partially funded by the "Genomics of Lipid-associated Disorders-GOLD" of the "Austrian Genome Research Programme GEN-AU" and by the Austrian Heart Fund and the Austrian National Bank (Project-Nr. 13662). GenePAD was supported by grants RO1 HL-75774, 1K12 HL087746, 1P50HL083800, as well as grant M01 RR 00070 (General Clinical Research Center, Stanford University School of Medicine) and the Stanford Cardiovascular Institute. The LIPAD project was supported in part by a grant from the Upper Austrian Government. Genotyping was supported by a grant from the Austrian Heart Fund.

CLINICAL PERSPECTIVE

Little is known about the genetic susceptibility to peripheral arterial disease (PAD). We conducted a meta-analysis of genome-wide association study findings for the ankle-brachial index (ABI), a noninvasive measure of PAD, within an international consortium of 21 population-based cohort studies that included over 40 000 participants of European descent, and conducted replication analyses in over 16 000 individuals from population-based cohorts and clinically-based studies of PAD. We identified and replicated 1 genome-wide significant association between a genetic variant in the chromosome 9p21 region and a lower ABI. Common genetic variants in the 9p21 locus are associated strongly with coronary artery disease and confer risk for other atherosclerotic diseases. Therefore, the primary effect of the 9p21 region may be on the atherosclerotic process itself, and there are likely many other factors, both genetic and environmental, that determine whether it manifests as coronary disease, PAD, or another clinical atherosclerotic phenotype. The primary biological mechanism underlying the association with ABI is unknown but appears independent of 2 major PAD risk factors, diabetes and smoking, as the ABI single nucleotide polymorphisms (SNP) in the 9p21 region we identified is not in linkage disequilibrium with the SNPs in the region associated with diabetes or smoking-related behaviors. PAD represents a diffuse form of atherosclerosis associated with increased risk for death and incident CVD events. Identification of genetic variants associated with ABI may provide an opportunity to unravel the biological basis of PAD.

Supplemental Material

Association between chromosome 9p21 variants and the Ankle-brachial Index identified by a meta-analysis of 21 genome-wide association studies

1. Study Specific Phenotype and Genotype Information

1.1 Discovery cohorts: non-isolated populations

1.1.1 Atherosclerosis Risk in Communities Study (ARIC)

The ARIC study is a predominantly bi-racial prospective study of the etiology and natural history of subclinical and clinical atherosclerosis among 15,792 middle-aged men and women, aged 45 to 64 years old at recruitment in 1987 to 1989 [(1)]. Study participants were selected as a probability sample from four US communities: Forsyth Co, NC; Jackson, MS; seven northwestern suburbs of Minneapolis, MN; and Washington Co, MD. African-Americans were over-sampled in Forsyth CO and were exclusively sampled in Jackson. Participants were examined at baseline with collection of medical, social, and demographic data and at three triennial follow-up exams, the last of which occurred in 1999. Annual follow-up continues to ascertain vital status as well as CHD and stroke, including hospitalizations and deaths. GWAS data are available from 8,861 self-identified white ARIC participants.

1.1.2 Cardiovascular Health Study (CHS)

The CHS is a population-based cohort study of risk factors for CHD and stroke in adults age 65 years and older conducted across four field centers in the United States [(2)]. The original predominantly Caucasian cohort of 5201 persons was recruited in 1989-1990 from a random sample of people on Medicare eligibility lists and an additional 687 African-Americans were enrolled subsequently for a total sample of 5,888.

DNA was extracted from blood samples drawn on all participants at their baseline examination in 1989 to 1990. Genotyping was performed from 2007 to 2008 at the General Clinical Research Center's Phenotyping/Genotyping Laboratory at Cedars- Sinai on the 3,980 CHS participants who had consented to genetic testing and were free of CVD at baseline. A total of 1,908 persons were excluded for lack of available DNA or prevalent coronary heart disease, congestive heart failure, peripheral vascular disease, valvular heart disease, stroke, or transient ischemic attack. Because the other cohorts were predominantly white, the African-American participants were excluded from this analysis to limit the potential for false positive associations due to population stratification, leaving 3397 Caucasians successfully genotyped, 3291 had measures of ABI.

1.1.3 Family Heart Study (FamHS)

The Family Heart Study (https://dsgweb.wustl.edu/PROJECTS/MP1.html) was begun in 1992 with the ascertainment of 1,200 families, half randomly sampled, and half selected because of an excess of coronary heart disease (CHD) or risk factor abnormalities as compared with age- and sex-specific population rates [(3)]. The families, with approximately 6,000 individuals, were sampled on the basis of information on probands from four population-based parent studies: the Framingham Heart Study, the Utah Family Tree Study, and two ARIC centers (Minneapolis, and Forsyth County, NC). A broad range of phenotypes were assessed at a clinic examination (exam 1) in broad domains of CHD, atherosclerosis, cardiac and vascular function, inflammation and hemostasis, lipids and lipoproteins, blood pressure, diabetes and insulin resistance, pulmonary function, and anthropometry. Approximately 8 years later, study participants belonging to the largest pedigrees were invited for a second clinical exam. A total of 2,767 Caucasian subjects in 510 extended families were examined. This sample is the focus of the genome-wide association study (GWAS).

A two-stage design was adopted for the GWAS. In the first stage, 1016 subjects were chosen, equally distributed between the upper and lower quartile of age- and sex-adjusted values for coronary artery calcification, assessed by CT scan. These subjects were chosen to be largely unrelated; 34% of the subjects were from unique families, while 200 other subjects had 1 or more siblings selected into the sample, yielding a sample of 465 unrelated subjects. The remaining family members (n=1,753) will be genotyped in the second stage for replication of the top hits from the first stage.

1.1.4 Framingham Heart Study (FHS)

The FHS is a National Heart Lung and Blood Institute contract-funded observational cohort study initiated in 1948 to examine the determinants of cardiovascular disease and its risk factors (http://www.framinghamheartstudy.org/). The Original Cohort comprised 5,209 men and women, aged 28-62 years at enrollment who have undergone routine biennial examinations [4,5]. In 1971, 5,124 Offspring of the Original Cohort participants and Offspring spouses, aged 5 to 70 years, were enrolled into the Framingham Offspring Study and have been examined approximately every 4 years [6,7]. In the 1990s, DNA was obtained for genetic studies from surviving Original cohort and Offspring participants. Routine examinations for all FHS cohorts included a standardized physician administered medical history interview and physical examination, direct measurement of cardiovascular risk factors, laboratory assessment, and various questionnaires and noninvasive cardiovascular tests specific to the given examination cycle. Cardiovascular events were adjudicated by a panel of senior investigators using previously reported criteria. FHS examinations were approved by the Institutional Review Board of the Boston University Medical Center and all participants provided written informed consent.

1.1.5 Genetic Epidemiology Network of Arteriopathy Study (GENOA)

The Family Blood Pressure Program (FBPP), established by the National Heart Lung and Blood Institute in 1996, joined existing research networks that were investigating hypertension and cardiovascular diseases (http://public.nhlbi.nih.gov/GeneticsGenomics/home/fbpp.aspx). One of the four FBPP networks is the Genetic Epidemiology Network of Arteriopathy (GENOA), which recruited hypertensive, Caucasian sibships for linkage and association studies to investigate genetic contributions to hypertension and hypertension-related target organ damage. Sibships containing at least two individuals with clinically-diagnosed essential hypertension before age 60 years were recruited from Rochester, Minnesota. After identifying each hypertensive sibship, all members of the sibship were invited to participate regardless of their hypertension status. Informed consent was obtained from all subjects and approval was granted by participating institutional review boards. Participants were diagnosed with hypertension if they had either 1) a previous clinical diagnosis of hypertension by a physician with current anti-hypertensive treatment, or 2) an average systolic blood pressure (SBP) ≥ 140 or diastolic blood pressure (DBP) ≥ 90 on the second and third clinic visit as stipulated by the Joint National Committee-7 guidelines [8]. Exclusion criteria were secondary hypertension, alcoholism or drug abuse, pregnancy, insulin-dependent diabetes mellitus, or active malignancy.

1.1.6 Gutenberg Heart Study (GHS)

The Gutenberg Health Study (GHS) is designed as a population-based, prospective, observational single-center cohort study in the Rhein-Main-Region in western Mid-Germany to evaluate and improve cardiovascular risk stratification. It also investigates cancer, eye diseases, diseases of the immune system

and the metabolism. The sample was drawn randomly from the governmental local registry offices in the city of Mainz and the district of Mainz-Bingen. The sample was stratified 1:1 for gender and for urban and rural residence with equal strata for decades of age. Individuals between 35 and 74 years of age were enrolled, and written informed consent was obtained from all participants. Exclusion criteria were insufficient knowledge of the German language, and physical or psychological inability to participate in the examinations at the study center. All participants underwent a five hour examination including a biobanking in the study center. Follow-up examinations are carried out after 2.5 and 5 years. The study protocol was approved by the local ethics committee and the local data safety commissioner and the sampling design by the federal data safety commissioners. All subjects gave written informed consent.

1.1.7 Health, Aging, and Body Composition(Health ABC) Study

The Health Aging and Body Composition (Health ABC) Study is a NIA-sponsored ongoing cohort study of the factors that contribute to incident disability and the decline in function of healthier older persons, with a particular emphasis on changes in body composition in old age. Health ABC enrolled well-functioning, community-dwelling black (n=1281) and white (n=1794) men and women aged 70-79 years between April 1997 and June 1998. Participants were recruited from a random sample of white and all black Medicare eligible residents in the Pittsburgh, PA, and Memphis, TN, metropolitan areas. The key components of Health ABC include a baseline exam, annual follow-up clinical exams, and phone contacts every 6 months to identify major health events and document functional status between clinic visits. GWAS data are available from 1663 white participants.

1.1.8 Invecchiare in Chianti (InCHIANTI) Study

The InCHIANTI study is a population based longitudinal study designed to investigate the causes of decline in mobility in older subjects [(9)]. The study sample comprises 1,453 individuals of white European descent and is representative of the older population aged 65 years and older supplemented with at least 30 men and 30 women for each 10 year age group from 20 to 70 years from two small towns from the Chianti region in Tuscany, Italy. Interviews were conducted at the participants' homes by three experienced interviewers. Within three weeks, participants attended a study clinic for blood drawing tests, having fasted for at least 8 and just concluded the 24-hour urine collection. On the same day, the participants received a series of medical examinations, including an assessment of the ankle-brachial index. On the second appointment a clinical evaluation and a comprehensive motor and cognitive performances session were performed by an experienced geriatrician and a trained physical therapist, respectively. INRCA Ethical Committee approved the entire study protocol.

1.1.9 and 1.1.10 Cooperative Health Research in the Region of Augsburg, Kooperative Gesundheitsforschung in der region Augsburg (KORA F3, KORA F4)

The KORA surveys S3 and S4 (Kooperative Gesundheitsforschung in der Region Augsburg [(10)]) are population-based samples drawn from the general population of the South-German city of Augsburg and surrounding counties stratified by age (25 to 74 years) and sex. The follow-ups of these surveys were conducted in 2004/05 (KORA F3) and 2006-2008 (KORA F4). All participants had a German passport, were of European origin and underwent a standardized face-to-face interview by certified medical staff and a standardized medical examination. Genome-wide data are available for a subset of 1,644 subjects randomly chosen from

KORA F3 and for 1814 subjects from KORA F4. ABI-measures were additionally available for n=1,581 (KORA F3) and n=1,407 (KORA F4).

1.1.11. Netherlands Study of Depression and Anxiety (NESDA)

The Netherlands Study of Depression and Anxiety (NESDA) [11], is a multi-centre study designed to examine the long-term course and consequences of depressive and anxiety disorders (http://www.nesda.nl). NESDA included both individuals with depressive and/or anxiety disorders and controls without psychiatric conditions. Inclusion criteria were age 18-65 years and self-reported western European ancestry, exclusion criteria were not being fluent in Dutch and having a primary diagnosis of another psychiatric condition (psychotic disorder, obsessive compulsive disorder, bipolar disorder, or severe substance use disorder).

For all participants DNA was isolated from the baseline blood sample. Through funding from the fNIH GAIN program (www.fnih.gov/gain), whole genome scan analysis was conducted for 1,859 NESDA (1,702 depressed cases and 157 controls) participants. A hundred subjects were excluded because of various quality control issues [12].

1.1.12 Nijmegen Biomedical Study (NBS)

The Nijmegen Biomedical Study is a population-based cross-sectional study conducted by the Radboud University Nijmegen Medical Centre [13]. Nijmegen is a town in the eastern part of The Netherlands with 156,000 inhabitants, approximately 87% of Caucasian descent. Age and sex stratified randomly selected adult (age 18 years and older) inhabitants of Nijmegen (N=22,452) received an invitation to fill out a postal questionnaire on lifestyle and medical history. A total of 6,434 participants donated blood for DNA-isolation. GWA-data were available for 1,832 participants [14]. We invited participants aged 50–70 yrs to come to the hospital and performed ABI at rest and after exercise. In total 1517 participants from the Nijmegen Biomedical Study were included [15]. For 544 participants both ABI and GWA-data were available. Approval to conduct the study was obtained from the Institutional Review Board.

1.1.13 and 1.1.14 The Rotterdam Study I and II (RS-I and RS-II)

The Rotterdam Study is a prospective population-based cohort study to investigate the determinants of chronic diseases among participants aged 55 years and older [16]. Briefly, residents of Ommoord, a district of Rotterdam, in the Netherlands, 55 years of age or older, were asked to participate, of whom 7,983 participated (RS-I). The baseline examination was conducted in 1990 -1993 and consisted of a home interview and research center visit for blood samples. In 1999, inhabitants who turned 55 years of age or moved into the study district since the start of the study were invited of whom 3,011 participated (RS-II). In total, at the time of the current Analyses, ABI data were available for 5,169 participants with GWA study data for RS-I and for 1,642 participants from RS-II. The Medical Ethics Committee of Erasmus MC approved the study, and all participants gave informed consent.

1.1.15 Study of Health in Pomerania (SHIP)

The Study of Health in Pomerania (SHIP) is a population-based survey in West Pomerania, the north-east area of Germany [17,18]. A sample from the population aged 20 to 79 years was drawn from population registries. First, the three cities of the region (with 17,076 to 65,977 inhabitants) and the 12 towns (with 1,516 to 3,044 inhabitants) were selected, and then 17 out of 97 smaller towns (with less than 1,500 inhabitants), were drawn at random. Second, from each of the selected communities, subjects were drawn

at random, proportional to the population size of each community and stratified by age and gender. Only individuals with German citizenship and main residency in the study area were included. Finally, 7,008 subjects were sampled, with 292 persons of each gender in each of the twelve five-year age strata. In order to minimize drop-outs by migration or death, subjects were selected in two waves. The net sample (without migrated or deceased persons) comprised 6,267 eligible subjects. Selected persons received a maximum of three written invitations. In case of non-response, letters were followed by a phone call or by home visits if contact by phone was not possible. The SHIP population finally comprised 4,308 participants (corresponding to a final response of 68.7%). Baseline examinations were performed between 1997 and 2001 (SHIP-0). Follow-up examinations were conducted between 2002 and 2006 (SHIP-1) as well as between 2008 and 2012 (SHIP-2). Data for the present analyses were taken from a sample of SHIP-2.

1.2 Discovery cohorts: isolated populations

1.2.1 The Old Order Amish Study (Amish)

The Old Order Amish individuals included in this study were participants of several ongoing studies of cardiovascular health carried out at the University of Maryland [19,20]. Participants were relatively healthy volunteers from the Old Order Amish community of Lancaster County, PA. and their family members. Examinations were conducted at the Amish Research Clinic in Strasburg, PA. All protocols were approved by the Institutional Review Board at the University of Maryland and informed consent was obtained, including permission to use their DNA for genetic studies.

1.2.2, 1.2.3 and 1.2.4 CROATIA-Vis, CROATIA-Korcula and CROATIA-Split

The CROATIA studies recruited adult individuals within each community irrespective of any specific phenotype. Fasting blood samples were collected, biochemical and physiological measurements taken and questionnaire data for medical history as well as lifestyle and environmental exposures were collected following similar protocols. The CROATIA study conformed to the ethical guidelines of the 1975 Declaration of Helsinki and were approved by appropriate ethics boards with all participants signing informed consent prior to participation.

The CROATIA-Vis study includes 1008 Croatians, aged 18–93 years, who were recruited from the villages of Vis and Komiza on the Dalmatian island of Vis during 2003 and 2004 within a larger genetic epidemiology program. The CROATIA-Korcula study includes 969 Croatians between the ages of 18 and 98. The field work was performed in 2007 and 2008 in the eastern part of the island, targeting healthy volunteers from the town of Korčula and the villages of Lumbarda, Žrnovo and Račišće. The CROATIA-Split study includes 499 Croatians between the ages of 18 and 85 recruited in 2009 from the city of Split.

1.2.5 Erasmus Rucphen Family Study (ERF)

The Erasmus Rucphen Family study (ERF) is a cross-sectional family-based study. The study population essentially consists of one extended family of descendents from 20 related couples who lived between 1850 and 1900 and had at least 6 children baptized in the community church. The detailed information about ERF can be found elsewhere [21]. The Medical Ethical Committee of the Erasmus Medical Center, Rotterdam approved the study and informed consent was obtained from all participants.

1.2.6 Orkney Complex Disease Study (ORCADES)

The Orkney Complex Disease Study (ORCADES) is an ongoing family-based, cross-sectional study in the isolated Scottish archipelago of Orkney. Genetic diversity in this population is decreased compared to Mainland Scotland, consistent with the high levels of endogamy historically. Data for participants aged 18-91 years, from a subgroup of ten islands, were used for this analysis. Fasting blood samples were collected and over 300 health-related phenotypes and environmental exposures were measured in each individual. All participants gave informed consent and the study was approved by Research Ethics Committees in Orkney and Aberdeen.

1.3 Replication studies

1.3.1 Bruneck Study

The Bruneck Study is a prospective, population-based survey on the epidemiology, pathophysiology and prevention of cardiovascular and cerebrovascular disease [22-26]. In 1990, 1000 individuals aged 40-79 years were randomly chosen from the inhabitants of the town of Bruneck (South Tyrol, Italy) on the basis of an age- and sex-stratified strategy (125 persons per sex and decade). The population of Bruneck is exclusively Caucasian and of heterogeneous geographic origin with sizeable segments of Austro-German or Italian background. Population mobility within the survey area was low at 0.2% per year. Follow-up examinations were performed in 1995, 2000 and 2005 with participation rates exceeding 90%. Analyses for the current investigation focused on the 1995 evaluation. The study protocol was approved by the pertinent ethics committee, and all participants gave their written informed consent.

1.3.2 Copenhagen City Heart Study (CCHS)

CCHS is a prospective cardiovascular study of the Danish general population initiated in 1976-1978 with follow-up examinations in 1981-1983, 1991-1994 and 2001-03 [27-29]. Individuals were selected based on the Central Population Register Code to reflect the adult Danish general population aged 20-80+ years. Blood samples for DNA extraction are available for 10,594 participants. For 5,467 participants of this study ABI measurements are available from the 2001-03 examination.

1.3.3 Multi-Ethnic Study of Atherosclerosis (MESA)

MESA is an NHLBI-sponsored population-based, prospective, multi-center cohort study including participants recruited from six field sites in the United States – Forsyth County, NC (Wake Forest University), Northern Manhattan/Bronx, NY (Columbia University), Baltimore/Baltimore County, MD (Johns Hopkins University), St. Paul, MN (University of Minnesota, Twin Cities), Chicago, IL (Northwestern University), and Los Angeles County, CA (UCLA). Details of recruitment and study design have been previously published elsewhere [30]. Briefly, the MESA cohort comprises 6,814 men and women of diverse ethnic background who were 45 to 84 years old at the baseline exam and free of clinically overt cardiovascular disease (CVD) who were recruited to elucidate the determinants and natural history of subclinical CVD, and study progression of subclinical CVD. The cohort is 53% women with an ethnic composition of approximately 40% White, 30% African American, 20% Hispanic and 10% Asian primarily of Chinese descent. The MESA was approved by the Institutional Review Board of all participating field sites and reading centers and participants gave informed consent for participation and use of DNA specimens. Genotyping took place

using the Affymetrix 6.0 array. There were n=2611 participants of European descent who consented the use of DNA for research studies and had imputed GWAS data for the contributed SNPs as well as ABI measurements.

1.3.4 National Health and Nutrition Examination Surveys (NHANES)

The National Health and Nutrition Examination Surveys (NHANES) are conducted by the National Center on Health Statistics (NCHS) at the Centers for Disease Control and Prevention (CDC). NHANES is a collection of diverse, population-based cross-sectional surveys of non-institutionalized Americans regardless of health status at the time of ascertainment (http://www.cdc.gov/nchs/nhanes.htm). NHANES is considered a complex survey given that specific age groups (such as the elderly) and racial/ethnic groups (non-Hispanic blacks and Mexican-Americans) are oversampled. The NHANES data accessed for this work includes NHANES 1999-2000 and NHANES 2000-2001. Collectively, these surveys contain 7,839 DNA samples linked to demographic, health, and lifestyle data. Participants were consented by the CDC at the time of the survey and sample collection, and consent included the storage of data and biological specimens such as blood for future research [31,32]. The present study was approved by the CDC Ethics Review Board. Because the study investigators did not have access to personal identifiers, this study was considered non-human subjects research by the Vanderbilt University Internal Review Board.

Race/ethnicity is self-described and was categorized as non-Hispanic white, non-Hispanic black, Mexican-American, and others. Only data for non-Hispanic whites were included here for replication efforts. The ankle brachial pressure index (ABPI), also referred to as the ankle arm blood pressure index (AAI), is a noninvasive technique to measure peripheral vascular disease in population-based and clinical studies. ABPI was defined as the ratio of the systolic blood pressure in the ankle compared with that in the arm. ABPI measurement was performed by a health technician on all adults ≥40 years of age at interview. Exclusions for these procedures were bilateral amputation, casts, ulcers, dressings, or other conditions which make blood pressure readings at these sites impossible. The presence of these conditions on one limb did not exclude the study participant, but they were excluded if they occurred bilaterally. Systolic pressure was measured in one arm (brachial vessel, right arm if accessible) and both ankles. ABI was defined as the ratio of the systolic blood pressure in the ankle compared with that in the arm. The lower ABI of the two legs was used in the analysis. ABI > 1.4 and equal to 0 were excluded from the analysis. Serum HDL-C, triglycerides, and total cholesterol were measured using standard enzymatic methods. LDL-C was calculated using the Friedewald equation, with missing values assigned for samples with triglyceride levels greater than 400 mg/dl. Fasting status was recorded at time of blood draw. Body mass index was calculated from height and weight measured in the Mobile Examination Center by CDC medical personnel. Current smoking was defined by “do you smoke cigarettes now?” or cotinine levels > 15ng/ml. Former smoking was defined among non-current smokers by the answer “yes” to the question “Smoked at least 100 cigarettes in life“. Participants were considered to have type 2 diabetes if they answered “yes” to “Ever been told you have sugar/diabetes?” or if they had fasting blood glucose levels >126 mg/dL. Hypertension was defined if average systolic blood pressure was≥140 or average diastolic blood pressure was ≥90 or if the study participant reported taking medication for high blood pressure. Prevalent cardiovascular disease was defined by “Ever told you had heart attack”. Lipid lowering medication use was defined by “now taking prescribed medicine” to lower cholesterol.

Genotyping was performed for nine SNPs in all of NHANES 1999-2002 (n=7,839) using Sequenom in the Vanderbilt DNA Resources Core. SNPs targeted for genotyping included rs10757269, rs16824978, rs4659996, rs7003385, rs7100623, rs819750, rs9485528. In addition to genotyping experimental NHANES samples, we genotyped blind duplicates provided by CDC. All SNPs reported here save for rs16824978 passed CDC quality control metrics and are available for secondary analyses through NCHS/CDC.

Tests of association were performed unweighted using linear regression, unadjusted and adjusted for covariates as specified in the analysis plan. All statistical analyses were conducted remotely in SAS v9.2 (SAS Institute, Cary, NC) using the Analytic Data Research by Email (ANDRE) portal of the CDC Research Data Center in Hyattsville, MD.

1.3.5 PREVEND

The Prevention of REnal and Vascular ENd stage Disease study is an ongoing prospective study investigating the natural course of increased levels of urinary albumin excretion and its relation to renal and cardiovascular disease. Inhabitants 28 to 75 years of age (N=85,421) in the city of Groningen, The Netherlands, were asked to complete a short questionnaire, 47% responded, and individuals were then selected with a urinary albumin concentration of at least 10 mg/L (N= 7,768) and a randomly selected control group with a urinary albumin concentration less than 10 mg/L (N=3,395). Details of the protocol have been described elsewhere (www.prevend.org). Genotyping was performed in a subset of subjects. All subjects provided written informed consent.

1.3.6 Cardiovascular Disease in Intermittent Claudication (CAVASIC) Study

The CAVASIC Study (CArdioVAScular disease in Intermittent Claudication) is a prospective case-control study which was initiated in 2002 to identify cardiovascular risk factors in patients with intermittent claudication [(33)]. Patients and controls were enrolled in two clinical centers, the Department of Vascular Surgery, Medical University Innsbruck and the 3rd Medical Department of Metabolic Diseases and Nephrology, Hietzing Hospital, Vienna, Austria. Patients were consecutively included in the study when they presented with or had a history of intermittent claudication (PAD IIa or IIb according to the criteria of Fontaine), regardless of whether they had already undergone a treatment procedure (bypass surgery or intervention). Patients were excluded from the study for any of the following: presence of acute or critical limb ischemia (Fontaine III or IV); impaired liver function with elevated enzymes (AST>50U/L, ALT >25U/L, Gamma GT >60U/L); impaired kidney function with serum creatinine >1.5 mg/dL; malignancy; past organ transplantation; therapy with nicotinic acid or corticosteroids. Furthermore controls were recruited from the same geographical region matched for age and presence of type 2 diabetes mellitus (T2DM). All members of the control group volunteered to participate in the study following a public invitation in newspapers. We applied the same exclusion criteria to the control group as used for patients. Controls with symptomatic PAD were excluded, but those with a history of cardiovascular disease were allowed to participate.

Neither the patients nor the controls suffered from acute illnesses or clinically detectable inflammatory processes at the time of enrollment. All subjects provided written informed consent and the examination protocol was approved by the Ethical Committee of the participating study centers. To minimize interobserver bias all interviews and examinations were performed by one physician at each of the two clinical centers who was specially trained in vascular examinations and echocardiography.

1.3.7 GENEPAD

The GENEPAD study was approved by the Institutional Review Boards at Stanford University and Mount Sinai; and registered at http://clinicaltrials.gov (NCT 00380185). Participants were recruited from patients undergoing elective, non-emergent coronary angiogram for angina, shortness of breath, abnormal stress test, or known CAD at Stanford University and Mount Sinai Medical Centers between April 2004 and February 2008, for whom the PAD status was not known to the investigators at the time of informed consent and recruitment into the study. This cross-sectional design allowed for two sharply defined phenotypes to emerge (i.e., patients with hemodynamically significant CAD alone, versus those with hemodynamically significant CAD and PAD). Cases were defined as patients with CAD and PAD while controls were defined as subjects with CAD alone. Furthermore, with this study design, confounding clinical covariates (e.g., traditional cardiovascular risk factors) would contribute minimally to the difference between the two phenotypes. This design would maximize our chances for discovery of novel factors that affect the distribution of atherosclerotic plaque. All participants provided written informed consent. Patients admitted for emergent catheterizations, or screening catheterizations prior to organ transplants were excluded. Additional exclusions included being younger than 40 years of age and having a history of radiation treatment, known chronic infectious diseases such as HIV, hepatitis B or C, or a language barrier.

1.3.8 Linz Peripheral Arterial Disease (LIPAD) Study

The LIPAD Study was performed from April 2000 to April 2002 at the St. John of God Hospital, Department of Surgery, Linz, Austria. Of the patients admitted for inpatient evaluation of suspected or definite PAD during the given time interval, all patients with chronic atherosclerotic occlusive disease of the lower extremities associated with typical symptoms were included into this study on the basis of the final clinical diagnosis established by the attending vascular surgeons. The diagnosis was verified by interview, physical examination, noninvasive techniques, and angiography, as detailed below. All cases with acute ischemia were excluded. Further exclusion criteria were PAD caused by nonatherosclerotic causes (cardioembolic disease, thromboangiitis obliterans, vasculitis, or congenital or metabolic vascular disease) and the history or presence of any malignancy. Doppler segmental blood pressure of the lower limbs, including continuous-wave spectral analysis and resting ankle-brachial index (ABI) measurements were performed in all patients with symptomatic PAD and control subjects as previously described [(34)]. In addition to these measurements, intra-arterial aortofemoral angiography was performed in all patients to confirm the presence of PAD and to determine the location and extent of wall changes.

Control subjects were matched to the patients with PAD in a 1:1 design by sex, age (±2 years), and diabetes mellitus status. All control subjects were patients in our hospital and fulfilled the following criteria: no clinical indication of PAD by history and physical examination; ABI ≥0.9; no pathologic pattern of pulse waves in lower limbs by continuous-wave spectral analysis; no CAD; no CVD; no previous vascular surgery or stenting of the internal carotid arteries; no stenosis of the internal carotid artery greater than 50% by color duplex ultrasound scans; no history of venous thromboembolism; and no history or presence of any malignancy. All control subjects were generally in good health and were admitted for treatment of minor health problems, such as cataract surgery, vertebragenic pain, or nonvascular surgery. The study protocol was approved by the local ethics committee in accordance with the Declaration of Helsinki, and all study participants gave informed consent.

2. Bioinformatic Analysis

Data mining in publicly available databases was used to search for biological support for the signals selected for replication. Transcript structure and functional descriptions for every gene located +/- 50 kb from each SNP (+/- 200 kb for intergenic SNPs) were automatically retrieved from different bioinformatic databases (NCBI Entrez RefSeq, EBI SRS, and the UCSC Genome Browser) using Genowatch (now named Variowatch) [(35)] and further supplemented for interesting candidates by ad-hoc searches in OMIM and Pubmed. Additionally, the Genetic Association Database, the NHGRI GWAS Catalog [(36)] and the HuGE Navigator [(37)] database were mined for already known phenotype associations. Finally, in order to refine the functions of genes without clearly associated functions in the public databases pathway, we evaluated the pathway assignments in NCBI Entrez Gene were and used Genomatix Bibliosphere Software (Genomatix GmbH, Munich, Germany) to perform an automated literature and pathway analysis. The generated gene networks were then inspected for relevant tissue types and disease associations using build-in filter functions. However, this approach was inconclusive, probably due to the little data available in PubMed, and was thus not further pursued.

3. Statistical methods used for the candidate gene look-up

In the following, the statistical methods used for the look-up of PAD/ABI and CAD candidate genes will be explained in detail, exemplified on the *CYBA* gene region:

1. All SNPs were identified, which lie in the chromosomal region defined by each of the candidate genes ±100 kb upstream or downstream of the gene. In the case of *CYBA*, 138 SNPs lie within this defined region.
2. We then identified the most strongly associated SNP in each gene region using the discovery meta-analysis results for ABI (excluding isolates): for *CYBA* this was rs3794624 with a p-value of 6.30E-05.
3. Since the lowest p-value within each gene region was selected adjusting for multiple testing within each gene region is necessary. Neighboring and densely spaced SNPs are likely to be in high LD. Furthermore, the SNPs are given as genotype scores (allelic dosages between 0 und 2) derived from an imputation algorithm using HapMap. In this situation with high correlation between SNPs, simple Bonferroni correction with the number of SNPs would be too conservative. Therefore, the effective number of loci was calculated for each gene region using an algorithm by Gao et al [(38)]. This method reduces the dimension of the parameter space. In the case of *CYBA*, the 138 SNPs could be explained sufficiently by a linear combination of 58 independent variables. Now, this so called effective number of loci can be used as the denominator in the Bonferroni correction formula. This leads to a corrected p-value of 6.30E-05 / 58 = 3.60E-03 for the *CYBA* gene region.
4. So far, we have applied the Bonferroni correction within each gene region separately resulting in gene-region-wide corrected p-values. Since we have looked at 55 independent gene regions, further correction, however, is needed. The False Discovery Rate (FDR [(39)]) was calculated on the 55 corrected p-values. This approach accounts for the multiple comparisons problem. Traditional methods like Bonferroni control the Family-wise error rate, the probability for at least on false positive among all tests. The False discovery rate on the contrary is the expected proportion of false positives amongst all rejected null hypothesis. It has a greater power than the methods controlling the Family-wise error rate

with the higher risk of false positives, however. In our analysis we have set the FDR threshold to 0.1, meaning that we are tolerating 10% of false positives out of the resulting list of significant findings. Since we are only including former PAD/ABI candidate gene regions, we are convinced that the prior knowledge outweighs the higher risk of false positives. For *CYBA*, a FDR of 0.0665 has been calculated.

5. For the CAD candidate genes, we have been looking at the specific reported SNPs rather than complete gene regions. In conclusion, we are sparing us the step of accounting for the number of SNPs within each gene region. Therefore, we are calculating the FDR directly on the p-valued derived from the discovery meta-analysis results for ABI.

Supplementary Table 1. ABI Protocol and Calculation for Discovery Cohorts and Replication Studies

Cohort (ABI measurement date)	ABI protocol	ABI calculation
Discovery Cohorts		
ARIC (1987-1989)	Systolic blood pressures were measured with Dinamap 846 Sx automated oscillometric device in one arm and one ankle (posterior tibial artery).[96] The ankle was randomly selected and measurement was taken in the supine position. Arm blood pressure was measured in the seated position and usually taken in the right arm. Repeat measures were obtained for the ankle about 5 to 8 minutes apart and for the arm about 5 minutes apart.	Mean systolic blood pressure in the ankle / mean of the seated arm systolic blood pressure
CHS (1989-1990)	Systolic blood pressure obtained with Doppler stethoscope (8 MHz, Parks Electronics, Aloha, OR) in right arm and both ankles (posterior tibial artery) and duplicate measures obtained for each location. [97]	The minimum of the mean systolic blood pressure in each ankle / mean of the right arm systolic blood pressure
FamHS (1994-1995)	Systolic blood pressures were measured with Dinamap 1846 Sx automated oscillometric device (Critikon, Inc., Tampa, FL). The ankle was randomly selected and a single systolic blood pressure was taken over the posterior tibial artery with the participant resting in the supine position. After three arm blood pressures were taken over the brachial artery, usually in the right arm, about 5 minutes apart.	Single systolic blood pressure in the ankle / mean of the three right arm systolic blood pressures.
FHS (Cohort:1994-1995; Offspring 1995-1998)	Participants rested for a minimum of five minutes in the supine position on the examining table prior to blood pressure measurement. Systolic blood pressure obtained with Doppler device (Parks Medical Electronics, Inc) in both arms and both ankles (posterior tibial artery) and repeat measurement in each limb obtained.[98,99] Dorsalis pedis pressure was measured if posterior tibial artery pressure could not be obtained.	Mean systolic blood pressure in each ankle site / higher of the two brachial systolic blood pressures
GENOA (1996)	ABI was measured in the supine position following 5 minutes of rest. Single systolic blood pressure obtained with Doppler device (Medisonics, Minneapolis MN) in both arms and both ankles (posterior tibial artery and dorsalis pedis).[100]	Systolic blood pressure in each ankle site (posterior tibial and dorsalis pedis/ higher of the two arm pressures. Lowest of the four ABI ratios was used for analysis.[20]
GHS (2007-2008)	ABI was measured in supine position after 10 minutes of rest. Systolic blood pressure was measured at the left arm with a Omron HEM 705-CP II. The peripheral systolic blood pressure was measured at the posterior tibial artery at both ankles with a hand-held 8-MHz Doppler probe (handydop, Elcat) and a conventional aneroid sphygmomanometer.	To calculate the ABI, the mean systolic blood pressure of the posterior tibial artery at both ankles was divided by the systolic blood pressure of the left arm.
Health ABC (1997-1998)	Arterial systolic blood pressure (SBP) was measured by a hand-held, 8-MHz Doppler probe (Huntleigh Technology, Inc., Manalapan, NJ, USA) placed directly over the artery and a conventional mercury sphygmomanometer. [42]	Means of the first and second SBP measurements for each leg and right arm were used to attain ABI. ABI was defined as the lowest ratio of SBP of either the right ankle to the right upper-arm or the left ankle to the right upper-arm.

InCHIANTI (1998)	Systolic blood pressure was obtained with a hand-held Doppler stethoscope (Parks Electronics model 41-A, Aloha, OR) in the right brachial and both posterior tibial arteries with duplicate measurements.[101]	The highest systolic pressure at each site was used. The ABI was calculated using the lower of the right and left posterior tibial pressures / brachial artery pressure.
KORA F3 (2004-2005)	Systolic blood pressure obtained with Doppler device (HNE Healthcare, Mini Doppler Modell Nr. D 900) in the right arm and both ankles (posterior tibial artery). We generally performed two measurements and used the mean of the two measurements for further calculations. If we observed a difference of 10 mmHg or more for the two measurements, we performed a third measurement and calculated the mean of the two measurements which were closest to each other.	Mean systolic blood pressure of that ankle side which was lowest / mean of the two brachial systolic blood pressures of the right arm
KORA F4 (2006-2008)	Systolic blood pressure obtained with Doppler device (HNE Healthcare, Mini Doppler Modell Nr. D 900) in the right arm and both ankles (posterior tibial artery). We generally performed two measurements and used the mean of the two measurements for further calculations. If we observed a difference of 10 mmHg or more for the two measurements, we performed a third measurement and calculated the mean of the two measurements which were closest to each other.	Mean systolic blood pressure of that ankle side which was lowest / mean of the two brachial systolic blood pressures of the right arm
NESDA (2004-2007)	Both ankle and arm systolic blood pressure was measured by an ultrasound Doppler device at 8-MHz (UltraTech PD1v, Ultrasound Technologies Ltd, Itton, Chepstow, UK) in combination with an ordinary blood pressure cuff, as previously described. Blood pressure was assessed with the respondent in supine position.	Ankle-brachial index was calculated as the mean of two consecutive systolic right posterior tibial artery blood pressures divided by the mean of two consecutive systolic right humeral artery blood pressures.
NBS (2005-2008)	To measure ABI appropriately sized cuffs were placed around both arms above the elbow and around both legs just above the ankle. Resting blood pressures were measured at the left and right brachial artery, the left and right posterior tibial, and dorsalis pedis arteries using an 8-MHz hand-held Doppler probe (IMEXDOPCT; Biomedic, Almere, The Netherlands).	The highest of the two arm pressures was used to calculate ABI at rest for the posterior tibial and dorsalis pedis arteries. The lowest of the four ABI's was used in the analysis.
RS-I (1990-1993) RS-II (1999-2001)	Two seated blood pressures measured in right arm and a single systolic blood pressure obtained in each leg in supine position (posterior tibial) using Doppler device (Huntleigh 500 D, Huntleigh Technology) [102] and random-zero manometer.	Systolic blood pressure in each ankle / mean of the seated right arm systolic blood pressure. The lowest ABI in either leg was used in the analysis.
SHIP (2008-2009)	Systolic blood pressure was measured with a "Dopplex D900" (Huntleigh Healthcare Ltd.) doppler ultrasound probe and a blood pressure cuff (Welch Allyn) in both arms and both ankles (anterior and posterior tibial artery). Measurements were taken in the supine position after at least 10 minutes rest.	The highest systolic pressure at each ankle site was used. The ABI was calculated using the lower of the right and left tibial pressures / higher of the two brachial artery pressures.

Discovery Cohorts Population Isolates		
Amish (2001-2009)	Systolic blood pressure was measured with a Doppler ultrasound probe (Hokanson, MD6 Bidirectional Doppler) and a blood pressure cuff (Hokanson blood pressure cuff in two sizes, SC10 and SC12)in both arms and both ankles (anterior and posterior tibial artery). Measurements were taken in the supine position after at least 15 minutes rest.	The ABI for each leg was calculated separately by dividing the ankle pressure in that leg by the mean brachial pressure of the two arms or the highest of the 2 arms if the difference between the two arms was >=10 mmHg . Then the mean ABI for both legs was used for analysis.
Croatia-Vis (2003-2004) Croatia-Korcula (2007) Croatia- Split (2009-2010)	Participant asked to remove all tight clothing from arms and legs and lie flat for approx 5 min. Brachial measure: sphymomanometer cuff placed around the right arm just above the elbow. Doppler probe placed over the brachial pulse. Cuff inflated until the Doppler sound disappears then cuff slowly deflated until the sound returns. Repeated on left arm. Ankle measure: Cuff placed around left leg just above the malleolus and Doppler used to locate the dorsalis pedis pulse. Cuff inflated until the Doppler sound disappears then cuff slowly deflated until the sound returns. Repeated for posterior tibial pulse. Both repeated for right leg.	The lowest posterior tibial systolic blood pressure at either ankle was divided by the highest systolic blood pressure in the arm
ERF (2002)	Two seated blood pressures measured in right arm and a single systolic blood pressure obtained in each leg (posterior tibial) using Doppler device (Huntleigh 500 D, Huntleigh Technology) [(102)] and random-zero manometer.	Systolic blood pressure in each ankle/ mean of the seated right arm systolic blood pressure
Orcades (2005-2007)	Participant asked to remove all tight clothing from arms and legs and lie flat for approx 5 min. Brachial measure: sphygmomanometer cuff placed around the right arm just above the elbow. Doppler probe placed over the brachial pulse. Cuff inflated a further 10-20 mm Hg after the Doppler sound disappears then cuff slowly deflated until the pulse sound returns - measure recorded. Repeated on left arm. Ankle measure: Cuff placed around left leg just above the malleolus and Doppler used to locate the dorsalis pedis pulse. Cuff inflated a further 10-20 mm Hg after the Doppler sound disappears then cuff slowly deflated until the pulse sound returns - measure recorded. Repeated for posterior tibial pulse. Both repeated for right leg.	The lowest posterior tibial systolic blood pressure at either ankle was divided by the highest systolic blood pressure in the arm
Replication Studies		
Bruneck Study (1995)	The ankle-brachial index (ABI) was measured in a supine position. A cuff was inflated to 10 mmHg above systolic blood pressure and deflated at 2 mmHg/s. The first reappearance of the arterial signal at the ankle (posterior tibial artery) was taken as the systolic blood pressure (detected with a Doppler ultrasonic instrument).	To calculate the ABI for the right and left leg, the systolic blood pressure at each ankle was divided by the systolic blood pressure in the arm. The higher arm reading (right or left side) was used for ABI calculation. The lower ABI of the two legs was considered in the current analysis. Subjects with an ABI > 1.4 were

		excluded. There was no subject with an ABI of zero on both legs.
CCHS (2001-2003)	A standard brachial systolic and diastolic blood pressure was recorded on both arms, and systolic ankle blood pressure of the posterior tibial artery on both legs was obtained by Doppler (Huntleigh Mini Dopplex Doppler D900, Huntleigh, United Kingdom).	The ABI was the lowest ankle systolic blood pressure divided by the highest brachial systolic blood pressure.
MESA (2000-2002)	Systolic blood pressure obtained with Nicolet Doppler apparatus (EN50 LE 100, Nicolet vascular, Golden, CO) in both arms and both ankles (posterior tibial and dorsalis pedis). Approximately 20 elapsed between each pressure.	ABI is the minimum of the right and left ABI. The right ABI is calculated as the (maximum of the right dorsalis pedis and right posterior tibial)/ (mean right and left brachial), and the left ABI is calculated as the (maximum of the left dorsalis pedis and left posterior tibial)/ (mean of the left and right brachial). For right ABI and left ABI, if the two brachial (arm) BPs differ by 10 mmHg or more, use the higher arm pressure as the denominator.
NHANES (1999-2002)	The ankle brachial pressure index (ABPI), also referred to as the ankle arm blood pressure index (AAI), is a noninvasive technique to measure peripheral vascular disease in population-based and clinical studies. ABPI was defined as the ratio of the systolic blood pressure in the ankle compared with that in the arm. ABPI measurement was performed by a health technician on all adults ≥40 years of age at interview. Exclusions for these procedures were bilateral amputation, casts, ulcers, dressings, or other conditions which make BP readings at these sites impossible. The presence of these conditions on one limb did not exclude the study participant, but they were excluded if they occurred bilaterally. Systolic pressure was measured in one arm (brachial vessel, right arm if accessible) and both ankles (posterior tibial vessels) for ages 40 and above.	ABI was defined as the ratio of the systolic blood pressure in the ankle compared with that in the arm. The lower ABI of the two legs was used in the analysis. ABI > 1.4 and equal to 0 were excluded from the analysis.
PREVEND (1997-1998)	At the first visit, while the participant was in a supine position, systolic blood pressure was measured each minute with an automatic Dynamap XL Model 9300 series device at the right brachial artery (ten times total). Within the first 5 min, systolic ankle pressure at each leg was measured at the same time a brachial pressure was performed. For ankle pressure measurements, the posterior tibial artery was measured using an 8-MHz continuous-wave Doppler probe (Huntleigh Model D900, Huntleigh Diagnostics) and a random-zero sphygmomanometer.	The ABI was calculated as the ratio of the systolic blood pressure of the ankle and arm for each leg. The lowest ankle-brachial index in either leg was used in the analysis.
CAVASIC (2002)	For the ABI measurement, the systolic blood pressure was measured in both arms and then two additional measures were obtained on the arm with the higher systolic blood pressure. The systolic blood pressure was obtained three times for both the posterior tibial and dorsalis pedis artery in each leg. [(33)]	The mean of the second and third systolic blood pressure measurement at each site was used to calculate the ABI for each of the 4 lower extremity sites. The ABI was calculated as the ratio of the mean systolic blood pressure at each of four sites to the mean systolic blood pressure in the arm.

		The lowest ABI from the four sites was used in analysis.
GenePAD (2004-2008)	The ABI (i.e. the ratio of ankle and arm systolic blood pressure) was measured using previously established methods.[103,104] In brief, prior to undergoing coronary angiogram, each participant rested in the supine position for 5 minutes, then, using a 5-MHz Doppler ultrasound (Nicolet Elite 5-MHz vascular model 110R Doppler; Nicolet Vascular, Golden, CO, USA), systolic pressures were measured in the posterior tibial, dorsalis pedis, and brachial arteries. Each pressure was measured twice in sequential and reverse order as listed. With an IV in one arm, only the contralateral arm was used for the brachial pressures. [105]	The ABI for each leg was calculated separately by dividing the higher of the two ankle pressures in that leg by the brachial pressure. If the ABI was less than 0.9 in either leg, the patient was considered to have PAD. The index leg was defined as the leg with the lower ABI.
LIPAD (2002)	ABI measurements in the LIPAD study were done according to [34]: with the patient placed in a supine position, the brachial and ankle systolic pressure measurements are obtained.	The higher systolic pressure of the anterior tibial or posterior tibial measurement for each foot / the higher of the left and right brachial systolic blood pressure

SNPs ordered by strength of the ABI association p value

* SNP is located within the gene

Supplementary Table 10: Literature-reported candidate genes for ankle-brachial-index (ABI) and/or peripheral arterial disease (PAD) and their association with ABI in the CHARGE GWAS discovery sample (population isolates excluded). The table reports the most strongly associated SNP (according to p-value) within the gene region ± 100 kb upstream and downstream of the candidate gene. We selected a candidate gene only if an association study with at least 100 cases and 100 controls was available independent whether the study was positive or negative. This decision was made on the basis that most of the negative studies were largely underpowered to exclude an association.

						Most strongly associated SNP within the gene region ± 100 kb upstream and downstream of the candidate gene

PubMed search terms "((ankle-brachial index) OR (peripheral arterial disease)) AND polymorphism"

For all candidate genes the official HGNC-approved gene names are reported and, where needed, the alias names used in the publications are provided in brackets. The chromosomal coordinates refer to the plus-strand according to HapMap Rel 24 (based on NCBI Genome Build 36 and dbSNP b.126). In the case that more than one RefSeq transcript is known, the +/- 100 kb gene region was defined starting from the coordinates which comprised all known transcripts (i.e. starting from the beginning of the outmost 5' exon to the end of the outmost 3' exon). The strand actually encoding the candidate gene is reported in the column "coding strand".

* Effective number of independent loci calculated using the function reported by Gao [(38)] based on imputed genotype data in KORA F4
** P-value Bonferroni corrected within each gene region using the effective number of loci
*** Chromosome 11 region: Chromosomal region identified by admixture mapping
‡ Using the corrected p-values of the SNP in association to ABI, we calculated a false discovery rate (FDR) to account for the number of gene regions examined. An FDR <0.10 defined evidence of a significant association.

Supplementary Table 11: Candidate SNPs for myocardial infarction and /or coronary artery disease and their association with ABI in the CHARGE GWAS discovery sample (population isolates excluded) †.

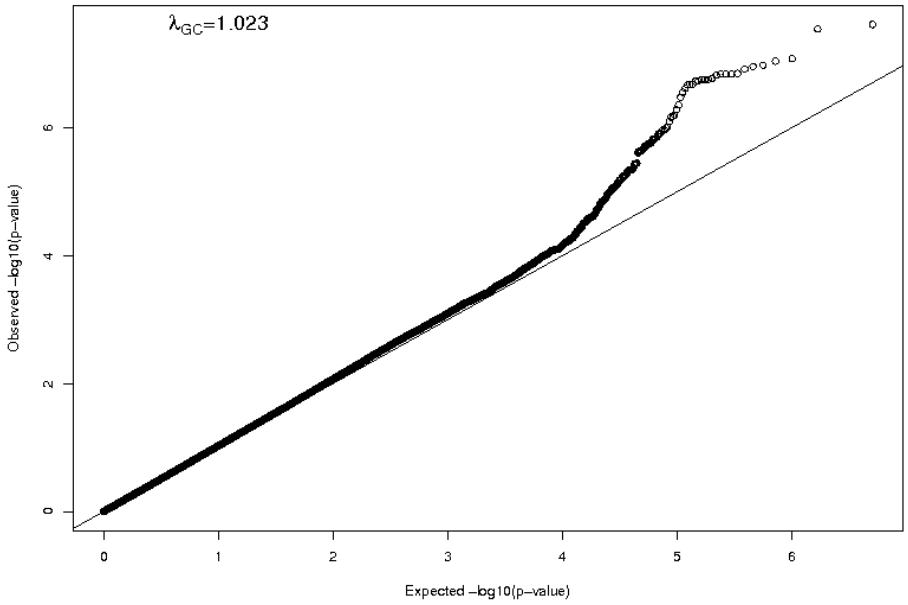
† Candidate genes for look-up of association with ABI were identified by recent GWAS to be genome-wide significantly associated with CAD.

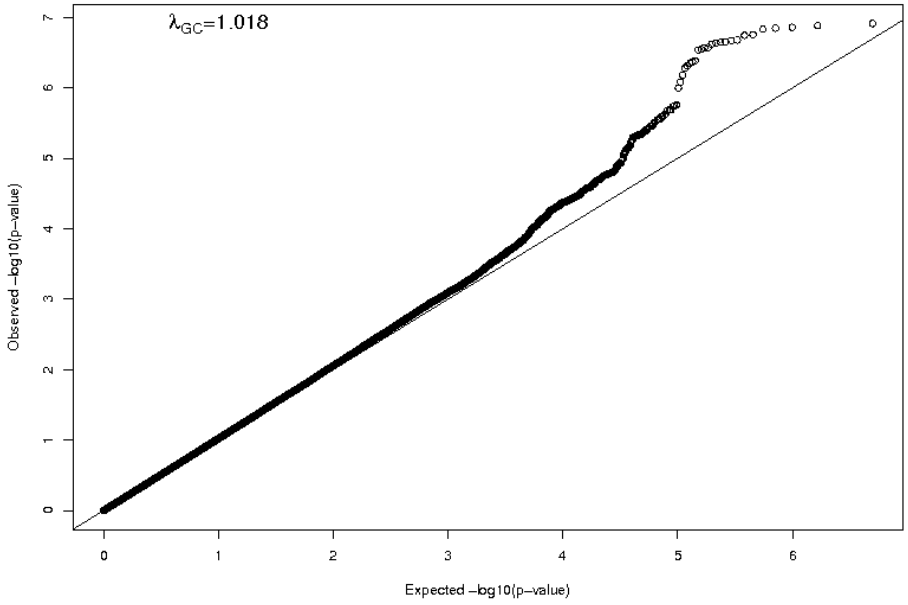
‡ Using the p-values of the SNP in association to ABI, we calculated a false discovery rate (FDR) to account for the number of gene regions examined. An FDR <0.10 defined evidence of a significant association.

Suppl Figure 1: **Quantile-quantile plots of the meta-analysis of GWAS of ABI.** The dots represent the observed -log10 p-values associated with ABI. The expected distribution of -log10 p-values under the null hypothesis is shown by the straight line. A) excluding the population isolates; B) including the population isolates

A



B



Suppl Figure 2: Manhattan plots of the meta-analysis of GWAS of ABI. X-axis represents the chromosomal position for each SNP, and the y-axis the -log10 p-value for association with ABI. The horizontal dotted line represents the genome-wide significance level of P<5x10-8. A) excluding the population isolates; B) including the population isolates

Acknowledgments/Funding Sources

Study	Acknowledgements/Funding
Amish Study (Amish)	This work was supported by research grants R01 088119, R01 AR046838, U01 HL72515, and R01 AG18728. Additional support was provided by the University of Maryland General Clinical Research Center, Grant M01 RR 16500, Mid-Atlantic Nutrition Obesity Research Center Grant P30 DK072488, General Clinical Research Centers Program, National Center for Research Resources (NCRR), NIH, and the Baltimore Veterans Administration Geriatric Research and Education Clinical Center (GRECC). Dr. Montasser was supported by T32 training Grant AG000219. We gratefully acknowledge our Amish liaisons and field workers and the extraordinary cooperation and support of the Amish community without which these studies would not have been possible.
Atherosclerosis Risk in Communities Study (ARIC)	The Atherosclerosis Risk in Communities Study is carried out as a collaborative study supported by National Heart, Lung, and Blood Institute contracts (HHSN268201100005C, HHSN268201100006C, HHSN268201100007C, HHSN268201100008C, HHSN268201100009C, HHSN268201100010C, HHSN268201100011C, and HHSN268201100012C), R01HL087641, R01HL59367 and R01HL086694; National Human Genome Research Institute contract U01HG004402; and National Institutes of Health contract HHSN268200625226C. The authors thank the staff and participants of the ARIC study for their important contributions. Infrastructure was partly supported by Grant Number UL1RR025005, a component of the National Institutes of Health and NIH Roadmap for Medical Research.
Cardiovascular Health Study (CHS)	This CHS research was supported by NHLBI contracts N01-HC-85239, N01-HC-85079 through N01-HC-85086; N01-HC-35129, N01 HC-15103, N01 HC-55222, N01-HC-75150, N01-HC-45133 and NHLBI grants HL080295, HL075366, HL087652, HL105756 with additional contribution from NINDS. Additional support was provided through AG-023629, AG-15928, AG-20098, and AG-027058 from the NIA. See also http://www.chs-nhlbi.org/pi.htm. DNA handling and genotyping was supported in part by National Center for Research Resources grant M01-RR00425 to the Cedars-Sinai General Clinical Research Center Genotyping core, Cedars-Sinai Board of Governors' Chair in Medical Genetics (JIR), and National Institute of Diabetes and Digestive and Kidney Diseases grant DK063491 to the Southern California Diabetes Endocrinology Research Center.
Family Heart Study (FamHS)	The Family Heart Study GWAS was funded by gran HL08770002 and the work was supported by contract numbers R01HL08770003 from the NHLBI, and R01DK06833603 and R01DK07568101 from NIDDK.
Framingham Heart Study (FHS)	This research was conducted in part using data and resources from the Framingham Heart Study of the National Heart Lung and Blood Institute of the National Institutes of Health and Boston University School of Medicine. The analyses reflect intellectual input and resource development from the Framingham Heart Study investigators participating in the SNP Health Association Resource (SHARe) project. This work was partially supported by the National Heart, Lung and Blood Institute's Framingham Heart Study (Contract No. N01-HC-25195) and its contract with Affymetrix, Inc for genotyping services (Contract No. N02-HL-6-4278). A portion of

	this research utilized the Linux Cluster for Genetic Analysis (LinGA-II) funded by the Robert Dawson Evans Endowment of the Department of Medicine at Boston University School of Medicine and Boston Medical Center.A portion of this research was conducted using the Linux Cluster for Genetic Analysis (LinGA-II) funded by the Robert Dawson Evans Endowment of the Department of Medicine at Boston University School of Medicine and Boston Medical Center.
Genetic Epidemiology Network of Arteriopathy (GENOA)	"Genetic Epidemiology Network of Arteriopathy (GENOA) study is supported by the National Institutes of Health, grant number 5R01HL087660 from National Heart, Lung and Blood Institute."
Gutenberg Heart Study (GHS)	The Gutenberg Heart Study is funded through the government of Rheinland-Pfalz ("Stiftung Rheinland Pfalz für Innovation", contract number AZ 961-386261/733), the research programs "Wissen schafft Zukunft" and "Schwerpunkt Vaskuläre Prävention" of the Johannes Gutenberg-University of Mainz and its contract with Boehringer Ingelheim and PHILIPS Medical Systems including an unrestricted grant for the Gutenberg Heart Study. This research was also supported by the National Genome Network "NGFNplus" (contract number project A3 01GS0833 and 01GS0831) by the Federal Ministry of Education and Research, Germany
Health, Aging and Body Composition (Health ABC)	This research was supported by NIA contracts N01AG62101, N01AG62103, and N01AG62106. The genome-wide association study was funded by NIA grant 1R01AG032098-01A1 to Wake Forest University Health Sciences and genotyping services were provided by the Center for Inherited Disease Research (CIDR). CIDR is fully funded through a federal contract from the National Institutes of Health to The Johns Hopkins University, contract number HHSN268200782096C.
Invecchiare in Chianti Study (InCHIANTI)	The InCHIANTI study baseline (1998-2000) was supported as a "targeted project" (ICS110.1/RF97.71) by the Italian Ministry of Health and in part by the U.S. National Institute on Aging (Contracts: 263 MD 9164 and 263 MD 821336); the InCHIANTI Follow-up 1 (2001-2003) was funded by the U.S. National Institute on Aging (Contracts: N.1-AG-1-1 and N.1-AG-1-2111); the InCHIANTI Follow-ups 2 and 3 studies (2004-2010) were financed by the U.S. National Institute on Aging (Contract: N01-AG-5-0002);supported in part by the Intramural research program of the National Institute on Aging, National Institutes of Health, Baltimore, Maryland. This research was supported in part by the Intramural Research Program of the National Institute on Aging. A portion of the support was through a R&D contract with MedStar Health Research Institute.
Cooperative Health Research in the Region of Augsburg (KORA F3, KORA F4)	This study was partially funded by the "Genomics of Lipid-associated Disorders - GOLD" of the "Austrian Genome Research Programme GEN-AU" and by the Austrian Heart Fund to F. Kronenberg and by the Austrian National Bank (Project-Nr. 13662) to Barbara Kollerits. The MONICA/KORA Augsburg cohort study was financed by the Helmholtz Zentrum München and the German National Genome Research Net NGFN2 and NGFNplus (H.-E. Wichmann 01GS0823).
Netherlands Study of Anxiety and Depression (NESDA)	NESDA was supported by the Geestkracht program of ZonMW [grant 10-000-1002]; matching funds from universities and mental health care institutes involved in NESDA (GGZ Buitenamstel-Geestgronden, Rivierduinen, University Medical Center Groningen, GGZ 25 Lentis, GGZ Friesland, GGZ Drenthe). Genotyping was funded by the Genetic Association Information Network (GAIN) of the Foundation for the US National Institutes of Health, and analysis was supported by grants from GAIN and

	the NIMH (MH081802). Genotype data were obtained from dbGaP (http://www.ncbi.nlm.nih.gov/dbgap, accession number phs000020.v1.p1). Statistical analyses were carried out on the Genetic Cluster Computer (http://www.geneticcluster.org), which is financially supported by the Netherlands Scientific Organization (NWO 480-05-003) along with a supplement from the Dutch Brain Foundation.
Nijmegen Biomedical Study (NBS)	The Nijmegen Biomedical Study (NBS) was initiated in 2000 as a large study among the inhabitants of the municipality of Nijmegen by the departments of Epidemiology, Biostatistics and HTA, Clinical Chemistry, and Endocrinology of the Radboud University Nijmegen Medical Centre (RUNMC) in collaboration with the municipality of Nijmegen en de community health service of Nijmegen. Support was obtained from RUNMC. The measurements of ABI and other non-invasive measurements of atherosclerosis (NIMA) was supported by Grant 2003B057 of the Netherlands Heart Foundation. This work was sponsored by the Stichting Nationale Computerfaciliteiten (National Computing Facilities Foundation, NCF) for the use of supercomputer facilities, with financial support from the Nederlandse Organisatie voor Wetenschappelijk Onderzoek (Netherlands Organization for Scientific Research, NWO).
Rotterdam Study (RS-I and RS-II)	The Rotterdam GWA study was funded by the Netherlands Organisation of Scientific Research NWO Investments (nr. 175.010.2005.011, 911-03-012), the Research Institute for Diseases in the Elderly (014-93-015; RIDE2), the Netherlands Genomics Initiative (NGI)/Netherlands Consortium for Healthy Aging (NCHA) project nr. 050-060-810. This study is further supported by NWO grant (vici, 918-76-619). The Rotterdam Study is funded by Erasmus Medical Center and Erasmus University, Rotterdam, Netherlands Organization for the Health Research and Development (ZonMw), the Research Institute for Diseases in the Elderly (RIDE), the Ministry of Education, Culture and Science, the Ministry for Health, Welfare and Sports, the European Commission (DG XII), and the Municipality of Rotterdam. The authors are very grateful to the participants and staff from the Rotterdam Study, the participating general practioners and the pharmacists. We thank Pascal Arp, Mila Jhamai, Dr Michael Moorhouse, MarijnVerkerk, and Sander Bervoets for their help in creating the GWAS database. We would like to thank Dr. Tobias A. Knoch, Luc V. de Zeeuw, Anis Abuseiris, and Rob de Graaf as well as their institutions the Erasmus Computing Grid, Rotterdam, The Netherlands, and especially the national German MediGRID and Services@MediGRID part of the German D-Grid, both funded by the German BundesministeriumfuerForschung und Technology under grants #01 AK 803 A-H and # 01 IG 07015 G, for access to their grid resources.
Study of Health in Pomerania (SHIP)	SHIP is part of the Community Medicine Research net of the University of Greifswald, Germany, which is funded by the Federal Ministry of Education and Research (grants no. 01ZZ9603, 01ZZ0103, and 01ZZ0403), the Ministry of Cultural Affairs as well as the Social Ministry of the Federal State of Mecklenburg-West Pomerania. Genome-wide data have been supported by the Federal Ministry of Education and Research (grant no. 03ZIK012) and a joint grant from Siemens Healthcare, Erlangen, Germany and the Federal State of Mecklenburg- West Pomerania. The University of Greifswald is a member of the 'Center of Knowledge Interchange' program of the Siemens AG.
CROATIA Study (Croatia-Vis,	The CROATIA study would like to acknowledge the invaluable contributions of the recruitment teams (including those from the Institute of Anthropological Research

Croatia-Korcula, Croatia-Split)	in Zagreb) in Vis and Korcula and at the Croatian Centre for Global Health at the University of Split, the administrative teams in Croatia and Edinburgh and the people of Vis, Korcula and Split. Genotyping was performed at the Wellcome Trust Clinical Research Facility in Edinburgh for CROATIA-Vis, by Helmholtz Zentrum München, GmbH, Neuherberg, Germany for CROATIA-Korcula and by AROS Applied Biotechnology, Aarhus, Denmark for CROATIA-Split. These studies were supported by grants from the Medical Research Council UK and Ministry of Science, Education and Sport of the Republic of Croatia (No. 108-1080315-0302) and CROATIA-Vis by the European Union framework program 6 European Special Populations Research Network (EUROSPAN) project (contract LSHG-CT-2006-018947)
Erasmus Rucphen Family Study (ERF)	The genotyping for the ERF study was supported by EUROSPAN (European Special Populations Research Network) and the European Commission FP6 STRP grant (018947; LSHG-CT-2006-01947). The ERF study was further supported by grants from the Netherlands Organisation for Scientific Research, Erasmus MC, the Centre for Medical Systems Biology (CMSB) and the Netherlands Brain Foundation (HersenStichting Nederland). We are grateful to all patients and their relatives, general practitioners and neurologists for their contributions and to P. Veraart for her help in genealogy, Jeannette Vergeer for the supervision of the laboratory work and P. Snijders for his help in data collection.
Orkney Complex Disease Study (Orcades)	ORCADES was supported by the Chief Scientist Office of the Scottish Government, the Royal Society and the European Union framework program 6 EUROSPAN project (contract no. LSHG-CT-2006-018947). DNA extractions were performed at the Wellcome Trust Clinical Research Facility in Edinburgh. We would like to acknowledge the invaluable contributions of Lorraine Anderson and the research nurses in Orkney, the administrative team in Edinburgh and the people of Orkney.
Bruneck Study (Bruneck)	The study was supported by the Pustertaler Verein zur Prävention von Herz- und Hirngefaesserkrankungen, Gesundheitsbezirk Bruneck, and the Assessorat fuer Gesundheit, Province of Bolzano, Italy.
Copenhagen City Heart Study (CCHS)	This work was supported by a Specific Targeted Research Project grant from the European Union, Sixth Framework Programme Priority (FP-2005-LIFESCIHEALTH-6) contract 037631, the Danish Medical Research Council (Copenhagen), the Research Fund at Rigshospitalet, Copenhagen University Hospital (Copenhagen), Chief Physician Johan Boserup and Lise Boserup's Fund (Copenhagen), Ingeborg and Leo Dannin's Grant (Copenhagen), and Henry Hansen's and Wife's Grant (Copenhagen). Genotyping was supported by a grant from the Austrian Heart Fund to F. Kronenberg.
National Health and Nutrition Examination Surveys (NHANES)	The study participants derive from the National Health and Nutrition Examination Surveys (NHANES), and these studies are supported by the Centers for Disease Control and Prevention. We would like to thank Dr. Geraldine McQuillan and Jody McLean for their help in accessing the Genetic NHANES data. The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention. The Vanderbilt University Center for Human Genetics Research, Computational Genomics Core provided computational and/or analytical support for this work. Genotyping was performed in the Vanderbilt DNA Resources Core by Paxton Baker under the direction of Dr. Holli Dilks and Cara Sutcliffe.
Multi-Ethnic Study of	MESA and the MESA SHARe project are conducted and supported by the National Heart, Lung, and Blood Institute (NHLBI) in collaboration with MESA investigators.

Atherosclerosis (MESA)	Support is provided by grants and contracts N01 HC-95159, N01-HC-95160, N01-HC-95161, N01-HC-95162, N01-HC-95163, N01-HC-95164, N01-HC-95165, N01-HC-95166, N01-HC-95167, N01-HC-95168, N01-HC-95169 and RR-024156. MESA SNP Health Association Resource (SHARe): “Funding for SHARe genotyping was provided by NHLBI Contract N02-HL-6-4278.”
Prevention of Renal and Vascular End-stage Disease (PREVEND)	The PREVEND study is supported by the Dutch Kidney Foundation (Grant E033), EU project grant GENECURE (FP-6 LSHM CT 2006 037697), and NWO VENI (grant number 916.76.170)
Cardiovascular Disease in Intermittent Claudication (CAVASIC)	This study was partially funded by the "Genomics of Lipid-associated Disorders - GOLD" of the "Austrian Genome Research Programme GEN-AU" and by the Austrian Heart Fund to F. Kronenberg and by the Austrian National Bank (Project-Nr. 13662) to Barbara Kollerits.
Genetic Determinants of Peripheral Arterial Disease (GenePAD)	This study was supported by grants from the National Heart, Lung and Blood Institute (RO1 HL-75774, 1K12 HL087746, 1P50HL083800) as well as a National Institutes of Health grant M01 RR 00070 (General Clinical Research Center, Stanford University School of Medicine) and the Stanford Cardiovascular Institute.
Linz Peripheral Arterial Disease (LIPAD)	This project was supported in part by a grant for scientific research from the Upper Austrian Government. Genotyping was supported by a grant from the Austrian Heart Fund to F. Kronenberg.

Genetic factors clearly contribute to exceptional longevity and healthy aging in humans, yet the identification of the underlying genes remains a challenge. Longevity is a complex phenotype with modest heritability. Age-related phenotypes with higher heritability may have greater success in gene discovery. Candidate gene and genome-wide association studies (GWAS) for longevity have had only limited success to date. The Cohorts for Heart and Aging Research in Genomic Epidemiology Consortium conducted a meta-analysis of GWAS data for longevity, defined as survival to age 90 years or older, that identified several interesting associations but none achieved genome-wide significance. A recent GWAS of longevity conducted in the Leiden Longevity Study identified the *ApoE* E4 isoform as deleterious to longevity that was confirmed in an independent GWAS of long-lived individuals of German descent. Notably, no other genetic loci for longevity have been identified in these GWAS. To examine the conserved genetic mechanisms between the mouse and humans for life span, we mapped the top Cohorts for Heart and Aging Research in Genomic Epidemiology GWAS associations for longevity to the mouse chromosomal map and noted that eight of the ten top human associations were located within a previously reported mouse life-span quantitative trait loci. This work suggests that the mouse and human may share mechanisms leading to aging and that the mouse model may help speed the understanding of how genes identified in humans affect the biology of aging. We expect these ongoing collaborations and the translational work with basic scientists to accelerate the identification of genes that delay aging and promote a healthy life span.

Key Words: Longevity—Genetics—Epidemiological studies.

IT is well established that both genetic factors and health-related behaviors influence survival to old age and survival to old age in good health. Longitudinal cohort studies demonstrate that lower levels of cardiovascular risk factors measured in midlife or early older years predict survival and healthy survival to 85 years of age (1,2) and beyond (3,4). Longevity has been observed to cluster within families so that parents and siblings of centenarians have a greater likelihood of attaining advanced age (5–7), and offspring of centenarians appear to have a delay in age-related disease (8,9). Studies of families clustered for longevity both in the United States and Europe (Long Life Family Study and Leiden Longevity Study) have demonstrated that offspring of long-lived participants has more favorable midlife risk factor profiles and less age-related disease (10,11). Similarly in the community-based Framingham Heart Study, adults with at least one parent surviving to old age have lower risk factor levels compared with individuals whose parents died younger and the risk factor advantage persists over time (12). The genetic contribution to longevity and human aging is likely to result from many genes each with modest effects. Some genes will likely affect longevity by increasing susceptibility to age-related disease and early death, whereas other genes are likely to slow the aging process itself leading to a long life. How genetic factors and their interaction with modifiable behavioral and environmental factors contribute to longevity remains unknown.

Longevity and Healthy Aging Phenotypes: Definitions and Heritability

Longevity is often defined as age at death or survival to an exceptional age such as 90 years or older or 100 years or older. Because life expectancy has improved dramatically across birth cohorts since 1900, care must be taken when study designs compare long-lived with younger cohorts. Women live longer than men and make up a larger proportion of the older population especially at exceptional old ages. For example, among the original 5,209 Framingham Heart Study participants with follow-up through 2011, there are 43 centenarian women and only six centenarian men, whereas at study entry (1948–1953), 55% of participants were women. Men are more likely to attain extreme old age escaping common age-related disease, whereas women are more likely to attain 100 after surviving common morbidities (13). While these observations raise the hypothesis that genetic and environmental factors influence the path to longevity differently in men and women, whether genetic factors play a greater or lesser role in men than in women is an area of debate (3,14). In a study of centenarians (100–104 years), semisupercentenarians (105–109 years), and supercentenaians (110–119 years), there was a progressive delay in the onset of age-related disease and onset of physical and cognitive function impairment with increasing age (15). Whether genes that influence survival to these extreme ages also play a role in survival to age older than 90 years is unknown.

The genetic contribution to longevity (age at death) has been estimated using both large twin registries and population-based samples (Table 1). Most heritability estimates from twin registries range between 20% and 30% (16,17), whereas estimates from population-based samples are slightly lower, ranging from 15% to 25% (18,19), suggesting a significant but modest genetic contribution to the human life span. One study conducted among an ethnically diverse group suggests that genetic influences on life span may vary by ethnicity with heritabilities ranging from a low of 4% for African Americans to 29% and 26% for Caribbean Hispanics and Caucasians, respectively (21). Using data from the GenomeEUtwin project that included more than 20,000 Nordic twins, Hjelmborg and coworkers (42) noted that genetic effects on life span were minimal prior to 60 years of age, but genetic effects on life spans greater than 60 years of age were significant and constant to increasing with advancing age. Starting at about age 60 years, the relative recurrence risk of an individual living past a specified age given that his/her cotwin also lived past that age increased with increasing age cut point in both men and women so that at age 92, the recurrence risk was 4.8 and 1.8 in monozygotic and dizygotic male twins and 2.5 and 1.6 in monozygotic and dizygotic female twins. Notably, recurrence risks similar to men occurred in women at a 5- to 10-year older age perhaps reflecting the longer average longevity in women. Using the Framingham Heart Study cohorts, we explored whether genetic influences on life span increase with achievement of older ages by examining age at death as a dichotomous trait using a liability threshold model adjusting for sex and birth year (20). In contrast to the modest heritability estimate for continuous age at death (16%), heritability of surviving past 65 years and surviving past 85 years was substantial at 36% ($p = 4.2 \times 10^{-10}$) and 40% ($p = 9.0 \times 10^{-10}$), respectively. Thus, genetic effects appear to be greater for survival to more advanced ages. In the Framingham Heart Study cohorts, heritability appears to increase with each 10-year increment in survived age (65 years, 75 years, and 85 years) for men, but not women, again suggesting that genetic effects on aging may be more substantial for men than women (20).

Table 1. Familiality of Aging Phenotypes

Exceptional survival: centenarians	Sibling survival probability
New England Centenarian Study, likelihood of achieving age 100 (6)	Women eightfold; men 17-fold
Okinawa Centenarian Study (7), likelihood of achieving age 90	Women 2.6-fold; men 5.4-fold
Age at death	**Heritability**
Twin registries (16,17)	20%–30%

*60% of sample did not participate in 4 year follow-up, half lost to mortality.

†Cluster analysis approach based on mini-mental state examination, activities of daily living, self-reported health status, and handgrip strength.

‡Not previously published.

The longevity phenotype measures overall life span without consideration of health and physical or cognitive function and hence is a very heterogeneous phenotype that may be affected by many environmental and other nongenetic factors. The relative contribution of additive genetic effects may be greater for more homogeneous phenotypes that describe specific aspects of aging and in turn may result in greater success in gene discovery. The heritability of reproductive aging phenotypes is at least 50%, and heritability is even higher for age-related diseases such as osteoporosis (low bone mineral density) and Alzheimer's disease (Table 1). Genetic association studies have been successful in identifying genetic variants for these aging phenotypes and have the potential to uncover new biologic insights into the associated underlying aging processes (43–49).

Epidemiological studies that have followed participants over adulthood and collected a wealth of information in a standardized fashion have been important sources for development of aging-related phenotypes. Alternative aging phenotypes include disease-free survival, preservation of high levels of function including maintenance of cognitive function (50) and avoidance of bone loss (51), and successful aging (reaching advanced age with intact cognitive ability, physical function, and social engagement) (52). An index of physiologic age developed in the Cardiovascular Health Study by combining data across multiple systems was found to be a better predictor of death and disability than age itself (53). A frailty phenotype defined by five criteria, including unintentional weight loss, exhaustion, weakness, low physical activity, and slow walking speed (54), is distinct from physical disability and itself is predictive of mortality and other adverse outcomes. Although the frailty phenotype was developed in the Cardiovascular Health Study sample, it was found to be applicable across diverse studies (55). Many components of the multidimensional aging phenotypes developed in longitudinal studies are heritable, such as weakness (defined using handgrip strength) and lower extremity function, suggesting the potential for a genetic contribution to the overall phenotype (26,31).

In the family-based Framingham Heart Study, we estimated the heritability of several of the age-related phenotypes including longevity, morbidity-free survival, physical function, and frailty as well as walking speed and handgrip strength (Table 1). For quantitative traits, we used the variance components model, and for dichotomous traits, we used the liability model implemented in the software Sequential Oligogenic Linkage Analysis Routines (56). For both, we defined heritability as the proportion of phenotypic variance due to additive genetic effects only. The heritability of the physical function and frailty phenotypes in the Framingham sample has not previously been reported. For physical disability, three items from the Rosow–Breslau Functional Health Scale (are you able to walk a half mile without help? are you able to walk up and down one flight of stairs without help? are you able to do heavy work around the house without help? [57]) and five items from the Katz Activities of Daily Living Scale (can you do the following five activities independently: dressing, bathing, eating, toileting, and transferring) (58) were used. Physical disability was defined as present if the participant was unable to do any of the items. We examined the presence of physical disability at age 75 years using the exam at which the participant was closest to and within 5 years from age 75 using both the original cohort and offspring samples. Among the 2,614 individuals included in the analysis, 42% reported physical disability at age 75, and the heritability was 44% ($p = .0002$). We estimated heritability of frailty and two of its components handgrip strength and walking speed in the Framingham Offspring cohort participants who attended the last completed research examination (2005–2008) during which the short physical performance battery was administered including a timed 4-m usual paced and quick walk (59). Frailty was defined if three of the five criteria proposed by the Cardiovascular Health Study investigators were present and prefrailty if one to two criteria were present (54). The analysis was adjusted for age and sex and included only participants aged 60 and older. The prevalence of frailty and prefrailty among the 2,207 individuals in this sample was 5% and 41%, respectively, and the combined trait of prefrailty and frailty was modestly heritable ($h^2 = 19\%$, $p = .05$). The usual and fast paced walking times in participants aged 65 years and older were rank normalized to reduce skewness and adjusted for age, sex, body mass index, and height. In contrast to frailty, both the usual and quick walk had a substantial genetic contribution with heritabilities of nearly 40% (usual walk: $h^2 = 0.38$, $p = .0002$; quick walk: $h^2 = 0.36$, $p = .0003$). Next, we estimated heritability of handgrip strength in all offspring participants (mean age 67, range 43–93 years). Handgrip strength was measured three times in each hand with a JAMAR dynamometer. The maximum of the six trials was used in the analysis. Consistent with reports from twin studies, handgrip strength adjusted for age and sex had a heritability of 38% ($p = 5 \times 10^{-15}$). Aging phenotypes are associated with varied heritabilities (Table 1), and thus, the genetic contribution to the phenotype may be quite modest. Populations that differ in environmental factors may produce different heritability estimates even if the genetic factors influencing the trait are the same. Hence, it is remarkable that the heritability estimates for many of the age-related phenotypes are similar. Longevity and age-related phenotypes with higher heritability are of higher priority for genetic association studies, as these phenotypes are more likely to result in multiple genetic associations.

Genetic Association Studies

Genome-wide association studies (GWAS) test genetic variants across the entire genome for association with a phenotype and have proven highly successful for discovery of novel genes and biologic pathways involved in many common complex conditions (Table 2). However, few GWAS of longevity have been conducted to date. The Framingham Heart Study 100K project was the first investigation of the

Table 2. Genetic Association Studies for Human Longevity

GWAS approach for longevity and aging traits (76). The project was relatively small in size including just 1,345 Framingham participants from the largest 310 families and limited in coverage of the genome as the genotyping was conducted with the 100K Affymetrix GeneChip. Modest associations between longevity (defined as age at death) and single nucleotide polymorphisms (SNPs) in or near *FOXO1a*, a gene important for life span in animal models, as well as other candidate genes were observed but failed to reach genome-wide statistical significance. Results of this investigation are considered hypothesis-generating and remain to be replicated. Lending some support to the Framingham 100K longevity investigation, a genome-wide linkage study looking for chromosomal regions linked to successful aging in the Amish Study identified a linkage region near one of the SNPs associated with age at death (52). In 2007, more than 9,300 Framingham Heart Study participants were genotyped with the Affymetrix 500K mapping array plus 50K gene centric supplemental array as part of the National Heart, Lung, and Blood Institute's SNP Health Association Resource project (http://www.ncbi.nlm.nih.gov/projects/gap/cgi-bin/study.cgi?study_id=phs000342.v2.p6, accessed March 9, 2012). At the same time, multiple large population-based longitudinal cohort studies in the United States and Europe with richly phenotyped participants planned to conduct genome-wide genotyping. Thus, in 2008, the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium was formed to facilitate GWAS meta-analyses and replication opportunities to enhance gene discovery for many phenotypes (77). The CHARGE aging and longevity working group conducted a meta-analysis of GWAS results for longevity defined as survival to age 90 and older from four cohort studies (Age, Gene/Environment, Susceptibility-Reykjavik Study, the Cardiovascular Health Study, the Framingham Heart Study, and the Rotterdam Study) (64). The CHARGE collaboration permitted the assembly of one of the largest samples of long-lived individuals with genome-wide genotyping available at that time (1,836 individuals achieved aged ≥90 years). The comparison group was drawn from the same cohorts and included only deceased participants to ensure that no individual achieved longevity. The investigation detected 273 SNP associations for longevity that achieved $p < .0001$, but none of the associations achieved genome-wide significance ($p < 5 \times 10^{-8}$). In the next stage of the discovery analysis, among the 24 strongest independent SNP associations in the CHARGE meta-analysis, 16 SNPs were successfully genotyped in the Leiden Longevity Study and the Danish 1905 cohort, and one SNP near the *MINPP1* gene was associated with longevity with $p = 6.8 \times 10^{-7}$ in the combined stage 1 and stage 2 discovery samples. The minor (less frequent) allele was associated with a lower odds of achieving longevity (odds ratio 0.8). *MINPP1* is a highly conserved gene involved in cellular proliferation. The CHARGE aging and longevity working group now includes investigators from over 15 cohort studies permitting future investigations of even larger samples of long-lived individuals with genome-wide genotyping and additional aging phenotypes that may improve our power to detect age-related genetic variation and provide support to our initial findings. We have subsequently conducted a meta-analysis of GWAS data from nine studies in more than 25,000 individuals aged 55 years and older for two age-related phenotypes, all-cause mortality and survival free of major disease and death (63). Although none of the SNP associations for either phenotype achieved genome-wide significance, 14 independent SNPs were associated with mortality, and 8 independent SNPs were associated with event-free survival. The SNPs were in or near genes highly expressed in the brain, genes involved with neural function, and genes associated with a variety of age-related diseases. Thus, our findings suggest that neural processes may be important in regulating aging.

A GWAS conducted in 403 nonagenarians from the Leiden Longevity Study, and 1,670 younger population controls identified 62 SNPs associated with longevity at $p < 1 \times 10^{-4}$ (61). Successful genotyping of 58 of these SNPs was conducted in three independent studies: the Rotterdam Study, Leiden 85-plus Study, and Danish 1905 cohort. A meta-analysis of the 58 SNPs in all four studies that included more than 4,000 nonagenarians and 7,500 younger controls identified only one genome-wide significant SNP rs2075650 in *TOMM40* at chromosome 19q13.32 close to the *ApoE* gene. The minor allele was associated with lower odds of longevity (odds ratio 0.71, $p = 3.4 \times 10^{-17}$). No other SNPs were associated with longevity. SNP rs2075650 was noted to be in moderate linkage disequilibrium with rs429358, the SNP that defines the *ApoE* E4 isoform and in very low linkage disequilibrium with rs7412, the SNP that defines the *ApoE* E2 isoform. In conditional analysis, with all three SNPs in the model, rs2075650 was no longer associated with longevity, whereas the minor allele of rs429358 had a deleterious effect on longevity, and rs7412 a protective effect leading the authors to conclude that rs2075650 effect on longevity was most likely mediated through the isoforms of the *ApoE* gene. A case-control GWAS conducted in 763 German nonagenarians and centenarians, and 1,085 controls (mean age 60 years) identified rs4420638 near the *APOC1* gene and replicated the finding in an independent sample (60). This finding was also fully explained by linkage disquilibrium with *ApoE* E4 isoform confirming the prior report. These results are intriguing as the *ApoE* gene is one of only two candidate genes with consistent evidence for association with longevity in humans (73). The *ApoE* E4 isoform has been linked to elevated cholesterol, cardiovascular disease, age-related cognitive decline, and dementia. The *ApoE* E4 isoform is more strongly associated with Alzheimer disease than longevity and other conditions. Homozygosity for the *Apo E* E4 allele confers up to a 15-fold risk for Alzheimer's disease in whites and an 8-fold risk in African Americans compared with the most

common *ApoE* genotype (E3/E3 [78]). Thus, *ApoE* may influence longevity through premature atherosclerosis and age-related diseases. Notably, the CHARGE study did not observe genome-wide significant associations between the *ApoE* gene region and longevity. However, neither of the two SNPs (rs429358 and rs7412) that define the *ApoE* E4 polymorphism nor any strong proxies appear on any of the chips used by the CHARGE consortium studies. In the CHARGE meta-analysis, the odds of living past age 90 years associated with the minor allele of rs2075650 was 0.85 (p = .046); hence, the effect is consistent with the prior reports.

FOXO3a was first noted to be associated with longevity in a candidate gene study conducted in male centenarians of Japanese descent (65) and subsequently replicated in diverse samples of centenarians and long-lived individuals (66–69). Remarkably neither the Leiden or German studies nor the CHARGE GWAS identified an association between longevity and *FOXO3a*. Finally, a recent GWAS of 410 long-lived individuals and 553 young controls from Southern Italy identified an SNP in an intron of the *CAMKIV* gene among the top associations. This association was replicated in a sample of 116 long-lived and 160 young controls ($p < 10^{-4}$ discovery analysis, joint replication analysis $p = 1.7 \times 10^{-6}$) (62). Interestingly, in vitro work suggests that this gene activates proteins in candidate genes for longevity (*AKT*, *SIRT1*, and *FOXO3a*). About 300 genetic variants in 30 genes in the insulin/insulin-like growth factor 1 (IGF-1) signaling pathway were genotyped in older women participating in the Study of Osteoporotic Fracture. Replication studies were conducted in the Cardiovascular Health Study and an Ashkenazi Jewish Centenarian Study (70). SNPs in two genes in this pathway (*AKT1* and *FOXO3a*) were significantly associated with human life span. A better understanding of the biological mechanisms by which the *FOXO3a* and *AKT1* variants influence human longevity will be important to development of interventions to delay aging (79).

Individuals with a family history of longevity have lower mortality for most age-related diseases (80). Therefore, researchers tested the hypothesis that this may be due to the absence of susceptibility alleles for common diseases in the Leiden Longevity Study and the Leiden 85 Plus Study. They examined whether the long-lived individuals had fewer copies of 30 alleles discovered through GWAS to be associated with coronary artery disease, cancer, and type 2 diabetes compared with a younger comparison group (81). Notably, no difference in the number of risk alleles was detected, suggesting that at least in these populations, survival to old age is not determined by the absence of risk alleles identified to date for age-related disease.

The effort to identify genes that affect longevity through candidate gene and GWAS studies has had only modest success to date. This is likely due to a combination of factors including the heterogeneity of the phenotype, the influence of environmental and dietary factors, which vary widely across populations and the relatively small sample sizes of published longevity GWAS. Many of the successful GWAS with many replicating genome-wide significant signals have sample sizes of more than 10,000, and some published studies of quantitative traits such as age at menarche have had sample sizes of more than 80,000 (43). It is clear that defining more homogeneous phenotypes through age-related traits such as age at menopause and bone mineral density leads to greater success in identifying aging-related genes. Another potential explanation for the lack of identification of risk variants for longevity is that the bulk of the genetic effects are due to rare variants or structural variation in the genome. The GWAS chips used to date have focused on common SNP variants, which typically do not tag rare variants well. Recent work within the CHARGE consortium studies suggests that copy number variants are associated with mortality (82). With the advent of low-cost exome and whole genome sequencing as well as higher-density SNP chips with 5 million or more variants, we will soon have the opportunity to determine whether rare or structural variants explain a substantive proportion of the heritability of longevity and other aging traits.

Translation

Comparison across genomes of different organisms may greatly facilitate the process of gene identification and testing of homologous genes in humans (83). Genome-wide mapping studies of longevity have been conducted in animal models, including *Caenorhabditis elegans* and Drosophila (84). Through the National Institute of Aging's Longevity Consortium (http://longevityconsortium.org/, accessed August 15, 2011) that brings together scientists from multiple disciplines, investigators from the CHARGE consortium, and the Aging Center at the Jackson Laboratory in Maine began to examine the conserved genetic mechanisms between humans and the mouse for life span (85). The laboratory mouse is an excellent model organism for understanding mammalian physiology and genetics for several reasons, including the availability of extensive genetic resources, such as hundreds of inbred, congenic, consomic, and recombinant inbred strains, as well as the ability to add and delete genes via transgenesis and targeted mutagenesis (86,87). Sequence analyses have demonstrated that mice and humans share more than 99% of their genes and that these genes are arranged in a homologous fashion on chromosomes, a phenomenon termed synteny. The appearance of quantitative trait loci (QTL) for a given phenotype in syntenic regions of two different species is evidence that the same gene regulates the phenotype in both species (88). In the past 30 years, seven mouse life-span QTL studies have been carried out in two groups of recombinant inbred strains and 3 four-strain crosses (85).

Although none of the SNP associations for longevity in the CHARGE GWAS achieved genome-wide significance (64), 8 of the top 10 hits were located within a mouse QTL, and five of the human signals were located within 10 Mb of

a mouse QTL peak; the probability that this is due to chance is very low (p = .0025 using Fisher's exact test, based on life-span QTL covering 860 Mb of the 2,700 Mb genome and each human peak being 1 Mb in size) (85). The colocalizations of the human peaks and mouse longevity QTL are especially notable in the distal region of mouse chromosome 1 (summarized in Figure 1). In this region, Gelman (90) first reported a longevity QTL that was identified in recombinant inbred lines of C57BL/6J X DBA/2. Recently, Yuan and coworkers identified two longevity QTL in this region in a backcross mouse population (POHN/DehJ × C57BL/6J) × POHN/DehJ (unpublished data, 2011). The peak of Gelman's QTL overlaps with the peak of one of the Yuan and coworkers QTL, around 160 Mb–163 Mb. The peak of the other Yuan and coworkers QTL was 14 Mb apart, around 175 Mb. Syntenic regions of 2 of the 10 highest peaks (rs16850255 and rs4443878) identified in the CHARGE study are found around 161 Mb and 176 Mb, colocalizing with the mouse longevity QTL. This suggests that human and mouse may share some mechanisms that regulate life span.

Interestingly, around 160 Mb and 175 Mb, one peak from a mouse genome–wide association study and one QTL of IGF-1 have been reported (Figure 1). Yuan and coworkers reported that across mouse inbred strains, lower IGF-1 levels are associated with longer life span. The overlap between longevity QTL and IGF-1 QTL suggests that this region may contain genes that could regulate longevity through the regulation of IGF-1 level. Although this hypothesis must be further verified, the combination of such human and mouse genetic studies establishes a foundation for a powerful translational strategy. We plan to integrate data for additional age-related traits and use bioinformatics and genetic resources in the mouse to test promising candidate genes for longevity. Although genetic association studies in humans can help identify potential genes linked to longevity, the mouse model may be very useful in uncovering the underlying biologic mechanisms that lead to aging.

Other investigators have examined human–chimpanzee orthologous gene pairs to explore evolutionary forces on genes related to aging (93). Genes that appeared to have a pattern of selection tended to have important biological functions that were conserved among mammals (93). Of interest, the study findings suggest that one gene that may have undergone rapid evolution is *WRN*. Defects in *WRN* cause Werner's syndrome characterized by premature aging.

Ultimately, we hope that the identification of genes influencing human longevity will provide insights into the biology of aging and in turn new therapeutics to slow aging and improve health. Evidence from both human and animal studies has identified genes in the IGF1/insulin signaling pathway influencing life span. Therefore, interest in resveratrol, a compound shown to extend life span in animals and improve insulin secretion and insulin sensitivity among many other benefits, is not surprising. A recent pilot study

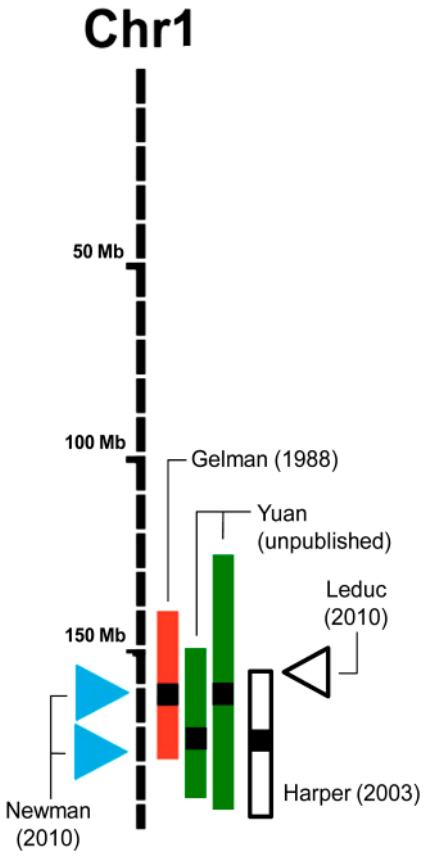

Figure 1. Quantitative trait loci (QTL) for mouse longevity and insulin-like growth factor 1 (IGF-1) as well as genome-wide association peaks for human longevity and mouse IGF-1, both depicted on the mouse genome, mouse chromosome 1 (mapped in Mb). Colored bars are longevity QTL; the open bar is an IGF-1 QTL. The height of the bars represents the 95% confidence interval if reported or an estimated 40 Mb if not reported; the black squares in the bars represent the QTL peaks. We determined the Mb position using a recently revised mouse map (89) and the Mouse Map Converter from the Center for Genome Dynamics (http://cgd.jax.org/mousemapconverter/). Arrows to the left of the chromosome represent human genome-wide association peaks at the homologous mouse genome locations. The arrow on the right of the chromosome is the mouse genome-wide association peak of IGF-1. (Figure is modified from Figure 1 of Yuan et al [85]). Chr = chromosome. Gelman et al (90), Harper et al (91), Leduc et al (92), Newman et al (64).

conducted in 10 older adults suggests that resveratrol improved insulin sensitivity in individuals with impaired glucose tolerance (94). These data combined with animal studies provide support for larger studies of the benefits of resveratrol in humans (95).

Future Directions

Technological advances now permit the complete sequencing of all protein-coding portions of the genome (the "exome"), and the ability to sequence the whole genome of individuals quickly and efficiently is just beginning. Sequencing represents an opportunity to detect rare potentially functional genetic variants unlikely to be discovered with the GWAS that focus on common genetic variation (minor allele frequencies of >5%). The National Human Genome Research Institute and National Heart, Lung, and

Blood Institute (NHLBI) funded the Exome project with the goal of identifying genes contributing to heart, lung, and blood disorders (http://www.nhlbi.nih.gov/resources/exome.htm, accessed August 15, 2011). This innovative technology and the analytic tools under development will be able to be extended to longevity and age-related traits. The sequencing of centenarian genomes may uncover rare genetic variants underlying human extreme longevity and provide insights into the basic biology of aging.

Changes in gene expression that occur as a result of molecular mechanisms that do not change the primary DNA sequence are referred to as epigenetics (http://www.ncbi.nlm.nih.gov/books/NBK45788/#epi_sci_bkgrd.About_Epigenetics, accessed March 9, 2012). Epigenetic mechanisms influence phenotypic expression and are affected by development, the environment, diet, drugs, and aging. One of the best studied epigenetic mechanisms called DNA methylation usually results in suppression of nearby genes. A study of global DNA methylation in an Icelandic cohort and a family-based Utah cohort demonstrated familial clustering of DNA methylation changes and changes in DNA methylation over time (96). The changes in DNA methylation that occur with aging may alter normal gene expression and in turn contribute to development of age-related disease and functional decline (97). Epigenetic changes can be identified using genome-wide analysis with microarrays (ChIP-chip) or next generation sequencing (ChIP-Seq). These new technologies may be used in longitudinal cohort studies in the future to uncover the role of epigenetics in human longevity.

Conclusions

Genetic factors undoubtedly contribute to human aging and longevity, yet candidate gene and GWAS have yielded few replicated longevity-gene associations to date with the exceptions of the *ApoE* and *FOXO3A* genes. Genome-wide genotyping of participants in longitudinal cohort studies, family-based studies, and special populations of long-lived individuals such as centenarians along with unprecedented collaboration among investigators in the United States, Europe, and worldwide provide the opportunity for the assembly of the large discovery and replication samples needed for genetic discoveries. Existing consortia that include both population-based and laboratory-based scientists may speed the translation of newly discovered genetic associations by uncovering the function of the identified genetic variants and ultimately the biologic mechanisms leading to human aging. Many epidemiological studies are poised to use new technologies to move beyond common genetic variants to explore the contribution of low frequency and rare genetic variants, structural changes, and epigenetic changes to human longevity and aging.

This continuing educational activity will expire for physicians on April 30, 2013.

PURPOSE:

To enhance the learner's competence in pressure ulcer (PrU) prevention through a literature review of comprehensive programs.

TARGET AUDIENCE:

This continuing education activity is intended for physicians and nurses with an interest in skin and wound care.

OBJECTIVES:

After participating in this educational activity, the participant should be better able to:

1. Analyze the findings of the PrU prevention program studies found in the literature review.

2. Apply research findings to clinical practice.

ABSTRACT

OBJECTIVE: The objective of this study was to examine the evidence supporting the combined use of interventions to prevent pressure ulcers (PrUs) in acute care and long-term-care facilities.

DESIGN: A systematic review of the literature describing multifaceted PrU prevention programs was performed. Articles were included if they described an intervention implemented in acute care settings or long-term-care facilities, incorporated more than 1 intervention component, involved a multidisciplinary team, and included information about outcomes related to the intervention.

MAIN RESULTS: Twenty-four studies were identified. Recurring components used in the development and implementation of PrU prevention programs included preparations prior to the start of a program, PrU prevention best practices, staff education, clinical monitoring and feedback, skin care champions, and cues to action. Ten studies reported PrU prevalence rates; 9 of them reported decreased prevalence rates at the end of their programs. Of the 6 studies reporting PrU incidence rates, 5 reported a decrease in incidence rates. Four studies measured care processes: 1 study reported an overall improvement; 2 studies reported improvement on some, but not all, measures; and 1 study reported no change.

CONCLUSIONS: There is a growing literature describing multipronged, multidisciplinary interventions to prevent PrUs in acute care settings and long-term-care facilities. Outcomes reported in these studies suggest that such programs can be successful in reducing PrU prevalence or incidence rates. However, to strengthen the level of evidence, sites should be encouraged to rigorously evaluate their programs and to publish their results.

KEYWORDS: preventing pressure ulcers, multidisciplinary interventions to prevent pressure ulcers, reducing incidence of pressure ulcers

ADV SKIN WOUND CARE 2012;25:167-88; quiz 189-90.

SCOPE OF THE PROBLEM

Pressure ulcers (PrUs) remain a national priority in American healthcare. Every year, tens of thousands of patients develop these skin lesions. Although rates vary widely among different care settings, a 2009 survey among self-selected sites in the United States found an overall PrU prevalence rate of 11.9% and a facility-acquired rate of 5.0% in acute care facilities.[1] Along with pain and the risk for serious infections, PrUs result in increased healthcare utilization and costs. A survey using Medicare inpatient data found that, between 2005 and 2007, PrUs accounted for up to $2.41 billion in excess healthcare costs.[2]

Some PrUs may be avoidable, and in the past decade, the prevention of PrUs has gained increased emphasis in clinical practice. In the quest to reduce harm to patients from serious preventable events, institutions such as the National Quality Forum, the Agency for Healthcare Quality and Research, and the Joint Commission, among others, selected PrUs as indicators for patient safety and quality of hospital care. In similar efforts, the 5 Million Lives Campaign, led by the Institute for Healthcare Improvement, brought additional attention to the importance of preventing PrUs in healthcare facilities. Furthermore, in 2008, the Centers for Medicare & Medicaid Services implemented new payment rules that included PrUs on the list of ''never events'' and stopped reimbursement to hospitals for the costs of care resulting from facility-acquired Stages III and IV PrUs.[3]

This article will help clinicians identify best practice evidence supporting the combined use of interventions to prevent PrUs in acute care and long-term-care facilities.

PRESSURE ULCER BEST PRACTICES

In the United States, best practices to prevent PrUs have been identified in randomized controlled trials and have been widely disseminated through clinical practice guidelines. A number of systematic studies have evaluated the efficiency of individual best practices, such as the use of special support surfaces or standardized tools to assess risk for PrU development.[4,5] However, the systematic implementation of best practices one at a time in the standard care environment has been shown to be a challenge for many facilities. Studies have found low adherence rates to best practices for PrU prevention in different care settings. For example, 1 study found that although hospitalized older adults were assessed for PrU risks, only 15% had a supportive device in place by day 3 of hospitalization.[6] Another study found that, of 2425 hospitalized Medicare beneficiaries from across the nation, only 23% of immobile patients were documented as being at risk within 48 hours of admission, 66% were repositioned every 2 hours, and 8% received a pressure-reducing device.[7] A third study surveyed medical records of 834 residents in Veterans Health Administration long-term-care facilities and found that overall adherence to 6 critical best-care practices (such as standardized risk assessment and regular repositioning) was only 50%.[8] Rather than implementing single best practices, care facilities have increasingly begun to bundle best practices together and implement them as part of comprehensive programs in their facilities. The aim of this review was to examine the evidence supporting the combined use of multiple interventions to prevent PrUs in acute care and long-term-care facilities. Two questions guided the analysis of the literature:

- Are there any specific components that have consistently been included in multifaceted programs?
- Is there evidence that these comprehensive programs reduce PrU incidence and/or prevalence?

METHODS

For this review, Ovid MEDLINE and Ovid CINAHL were searched using combinations of the following search terms: *pressure ulcer*, *bed sore*, *decubitus ulcer*, *prevention*, *protocol*, *best practice*, *quality assurance*, and *tool*. In addition, reference lists were reviewed, and clinical experts were contacted to identify further relevant studies. The search was limited to articles published in English between January 1995 and December 2010. To be included, the studies needed to describe a program to prevent PrUs that

- was implemented in an acute care or long-term-care facility,
- consisted of more than 1 intervention component,
- was not limited to site-specific PrUs (such as heel ulcers),
- was delivered through multidisciplinary efforts, and
- measured and reported PrU prevalence or incidence rates before and after implementation of the program.

RESULTS

Twenty-four articles were identified describing comprehensive PrU prevention programs. Twenty studies described single-site interventions and four described multisite interventions. All of the reviewed studies used a longitudinal 1-group pretest-posttest design. No randomized controlled trials were reported. An in-depth review of the studies was performed, and each study was analyzed for the following elements: setting and scope of the program, implementation team and preparations prior to program implementation, intervention components, methods of data collection, and results. The different intervention components were categorized into the following groups: PrU prevention best practices, staff education, clinical monitoring and evaluation, skin care champions, other campaign elements, and strategies to ensure sustainability. The findings of this review are shown in Table 1 and are summarized in the following sections.

Setting and Scope

Of the 20 programs reviewed in acute care settings,[9–28] all but one[17] were rolled out on multiple units or hospital-wide. Two studies reported spreading the program throughout the system after testing it on a small number of pilot units.[18,22] Long-term-care facility initiatives included between 1 and 20 participating facilities.[29–32]

Team

The individuals who initiated and led the improvement efforts were not specified in any of the reviewed articles. However, a distinction was found between programs that were initiated and led internally by staff members[9–13,15–28] and programs that were designed by external experts and implemented in collaboration with the facility in question.[14,29–32] Once the need for change was identified, several facilities chose to establish a team responsible for the design and/or implementation of the intervention. Teams responsible for designing and implementing the programs were generally multidisciplinary and, if specified, included combinations of nurses and nursing aides, wound experts, dietitians, pharmacists, physical therapists, physicians, clinical researchers, educators, information technology staff, managers, and directors.[10,11,15,18,20–25,27]

Program Components

Preparations. Twelve of the reviewed studies specified a set of activities completed prior to developing and implementing their initiatives.[10–13,15,16,18,20,22,24,27,31] Preparations included literature reviews of best practices for prevention and treatment of PrUs; baseline prevalence and incidence surveys; assessments of current state of staff knowledge, existing policies, and care processes; and the testing, evaluation, and selection of pressure relief equipment or skin care products.

Pressure Ulcer Prevention Best Practices. Consistent with existing clinical practice guidelines, studies that described their PrU prevention protocol most commonly reported the use of standardized tools for assessing risk for PrUs; regular skin (re)assessment; an individualized care plan for patients at risk for PrUs; the use of pressure relief equipment, such as low-air-loss mattresses and heel lifts; nutritional assessment and consultation for at-risk patients; frequent turning and repositioning; and the use of skin care products and moisture barrier creams.

Staff Education. All but 4 studies[13,16,23,30] described some form of education or training to increase staff knowledge. Generally, education was targeted at nursing staff and included instructions on PrU treatment and prevention practices, presentations of new or existing facility guidelines and policies, and training on the use of skin care products and support surfaces. Two studies reported educational programs for physicians.[20,28] Most of the studies reported formal staff educational activities, such as unit in-service sessions and workshops, computerized educational modules, educational packages for staff, skin fairs, and wound conferences.[9–12,14,15,18–22,24–29,31,32] Three studies furthermore reported the integration of PrU prevention and treatment into their orientation of new hires.[18,20,21]

In addition to formal activities, several studies described more informal ways of teaching PrU prevention.[9,11,17,22,27,31] One-on-one mentoring, consultation, and support at the bedside through certified nursing staff, training provided in preparation of PrU data collection, and individual case reviews of hospital-acquired PrUs were among the opportunities seized to provide ongoing training.

Clinical Monitoring and Feedback. Ongoing clinical monitoring was frequently used to encourage behavior change and ensure compliance with the PrU prevention practices. Staff compliance with existing protocols was monitored through daily, weekly, or monthly rounding of the wound nurses or other nursing staff; regular chart audits; and PrU tracking forms and compliance monitoring tools.[9–13,15,18,21,22,24,26–28,30,31] Additional strategies for continuous improvement included preventability or root-cause analyses when a patient developed a PrU and the development of action plans when results of the surveys were unsatisfactory.[13,18,26]

Table 1.
STUDIES DESCRIBING MULTIFACETED PRESSURE ULCER PREVENTION PROGRAMS (LISTED IN ALPHABETICAL ORDER)

Reference	Authors	Setting and Scope	Team	Preparations	Best Practices	Staff Education
Acute care setting						
9	Baldelli and Paciella, 2008	Hospital intensive care unit (ICU) medical-surgical (United States)	Task force (not specified)	Not reported	Risk assessment Skin assessment Head of bed <30 degrees Incontinence skin care Turning, positioning Heel elevation Nutritional assessment Pressure relief	Presentation (at launch) Bedside education (ongoing)

11	Catania et al, 2007	All 5 inpatient units at hospital (Cancer hospital; USA)	Multidisciplinary QI team: Clinical nurse specialist (CNS) Nursing director ET registered nurse (RN) quality manager Staff development specialist	*Initial intervention*: chart audits by CNS *Second intervention*: assessment of state of practice	Risk assessment Skin assessment Individualized care plan based on Braden subscores and linked to products/services available at the facility	*Initial intervention:* Unit in-service sessions *Second intervention:* Information packets (at launch) CNS available to assist and mentor staff

Providing feedback on the quality improvement process and sharing PrU rates with the staff at all levels was a priority reported in the majority of studies. Eight of the 24 studies highlighted the importance of sharing the results from their surveys with the staff by posting the PrU rates on unit billboards; publishing them in unit newsletters; distributing them to unit managers, directors, and senior leadership; or discussing them at staff meetings.[9,12,17,18,20,21,30,32]

Skin Care Champions. Seven of the acute care studies created the role of a skin care champion as part of their PrU prevention

Clinical Monitoring/Feedback	Skin Care Champions	Other Elements	Sustainability	Pressure Ulcer (PrU) Rates	Care Process Measures

program.[10,13–15,21,26,27] The roles and responsibilities of skin care champions varied slightly from site to site. Generally, the staff members received additional training in PrU treatment and prevention, and their responsibilities included a combination of the following elements: to introduce the new policies and interventions on the unit, to serve as skin care resource and mentor to coworkers, to serve as liaison between the unit and other parties involved in the improvement efforts, and to participate in the data collection and ongoing process monitoring.

Other Elements. To increase awareness and provide cues to action for consistent and correct implementation of the new clinical practices, several programs utilized audiovisual support and other isolated activities. [9,10,12,13,15,17,18,20–22,24,27,29–32] Examples of these support elements included use of turn clocks, stickers in the patient charts or outside patient rooms to identify patients with PrUs or at risk for developing one, PrU pocket guides and reference cards, theme songs played every 2 hours, penlights for skin assessments, weekly skin care newsletters, posters on the units, and manuals or guidebooks on skin care products, support equipment, or PrU prevention and treatment protocols. Another strategy to ensure continued awareness of the program was the development of acronyms and themes related to the program. The following themes were identified in the reviewed literature: ''Check, Rock & Roll Around the Clock''[9]; PUPPI (Pressure Ulcer Prevention Protocol Interventions)[11]; ''Save Our Skin''[13,27]; SKIN (*S*urfaces, *K*eep the patients turning, *I*ncontinence management, *N*utrition)[18]; and TOE (*T*urn, *O*verlay, *E*levate).[22]

Strategies to Sustain Efforts. It is not evident in the literature if initiatives were discontinued after completion of the project period, or whether all or certain intervention components were continued even after the formal study phase. A number of studies, however, suggested ongoing measurement and reporting of PrU rates as a strategy for ensuring continued awareness of PrU prevention.[9,11,13,14,18,23,24,26] Four studies reported identification of new practice issues as a way for sustaining the momentum of the prevention efforts.[16,18,24,28] Finally, 1 study noted that additional visual and auditory cues were introduced after completion of the study to ensure consistent adherence to PrU prevention protocols.[22]

Clinical Monitoring/Feedback	Skin Care Champions	Other Elements	Sustainability	Pressure Ulcer (PrU) Rates	Care Process Measures
					Evaluation form for training sessions
Weekly feedbacks on staff compliance with training Weekly reports by management to staff of PrU incidence	Not reported	Penlights for skin assessment Caregivers required to wear TAP card $75 if the incidence of PrUs was reduced below the goal $10 for completion of training program	Not reported	Monitored the incidence of PrUs during the 48-wk program *Baseline* HAPU incidence: 28.3% *Intervention* HAPU incidence: 9.3% Reduction of PrU incidence was highest during the 12-wk intervention phase; results were not sustained without the support of the research team	Not reported

Outcomes

PrU Rates. The majority of studies reported positive outcomes from their PrU prevention initiatives; however, *P* values assessing statistical significance were rarely reported. Almost all of the reviewed studies measured PrU prevalence rates before and after implementation of their quality improvement projects.[9–28] Seven studies did not sufficiently describe the results of their prevalence surveys to draw meaningful conclusions.[12,13,18,22,26–28] Eleven studies saw a decrease in prevalence rates over the course of the study period,[9,10,11,14–17,20,21,23,24] whereas 2 programs reported no significant changes.[19,25]

Ten studies reported PrU incidence rates.[9,12,13,18,24–29,32] Eight of these studies reported a decrease in rates between baseline and follow-up; 1 study reported that incidence rates increased between project year 1 and year 4 without statistical significance,[25] and 1 study noted that results could not be sustained during the postimplementation phase.[32]

Care Processes. Process measures were reported by 2 acute care-setting studies[14,16,] and 3 long-term-care-facility studies.[29–31] One acute care-setting study measured the use of a new mattress and implementation of a repositioning schedule and found no significant change in preventive behavior when the use of new support mattresses was not taken into account.[14] The other acute care study reported minimal improvements in some of the measured care processes.[16] Among the 3 multisite long-term-care facility programs, one reported an overall improvement of clinical practice benchmarks across all participating facilities after implementation of the 8-week program.[31] The other 2 multisite studies saw significant improvement in 8 of 12 and 9 of 12 care processes when aggregated across the participating sites.[29,30]

Other Outcomes. Positive outcomes, such as increased staff awareness and knowledge, as well as change in attitudes toward

PRESSURE ULCER TOOLKIT

This literature review was performed as part of the process for developing a toolkit to reduce PrUs using a multifaceted quality improvement approach. The free toolkit is available on the Agency for Healthcare Research and Quality's website: http://www.ahrq.gov/research/ltc/pressureulcertoolkit/.

PrU prevention, were noted in several of the articles. However, reports of these outcomes were mostly anecdotal and were not validated by any formal evaluation.

DISCUSSION

This review showed that there is an array of studies describing the use of multipronged initiatives to prevent PrU development among patients in hospitals and long-term-care facilities. Moreover, many programs reported impressive improvements in PrU prevalence or incidence rates. These results suggest that multifaceted, multidisciplinary programs are effective in preventing PrUs.

A number of approaches were widely used as components of the multipronged approach and are likely to contribute to its success. In preparation of implementation, literature reviews or assessment of the current state of PrU practice was often used to provide a baseline for the data collection and identify areas in need for improvement. Intervention components included the use of a ''bundle'' of best practices for PrU prevention, the reliance on a unit skin care champions, and an emphasis on staff education. Strategies to generate staff enthusiasm and increase awareness and adherence to the best practices, such as turning clocks or skin care newsletters, often were used. The involvement of frontline staff members in all stages of program design and implementation was considered to be essential by many studies to ensure staff engagement, ownership, and dedication. Providing frequent real-time data feedback and giving staff credit for improvement, celebrating success, and stimulating a healthy competition among the units were frequently described as ways of engaging the staff and providing them a sense of pride in their accomplishments. Finally, regular monitoring of charts, weekly or monthly rounding, and root-cause analysis to examine what went wrong when a PrU developed were also used successfully.

Few studies commented on long-term sustainability of the intervention, and there was little in the literature to suggest how improvements could be maintained. Continuous monitoring of PrU rates, the presence of a wound care team or unit champions, and continued formal and informal education seemed to be some of the elements that could positively influence the maintenance of positive outcomes.

Despite the number of studies showing benefit, results must be interpreted with caution. Foremost, the level of evidence is weak. Studies mostly consisted of a longitudinal 1-group pretest-posttest design. They have neither randomization to interventions nor control groups. Description of methods for data collection and analysis was often neglected in the publications. Only 5 studies reported process measures. This makes it difficult to determine whether the interventions contributed to increased staff compliance with new PrU prevention practices. In addition, some of the studies that measured care processes showed that albeit improved, adherence to certain best practices still remained low. One of the studies, for example, found that the proportion of residents with appropriate risk assessment completed within 2 days of admission increased from 2.2% to only 15.3%, whereas the proportion of residents with PrUs that receive weekly skin assessments increased from 12.6% to 32.8%.[29]

Furthermore, the components of the multifaceted programs were not evaluated individually, and it is therefore not possible to determine the impact of each single component. There is also a high likelihood of publication bias. Nearly all published studies were positive in showing a benefit. Given the multitude of interventions, it is not plausible that all programs would work. More likely, those programs that showed a benefit were more likely to be written up and published. Finally, studies generally did not describe or analyze the processes by which the new programs were implemented, the challenges they faced, and how they did overcome them. However, organizational change requires attention not only to the content of the program, but also to the strategies needed to implement the program.

CONCLUSION

Improving PrU prevention remains an important issue for hospital patients. This literature review has identified many components that have consistently been included in successful multifaceted PrU interventions. A review of the studies supports previously reported exemplars of success in PrU reduction initiatives. This includes administrative support with active involvement of clinical staff at the patient care level, bundling of care practices and infusing them into routine care practice, creating systemwide change and communication that is individualized to the institution's culture, making visible the documentation of PrU prevention practices, and regular education of all levels of staff.[33] Prevention practices of risk assessment, pressure redistribution and repositioning, and attention to skin care are common bundle care elements. It appears that the more care practices are incorporated into usual care practices, the more staff are apt to perform them and not see them as ''another task to perform.'' For example, including skin inspection while taking vital signs and reporting a patient's PrU risk assessment status as part of the patient's handoff report are ways for staff to consistently perform suggested prevention interventions. The best outcomes are a result of PrU prevention bundle care practices performed consistently.

Pressure ulcer quality improvement teams that are empowered within their institutions appear to have more success. No one composition of the team has been identified as being best;

each institution must decide what mix of the interdisciplinary team needs to be included in its oversight of PrU reduction initiatives. Pressure ulcer reduction initiatives should be customized and prioritized for the needs of professionals in that institution.[34]

Making too many changes at one time may impact the sustainability of PrU prevention practices. Dahlstrom et al[35] found that also changing to an electronic medical record at the same time as their PrU prevention program decreased gains previously seen. Virani et al[36] have summarized factors that contribute to poor sustainability of evidence-based practices, including inadequate time for teaching new practices to staff, inadequate attention to barriers of acceptance of new practices, and organizational factors such as inadequate resources for equipment/supplies and infrastructure support. They recommend that "sustainability of practice changes therefore requires systematic, thoughtful planning and action to ensure that the changes are embedded into the various knowledge reservoirs in the organization."[36]

The authors agree with Virani et al,[36] who believe that a regular review of research literature and practice guidelines should be used to evaluate an institution's PrU practices. What did not work in one institution might work in another. Facilities that have implemented PrU programs, successfully or not, should be encouraged to rigorously evaluate their programs and publish their results to strengthen the level of evidence.

PRACTICE PEARLS

- The review of the literature supports multi-disciplinary, bundled approaches to PrU prevention.
- No one approach has been identified as being best; institutions should carefully plan and customize PrU prevention programs according to their needs and abilities.
- PrU prevention programs require attention to content, as well as implementation and sustainability strategies.
- Institutions having implemented PrU prevention programs are encouraged to share their strategies and results so that others can learn from the experience.

CONTINUING MEDICAL EDUCATION INFORMATION FOR PHYSICIANS

Lippincott Continuing Medical Education Institute, Inc. is accredited by the Accreditation Council for Continuing Medical Education to provide continuing medical education for physicians.

Lippincott Continuing Medical Education Institute, Inc. designates this journal-based CME activity for a maximum of 1 *AMA PRA Category 1 Credit™*. Physicians should only claim credit commensurate with the extent of their participation in the activity.

PROVIDER ACCREDITATION INFORMATION FOR NURSES

Lippincott Williams & Wilkins, publisher of the *Advances in Skin & Wound Care* journal, will award 2.9 contact hours for this continuing nursing education activity.

LWW is accredited as a provider of continuing nursing education by the American Nurses Credentialing Center's Commission on Accreditation.

This activity is also provider approved by the California Board of Registered Nursing, Provider Number CEP 11749 for 2.9 contact hours. Lippincott Williams & Wilkins is also an approved provider of continuing nursing education by the District of Columbia and Florida #FBN2454.

Your certificate is valid in all states.

The ANCC's accreditation status of Lippincott Williams & Wilkins Department of Continuing Education refers only to its continuing nursing education activities and does not imply Commission on Accreditation approval or endorsement of any commercial product.

CONTINUING EDUCATION INSTRUCTIONS

- Read the article beginning on page 167.
- Take the test, recording your answers in the test answers section (Section B) of the CE enrollment form. Each question has only one correct answer.
- Complete registration information (Section A) and course evaluation (Section C).
- Mail completed test with registration fee to: Lippincott Williams & Wilkins, CE Group, 2710 Yorktowne Blvd, Brick, NJ 08723.
- Within 3 to 4 weeks after your CE enrollment form is received, you will be notified of your test results.
- If you pass, you will receive a certificate of earned contact hours and an answer key. Nurses who fail have the option of taking the test again at no additional cost. Only the first entry sent by physicians will be accepted for credit.
- A passing score for this test is 12 correct answers.
- Nurses: Need CE STAT? Visit **http://www.nursingcenter.com** for immediate results, other CE activities, and your personalized CE planner tool. No Internet access? Call 1-800-787-8985 for other rush service options.
- Questions? Contact Lippincott Williams & Wilkins: 1-800-787-8985.

Registration Deadline: April 30, 2014 (nurses); April 30, 2013 (physicians)

PAYMENT AND DISCOUNTS

- The registration fee for this test is $24.95 for nurses; $22 for physicians.
- Nurses: If you take two or more tests in any nursing journal published by LWW and send in your CE enrollment forms together by mail, you may deduct $0.95 from the price of each test. We offer special discounts for as few as six tests and institutional bulk discounts for multiple tests. Call 1-800-787-8985 for more information.

Summary: The objective of this study was to estimate the prevalence and identify correlates of four sexually transmitted infections (STIs) among HIV-infected Russians reporting heavy alcohol use and recent unprotected sex, we conducted a cross-sectional analysis of baseline data from the HERMITAGE study. The primary outcome was any current STI, based on urine tests for *Neisseria gonorrhoeae*, *Chlamydia trachomatis* and *Trichomonas vaginalis* and serological testing for infection with *Treponema pallidum*. Data on potential demographic and behavioural predictors of STI were obtained from surveys administered at study entry. Of 682 participants, 12.8% (95% confidence interval [CI] 10.3, 15.3) tested positive for at least one STI. In a multivariable model adjusted for gender, age and marital status, only sex trade involvement over the last three months was significantly associated with an increased odds of STI (adjusted odds ratio [AOR] 2.00, 95% CI 1.13, 3.55). Given that STIs were common in this HIV-infected cohort, and that few patient characteristics predicted STI, the current practice of screening HIV-infected Russians for syphilis alone merits re-evaluation.

Keywords: sexually transmitted infection, HIV, AIDS, STIs, risk behaviour, alcohol drinking, Russia

INTRODUCTION

The HIV epidemic in Russia has expanded rapidly over the last decade and continues to grow, with an estimated one million HIV-infected people in 2010.[1] While the epidemic has been largely driven by injection drug use, the proportion of new infections attributed to sexual risk is increasing.[2,3] This shift has drawn attention to the possible role of sexually transmitted infections (STIs) in facilitating the spread of HIV in the country. Russia experienced rising STI rates in the period preceding its HIV epidemic[4] and STIs are known to increase both susceptibility to HIV and the infectiousness of those with HIV.[5,6]

Studies outside Russia have demonstrated that STIs, particularly gonorrhoea, chlamydia and syphilis, are prevalent in a number of HIV-infected subpopulations.[7–12] However, there are few studies addressing STIs among HIV-infected Russians.[12] Existing data derive from studies based on self-report of STI symptoms, or only a small number of HIV-infected participants.[2,13] These limited data suggest that STIs may make a significant contribution to heterosexual transmission of HIV in Russia: for example, among 32 HIV-infected injecting drug users (IDUs) in one study, 18 (56%) tested positive for infection with either *Chlamydia trachomatis* (herein referred to as chlamydia), *Neisseria gonorrhoeae* (gonorrhoea), *Treponema pallidum* (syphilis), *Trichomonas vaginalis* (trichomoniasis) or herpes simplex virus type-2.[13] Data from a larger sample on the prevalence and correlates of STIs among those infected with HIV in Russia could inform clinical practice as to the appropriate role for STI screening for this group, which, according to national guidelines, is screened routinely only for syphilis, but not for other STIs.

The HERMITAGE (HIV Evolution in Russia – Mitigating Infection Transmission and Alcoholism in a Growing Epidemic) study provided an opportunity to investigate the prevalence and correlates of four STIs among 682 HIV-infected Russians. HERMITAGE is a randomized controlled trial of a behavioural intervention to reduce high-risk sexual activity and substance use among HIV-infected heavy alcohol users who reported recent unprotected sex in St Petersburg. The current study was a cross-sectional, secondary analysis which investigated the prevalence of gonorrhoea, chlamydia, syphilis and trichomoniasis at study entry, and examined which behaviours and demographic characteristics were associated with testing positive for one or more of these STIs.

METHODS

Study design and participants

From October 2007 to April 2010, the HERMITAGE study recruited HIV-infected heavy drinkers who reported recent unprotected sex from five inpatient and outpatient HIV and substance use care sites in St Petersburg, Russia. In the clinical settings, research associates approached patients, assessed eligibility, offered participation and conducted assessments. At the non-clinical recruitment site, a needle exchange, research associates gave potential participants information on the study and referred them to one of the clinical sites for eligibility assessment.

Patients were eligible for inclusion in the study if they were 18 years of age or older; HIV-infected; reported anal or vaginal sex without a condom in the past six months; and reported past six month National Institute on Alcohol Abuse and Alcoholism (NIAAA) 'at risk' drinking levels (defined as >14 drinks per week or >4 drinks on a single occasion for men, and >7 per week or >3 on a single occasion, for women), described as 'heavy drinking' herein.[14] Exclusion criteria included cognitive impairment, acute illness precluding participation, pending legal issues which could lead to incarceration or ongoing efforts to conceive.

Procedure

After eligibility assessment, all participants provided written informed consent. Baseline data were collected via: (a) a face-to-face interview with a research associate and (b) a self-administered questionnaire for particularly sensitive questions (e.g. about sexual victimization). A medical chart review was performed for participants recruited from medical settings. All participants were asked to provide a urine and blood sample for STI screening at the baseline assessment. Those testing positive for an STI at baseline were offered treatment.

Interviews were conducted in Russian. Participants were compensated 200 rubles, the equivalent of approximately seven US dollars, for the baseline assessment and received 30 condoms. The HERMITAGE study was approved by the Institutional Review Boards of Boston Medical Center and St Petersburg Pavlov State Medical University.

Measures

Outcome measures

The primary outcome of the current study was a diagnosis of one or more STIs (gonorrhoea, chlamydia, trichomoniasis and/or syphilis) based on biological testing at study entry. Urine specimens were tested for *N. gonorrhoeae*, *C. trachomatis* and *T. vaginalis* using polymerase chain reaction (PCR)-based nucleic acid amplification (Amplisens PCR Kits, Ecoli Ltd, Moscow, Russia) in compliance with quality guidelines by the Federal State Institution of Science, Central Research Institute of Epidemiology, Moscow, Russia).[15,16] Serum was tested for syphilis using the venereal diseases research laboratory test (VDRL, Institute of Vaccines and Sera, St Petersburg, Russia) and an enzyme-linked immunoassay (ELISA) that employs recombinant antigen to detect both IgM and IgG antibodies to *T. pallidum*. (RecombiBest AntiPallidum, ZAO Vector-Best, Novosibirsk, Russia). Subjects were defined as having syphilis when both the ELISA and VDRL were positive and they had not been previously treated for syphilis. Participants with a positive VDRL and negative ELISA were considered false-positives. None of the participants with a positive ELISA and no prior treatment had a negative VDRL.

Potential predictors

Potential predictors of STI were identified from the baseline assessment. Sociodemographic characteristics of interest included age, gender and marital status. Potential health-related predictors included self-report of current antiretroviral therapy or past history of STI, as well as the most recent CD4 count according to a medical record review. Sexual risk behaviours over the last three months were assessed, and included the number of sexual partners; the number of sexual encounters when a condom was not used; buying or selling sex for drugs or money; and, for men, any sexual activity with other men (MSM).[17] In addition, the assessment asked about the use of alcohol or drugs before or during sex in the last 30 days, a lifetime history of sexual victimization and the propensity to seek out novel or risky sexual stimulation, using Kalichman's 11-item sexual sensation-seeking scale. This scale generates scores ranging from 1 to 4, with higher scores reflecting greater sensation seeking.[18] To assess potential alcohol-related predictors of STI, participants were asked about the quantity and frequency of alcohol consumption using a 30-day time-line follow-back.[19] Heavy alcohol use was defined according to the NIAAA definition, described above.[14] Alcohol dependence over the last year was evaluated using the Composite International Diagnostic Interview Short-Form (CIDI-SF).[20] Drug-related variables included any use of heroin, prescription analgesics, marijuana, sedatives, tranquilizers or stimulants (including amphetamines and cocaine) over the last year, drug dependence according to the CIDI-SF and past history of injecting drug use.

Data analysis

Descriptive statistics were used to characterize the study sample at baseline, both overall and by STI status. The frequency and proportion of STIs (i.e. testing positive by biological testing for any of 4 specific STIs), and of any history of STI by self-report were also described. To identify factors associated with testing positive for an STI, a series of logistic regression models were built using the following manual, iterative model building approach. First, unadjusted logistic regression models for each factor of interest were fit. Factors with a P value of less than 0.15 were then included together in a single multivariable model. In addition, covariates considered to be important potential confounders (i.e. gender, age and marital status) were forced into the multivariable model. Factors in this multivariable model with a P value greater than 0.15 were removed one at a time. Finally, factors not selected based on the initial unadjusted analyses were included one at a time in the current multivariable model to assess their importance in the presence of other variables. The continuous variables of age, sexual sensation seeking score and number of unprotected sexual encounters were included as tertiles. CD4 count was included as a dichotomous variable ($\geq$350 versus $<$350 cells/mm^3) as was the number of sexual partners ($<$2 versus $\geq$2), which is consistent both with the distribution of our data and the standard approach for measuring multiple partnering over fairly short time periods.[21] To minimize the

potential for collinearity, we assessed the correlation between all pairs of independent variables and verified that no pair of variables included in the same regression model was highly correlated (i.e. $r > 0.40$). Due to a large number of missing values for CD4 cell count (30% of the sample), we used an indicator variable to create a category for missing values for this variable.

Secondary, exploratory analyses were also conducted to assess gender as a possible effect modifier. This analysis aimed to test the hypotheses that younger age may be a more important risk factor for STIs among women than men, and that the effects of certain behaviours on STI risk may also differ by gender.[20] Potential interactions between gender and four factors hypothesized to have differential effects on STI risk among women and men (age, any alcohol use before or during sexual activity, sex trade involvement and past year cocaine use) were evaluated.

All reported P values were two-tailed, and a P value of less than 0.05 was considered statistically significant. Analyses were performed using SAS software (version 9.1; SAS Institute, Cary, NC, USA).

RESULTS

As shown in Figure 1, 921 individuals were screened for eligibility. Of the 190 ineligible individuals, 110 did not meet the alcohol-related criteria and 134 did not meet the sex risk criteria. Seven hundred of the 731 eligible individuals (96%) agreed to participate. Among these, 682 had available STI results, and were included in the current analysis.

Demographic, health-related and behavioural characteristics of the study cohort are shown in Table 1. In general, the sample was young, 40% were women, and, reflecting study eligibility criteria, had a high prevalence of heavy alcohol use and unprotected sex.

The prevalence of any STI among the 682 participants was 12.8% (95% confidence interval [CI] 10.3, 15.3; Table 2). The prevalence appeared similar in women and men. Only 1.9% of all participants ($n = 13$) had more than one STI. Chlamydia was diagnosed among 40 participants (5.8%); it was more prevalent among men than women (7.3% of men versus 3.6% of women). Trichomoniasis was also common with 37 participants (5.4%) testing positive; prevalence was 8.2% among women and 3.4% among men. Fourteen participants (2.0%) had gonorrhoea and 13 (1.9%) met the case definition of untreated syphilis infection. About half of participants (47.7%) reported a past diagnosis of an STI, including syphilis, gonorrhoea, chlamydia, trichomoniasis, genital warts or herpes.

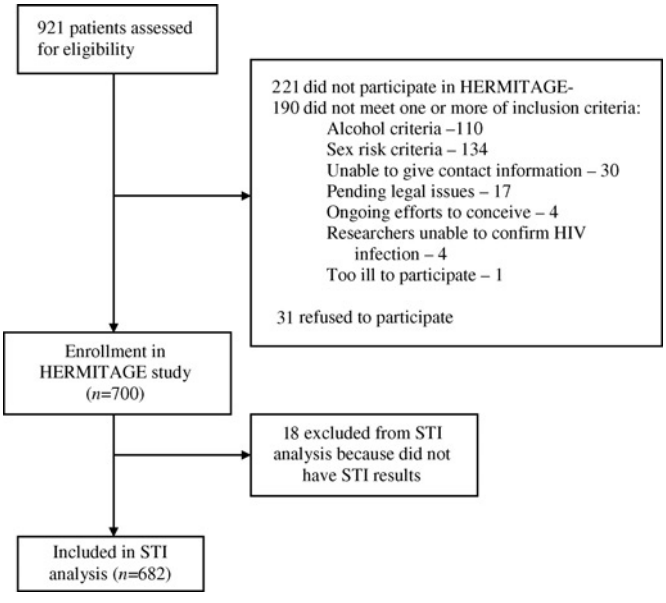

Figure 1 **Enrollment of participants in the HERMITAGE study and inclusion in the current analysis of sexually transmitted infection (STI) data**

Bivariate analyses

Based on the preliminary bivariate analyses, seven independent variables met criteria for entry into the initial multivariable model: the number of unprotected sexual encounters (odds ratio [OR] 0.61, 95% CI 0.34, 1.10 for the middle versus lowest tertile; OR 1.13, 95% CI 0.67, 1.91 for the highest versus lowest tertile); buying or selling sex (OR 1.87, 95% CI 1.08, 3.24); any history of STI (OR 1.49, 95% CI 0.95, 2.34); MSM (OR 2.82, 95% CI 0.86, 9.20); using drugs or alcohol before sex (OR 1.50, 95% CI 0.95, 2.37); using alcohol before sex (OR 1.53, 95% CI 0.98, 2.41); and past year cocaine use (OR 1.92, 95% CI 1.01, 3.62). Using drugs *or* alcohol before sex was not included in the multivariable model due to its potential collinearity with using alcohol before sex, and past IDU was not included due to its potential collinearity with past year heroin use. None of the other potential predictors described in the Methods section met criteria for inclusion in the multivariable model.

Final multivariable model

Using the model building approach outlined in the Methods, a final multivariable model was developed and is shown in Table 3. In this model, buying or selling sex was associated with a two-fold increased odds of having an STI (adjusted odds ratio [AOR] 2.00, 95% CI 1.13, 3.55). No other factors were significantly associated with testing positive for an STI, though there were notable, non-significant increases in the odds of an STI among those reporting a past STI (AOR 1.46, 95% CI 0.91, 2.35) and among MSM compared with men reporting sex with women only (AOR 2.72, 95% CI 0.78, 9.49).

In secondary, exploratory analyses, there was no statistically significant interaction between gender and any of the following variables: age, sex trade, cocaine use in the past year or alcohol use before or during sexual activity.

DISCUSSION

The prevalence of STIs in the HERMITAGE cohort of 682 HIV-infected heavy drinkers in Russia was 13%. This is comparable with what has been described in HIV-infected populations in other countries.[12] Many in this group reported past injecting drug use, which, consistent with the epidemiology of HIV in Russia, likely led to their HIV infection. However, sexual transmission of HIV is a growing concern in Russia,[2] and the substantial prevalence of STIs in this sexually active cohort indicates a likely role for such infections in facilitating HIV transmission to others.

Table 1 **Baseline characteristics of HIV-infected heavy drinkers with recent unprotected sex in St Petersburg**

Characteristic	*n* (%), total (*n* = 682)	*n* (%), any STI (*n* = 87)	*n* (%), no STI (*n* = 595)
Demographics

Tested positive for more than one STI	13 (1.9) (1.0–3.2)
Self report of lifetime STI	334 (47.7) (44.0–51.4)

*Gonorrhoea, chlamydia, trichomoniasis or syphilis

It is thus important to examine factors that may be associated with testing positive for an STI in this subgroup of HIV-infected Russians. In this study, the only variable that was significantly predictive of having an STI was buying or selling sex over the last three months, which doubled the odds of STI. The association between selling sex and STIs has been noted in many other studies, including several from Russia,[22–24] where sex work is an important risk factor for HIV itself.[23] However, there have been fewer data on the association between sex trade involvement and STIs from HIV-infected cohorts, a group whose risk behaviours may be different from those without HIV.[7,11] Also of note in the current study was the finding that despite the relationship between sex trade and STIs, there was no relationship between testing positive for an STI and either the number of sexual partners or the number of unprotected sexual encounters. Such a pattern has been observed in at least one other Russian study,[24] suggesting that other, unmeasured sex risk factors (for example, being part of a particular sexual network with a high prevalence of STIs) may help account for STI risk among those who buy and sell sex in Russia.

Table 3 **Characteristics associated with STI in the final multivariable model**

Characteristic	Adjusted OR (95% confidence interval)	*P* value
Age (years)		
18–27	Referent	0.78
28–31	0.95 (0.54, 1.67)	
32–57	0.84 (0.47, 1.50)	
Gender		
Male	0.88 (0.54, 1.43)*	0.60
Marital status		
Married or living with partner	0.92 (0.54, 1.43)	0.76
Number of unprotected sexual encounters† (tertiles)		
1–2	1.00	0.10
3–14	0.59 (0.32, 1.09)	
15–483	1.12 (0.64, 1.94)	
Bought or sold sex in past 3 months	2.00 (1.13, 3.55)	0.02
Past history of STI	1.46 (0.91, 2.35)	0.12
Men who have sex with men	2.72 (0.78, 9.49)‡	0.12

STI = sexually transmitted infection
*Odds ratio (OR) represents comparison of men who report sex with women only versus women
†Over the past three months
‡OR is comparison of men who report any sex with men versus men who report sex with women only, over the last three months

Despite the small number (14, 3.4%) of men who reported MSM, this variable nearly achieved statistical significance as a predictor of STI and had a large magnitude of association with an OR of 2.72. Particularly given that the number of MSM may be an underestimate due to underreporting of stigmatized behaviour in Russia,[25] the finding may be clinically important.

Several independent variables surprisingly did not appear to have strong associations with STIs, most notably age and gender. In many other studies, including some of HIV-infected cohorts, age under 25 years and female gender have been found to be strongly associated with STI.[7,10,23,24,26–28] The impact of both age and gender on overall STI rates in the current study could have been attenuated by the high-risk behaviour exhibited by both men and women who participated. In addition, given that some studies have shown particularly high rates of STIs among 15–19 year olds,[27] the fact that all participants were 18 and over may have lessened the particular effect of age as a predictor in this cohort. The expected effect of gender would also not be seen if the men in this study were involved in disproportionately high-risk sexual activity, such as MSM, that they underreported. In other words, if MSM (or another high-risk, potentially under-reported behaviour among men) was in reality more common than reflected in the data, residual confounding would prevent us from gauging the true impact of gender alone on STI risk in multivariable analysis.

Patterns of alcohol use and the number of unprotected sexual encounters were not significantly associated with having an STI. The study's selection criteria meant that all participants reported heavy drinking and at least one episode of unprotected sex over the last six months. In this context, it may be understandable that neither increasing severity of the alcohol-related problem nor an increasing number of unprotected sexual encounters over the last three months was associated with increased STI risk.

The study also found that neither users of particular drugs, nor those with drug dependence were more likely to have STIs, in contrast to findings from several past studies in both HIV-infected and uninfected populations in the USA in which drug use, particularly marijuana and stimulant use, were risk factors for STI.[7,11,29] This raised the possibility that drug use had a differential effect on STI risk among men compared with women, as was seen in a recent study from India in which alcohol was more strongly associated with condom non-use among men (perhaps because men had more control than women over the decision to use condoms).[30] A secondary analysis was conducted in the current study, to investigate whether a similar process could have occurred for drug use and STI risk in the HERMITAGE cohort. There was, however, no significant interaction seen between gender and cocaine use or alcohol use before sex.

Future studies should investigate the prevalence of STIs in other groups of HIV-infected Russians. Should the current findings be replicated, the data may have implications for STI screening practices in Russia, where current guidelines (in contrast to those issued by the United States Center for Disease Control and Prevention)[31] recommend that HIV-infected patients be screened for syphilis alone. HIV-infected Russians typically receive this screening from their HIV providers, while public STI clinics are available for treatment of symptomatic STIs. Given that STIs are often asymptomatic, many cases likely go untreated with this approach. Our analysis suggests furthermore that screening for STIs only among HIV-infected patients who report certain behavioural risk factors may also be insufficient, since few factors predicted STI in the current cohort, and those factors that were associated with STI (sex trade and perhaps MSM) are stigmatized behaviours that patients may not consistently report to providers. Future research could thus help clarify whether screening all HIV-infected Russians is indeed the optimal strategy, as our data suggest it to be, and whether screening is needed for all four of these treatable STIs or a subset of them.

Our study has several limitations. Rectal specimens, as opposed to urine samples alone, could have provided a more complete assessment for gonorrhoea, chlamydia and trichomoniasis. The lower prevalence of chlamydia among women compared with men additionally raises the possibility of reduced sensitivity of the urine assay among women. Unfortunately, the available peer-reviewed report on the performance characteristics of the Russian chlamydia assay lists a sensitivity for urine specimens (92.3%) that was determined from male specimens alone; only cervical and vaginal specimens were examined from women (sensitivity 87.2%) and these were not possible to obtain in the context of HERMITAGE.[16] Finally, cohort eligibility criteria limited our ability to discern a relationship between alcohol and STIs, or condom use and STIs, and may also limit the study's generalizability to other HIV-infected Russians. However, these behaviours appear to be common among HIV-infected people in Russia; of the 921 HIV-infected patients who were screened for the study, only 110 did not meet the alcohol criteria and 134 failed to meet the sex risk criteria.

In summary, STIs (gonorrhoea, chlamydia, trichomoniasis and syphilis) were common among HIV-infected Russian drinkers who reported recent unprotected sex. Multivariable analyses identified only sex trade involvement as a significant predictor of STI. Future research should investigate the prevalence of these four common, treatable STIs in a broader sample of HIV-infected Russians, to determine whether routine screening for all of these STIs, rather than syphilis

alone, in this population should be a component of HIV prevention efforts in Russia.

ACKNOWLEDGEMENTS

CAP, DL, SEW, AYW, AR, EK and JHS conceived the research question and designed the analysis. JHS obtained funding for the parent HERMITAGE study. DMC and SMC conducted the statistical analysis. All authors participated in interpretation of data. All authors participated in preparation of the manuscript and have approved the final draft for submission. The authors wish to acknowledge the participants in the HERMITAGE study, as well as the clinical and administrative study staff, particularly Elena Blokhina, Victoria Churchill and the Data Coordinating Center at Boston University. In addition, we are grateful to Aseem Mehta for assistance with the literature review, and Guillermo Madico for advice on STI laboratory testing. Support for this work came from the National Institute of Alcohol Abuse and Alcoholism (NIAAA; R01AA016059 and K24-AA015674), the National Institute of Drug Abuse (NIDA; R25DA13582) and the National Institute of Allergy and Infectious Diseases (NIAID; T32 AI052074-06A2).

Adherence to Conservative Management Recommendations for Abnormal Pap Test Results in Adolescents

Rebecca B. Perkins, MD, MSc, Jennifer R. Jorgensen, MD, MPH, Molly E. McCoy, MPH, Sharon M. Bak, MPH, Tracy A. Battaglia, MD, MPH, and Karen M. Freund, MD, MPH

OBJECTIVE: To investigate whether the 2006 American Society for Colposcopy and Cervical Pathology guidelines for conservative management of minimally abnormal Pap test results (atypical squamous cells of undetermined significance, human papillomavirus–positive, and low-grade squamous intraepithelial lesions) and moderate dysplasia (cervical intraepithelial neoplasia 2) in adolescents 1) resulted in fewer colposcopies and loop electrosurgical excision procedures (LEEPs) in adolescents or 2) resulted in unintended treatment changes in older age groups.

METHODS: We analyzed data from 1,806 women aged 18 years and older attending one of six community health centers who were diagnosed with abnormal Pap test results between January 1, 2004, and December 31, 2008. We used multivariable logistic regression to examine treatment differences in women with minimally abnormal Pap test results before and after guideline changes. Variables included date of abnormality, site of care, race or ethnicity, language, and insurance type. We used Fisher exact tests to examine rates of LEEP in patients with moderate dysplasia before and after guideline publication.

RESULTS: Among 206 women aged 18–20 years, rates of colposcopy after a minimally abnormal Pap test result decreased from 78% (n=102) to 45% (n=34) after guideline changes ($P<.001$). Colposcopy among women over age 21 (n=1,542) remained unchanged (greater than 90%). Multivariable logistic regression indicated that both date of abnormality and site of care were associated with colposcopy referral. After guideline changes, management of moderate dysplasia with LEEP in women aged 18–23 decreased from 55% to 18% ($P=.04$); rates remained stable in women ages 24 and older (70% compared with 74%; $P=.72$).

CONCLUSION: Health care providers quickly adopted new conservative management guidelines for low-income, minority adolescents, which may reduce preterm deliveries in these high-risk populations.

LEVEL OF EVIDENCE: II

Although persistent human papillomavirus (HPV) infection causes nearly all cases of cervical dysplasia and cervical cancer,[1] many mild and moderate dysplasias resolve without treatment in adolescent women.[2–4] Before 2007, excision of moderate dysplasia was recommended for all women.[5] However, excision procedures such as loop electrosurgical excision procedures (LEEPs) have been linked to adverse obstetric outcomes including preterm delivery and preterm premature rupture of membranes.[6,7] These risks may be compounded in low-income and minority women, who have higher rates of both HPV infection and preterm delivery than the general population.[8–10] In light of the evidence showing high rates of regression of cervical dysplasia in adolescents and increased risks of adverse obstetric outcomes after

ISSN: 0029-7844/12

LEEPs, the American Society for Colposcopy and Cervical Pathology published new clinical practice guidelines in 2006 recommending repeated Pap testing instead of colposcopy for females younger than 21 years old with minimally abnormal Pap test results, and repeated colposcopy instead of LEEPs for management of moderate dysplasia.[11]

Previous research indicated poor health care provider adherence to published guidelines in the area of cervical cancer screening.[12,13,15,16] Using a database that captured the follow-up of abnormal Pap test results in women aged 18 and older in six independent community health centers between 2004 and 2008, we investigated whether conservative management recommendations in the 2006 American Society of Colposcopy and Cervical Pathology consensus guidelines[11,14] resulted in less aggressive management of minimally abnormal Pap test results and moderate dysplasia in adolescent women, and whether the guidelines had unintended treatment consequences in older age groups.

MATERIALS AND METHODS

Our study is a secondary data analysis of the Boston Patient Navigation Research Program. The Patient Navigation Research Program was a multi-site national trial that evaluated the effects of patient navigation, defined as providing support and guidance to vulnerable persons with cancer or abnormal cancer screening tests, on timeliness and quality of care received. The Boston Patient Navigation Research Program is a community-based intervention implemented at six of Boston's neighborhood community health centers, which serve a population of approximately 50,000 low-income and minority women ages 18 and older.[17,18] Eligible participants for the cervical cancer screening arm of the Boston Patient Navigation Research Program, which constituted the total patient pool for the current study, included nonpregnant women 18 years of age and older with a cervical cancer screening abnormality at one of the participating community health centers. Patient charts were reviewed up until the point at which participants reached a definitive diagnosis of cancer or noncancer or were lost to follow-up. Patient and clinic data were collected from electronic medical records between January 1, 2004, and December 31, 2008. New recommendations regarding the management of abnormal Pap test results were published in October 2007, midway through the Boston Patient Navigator Research program study period, creating the opportunity for a natural experiment comparing management before new guidelines (January 1, 2004, through October 31, 2007) with management after the publication of new guidelines (November 1, 2007, through January 1, 2009). This study was approved by the Boston University School of Medicine Institutional Review Board.

Patient race and ethnicity data were collected at the time of clinical registration. For those with missing race and ethnicity, race was imputed using language and birth country using a cross-tab table in SAS. Five race-ethnicity mutually exclusive categories were used: white, black, Hispanic, Asian, and other. Patient age was collected from the medical record at the time of abnormal Pap test result and reported in years. Patient language was collected at the time of clinical registration. For those missing language, these data were pulled from the text of the participant's medical records. Insurance status was collected at the time of registration. Three insurance categories were used in analyses: public, private, and uninsured. The index abnormality for each patient was defined as the abnormal cervical cancer screening test that made the patient eligible for the study, and it included minimally abnormal Pap test results (atypical squamous cells of undetermined significance [ASC-US]) positive for HPV infection: ASC-US HPV+ and low-grade squamous intraepithelial lesions (LSIL) as well as high-grade squamous intraepithelial lesions. Data were collected during two distinct time periods: from January 1, 2004, through December 31, 2005, and from January 1, 2007, through December 31, 2008. The first time period represents baseline data collection and the second represents the intervention portion of the patient navigation study. The patient navigation intervention did not seek to address whether or not health care providers adhered to new guidelines.

We examined 1) whether treatment of women aged 18–20 years with minimally abnormal Pap test results (ASC-US HPV+ and LSIL) changed in response to new guidelines, specifically whether they were more likely to receive repeat Pap tests instead of colposcopy after guideline changes (defined as before or after October 31, 2007); 2) whether treatment of women ages 21 and older with minimally abnormal Pap test results (ASC-US HPV+ and LSIL) was inadvertently affected by the guidelines, specifically whether they were also more likely to be treated with repeated Pap test instead of colposcopy; 3) whether treatment of women ages 18–20 years with moderate dysplasia (cervical intraepithelial neoplasia [CIN] grade 2) changed in response to new guidelines, specifically whether they were more likely to be treated with repeated colposcopy instead of LEEPs;

and 4) whether treatment of women ages 21 and older with moderate dysplasia (CIN 2) was inadvertently affected by new guidelines, specifically whether they were also more likely to be treated with repeated colposcopy instead of LEEPs. To examine the outcomes related to the management of minimally abnormal Pap test results (ASC-US HPV+ and LSIL), patients were stratified by age into three groups: age 18–20, age 21–25, and age 26 and older. Within each age strata, we first performed univariable analyses to determine the relationships between sociodemographic and clinic characteristics of patients and their receipt of repeated Pap test or colposcopy. Because of the clinical site differences suggested in univariable analyses, we used multivariable logistic regression to examine adjusted effects of the guidelines, patient characteristics, and clinic differences on study outcome. All variables were considered for inclusion in multivariable models. In addition, generalized estimating equation analysis was performed to estimate the effect of patient-level characteristics on adherence to guideline change while controlling for the clustering effect of clinical site of care.

To assess the outcomes related to the management of moderate dysplasia (CIN 2), we analyzed differences in the completion of LEEPs before and after guideline changes using the Fisher exact and χ^2 tests. Although guidelines recommend repeated colposcopy for women with moderate dysplasia (CIN 2) younger than age 21 and LEEPs for women ages 21 and older, literature on regression of lesions includes women up through age 25,[6,7] and some health care providers may choose to defer LEEPs in nulliparous patients older than age 21. Therefore, we performed separate analyses on women ages 18–20, 21–23, 24–25, and 26 years and older. We found similar changes in the rates of LEEPs before and after new guidelines in the 18–20 and 21–23 age groups but different treatment patterns in women older than age 23. Because of similar management outcomes, women ages 18–23 were compared with women ages 24 and older in the final analysis. Analyses were conducted with SAS 9.1.

RESULTS

A total of 1,806 women were included in the analysis; 264 (15%) were aged 18–20 years, and 1,542 aged 21 and older. Demographic characteristics before and after guideline changes were similar with the exception of a larger proportion of 18- to 20-year-old patients before the guideline changes (15% compared with 13%) and a larger proportion of patients from smaller health centers before the guideline changes (17% compared with 7% from Health Center F) (Table 1).

LSIL, low-grade squamous intraepithelial lesions; HSIL, high-grade squamous intraepithelial lesions.
Data are n (%) unless otherwise specified.
* Some observed differences may be due to differences in data collection: data collected in 2004–2005 (baseline and feasibility study) included all patients with high-grade lesions and a random selection of patients with low-grade lesions, and data from 2007–2008 (intervention) included all patients with abnormal Pap test results.

Analysis of the management of minimally abnormal Pap test results (ASC-US HPV+ and LSIL) in women younger than age 21 revealed that most health care providers adopted the new guidelines. Before guideline changes, 78% of young women with minimally abnormal Pap test results (ASC-US HPV+ and LSIL) underwent colposcopy, compared with 45% after guideline changes. Multivariable logistic regression demonstrated a 10-fold increase in the likelihood of receiving a repeated Pap test instead of colposcopy after guideline changes ($P<.001$) (see Table 2). Other factors associated with management of minimally abnormal Pap test results (ASC-US HPV+ and LSIL) in women ages 18–20 included

LSIL, low-grade squamous intraepithelial lesions; ASC-US, atypical squamous cells of undetermined significance; HPV, human papillomavirus.

* Forty-four patients were excluded from analysis owing to missing diagnostic data (eg, lost to follow-up), and 14 were excluded because their index Pap test indicated high-grade squamous intraepithelial lesions.

† All variables are included in multivariable analysis: date of abnormal finding, site of care, insurance status, language, and race or ethnicity.

clinical site, with patients attending Health Centers A and D being less likely to receive a repeated Pap test than those attending Health Center B. Women who spoke Spanish or were of Latina ethnicity were less likely to receive repeated Pap tests in univariable analyses but not in multivariable analyses; 50% of Latina patients attended health centers with lower guideline adherence (A and D). Assignment to the control or intervention arm of the patient navigation study was not associated with guideline adherence. The clustering analysis using generalized estimating equations controlling for clinical site of care showed similar results, with a significant increase in likelihood of receiving a Pap test instead of colposcopy after guideline change (odds ratio 6.09, 95% confidence interval 2.72–13.65). No patient characteristics were found to have an effect on receiving a Pap test before or after guideline change in the analysis using generalized estimating equations.

We performed analyses of women ages 21–25 (n=532) and 26 and older (n=702) with the goal of estimating whether guidelines had unintended effects among adult women, and we found no difference in the management of minimally abnormal Pap test results (ASC-US HPV+ and LSIL) before and after guideline changes. Among 21- to 25-year-olds, rates of colposcopy were 96% and 93% (*P*=.22) before and after guidelines; rates for women aged 26 and older were 95% and 95%, respectively (*P*=.88). Consistent with these stable, high rates of colposcopy, no demo-

graphic or clinical factors significantly predicted management with respect to date of guideline publication in multivariable analyses of these age groups.

To determine the effects of guideline changes on the management of moderate dysplasia (CIN 2) in young women, we examined the management of all cases of moderate dysplasia (CIN 2) in our dataset (n=128). Among 18–20 year olds, 6 of 16 (38%) underwent LEEPs when the initial abnormal Pap test result occurred before guideline changes, compared with 0 of 3 after guideline changes (P=.52). Among 21- to 23-year-olds, 17 of 26 (65%) underwent LEEPs when the initial abnormal Pap test result occurred before guideline change, compared with 2 of 8 (25%) after guideline changes (P=.10). No change was seen in women ages 24 and older: 31 of 44 (70%) underwent LEEPs before guideline changes compared with 23 of 31 (74%) after guideline changes (P=.72). Because women aged 18–20 and 21–23 were treated similarly, we combined these age groups in our analysis of LEEP completion. Fisher exact analysis of women aged 18–23 revealed a significant decrease in the number of LEEPs performed, from 55% before guideline changes to 18% after guideline changes (P=.04) (Fig. 1).

DISCUSSION

We used data from six community health centers serving more than 50,000 low-income and minority women to determine health care provider adherence to the 2006 American Society for Colposcopy and Cervical Pathology guidelines for conservative management of minimally abnormal Pap test results (ASC-US HPV+ and LSIL) and moderate dysplasia (CIN 2) in young women. We observed an overall decrease in the performance of colposcopies in 18- to 20-year-old women with minimally abnormal Pap test results and reduced numbers of excision procedures in 18- to 23-year-old women with moderate dysplasia after publication of the guidelines. These findings show that the new guidelines were sufficient to change clinical practices among this cohort of health care providers serving an urban population of low-income and minority women.

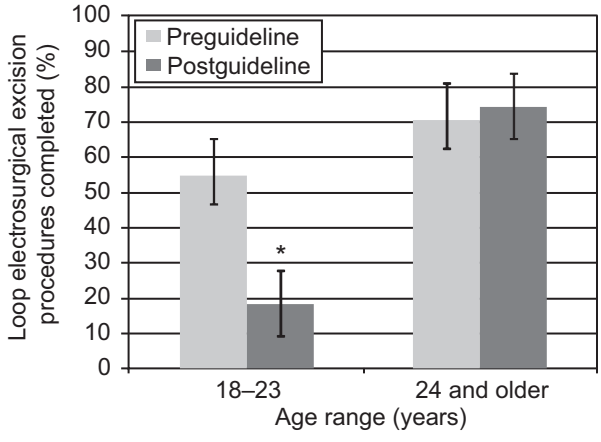

Fig. 1. The rate of loop electrosurgical excision procedures among women aged 18–23 years with moderate dysplasia (cervical intraepithelial neoplasia 2) decreased after guideline changes; no decrease was seen among older women. *P=.04.

Perkins. Adherence to Pap Test Guidelines. Obstet Gynecol 2012.

Existing literature highlights reasons why these guidelines may have been rapidly adopted. First, clinical practice guidelines that are based on clear scientific evidence are adhered to more frequently by health care providers,[19,20] and a robust literature accumulating over more than a decade indicated both high rates of regression of HPV infection and moderate dysplasia (CIN 2) in young women[5–7] as well as clear obstetric harms from treatment of cervical dysplasia with excision procedures.[9,21] These findings were highlighted in medical journals and at national meetings including those of the American Society of Colposcopy and Cervical Pathology and the American Congress of Obstetricians and Gynecologists before publication of the final consensus guidelines, thus health care providers may have been aware of the science underlying the guideline changes. In fact, our data indicated that some adolescents received repeated Pap tests for minimally abnormal Pap test results (ASC-US HPV+ and LSIL) and colposcopy for moderate dysplasia (CIN 2) before publication of guidelines. Another reason for rapid adoption of guidelines may reflect the medical mantra "first, do no harm." To avoid harming patients, many health care providers rapidly stop practices that are associated with negative outcomes, a prominent example being the dramatic decrease in use of postmenopausal hormone therapy after publication of the results of the Women's Health Initiative.[22,23] Therefore, clinicians aware of the obstetric complications associated with excision procedures (LEEP and cold knife cone) may have been eager to adopt guidelines published with the intent of avoiding these potentially harmful procedures in young women.

Multivariable analysis revealed that site of care affected the management of minimally abnormal Pap test results (ASC-US HPV+ and LSIL), with women attending Health Centers A and D being more likely to receive colposcopy instead of repeated Pap testing than were women at Health Center B. Differences in

practice have been noted at the regional, local, and individual health care provider level,[24–26] and a combination of individual and clinical systems factors may have played a role in guideline adoption in this case. Although the design of this study did not specifically examine system factors within health centers or individual health care provider factors that may have contributed to early or late adoption of guidelines, individual health care provider factors seem to be most prominent based on the workflow related to abnormal Pap test result management in these clinical sites. The six clinical sites encompassed 17 separate practices (pediatrics, family medicine, and internal medicine) in which 108 health care providers provided primary care including Pap testing during the study period. In 16 of these practices, abnormal Pap test results were routed directly back to the health care provider who ordered the Pap test, and that individual made the recommendation for colposcopy or repeated Pap test. Only one practice had a referral clinician who triaged all abnormal results. When patients with abnormal Pap test results were diagnosed with moderate dysplasia (CIN 2) via colposcopic biopsy, the decision to perform a repeated colposcopy or a LEEP was made on an individual basis by the health care provider who had taken the biopsy.

This study has several limitations related to the use of retrospective data from electronic medical records. We accessed data related to the health care providers' documentation in the patient's medical chart and procedures ordered, but we do not know the extent of health care provider–patient discussion around management options, nor the degree to which patient preference influenced therapeutic choices. We also did not collect data on patient characteristics that may have influenced the decision to perform an invasive procedure, such as a history of abnormal Pap test results, human immunodeficiency infection, or previous noncompliance with recommended follow-up. In addition, the influence of clinical site on the management of abnormal Pap test results could have reflected health center policy, health care provider education, or provider or patient attitudes, factors that could be explored in future research.

New guidelines for conservative management of minimally abnormal Pap test results and moderate cervical dysplasia in adolescents were quickly adopted among this group of community health centers serving low-income, urban populations. If this trend is observed nationwide, the resulting decrease in LEEPs may reduce racial disparities in preterm deliveries in the future.

Parental Intermittent Claudication as Risk Factor for Claudication in Adults

Scott G. Prushik, MD[a,†], Alik Farber, MD[b,†], Philimon Gona, PhD[c,d], Peter Shrader, BA[c,e], Michael J. Pencina, PhD[c,d], Ralph B. D'Agostino, Sr, PhD[c,d], and Joanne M. Murabito, MD, ScM[d,f,*]

Little is known about the familial aggregation of intermittent claudication (IC). Our objective was to examine whether parental IC increased the risk of IC in adult offspring, independent of the established cardiovascular risk factors. We evaluated the Offspring Cohort Participants of the Framingham Heart Study who were ≥30 years old, cardiovascular disease free, and had both parents enrolled in the Framingham Heart Study (n = 2,970 unique participants, 53% women). Pooled proportional hazards regression analysis was used to examine whether the 12-year risk of incident IC in offspring participants was associated with parental IC, adjusting for age, gender, diabetes, smoking, systolic blood pressure, total cholesterol, high-density lipoprotein cholesterol, and antihypertensive and lipid treatment. Of the 909 person-examinations in the parental IC history group and 5,397 person-examinations in the no-parental IC history group, there were 101 incident IC events (29 with parental IC history and 72 without a parental IC history) during follow-up. The age- and gender-adjusted 12-year cumulative incidence rate per 1,000 person-years was 5.08 (95% confidence interval [CI] 2.74 to 7.33) and 2.34 (95% CI 1.46 to 3.19) in participants with and without a parental IC history. A parental history of IC significantly increased the risk of incident IC in the offspring (multivariable adjusted hazard ratio 1.81, 95% CI 1.14 to 2.88). The hazard ratio was unchanged, with an adjustment for the occurrence of cardiovascular disease (hazard ratio 1.83, 95% CI 1.15 to 2.91). In conclusion, IC in parents increases the risk of IC in adult offspring, independent of the established risk factors. These data suggest a genetic component of peripheral artery disease and support future research into genetic causes. **(Am J Cardiol 2012;109:736–741)**

A National Institutes of Health consensus statement has described family history as vital to patient care, because it can uncover information about factors that contribute to the risk of developing common diseases, such as diabetes mellitus, stroke, cancer, and heart disease.[1] The occurrence of cardiovascular disease (CVD) in a parent or sibling confers an increased risk of CVD in middle-age adults, distinct from the traditional risk factors.[2,3] The parental occurrence of stroke is associated with a threefold increase in the risk of offspring stroke.[4] However, little is known about the familial aggregation of peripheral artery disease (PAD). The subjects whose siblings were diagnosed with premature PAD were shown to have an almost threefold increase in PAD.[5] Finally, the early onset of symptomatic CVD is more common in first-degree relatives of patients with premature PAD than in the relatives of healthy persons.[6] The latter 2 studies were limited by the small sample size, an examination of PAD prevalence rather than incidence, and an inability to quantify the degree of familial aggregation of PAD that was independent of the established risk factors. The Framingham Heart Study (FHS) affords the unique opportunity to study intermittent claudication (IC) across 2 generations using prospectively collected data in a large community-based sample. The present study was undertaken to test the hypothesis that parental IC confers an increased risk of IC in adult offspring, independent of established CVD risk factors.

Methods

The FHS is a prospective epidemiologic cohort study that was established in 1948 when 5,209 residents of Framingham, Massachusetts, aged 28 to 62 years, were enrolled. The members of the original cohort have undergone examinations every 2 years. In 1971, the offspring of the original cohort (n = 3,548) and the spouses of the offspring (n = 1,576), aged 5 to 70 years, were enrolled into the Framingham Offspring Study.[7] The offspring cohort has undergone an examination about every 4 to 8 years. All participants provided informed consent, and the institutional

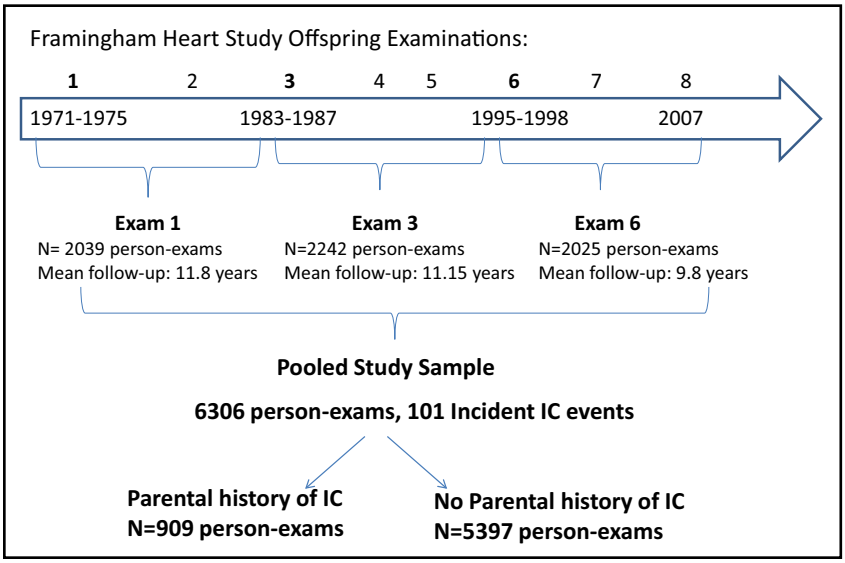

Figure 1. Study sample. Data from 3 baseline examinations, each with 12 years of follow-up were pooled.

review board of Boston University School of Medicine approved all study protocols.

The data from 3 offspring examinations (Figure 1), each with 12 years of follow-up, were pooled: offspring examination 1 (1971 to 1975), 3 (1983 to 1987), and 6 (1995 to 1998). The follow-up for the final examination ended in December 2007. Given the structure of the follow-up examinations in the offspring, we chose to study the 12-year incidence of IC to have a comparable length of nonoverlapping follow-up after each baseline examination. All offspring participants who were ≥30 years old at any of the 3 baseline examinations were eligible if both parents were enrolled in the original cohort and if the Offspring participant was free of CVD and IC at the examination. A total of 2,970 unique subjects (1,405 men) were included in our final study sample, including 346 with a parental history of IC and 2,624 with both parents free of IC. Parental IC was defined as the occurrence of IC in a parent before the offspring examination. Both parental IC events and incident IC events occurring in the offspring were adjudicated by a panel of 3 senior investigators using the same previously established criteria. The investigators were unaware of the parental IC status. All available information was used to determine the presence of IC, including the standardized physician-administered IC questionnaire that was a part of each routine FHS research clinic visit, any available records from the office visits with the participants' personal healthcare provider, and the hospital records pertaining to PAD.[8] The standardized physician-administered questionnaire asked about the presence of calf and leg discomfort brought on by exertion, the relation of the discomfort to the rapidity of walking or uphill walking, and whether the symptoms were relieved with rest. The final diagnosis of IC was determined from the clinical history only, without confirmatory testing. At the more contemporary FHS examinations, the participants were queried about lower extremity revascularization procedures and all self-reports were validated from the medical records.

At each offspring examination, the risk factors were directly measured and the occurrence of CVD was updated. Blood pressure at rest was measured twice. Current smoking was defined as smoking ≥1 cigarettes/day in the year preceding the examination. Blood was drawn, with the patient in the fasting state, for total cholesterol, high-density lipoprotein cholesterol, and triglyceride measurements. Diabetes was defined as a fasting glucose level of ≥126 mg/dl (7.0 mmol/L) or the use of insulin or oral hypoglycemic agents. CVD was defined as any of the following events: myocardial infarction, coronary insufficiency, angina pectoris, stroke, transient ischemic attack, congestive heart failure, or cardiovascular death.

The follow-up time within each 12-year period was calculated as the interval from each baseline visit date until the diagnosis date of IC for those participants who developed the disease and censored at the earliest of the date of the last examination, date of death, or end of the 12-year period for participants who did not develop the disease. The age- and gender-adjusted incidence rates and 95% confidence intervals (CIs) per 1,000 person-years were calculated in each parental IC history group by dividing the number of IC events observed by the total person-years. The Kaplan-Meier curves and the log-rank test were used to plot and compare the cumulative incidence rates. Pooled proportional hazards regression analyses were used to examine whether the 12-year risk of incident IC in offspring was associated with parental IC. This method of pooling person-examinations provides estimates of the effect similar to a time-dependent Cox proportional hazards model.[9] Furthermore, this method allowed us to update the risk factors and parental IC at each examination. The hazard ratios (HRs) and 95% CIs were calculated with the reference group consisting of participants with no parental IC before the examination. The covariates used in the multivariable model included age, gender, diabetes, current smoking, systolic blood pressure, antihypertensive treatment, total cholesterol, high-density lipoprotein cholesterol, and cholesterol lowering treatment. In the secondary analyses, we adjusted for the occurrence of CVD in the Offspring par-

Table 1
Baseline characteristics by parental history of intermittent claudication (IC)

Variable	Parental History of IC*		p Value
	No (n = 5,397 Person-Examinations)	Yes (n = 909 Person-Examinations)	
Age (years)	47.6 ± 11	49.9 ± 10.5	<0.0001
Women	2,927 (54%)	466 (51%)	0.10
Current smoker	1,501 (28%)	276 (30%)	0.12
Diabetes mellitus	202 (4%)	62 (7%)	<0.0001
Systolic blood pressure (mm Hg)	123 ± 17	126 ± 17	<0.0001

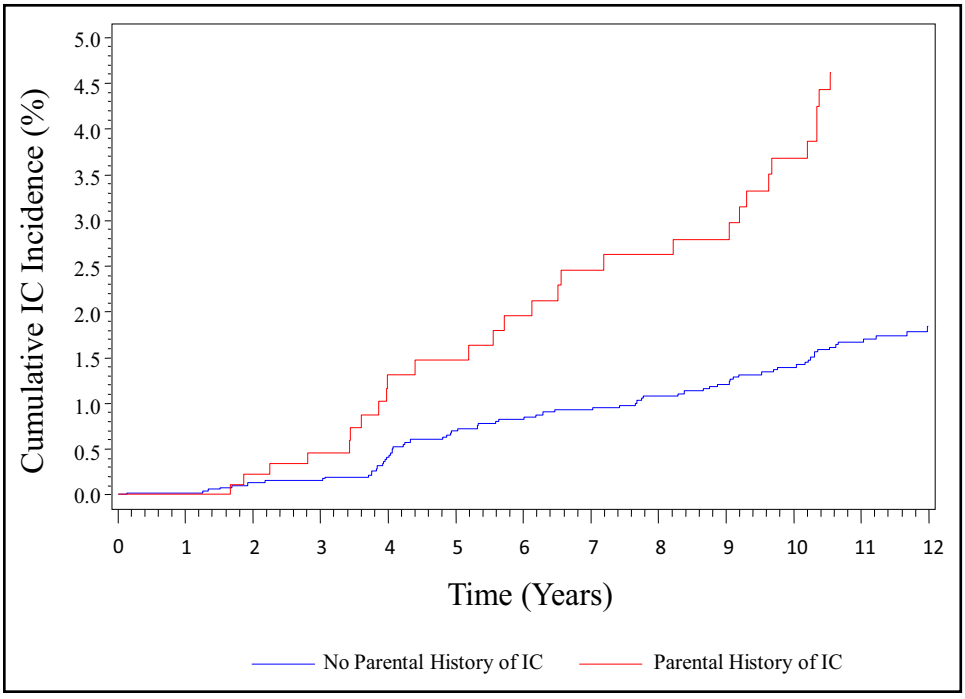

Figure 2. Age- and gender-adjusted cumulative incidence per 1,000 person-years of intermittent claudication.

ticipants using 2 approaches. First, we used Cox models in which CVD was entered as a time-dependent covariate. Next, the follow-up time was censored when an Offspring participant developed any CVD event to account for the fact that CVD increases the risk of IC. To assess the incremental predictive utility of parental IC history associated with incident IC in the offspring, we calculated the c-statistic for the model with clinical covariates alone and the full model with clinical covariates and parental IC history.[10,11] We assessed the model calibration (i.e., concordance of observed risk and that predicted by the model with parental IC history) by calculating the Hosmer-Lemeshow Chi-squared statistic for the Cox models.[10,11] To evaluate whether the inclusion of parental IC history improved the risk classification of participants, we calculated the enhanced "net reclassification improvement" (NRI) using an extension to survival analysis that uses Kaplan-Meier estimates of event probabilities at 12 years.[11] We used 12-year IC risk thresholds of <2%, 2% to 5%, and >5% for the NRI index. The NRI is used to assess how well a new marker "reclassifies" patients from 1 risk category to another. Because no categories for the absolute risk of IC have been previously established, we also assessed the "category-less" NRI, which assesses any upward or downward reclassification. Values >0 correspond to improved reclassification.[12] We performed a secondary analysis defining the incident events in the Offspring as IC and or lower extremity revascularization. All statistical analyses were performed using SAS statistical software, version 9 (SAS

Table 2
Twelve-year risk of intermittent claudication (IC) by parental occurrence of intermittent claudication (IC)

Model	HR	95% CI	p Value
Age and gender adjusted	2.29	1.49–3.54	0.0002
Multivariable adjusted*	1.81	1.14–2.88	0.01
Multivariable plus cardiovascular disease (time-dependent)	1.83	1.15–2.91	0.01
Multivariable plus censor for interim cardiovascular disease	1.92	1.16–3.19	0.01

* Multivariable model adjusted for following covariates: age, gender, diabetes, current cigarette smoking, systolic blood pressure, antihypertensive treatment, total cholesterol, high-density lipoprotein cholesterol, and lipid-lowering treatment.

Institute, Cary, North Carolina). Statistical significance was defined as a 2-tailed p value <0.05.

Results

The baseline characteristics of the offspring study sample are listed in Table 1. The group of participants with parental history of IC was older (mean age 49.9 vs 47.6 years, $p<0.0001$) and, with the exception of current smoking, had significantly greater risk factor levels compared to the group of participants without a parental history of IC. During the follow-up period, 101 incident IC events (29 in participants with a parental history of IC and 72 in participants with no parental history of IC) occurred. The age- and gender-adjusted 12-year cumulative incidence rate per 1,000 person-years was 5.08 (95% CI 2.74 to 7.33) in participants with a parental history of IC and 2.34 (95% CI 1.46 to 3.19) in participants with no parental history of IC (log-rank test, $p<0.0001$; Figure 2). Parental IC was associated with a significantly increased risk of incident IC in offspring (age- and gender-adjusted HR 2.29). The association was modestly attenuated but remained significant after adjustment for traditional risk factors (multivariable-adjusted HR 1.81, 95% CI 1.14 to 2.88; Table 2). The association was unchanged after additional adjustment for interim CVD and the magnitude and significance of the effect of parental IC persisted in the analysis in which the follow-up time was censored when the offspring participant developed an incident CVD event (Table 2). The addition of parental IC history to a multivariable model incorporating the baseline covariates increased the already high c-statistic from 0.831 (95% CI 0.794 to 0.868) to 0.837 (95% CI 0.801 to 0.873). The 2 c-statistics were not significantly different statistically ($p = 0.22$). The model with parental IC history had excellent calibration (Hosmer-Lemeshow Chi-squared 14.07; $p = 0.20$). The category-based NRI was modest (9.3%, 95% CI 1.9% to 17.3%) and the category-free NRI was 34.5% (95% CI 15.5% to 55.6%). The NRI estimates remained essentially unchanged, with adjustment for the occurrence of CVD entered as a time-dependent covariate or in a model in which the follow-up time was censored when a participant developed any CVD event. The association between parental IC and incident PAD, defined as IC and/or lower extremity revascularization ($n = 114$ events), was very similar to the primary analysis (multivariable-adjusted HR 1.76, 95% CI 1.14 to 2.72; additional adjustment for CVD as a time-dependent covariate [HR 1.77, 95% CI 1.15 to 2.73] and censoring at the first occurrence of CVD [HR 1.84, 95% CI 1.13 to 2.97] did not substantively change the association).

Discussion

In our community-based sample, parental IC confers a nearly twofold increased risk of IC in adult offspring even after accounting for traditional risk factors and the interim occurrence of CVD. Parental history of IC is quite powerful in predicting IC in adult offspring; however, the small improvement in the c-statistic and category-based NRI suggested a modestly improved prediction of offspring IC beyond that of the established risk factors. Our results suggest the presence of a genetic predisposition to IC. However, in addition to the genetic factors, environmental and lifestyle factors shared within families can contribute to the susceptibility to common diseases.[13] A person's family history provides a readily accessible and important clinical tool to gain insight into a person's risk of developing disease, including PAD. Knowledge of one's family history has the potential to motivate positive lifestyle changes, enhance individual empowerment, and influence clinical decisions with respect to preventative interventions.[1] This might be especially important for PAD, a disease that is often undetected and undertreated by clinicians[14] and underappreciated by the lay public for its association with the risk of myocardial infarction, stroke, and death.[15]

Little is known concerning the genetic determinants of PAD, but family aggregation and heritability estimates suggest a significant genetic contribution.[16,17] Recently, Zintzaras and Zdoukopoulos[18] created a publically available database that catalogs the genetic association studies of PAD. However, to date, the genetic associations for PAD remain inconclusive, with no strongly replicated results.[19] The genetic susceptibility to PAD and CVD is likely conferred by multiple genes interacting with a variety of environmental factors. Although PAD might share some genetic variants with CVD, likely a set of genetic variants exists that are unique to PAD, given the phenotypic diversity across the vascular system.[19]

Genome-wide association studies have identified a strongly replicated association between variants on chromosome 9p21 and myocardial infarction and coronary artery disease.[20] The chromosome 9p21 locus appears to play a broad role in arterial disease, because it is also associated with atherosclerotic stroke,[21] vascular stiffness,[22] and cerebral and abdominal aortic aneurysm.[23,24] The chromosome 9p21 locus was associated with clinically diagnosed PAD; however, the relation was no longer present when the coronary artery disease cases were removed from the sample.[24] Recently, this locus was reported to be associated with a greater prevalence of PAD and a lower mean arterial brachial index level in older adults from 3 population-based samples that was independent of risk factors and persisted even after removal of those with myocardial infarction.[25] The genome-wide association approach successfully identified genetic variants on chromosome 15q24 for nicotine dependence that conferred the risk of PAD.[26] Thus, the

genetic variants identified appeared to influence the risk of PAD through shared biologic mechanisms for CVD and smoking-related behaviors. Additionally, in a recent study of 1,292 patients with abdominal aortic aneurysms, the A allele of rs7025486 on chromosome 9q33 was associated with abdominal aortic aneurysm and PAD.[27] No association was found between this gene and the CVD risk factors, suggesting an independent genetic predisposition exists.[27]

Using a murine hind limb ischemia model of PAD, Dokun et al[28] identified genetic influences on PAD disease severity. Additional work is needed to elucidate the genes responsible for the association and their human orthologs. One study, using microarray analysis of femoral artery specimens, elucidated >400 genes that are either up- or down-regulated in patients with severe atherosclerosis.[29] Another similar study demonstrated that many of the genes involved in atherosclerosis are also involved in lipid synthesis and immune function pathways.[30] A clinical investigation that leads to the elucidation of the genetic basis of PAD might provide potential targets for future focused gene therapies.

Several strengths and limitations of the present study merit comment. The FHS is a large, community-based sample, with the data collected prospectively from both parents and offspring. The symptoms of IC were adjudicated by a panel of senior investigators using well-established criteria, and the risk factors were directly measured, rather than obtained by self-report from the participants, which could be subject to misclassification. Most FHS participants were of white, European ancestry, limiting the generalizability of the results to those from other race/ethnic backgrounds. The diagnosis of IC is determined by symptoms alone, without confirmatory testing; thus, some of the participants with IC in the present study might not have had PAD. In contrast, only about 50% of those with PAD have leg pain symptoms. The risk factors used for adjustment in the multivariable models were from a single-occasion measurement and might not represent an assessment of lifetime risk factor exposure. Hence, it is possible that the effect of a parental history of IC on the personal risk of IC might have been overestimated. Residual confounding might be present in that the parental history might reflect a low social class, passive smoking, diet, or sedentary behaviors that we were not able to account for in our study.

(*Received 18 January 2012; final version received 14 August 2012*)

Studies document a significant association between victimization from intimate partner violence (IPV) and sexually transmitted infections (STIs) and HIV among substance using women in Russia and elsewhere, but no study has examined IPV perpetration and STI among Russian men or HIV-infected men in Eastern Europe. This study was designed to assess the association between lifetime history of IPV perpetration and STI (lifetime and current) among substance using HIV-infected men in Russia. Cross-sectional analyses were conducted with baseline data from 415 male participants enrolled in a randomized HIV intervention clinical trial [the HERMITAGE Study]. Participants were HIV-infected men reporting recent heavy alcohol use and unprotected sex in St. Petersburg, Russia. Baseline surveys assessed demographics, IPV perpetration, risk behaviors, and STI history. Current STI was assessed via blood testing for syphilis and urine testing for gonorrhea, Chlamydia and Trichomonas. Multiple logistic regression analyses were used to assess the association between history of IPV with lifetime and current STI. Participants were aged 20–57 years. Almost half of participants (46%) reported a history of IPV perpetration; 81% reported past 30-day binge alcohol use, and 43% reported past 30-day injection drug use. Past and current STI was 41% and 12%, respectively. Men reporting a history of IPV perpetration had significantly higher odds of reporting ever having an STI (AOR = 1.6, 95% CI = 1.1, 2.4) but lower odds of testing positive for a current STI (AOR = 0.50, 95% CI = 0.26, 0.96). These findings demonstrate that a history of male IPV perpetration is common in HIV-infected Russian men and associated with a history of STI. Programmatic work toward IPV prevention is needed in Russia and may be beneficial in mitigating STIs, but more research is needed to understand how and why the association between IPV and STI changes over time in this population.

Keywords: HIV; Russia; IPV; substance use; STI

Introduction

More than one-third of women in Russia have been victims of male partner-perpetrated intimate partner violence (IPV) (Horne, 1999; Kalichman, Kelly, Shaboltas, & Granskaya, 2000; Lokhmatkina, Kuznetsova, & Feder, 2010), and victims of IPV are at increased risk for contracting HIV (World Health Organization [WHO], 2005). Mechanisms for the association between IPV and HIV include both greater sexual risk taking (e.g., sex trade involvement, non-use of condoms) and substance use (e.g., injection drug use, risky sex while intoxicated) among victims of IPV, according to findings from Russia (Kalichman et al., 2000; Zhan et al., 2012), Ukraine (Dude, 2007), South Africa (Jewkes, Dunkle, Nduna, et al., 2006), and the USA (Bogart et al., 2005; Dude, 2007; El-Bassel, Witte, Wada, Gilbert, & Wallace, 2001; El-Bassel, Gilbert, Wu, Go, & Hill, 2005a; Panchanadeswaran et al., 2010; Schmuel & Schenker, 1998; Silverman et al., 2011; Silverman, Raj, Mucci, & Hathaway, 2001). However, research from Russia and elsewhere also indicate that male perpetrators of IPV are more likely to engage in risky sex (e.g., concurrent sex partnering, non-use of condoms, buying sex) and substance use (Decker et al., 2008, 2009; Dunkle et al., 2006; El-Bassel, Fontdevila, et al., 2001; Jewkes, Dunkle, Koss, et al., 2006; Raj et al., 2006; Raj, Reed, Welles, Santana, & Silverman, 2008; Santana, Raj, Decker, La Marche, & Silverman, 2006; Silverman, Decker, Kapur, Gupta, & Raj, 2007; Zhan et al., 2012). Longitudinal studies with women and men in the US further indicate the bidirectional nature of these associations

(El-Bassel, Gilbert, Wu, Go, & Hill, 2005b; Gilbert, El-Bassel, Wu, & Chang, 2007). Little of this research has focused on HIV-infected populations outside the US and in Eastern Europe, and may have growing importance given Russia's increasingly heterosexually driven epidemic (Goliusov et al., 2008). Thus, this study assesses lifetime IPV perpetration and its association with STI and high risk sexual behaviors among a sample of male HIV-infected substance users in St. Petersburg, Russia.

Methods

This study involved a cross-sectional analysis of baseline data from male participants of a randomized clinical trial of an HIV risk reduction intervention for HIV-infected risky drinkers in Russia (the HERMITAGE Study). Between July 2007 and April 2010, eligible adults were enrolled from four HIV or substance use clinical sites and one needle exchange program in St. Petersburg, Russia. Trained research associates recruited participants; those indicating interest were escorted into a private room to assess eligibility and to obtain informed consent. Subsequent to consent, trained staff conducted the baseline survey assessment; urine and blood samples were then collected for STI testing. Baseline incentives of 300 rubles (US$7) were provided. Of 921 individuals screened, 732 were eligible, and 700 agreed to participate. Analyses involved data from men ($n = 415$), all men reported female sex partners. Institutional Review Boards of Boston University Medical Campus and Pavlov State Medical University approved this study.

Measures

Single items assessed subjects' age, marital status, education, incarceration, employment status, and whether the participant was currently on antiretroviral therapy (ART). Past 30-day drinking and binge drinking (5+ drinks per day) were assessed using the 30-day Timeline Follow Back (Sobell & Sobell, 1992, 1996). Past 30-day injection drug use (IDU) was assessed using an item from the Risk Behavior Survey (RBS) (Petry, 2001; Weatherby et al., 1994). Our primary independent variable, *IPV perpetration*, was assessed via three items based on the Conflict Tactics Scale-2 (Straus, Hamby, Boney-McCoy, & Sugarman, 1996): physical IPV perpetration ("threatened partner with violence, pushed or shoved partner or threw something at partner"), sexual IPV perpetration ("insisted on or made partner have sex with him"), and causing injury due to IPV ("injured partner during a fight"). A subject was classified as "yes" for IPV perpetration if a positive response was recorded for any of the three items.

STI ever, our primary outcome, was assessed via survey items on whether the participant had ever been diagnosed with each of the following: syphilis, gonorrhea, Chlamydia, Trichomonas, genital warts, and genital herpes. *Current STI*, our secondary outcome, was assessed via biologic testing of urine and blood samples for gonorrhea, Chlamydia, Trichomonas, and syphilis (see Pace et al., in press for details).

In terms of sex risk behaviors, our secondary outcomes of interest, subjects provided detailed information about their sexual partners in the past 90 days (Kalichman et al., 2001). For each of their five most recent partners in this period, starting with the most recent, participants were asked about number of sexual episodes and condom use during these episodes, as well as number of episodes involving drug or alcohol use prior to sex (past 30 days). They were then asked about any other sex partners beyond five in the past 90 days using these same questions. These items were used to create the following additional secondary outcomes: *number of unprotected sex episodes* in the past 90 days, *multiple sex partners* (2+) in the past 90 days, and *substance use before sex* in the past 30 days. Sex trade involvement items were taken from the Risk Assessment Battery (RAB) (Navaline et al., 1994); one item asked about *buying sex* with money or drugs in the past 90 days.

Data analysis

Descriptive statistics were obtained for demographics, ART, sex risk behaviors, substance use behaviors, and STI for the overall sample and stratified by IPV perpetration status. Bivariate associations were assessed via chi-squared analyses, *t*-tests, or the nonparametric Wilcoxon rank sum test as appropriate. To assess associations between IPV perpetration and dichotomous STI and sex risk behavior outcomes, simple logistic regression analyses as well as multiple logistic regressions analyses adjusted for demographics (age, marital status, and education), ART, and substance use (binge alcohol use and IDU) were conducted. Crude and adjusted overdispersed Poisson regression analyses were used to assess associations between IPV perpetration and the number of unprotected sex episodes. Odds ratios (ORs) are reported for logistic regression models and incidence rate ratios (IRRs) are reported for Poisson regression models; 95% CIs were used to determine significance. Statistical analyses were performed by using SAS software (version 9.1; SAS Institute, Cary, NC, USA).

Results

Sample characteristics

Participants ($N = 415$) were aged 20–57 years; 20.7% had not completed high school, and 48.4% had a history of incarceration. Most of participants (81.0%) reported past 30-day binge alcohol use, and 42.7% had injected drugs in this same timeframe. Half of participants (50.1%) reported alcohol or drug use before sex in the past 30 days, and one in eight had bought sex in the past 90 days. More than 1 in 10 men (11.8%) currently had an STI; 41.0% had a history of a STI diagnosis. Almost half of participants (46%, $n = 189$) reported a history of IPV perpetration (Table 1). Of these IPV perpetrators, 55.9% ($n = 105/189$) reported physical IPV perpetration; 63.0% ($n = 119/189$) reported sexual IPV perpetration, and 46.9% ($n = 87/189$) reported injury due to IPV perpetration.

Associations between IPV and STI and sex risk behaviors

Adjusted regression analyses demonstrated that lifetime IPV perpetration is associated with a higher odds of reporting a lifetime STI (AOR = 1.58, 95% CI = 1.04, 2.39), but a lower odds of having a current STI (AOR = 0.50, 95% CI = 0.26, 0.96) (Table 2). No significant associations between lifetime IPV perpetration and sex risk behaviors were observed in adjusted analyses.

Discussion

Almost half of study participants reported a history of IPV perpetration, a percentage higher than that seen in other studies of men from Russia (Lysova & Hines, 2008; Serbanescu & Goodwin, 2005; WHO, 2011; Zhan et al., 2012), and may be attributable to having an HIV-infected and risky drinking sample. Previous research from Russia and elsewhere documents a strong association between IPV perpetration and substance use, particularly alcohol use (Lysova & Hines, 2008; WHO, 2011; Zhan et al., 2011, 2012). History of IPV perpetration may also be disproportionately represented among men with HIV in Russia, a finding seen in South Africa and India (Dunkle et al., 2006; Silverman et al., 2007). Of note, the proportion of IPV perpetration among HIV-infected substance users in Russia is consistent with findings from a sample of HIV-infected IDUs (Frye et al., 2007), highlighting the relevance of considerations of IPV perpetration in this population of men.

Table 1. Demographic and HIV/STI risk profile of male HIV-infected risky drinkers in St. Petersburg, Russia ($N = 415$) and stratified by for total sample ($N = 415$) and by history of IPV perpetration.

	Total sample $N = 415$	No history of IPV perpetration $N = 226$	History of IPV perpetration $N = 189$	p-Value*
Age range (years)	(20–57)	(20–54)	(22–57)	0.52
Mean (SD)	30.6 (4.8)	30.5 (4.7)	30.8 (4.8)	
Married	131 (31.6%)	63 (27.9%)	68 (36.2%)	0.07

*p-Values based on chi-squared analyses, t-tests, or Wilcoxon test, as appropriate.

Table 2. Logistic and Poisson regression analyses assessing associations between IPV and the outcomes, STI and sex risk behaviors.

Outcomes	Crude OR (95% CI)	Adj[a] OR (95% CI)
Self-report STI ever	1.60 (1.08, 2.37) $p = 0.02$	1.58 (1.04, 2.39) $p = 0.03$
Current STI	0.55 (0.29, 1.03) $p = 0.06$	0.50 (0.26, 0.96) $p = 0.04$
Multiple sex partners	1.16 (0.76, 1.76) $p = 0.50$	1.24 (0.80, 1.93) $p = 0.33$
Buying sex	1.32 (0.75, 2.40) $p = 0.32$	1.36 (0.75, 2.48) $p = 0.31$
Alcohol or drug use before sex	1.33 (0.90, 1.96) $p = 0.15$	1.35 (0.89, 2.04) $p = 0.15$
	Crude IRR (95% CI)	Adj[a] IRR (95% CI)
Number of unprotected sex encounters	1.13 (0.78, 1.64) $p = 0.51$	1.06 (0.72, 1.58) $p = 0.76$

[a]Adjusted for age, marital status, education, ART, IDU, binge alcohol use.

Consistent with previous studies, findings indicate a higher odds of STI ever among those reporting a lifetime history of IPV perpetration. However, unexpectedly, history of IPV perpetration was not associated with current sexual risk behaviors and was negatively associated with current STI. These findings may in part be attributable to use of a lifetime IPV perpetration variable, which corresponds more directly to ever STI than current STI or recent sex risk behaviors, as such behaviors may change for men over time. Future research should examine whether recent IPV predicts current STI and sex risk behaviors in this population.

Study limitations include reliance on self-report of stigmatizing behaviors and STI over an "ever" timeframe; these data used are subject to recall and social desirability biases. Our IPV assessment had fewer items than the standard version, which may have resulted in underreporting. Use of differing time frames across some of our variables of interest (e.g., lifetime IPV perpetration, unprotected sex in past 90 days) likely affected some study findings. Cross-sectional data analyses do not allow an interpretation of the findings in terms of causality, and many potential relevant covariates such as knowledge and attitudes were not able to be considered by these analyses. Finally, the study may be limited in generalizability based on its focus on HIV-infected male risky drinkers recruited largely through health systems in the context of St. Petersburg, Russia. Despite limitations, study findings in conjunction with above described prior research document that IPV perpetration histories are a major concern among male HIV-infected risky drinkers in Russia and worthy of study with regard to their association with HIV acquisition and transmission in this national context.

LEARNING OBJECTIVES

After completing this course, the reader will be able to:

1. Describe the role and potential benefits of patient navigation in breast cancer care.
2. Explain disparities in breast cancer care and their impact on patient populations.

CME This article is available for continuing medical education credit at CME.TheOncologist.com.

ABSTRACT

The elimination of cancer disparities is critically important for lessening the burden of breast cancer (BC). Patient navigator programs (PNPs) have been shown to improve rates of BC screening in underserved communities, but there is a dearth of evidence regarding their benefits after the actual diagnosis of BC. We retrospectively examined sociodemographic characteristics, disease characteristics, and concordance to quality measures (QMs) of BC care among women participating in a PNP that services disadvantaged minority communities in the greater Boston area. Of the 186 PNP patients diagnosed with BC in 2001–2011 in three neighborhood community health centers, treatment data was available for 158 (85%) and race and disease stage information was available for 149 (80%). Regarding stage, 25% were diagnosed with in situ cancer, 32% had stage 1, 25% had stage 2, 13% had stage 3, and 5% had stage 4 BC. Guideline-indicated care was received by 70 of 74 patients (95%) for the hormonal therapy QM, 15 of 17 (88%) patients for the chemotherapy QM, and 65 of 71 (92%) patients for the radiation QM, all similar to published concordance rates at elite National Comprehensive Cancer Network institutions. These findings suggest that PNPs may facilitate evidence-based quality care for vulnerable populations. Future research should prospectively analyze quality metrics to assess measures to improve the process and outcomes of patient navigation in diverse underserved settings, compared with control non-navigated populations. ***The Oncologist*** 2012;17:1027–1031

Background

Despite major advances in cancer research, screening, and treatment, not all Americans with cancer have benefited equally. Although there was a 14% decrease in cancer-related deaths over the years 1991–2004, racial and ethnic minority patients continue to die disproportionately from cancer, compared with their white counterparts, even after adjusting for insurance status and income [1]. There is increasing evidence that the disconnect between discoveries in cancer care and their timely delivery to all Americans contributes to cancer disparities. Solutions to improve the equity of cancer care delivery are desperately needed [2].

Patient navigation programs (PNPs) have emerged as a potential solution for improving cancer care delivery [3, 4]. PNPs facilitate access to quality medical care by identifying barriers to care and by bridging gaps in care through culturally sensitive coordination. Patient navigators are resources for patients and providers and may assist with all phases of access, including primary cancer prevention, screening and follow-up care, cancer treatment, and survivorship care [5].

Extensive data have established the efficacy of navigation in improving the timeliness and receipt of cancer screening and diagnostic care after an abnormal screening test [6–11]. However, it is unknown whether or not PNPs improve patient care and outcomes following the actual diagnosis of cancer. We sought to evaluate the clinical outcomes of patients enrolled in the Massachusetts General Hospital (MGH) Avon Breast Care Program (MABCP) based on evidence-based national quality measures. The MABCP provides patient navigation services to racially and ethnically diverse communities seeking care at four federally qualified health centers in the greater Boston area, and thus represent a population vulnerable for poor cancer outcomes.

Methods

We performed a retrospective chart review of all 186 women diagnosed with breast cancer who participated in the MABCP in 2001–2011. Since its inception in 2001, the MABCP has served four community health centers and has provided primary screening services and diagnostic follow-up of abnormal screening examinations for ~4,000 patients. Of these 4,000 patients, 186 patients (4.7%) were diagnosed with breast cancer.

Patients in need of routine screening mammography are referred to the MABCP by their community health center primary care physician. The patient navigators automatically enroll all patients at these centers who have abnormal screening examinations and require diagnostic follow-up examinations. MABCP navigators follow the community health worker model [5] and are trained lay workers who are culturally diverse and generally representative of the population served by their community health center. Languages spoken by the navigators include Spanish, Bosnian, and Portuguese.

Most patients received their subsequent cancer care at either MGH or Boston Medical Center. Institutional review board approval was obtained at both sites. Sociodemographic data and treatment data were obtained by review of patient charts within the respective electronic medical records.

Table 1. Sociodemographic characteristics of Massachusetts General Hospital Avon Breast Care Program breast cancer patients ($n = 186$)

Characteristic	*n*	%
Race or ethnicity		
White	59	32
Black	30	16
Hispanic	52	28
Asian/Middle Eastern	8	4
Not disclosed	37	20

Median age (range), yrs	58 (19–93)	
Insurance status		
Uninsured	12	6
Free Care	5	3
Medicaid	23	12
Medicare	45	24
Private	58	31
Unknown	43	23
Highest education level		
None	2	1
≤Grade 8	25	13
Some high school	12	6
High school or general educational development	48	26
Some college	9	5
College graduate	12	6
Unknown	82	44

Descriptive statistics were used to analyze baseline sociodemographic characteristics. Clinical outcomes were analyzed using data abstracted from electronic medical records. Two physicians collected data using a chart abstraction form and entered the data into a secure Microsoft® Excel database. Abstracted clinical data were used to examine concordance with American Society of Clinical Oncology/National Comprehensive Cancer Network (ASCO/NCCN) quality measures.

Quality Measures

Three ASCO/NCCN quality measures based on NCCN level 1 evidence were analyzed to determine quality of cancer care. These included: (a) hormonal therapy within 1 year of diagnosis of hormone receptor $(HR)^+$ tumors >1 cm, (b) chemother-

Table 2. Race or ethnicity and disease stage of Massachusetts General Hospital Avon Breast Care Program breast cancer patients ($n = 149$)

Race or ethnicity	Stage 0	Stage 1	Stage 2	Stage 3	Stage 4	Race, *n* (%)
White	16	18	17	5	3	59 (40%)
Black	5	7	8	9	1	30 (20%)
Hispanic	16	19	11	3	3	52 (35%)
Asian or Middle Eastern	0	4	2	2	0	8 (5%)
Total (%)	37 (25%)	48 (32%)	38 (25%)	19 (13%)	7 (5%)	149

Table 3. Concordance rates with American Society of Clinical Oncology/NCCN guidelines (MABCP versus NCCN centers)

Quality measure	MABCP	NCCN Centers	*p*-value
Hormonal therapy	95% (70/74)	89% (2751/3091)	.72
Chemotherapy	88% (15/17)	87% (1044/1200)	.97
Radiation therapy	92% (65/71)	95% (2679/2829)	.85

Abbreviations: MABCP, Massachusetts General Hospital Avon Breast Care Program; NCCN, National Comprehensive Cancer Network.

apy within 120 days of diagnosis of HR^- tumors >1 cm for women aged <70 years, and (c) postlumpectomy radiation therapy.

Descriptive statistics were used to report patient characteristics and determine the proportion of navigated patients who had documented care that was in concordance with these three quality metrics. Concordance data for these quality measures across all NCCN institutions were used as a benchmark for MABCP patients [12]. Concordance rates between MABCP patients and NCCN institution patients were compared using χ^2 analyses.

Results

Self-reported sociodemographic data, including language spoken, age, insurance status, and level of education of MABCP patients diagnosed with breast cancer was available for the 186 patients in the MABCP. Missing data were attributed to patients declining to report these characteristics. In terms of race and ethnicity, 60% of the patients in the program were nonwhite black, Hispanic, and Asian or Middle Eastern. Forty-three percent of MABCP patients were non–English speaking. Twenty-one percent were either uninsured or were enrolled in Medicaid or Free Care. Thirty-seven percent had high school or general educational development education or greater (Table 1).

Of the 186 MABCP patients diagnosed with breast cancer, treatment data were available for 158 (85%) and race and breast cancer stage information was available for 149 (80%) (Table 2). In terms of stage of disease at diagnosis, 25% were diagnosed with in situ cancer, 32% had stage 1, 25% had stage 2, 13% had stage 3, and 5% had stage 4 breast cancer. Although there were no obvious differences between racial or ethnic groups with regard to breast cancer stage, the numbers are too small to make direct statistical comparisons. In our limited dataset, black patients appeared to be diagnosed with stage 3 disease more frequently than white patients. In terms of disease characteristics (data not shown), 91% of the navigated patients had HR^+ disease and 10% of the patients had human epidermal growth factor receptor 2–positive disease.

QMs

Table 3 illustrates concordance with ASCO/NCCN quality measure among MABCP patients compared with concordance rates for patients who received breast cancer care at NCCN institutions. For the hormonal therapy quality measure, 95% of the MABCP patients received hormonal therapy within 1 year of diagnosis for HR^+ tumors >1 cm. For the chemotherapy quality measure, 88% of the patients in the MABCP received chemotherapy within 120 days of diagnosis of HR^- breast cancer >1 cm. For the radiation quality measure, 92% of the patients received postlumpectomy radiation therapy. These concordance rates are comparable with rates from eight NCCN centers, largely viewed as elite cancer centers in the U.S. [12]. There was no significant difference ($p > .05$) between MABCP patients and NCCN patients with regard to each of the quality measures. Upon detailed review of the treatment records of MABCP patients, patients received standard adjuvant chemotherapy regimens such as doxorubicin, cyclophosphamide followed by paclitaxel, and docetaxel plus cyclophosphamide. With regard to endocrine therapy, the proper medication was prescribed to patients. For example, tamoxifen was prescribed for premenopausal patients and aromatase inhibitors were prescribed for postmenopausal patients.

Discussion

In this study, we demonstrated that breast cancer patients who received navigation services received high-quality cancer care, as defined by concordance with ASCO/NCCN quality measures. These navigated patients also had a favorable breast cancer stage distribution, with >50% having in situ or stage 1 disease, similar to that of white women reported by the Surveillance, Epidemiology, and End Results program [13]. This staging profile is also comparable with that of the white breast cancer population in Massachusetts as reported by the Massachusetts Cancer Registry [14, 15]. Our findings are particularly

notable given the sociodemographic characteristics of these patients, a significant proportion of whom are non–English speaking, are underinsured, and have a low level of education. Our findings add to the growing body of literature that suggests that navigation is a viable approach to reduce breast cancer health disparities by improving early detection rates and perhaps ensuring receipt of quality cancer treatment.

Much of the patient navigation literature addressing the care of cancer patients focuses on improving screening rates and the diagnostic management of abnormal screening results [9, 16, 17]. Most studies have shown better outcomes when patients receive patient navigation services. However, evidence that PNPs improve clinical outcomes after a cancer diagnosis is lacking. Arguably, patient navigation is equally, if not more, important after a cancer diagnosis given the logistical complexities and financial burdens of cancer treatment such as chemotherapy or radiation. In our patient population, 15% of the patients opted for treatment at other institutions, and therefore their treatment data were unavailable. However, among those patients with available data, at least 87% received care that adhered to guidelines. Some reports suggest that patient navigation after a cancer diagnosis improves patient satisfaction and reduces barriers to care [18, 19]. Guadagnolo and colleagues showed that patient navigation led to fewer cancer treatment interruptions and higher rates of clinical trial enrollment among Native American cancer patients, compared with historical controls [20]. Ell and colleagues showed that cancer treatment adherence was better than in historical controls among patients who received navigation services [21]. Our study offers additional data to support the efficacy of PNPs for patients diagnosed with cancer.

Our finding of a high concordance with level 1 ASCO/NCCN quality measures has important implications for the underserved and vulnerable patients diagnosed with breast cancer. These level 1 quality measures are based on randomized controlled clinical trials. Our data suggest that patient navigation may offer an effective strategy to overcome barriers that interfere with access to quality cancer care for underserved communities.

Major weaknesses of our study are that it was a retrospective analysis and data regarding the outcomes of 15% of the patients are missing. Fifteen percent of MABCP patients elected to receive their cancer care at institutions other than MGH or Boston Medical Center, and therefore we lack treatment data for these patients. However, their sociodemographic data otherwise closely matched those of the patients for whom we do have treatment data, suggesting that their treatment experience may match that of the larger population. Another weakness of our study is the extent of missing data, particularly with respect to education and insurance status. Our cohort may be disproportionately influenced by more highly educated and insured patients, leading to selection bias. Another weakness of this study is the lack of a closely matched control group that did not receive patient navigation. Similar studies in the literature often use historical controls as a reference group, but this strategy also has weaknesses, including the inability to account for improved outcomes with modern cancer therapies. We used data from patients receiving treatment at NCCN centers during the same time period as the benchmark to demonstrate that our navigated patients received similar quality care. Finally, another weakness of the study is the relatively small number of women diagnosed with breast cancer ($n = 186$) within the MABCP, making it difficult to draw definitive conclusions about this population.

Despite these weaknesses, our findings provide objective evidence that vulnerable populations may indeed receive quality cancer care when enrolled in a PNP, further prioritizing the need for rigorous research, ideally large, multicenter, prospective, randomized, controlled trials of patient navigation in patients diagnosed with cancer. Such trials are currently under way at the nine sites participating in the National Cancer Institute (NCI) Patient Navigation Research Program [22]. However, these trials are primarily enrolling patients for cancer screening, not after a cancer diagnosis. Additionally, the issue of randomizing patients to an intervention that is intuitively beneficial versus control (no intervention) raises ethical considerations. However, this national effort will provide insight into the role of patient navigation after a breast cancer diagnosis and, importantly, will allow evaluation of the cost-effectiveness of this approach [23, 24].

In conclusion, we have shown that patient navigation can lead to high-quality breast cancer care, as measured by concordance with national guidelines, among an underserved vulnerable population in an urban setting. Further research is needed to examine other metrics of quality care that may be improved with patient navigation during cancer treatment.

Abstract

Background—The Patient Navigation Research Program (PNRP) is a cooperative effort of nine research projects, each employing its own unique study design. To evaluate projects such as PNRP, it is desirable to perform a pooled analysis to increase power relative to the individual projects. There is no agreed upon prospective methodology, however, for analyzing combined data arising from different study designs. Expert opinions were thus solicited from members of the PNRP Design and Analysis Committee

Address for Correspondence: Richard Roetzheim, MD, MSPH, University of South Florida, Department of Family Medicine, 12901 Bruce B. Downs Blvd., MDC 13, Tampa, FL 33612, (813) 974-2445, (813) 974-4057 fax, rroetzhe@health.usf.edu.

[l]Other members of the PNRP Design and Analysis Committee are Joe Feinglass, Beth Calhoun, Diane Fairclough, Betsy Risendal, Victoria Warren-Mears, Kevin Fiscella, Ji-Hyun Lee, Nancy LaVerda, Paul Levine, Heather Hoffman, Ken Chu, Martha Hare, Mary Ann Van Duyn, Mollie Howerton

Purpose—To review possible methodologies for analyzing combined data arising from heterogeneous study designs.

Methods—The Design and Analysis Committee critically reviewed the pros and cons of five potential methods for analyzing combined PNRP project data. Conclusions were based on simple consensus. The five approaches reviewed included: 1) Analyzing and reporting each project separately, 2) Combining data from all projects and performing an individual-level analysis, 3) Pooling data from projects having similar study designs, 4) Analyzing pooled data using a prospective meta analytic technique, 5) Analyzing pooled data utilizing a novel simulated group randomized design.

Results—Methodologies varied in their ability to incorporate data from all PNRP projects, to appropriately account for differing study designs, and in their impact from differing project sample sizes.

Limitations—The conclusions reached were based on expert opinion and not derived from actual analyses performed.

Conclusions—The ability to analyze pooled data arising from differing study designs may provide pertinent information to inform programmatic, budgetary, and policy perspectives. Multi-site community-based research may not lend itself well to the more stringent explanatory and pragmatic standards of a randomized controlled trial design. Given our growing interest in community-based population research, the challenges inherent in the analysis of heterogeneous study design are likely to become more salient. Discussion of the analytic issues faced by the PNRP and the methodological approaches we considered may be of value to other prospective community-based research programs.

Introduction

Patient navigation is a promising approach to reduce cancer disparities and refers to support and guidance offered to persons with abnormal cancer screening or a new cancer diagnosis in order to more effectively access the cancer care system. [1] The primary goals of navigation are to help patients overcome barriers to care and facilitate timely, quality care provided in a culturally sensitive manner. Patient navigation is intended to target those who are most at risk for delays in care, including individuals from racial and ethnic minority and lower income populations.

Although patient navigation is an intervention that has clearly grown in popularity over the past decade, rigorous research on the efficacy of patient navigation is still new.[2] A number of studies conducted on patient navigation have been recently summarized.[2, 3] Patient navigation has generally shown improvements in timeliness of definitive diagnosis and initiation of cancer care. To date, there have been no published multicenter studies assessing patient navigation.

The Patient Navigation Research Program (PNRP) is the first multi-center program to critically examine the role and benefits of patient navigation. This program is sponsored and funded by the National Cancer Institute's (NCI) Center to Reduce Cancer Health Disparities (CRHCD), with additional support from the American Cancer Society. The five-year program focuses on four common cancers (breast, cervical, colorectal, and prostate) with screening tests having evidence of disparate outcomes in underserved populations.

The PNRP is a cooperative effort of nine research projects (see Figure 1), the funding agencies, and an evaluation contractor. Each PNRP project focuses on one or more of the four specified cancers. All projects targeted populations at greater risk of disparate cancer outcomes, such as racial or ethnic minorities, the uninsured or underinsured, or persons of lower socioeconomic status. As a cooperative endeavor, the PNRP utilizes a steering committee consisting of the nine project principal investigators, along with representatives from NCI-CRCHD, the American Cancer Society, and NOVA Research Company (NOVA), the evaluation contractor for the national outcomes studies. In order to advise the steering committee on methodological issues, a design and analysis committee was created composed of investigators having expertise in research design and methods from each project site, NOVA, and NCI-CRCHD.

The cooperative agreement did not require a uniform research design across all projects. This allowed for flexibility in implementing the patient navigation intervention that would be sensitive both to the specific patient populations as well as local system-level factors at each project. In addition, the nature of patient navigation requires involvement of the community with development of the research strategy in collaboration with community partners. Thus, each project had its own research design that included traditional randomized clinical trials (RCT), group-randomized trials (GRT), and non-randomized quasi-experimental designs (QE).

Despite the differences in research designs, all projects included characteristics specified by the steering committee, in order to support a single common evaluation of the PNRP. For example, all projects utilized a common definition of patient navigation and navigators received common national training in this role. In addition, all study designs share common well-defined outcomes with data elements from a single detailed data dictionary.

Navigation was hypothesized to shorten the time interval from cancer screening abnormality to definitive diagnosis (primary outcome) and for patients diagnosed with cancer, the time interval from definitive diagnosis through initial cancer treatment as well as improving satisfaction with care. Each project assessed these time intervals by medical record abstraction and the common data elements from all projects were uploaded to a national database to support a single common evaluation of the PNRP.

While each PNRP project was individually powered to address its hypotheses, a pooled analysis was desirable for many reasons. First, the increased statistical power from pooling data allows a more precise estimate of navigation effects across a variety of settings. In addition, while cancer screening abnormalities are common in primary medical care settings, cancer diagnoses are rare. The ability to address the hypothesis that navigation improves cancer care is strengthened by pooling data across projects to increase statistical power. Pooling of data also increases statistical power to explore navigation effects within patient subgroups at greater risk of adverse cancer outcomes (uninsured, racial-ethnic minorities, and persons of lower socioeconomic status). Pooling increases the generalizability of the findings by demonstrating the effect across a variety of settings and populations. Finally, pooling data enables exploration of heterogeneity of navigation effects (contrasting models of navigation for example), something that is not possible within individual PNRP projects.

For these reasons, a pooled analysis to evaluate the overall PNRP was desirable. The design and structure of PNRP, however, created a challenge in developing a suitable analytic method to evaluate the overall program. The PNRP was clearly different from standard multicenter trials that utilize a single study design with common shared protocols at all centers. In addition, while there was a common definition of navigation, its delivery could

differ among the PNRP projects. The design variations across the distinct projects do not lend themselves to traditional methods for analyzing data from a multi-center research trial.

Other fields, notably epidemiology, have recognized the need to analyze pooled data arising from heterogeneous study designs.[4, 5] These efforts generally involve retrospective analysis of published studies. To our knowledge, however, there is no agreed upon methodology for analyzing combined data arising from different study designs a priori or before each project has published their primary results, as opposed to retrospective analyses. The Design and Analysis Committee was therefore charged with the task of reviewing potential methodologies for analyzing combined data from PNRP projects. This review took place over a series of conference calls and the results of this assessment are presented below. In the following section, we describe each of the PNRP projects in more detail, and discuss five possible approaches that could be employed in this situation, including the pros and cons of each approach.

Methods

Summary of PNRP Research Designs

The PNRP is a collaborative effort involving nine separate research projects (Table 1). Eight of the nine sites contributed data to the national dataset. The ninth site focused solely on the American Indian / Alaska Native population of the northwestern US, and the data sharing agreements are specific to that setting. Each project designed the implementation of its intervention taking into account factors that were unique to their health care delivery system and patient population. Some projects were able to employ true experimental designs, while others implemented variations of quasi-experimental designs.

Four projects – Denver, Ohio, Rochester and Tampa – implemented true experimental designs, using random assignment of either individuals or clinics to the Intervention or Control conditions. Given adequate sample size, random assignment allows the analysis to make the assumption that treatment conditions formed through this process are equivalent, and observed differences between control and intervention treatment conditions can be attributed to the intervention effect.

Denver and Rochester used a more classical RCT design and randomly assigned *individuals* to either a control group or the intervention condition.[6] Ohio and Tampa used a GRT approach and randomly assigned *groups* (i.e., clinics) to either a control group or an intervention group. GRT is a comparative study design in which identifiable groups (i.e., study units) are assigned at random to study conditions and observations are made on members of those groups.[7] Studies with different units of assignment and observation exist in many disciplines and pose a number of design and analytic problems not present when individuals are randomized to study conditions. A central problem is that the intervention effect must be assessed against the between-group variance rather than the within-group variance.[8]

Furthermore, the between-group variance is usually larger if based on identifiable groups than if based on randomly constituted groups. This is the result of the positive intraclass correlation expected among responses from members of the same identifiable group[9]; that correlation reflects an extra component of variation attributable to groups above and beyond that attributable to their members. In addition, the degrees of freedom (df) available to estimate the between-group variance is normally less than that for the within-group variance when there are a limited number of groups per condition. The extra variation and limited df can combine to reduce power and therefore make it difficult to detect important intervention effects in an otherwise well-designed and properly-executed research trial.

Ohio originally identified 12 participating clinics and stratified them according to clinic type – university-based clinic (n = 8) vs. neighborhood health center (n = 4). Within clinic type, individual clinics were rank-ordered on the proportion of African-American patients and pairs were formed by clinics adjacent in rank. Clinics within each pair were then randomly assigned to either Navigation or Control conditions. This method of forming pairs should maintain balance between the two conditions on at least the variable that was used to rank the clinics in the first place. To the extent that this variable is also a surrogate for other variables (e.g., SES, insurance coverage) that might be correlated with the outcome, then this assignment process will permit a more direct interpretation of results. Data on these confounding variables can be examined for balance among the treatment conditions.

Tampa identified 12 clinics nested within five distinct health care organizations (the five organizations having 3, 3, 2, 2, and 2 clinics respectively). There was a further constraint that for health care organizations having 3 clinics, one was randomly assigned to be the Control clinic and the remaining 2 clinics were designated as Navigated clinics. Random assignment of clinics occurred within each health care organization. The Tampa project presents a case where the number of units to be randomly assigned is small and the degree to which equivalency between Control and Navigated conditions was achieved is of less certainty than the situation where several hundred individuals are randomly assigned.

The remaining 5 projects – Boston, Chicago-ACCESS, Chicago-VA, San Antonio and Washington DC, employed a quasi-experimental design,[10] with the distinguishing feature that patients (or clinics) were not randomly assigned to conditions. The decision to use non randomized designs reflected the nature of the intervention and the collaborations with community partners to develop and conduct the research. This leaves attribution of outcomes to Patient Navigation open to other plausible explanations. The same kinds of statistical analyses can be applied to data from quasi-experiments as from true experiments; it is the ability to directly interpret the findings and the confidence in the obtained results that separates these two kinds of designs. Random assignment eliminates many of the alternative plausible explanations for the obtained results that may be more difficult to eliminate in quasi-experimental designs, and facilitates generalizability of results to similar populations.

The Design and Analysis Committee considered the various study designs and proposed five possible analytic methods or approaches for a national evaluation of the major outcomes of the PNRP. Each approach was evaluated by the committee in regards to its strengths, weaknesses, and suitability to address the unique methodological issues of the PNRP. Results of that evaluation are presented below (see also Table 2).

Results

Approach #1: No presentation of combined findings. Each project in the PNRP would be separately analyzed and reported as an independent study

One possible approach to evaluate the PNRP is to make no attempt to combine the data, but instead present each project based on its own analysis. This approach would eliminate the difficulties in assessing the best method to combine data. This approach is useful if the findings of the individual projects are markedly different, allowing readers to more easily see which projects had a significant effect, and which did not. However, this approach does not provide a coherent summary of the overall PNRP program, and leaves the synthesis of the findings to the reader. An understanding of the effects of patient navigation from individual project analyses would only emerge over time as project results were published.

An example of such an analytic approach is the Centers for Medicare and Medicaid Services (CMS) funded program of 15 individual RCTs evaluating care coordination to improve quality of care, re-hospitalization rates and Medicare expenditures for Medicare beneficiaries. In this program, each project developed their own intervention and selected their own target diseases, study population, and established inclusion and exclusion criteria specific to their respective projects.[11] CMS developed a uniform evaluation procedure, using claims data and a standardized telephone survey. To summarize the effects of the overall program, the authors chose to present the data as 15 parallel RCTs, outlining the differences in each intervention and study population.

Interpretation of the findings primarily focused on the two projects that demonstrated positive effects, with an attempt to understand these findings in the context of differing study designs. This approach proved useful in the setting where trials utilized markedly different designs and where the nature of the intervention varied significantly from project to project. In contrast, the PNRP program allowed different study designs, but utilized a standard intervention strategy, study population, inclusion, and exclusion criteria.

Approach #2: Pool the data from all projects and analyze at the individual level ignoring any possible intraclass correlation

This analytical approach would combine data from all the projects, analyze at the individual level and ignore any possible intraclass correlation. The primary analysis would be a test of the mean difference in time from abnormal finding to diagnostic resolution for the Control condition compared to the Intervention (Navigated) condition. The analysis could be performed using standard methods based on the general linear model [12], such as t-tests or F-tests with df based on the number of individuals. While separate analyses could be performed for the different cancer sites – breast, cervical, colorectal, prostate – the basic analytical approach would be the same.

The major advantages of this approach are that it would use all data from all projects in a single analysis and that it would rely on familiar methods based on the general linear model.[12] Pooled data also yield larger sample sizes and increased power, and thereby permit the exploration of rarer events and the examination of the main effects on hypothesized sub-groups, such as patients with co-morbidities.

However, these advantages are offset by several serious disadvantages. A primary disadvantage is that this approach is inappropriate for GRTs and for quasi-experiments involving non-random assignment of identifiable groups. [7, 13] Another is that larger projects would contribute more information than smaller projects; if the results varied systematically by study size, the effects in the larger projects could wash out the effects in the smaller projects.

Approach #3: Pooling data from projects with similar designs

Some of the projects employed similar research designs allowing the possibility of pooling raw data from projects that used similar research designs. For example, two projects employed a GRT design (Ohio and Tampa) that targeted shared cancer sites (breast, colorectal). This approach would analyze data from these two GRT projects, employ statistical methods that are appropriate to the study design, and stratify on project so that overall results would be examined and differences between projects could also be evaluated. An advantage of this situation is that it would allow stratification by cancer site and project simultaneously. The committee considered whether to include data on cervical cancer (collected at Ohio but not Tampa) and concluded that such data could be included, increasing the generalizability of findings. Individual-level data would be analyzed, but for

these two projects, the intraclass correlation expected in the data would be addressed and df would be based on the number of groups, not the number of individuals. The analysis would be based on the general linear mixed model.[14]

Two projects, Denver and Rochester, designed and conducted projects in which individuals within clinics were randomly assigned to either the Control or Navigated conditions. Data from these 2 projects could be pooled for a single analysis using Approach #2. Project (Denver versus Rochester) would be a stratification variable to test the interaction effect. The approach would use standard methods based on the general linear model[12], such as t-tests or F-tests with df based on the number of individuals. An issue complicating this approach in this instance is that the major outcome variables are measuring different time frames; for Denver the time is from abnormal finding to diagnostic resolution in 80% of its population and from cancer diagnosis to initiation of treatment in 20%, while for Rochester the time for most of its patient population is from cancer diagnosis to initiation of treatment and/or completion of primary treatment. Hypothetically, however, it could be possible to pool the data across these two projects since both outcomes are measured in the same unit (# of days). This analytical approach could help answer the general question as to whether patient navigation reduces the time to obtain standard quality cancer care – whether that "care" is diagnostic resolution or initiation of cancer treatment. The challenge would be to find ways to appropriately combine and describe the relative merit of the data in reference to: 1) the overall effects of patient navigation (PN) on quality of cancer care; and 2) specific differential effects of PN on cancer diagnostic resolution and initiation of cancer treatment.

While randomization insures comparability of treatment arms on average, adjustment for patient level covariates is still advisable for several reasons.[15] First, despite randomization, imbalances in patient characteristics can occur by chance. Moreover, unadjusted analyses may yield results that are biased toward the null if there is heterogeneity of risk across strata.[16] Adjusted analyses may provide more precise estimates and a summary result closer to stratum specific results.[16, 17]

The primary advantage of approach three is that it would base the analysis on the design of the project: RCTs would be analyzed as RCTs and GRTs would be analyzed as GRTs. Interpretation would be straightforward in both analyses. The primary disadvantages are that this approach would accommodate only 4 of the 9 projects and present two sets of potentially conflicting results. With each analysis based on only two projects, power would also be reduced relative to other options, and questions may arise regarding unequal sample sizes of projects within type of design.

Approach #4: Prospective Meta-Analysis

Meta-analysis is the statistical synthesis of data from separate but similar projects that are combined so that a quantitative summary of the pooled results can be obtained.[18–21] An extension of this approach is prospective meta-analysis (PMA) in which studies are identified, evaluated and determined to be eligible before the results of any of the studies become known.[22] PMA addresses some of the limitations of retrospective approaches to meta-analysis. For example, retrospective analyses can be influenced by the individual study results, potentially affecting studies that are assessed (publication bias), study selection, what outcomes are assessed, and what treatment and patient subgroups are evaluated. In addition, PMA provides standardization across studies of instruments and variable definitions. PMA is an increasingly utilized approach reported in the literature.[23–32]

Using this PMA approach, data from each project would be analyzed separately using methods appropriate to the project design and an effect size of the intervention (Patient Navigation) would be calculated. These effect sizes would then be combined across projects

using standard meta-analytic techniques to obtain a summary measure of the general effect of Patient Navigation on the timely receipt of standard, quality cancer care.

This approach has several advantages. It recognizes the idiosyncrasies across projects and treats these as random effects. It retains individual projects' research designs and allows for stratification according to research design quality. The PMA approach also avoids another important disadvantage of retrospective meta-analyses, where the researcher conducting the meta-analysis is dependent upon the data that are published in the literature, or must request additional data from the authors. In the PNRP, all original data would be available for analysis.

The data for each project would be analyzed separately, maintaining each project's research design and using statistical methods appropriate to the projects' designs with particular attention to the unit of assignment. Effect sizes could be examined by type of design (Individually randomized, group randomized, non-randomized; or randomized versus non-randomized) to examine differences in the estimated magnitude of the effect of PN as a function of research design type or quality of research design.

A potential disadvantage is the risk that the analyses performed for the PMA might differ from the analyses eventually reported by the individual projects. That risk can be minimized by requiring the individual projects to specify in advance their primary analysis plan. However, if projects plan their primary analysis with the inclusion of data they collected beyond the common dataset, this analysis could not be completely replicated. If the individual projects have very different effect sizes (for example, several with a positive effect of navigation, and several with no effect or a negative effect in the navigated arm) then pooling the effect sizes would not be appropriate and presenting the individual project results would be recommended.

Approach #5: Simulated Group Randomized Design

In this approach, pairs of matched groups would be created within each project to mimic a pair-matched group-randomized trial. The grouping would occur so that the number of observations in each group formed within a particular project is balanced. The matching would be done such that factors most highly associated with outcomes were similarly distributed in both the control and navigated study conditions. Potential matching factors could include cancer site, health insurance coverage, ethnic and racial minority status, gender, and age. The distribution of these factors would first be examined to determine overall balance between navigated and control patients within each individual cancer site. There is no requirement that the number of groups per project be equal or that group as defined for one endpoint be the same group defined for another endpoint.

For projects where group randomization of clinics was used, subjects from each individual clinic would remain together in a single group, and not split into multiple groups even with a large sample size. In those cases where a 'group' was the unit of randomization or assignment, it would not be appropriate to split these units to obtain more groups; this would create groups that were not independent and violate the assumptions of the analysis plan. For some clinics that have small sample sizes it may be necessary to combine across clinics and match on cancer site to attain a sufficient number of observations per group. For projects where individual randomization was used, groups would be created based on cancer site and date of index event, in order to create well matched sets of navigated and control pairs. In the case where reasonable matching within strata has not been achieved with respect to the most influential covariates, it may be necessary to employ a mathematical model in the analysis to control for confounding.

Two methods of analysis could be considered for this approach, ANOVA and simple t-tests (or permutation tests for situations where the assumptions of normality are grossly violated). These methods have been described elsewhere.[7, 33, 34]

Strengths of this approach are that it would utilize all of the data from all eight projects and it would help insure balance in the number of observations in each constructed group within a project and in the number of groups in each condition. Balance is important in group-randomized trials as it helps limit the potential impact of other problems that can occur in GRT data. [35] The size of groups should be similar enough in magnitude that weighting of effects would not be required. Another advantage of this method is that by creating comparable groupings across all PNRP projects, confounding that occurs at the level of groups can be controlled in the analysis. Potential disadvantages are that this is an untested and novel approach, and more importantly, it would not reflect the original design of most of the PNRP projects.

Discussion

The PNRP presents some unusual analytic challenges. The PNRP is clearly distinct from traditional multicenter randomized trials and traditional methods of analysis of multicenter trials could not be applied.[36] Instead, we have considered 5 alternative approaches to the analysis of the PNRP data and examined their strengths and weaknesses. However, as community based participatory research gains strength as a methodology to address health disparities, we anticipate that other research groups will face similar challenges when analyzing multi site studies.

Though we considered Approach #1, we judged the weaknesses to outweigh the strengths. The PNRP was created with the overarching goal of estimating the value of patient navigation. The results from individual projects would certainly add to the research literature on this issue, but a unified summary would not emerge and readers would be left to find, evaluate, and synthesize the reports from the individual projects. In addition, this approach would not allow a thorough evaluation of heterogeneity of navigation effects across projects. The circumstance where this method would however be more applicable is the situation where the effect sizes from the different individual projects are in opposite directions, and therefore a synthesized effect size is not appropriate.

Another major disadvantage to Approach #1 was that a combined analysis should have greater power than a series of project-specific analyses. Pooling data allows sufficient sample size to explore effects of navigation across subpopulations of interest. Moreover, because the number of cancers arising in primary care settings is small, navigation programs that target primary care settings are unlikely to have sufficient numbers of cancers diagnosed to explore effects for each cancer site. By pooling data across cancer sites, there is a greater opportunity to examine the effects of navigation programs that target the full cancer continuum, from diagnosis through treatment.

Two analytic approaches that would pool data cross projects were considered unacceptable by the Design and Analysis Committee. First, simply combining all data and conducting an individual-level analysis would ignore intraclass correlation and each project's unique study design, greatly increasing the likelihood of a type 1 error.[7, 13] In addition, projects having large sample size would be weighted greater in Approach #2 which could unduly influence findings.[37] Approach #3 would combine data only from projects having similar study designs but was deemed undesirable as it would exclude data from five of the eight projects.

Each of these remaining two approaches has potential strengths and weaknesses. Strengths of the PMA approach included an analytic method that was familiar to most readers, the

ability to utilize data from all projects, and the ability to account for unique research designs of each project, the ability to avoid problems common to many meta-analytic efforts by virtue of having complete access to original data, and its prospective approach. A meta-analysis conducted in advance of publication of individual project results could risk inconsistencies with later reports from the separate projects. Inconsistencies can be potentially managed through governance such as enforcing (or at least negotiating) agreed upon analytic methods between that in the pooled analysis and that performed by individual PNRP projects. In addition, differences in analytic methods and resultant discrepancies in reported results between pooled analysis and individual projects would need full disclosure and explanation in subsequent publications.

Advantages of approach #5 which would construct a simulated pair-matched group-randomized trial include utilizing data from all projects, insuring balance between intervention and control conditions, and increased efficiency. Disadvantages include an untested analytic approach not familiar to reviewers or readers, a less transparent approach which lacks adherence to the original designs of the PNRP projects, difficulty achieving sufficient sample size per group, and finally issues of weighting if some projects contribute more groups than others.

Adequate control of confounding is an important analytic issue in all methods. In pooled analyses, confounding can occur at several levels; at the level of the PNRP project and cancer site, at the level of groups that occur within the pooled data (e.g. clinics or hospitals), and at the individual patient level. Factors that are highly correlated are difficult to separate in any analytic strategy. For example, three of the four sites examining cervical cancer are non-randomized while four out of five sites examining colon cancer are randomized. As a result it will be difficult to isolate the potential effects of cancer site from potential effects of the study design. Confounding of group level (e.g. clinic) characteristics is also important in all analytic methods. While group randomized trials have inherent groups that can be assessed, a potential strength of method five is that it creates similar groupings within other study designs allowing for control of confounding at this level.

There were a number of limitations considered in our discussion of analytic approaches. First, the conclusions reached were based on expert opinion and not derived from actual analyses performed. Because data collection is still underway, there was no attempt to perform simulations, for example, that contrasted results from different analytic strategies or assumptions. Finally, the issues faced were unusual and there is little existing literature to put these conclusions into context. Even so, programs that involve different designs and interventions addressing the same problem are not uncommon.

The PNRP faced an unusual situation in which timely program evaluation required the analysis of pooled data arising from projects having heterogeneous study designs. This situation could re-emerge in future multi-site, community based participatory research projects. The PNRP D&A Committee considered several analytic approaches and concluded that a prospective meta-analysis is one appropriate analytic strategy in these situations. A novel simulated group randomized approach was also proposed as an alternative analytic approach. Future research (e.g. data simulations) would help to understand how program evaluation results are influenced by the analytic method used.

Table 2

Comparison of Potential Analysis Methods

	Analysis Method	Description	PROs	CONs
Approach #1	Analyze and report each project separately	Each PNRP project would be separately analyzed and reported as an independent study. There would be no attempt to combine data from different projects.	• Accounts for differing study designs	• No summary measure of effect • Leaves synthesis of findings to readers • Summary of overall program may be biased by projects with favorable results.
Approach #2	Individual-level analysis ignoring any intraclass correlation	Combine data from all the projects, analyze using standard methods, ignoring any intraclass correlation All individuals receive equal weight in the analysis. Primary analysis compares mean difference in time to diagnostic resolution for navigated versus control subjects.	• All data are utilized – no subjects excluded	• Pooling data ignores each project's internal validity • Ignores "group" in group-randomized designs and non-randomized group designs • Projects with large sample sizes could overwhelm results
Approach #3	Pool data from projects having similar designs	Data from two projects that used group-randomized designs would be combined and analyzed. Two projects that randomized at individual level would similarly be pooled and analyzed.	• Interpretation more straightforward • Restricts analysis to projects with true experimental designs • Increases generalizability of findings	• Only four of the nine projects contribute to the analysis • Analyses yield two separate results
Approach #4	Prospective meta analysis	Data from each project analyzed separately to estimate effect size. Effect sizes would be combined using meta-analytic techniques to obtain overall measure of program effect.	• All data are available, not just that in published literature • Measures of effect for each program are computed • Allows comparisons across projects (by design, by type of navigation) • Avoids publication bias	• Meta-analysis in advance of the publication of project results risks inconsistencies with the reports by the projects
Approach #5	Simulated Group Randomized Design	For projects that did not randomize by group, pairs of matched, and balanced groups will be created from the individual data simulating a group randomized design.	• Utilizes all data from nine projects • Insures balance between intervention and control arms • Allows for control of confounding at level of 'group' across projects • Efficient use of available data	• Untested and novel approach. • Less transparent approach • Does not reflect original study designs in individual projects. • Projects with more groups have greater influence on analysis Small number of observations per group may require combining groups

Editorial

Improving the Management of Warfarin May Be Easier Than We Think

Adam J. Rose, MD, MSc, FACP

Performance variation is easy to find—all one needs to do is to look for it. We have long known that some nations achieve better control of hypertension than others,[1] some hospitals have shorter door-to-balloon times than others,[2] and some cardiac surgeons have better risk-adjusted mortality after coronary artery bypass graft surgery than others.[3] In fact, it is difficult to recall an instance when performance was found not to vary. Given that performance variation is ubiquitous, it is no longer shocking to find it; the more interesting question is why performance varies so much. The answer to this question would likely be a key step along the pathway to improving performance.

Article see p 2309

It is rather uncommon to find a single answer to the question of why performance variation exists. However, in the current issue of *Circulation*, Van Spall and colleagues[4] have found an unusually straightforward explanation for performance variation, at least in the context of the management of warfarin. The authors found that site-level adherence to a relatively simple algorithm regarding when to change the dose of warfarin and when not to change the dose predicted fully 87% of between-center variance. Adding patient-level clinical variables (ie, risk-adjustment), center-level variables, and country-level variables only increased the amount of explained variation to 89%. In short, management of warfarin doses appeared to be almost deterministic regarding the anticoagulation control that was achieved. Remarkably, the authors also found that greater adherence to the algorithm also predicted a reduced rate of the combined primary end point of stroke, major hemorrhage, or death at the site level. For each 10% increase in algorithm-consistent dosing at the center level, the annual rate of the combined end point was 8% lower, even after adjusting for a host of patient-level predictors. The algorithm has additional attractive features as well, not least of which is that it does not require a computer or proprietary software to use. In fact, it would be equally suitable to use in developing countries.

The authors deftly used a feature of their dataset to demonstrate that percent time in therapeutic range (TTR) really is in the causal pathway to adverse events. Because their dataset was drawn from a randomized trial of dabigatran versus warfarin, they were able to show that, whereas sites with more algorithm-consistent warfarin dosing had lower rates of adverse events among patients receiving warfarin, they did not have lower rates of adverse events among patients receiving dabigatran. Some have expressed doubts about whether TTR really is in the causal pathway to outcomes,[5] suggesting that instead, sites with higher TTR also might be delivering high-quality care in other ways. If this were true, then quality improvement efforts aimed at increasing TTR might not achieve the desired benefits in terms of preventing adverse events. The finding by Van Spall and colleagues[4] serves as a strong refutation for this line of reasoning, because if high-TTR sites were truly delivering other interventions responsible for preventing adverse events, we would have seen a similar reduction in adverse events among patients receiving dabigatran. The present study therefore serves as a strong endorsement of efforts to improve TTR at the site level and thereby prevent adverse events.

The algorithm studied by Van Spall and colleagues[4] was similar to others that are in widespread use. The algorithm suggested no dose change for an in-range international normalized ratio (INR) value, a 10% dose change when the INR was somewhat out of range (1.51–1.99 or 3.01–4.00), and a 15% dose change for greater deviations from the target range. The authors note that, although they distributed this algorithm, they cannot know to what extent the sites of care actually used it—in essence, their study examined the difference between care that would have been algorithm-concordant, as the authors put it, "whether intentionally or not." In a study by Kim et al,[6] a very similar (but not completely identical) dosing algorithm was shown to improve TTR. The Kim study complements the current study in that it shows that the introduction of a standardized dosing algorithm improved TTR considerably using a before–after design.[6] Although Van Spall and colleagues were able to show that algorithm-concordant care was important, they were unable to examine whether the introduction of the algorithm had actually increased the likelihood that such care would be delivered. Also, in the Kim study, algorithm-consistent dosing was highly correlated with patient-level TTR, which complements the site-level findings of the current study. Taken together, the 2 studies suggest that the algorithm is both valid (in the sense of predicting important outcomes)[4] and feasible (in the sense that it can successfully be introduced and change clinical practice).[6]

Table. Some Key Challenges to Improving Anticoagulation Control

Topic	Issue	Challenge or Knowledge Gap
Warfarin dose management	Limited use of computerized dose support or paper-based algorithms, both of which are shown to improve control	Promoting wider adoption of computerized dose support or paper-based algorithms
Loss to follow-up	Lack of functioning systems to track patients and detect loss to follow-up	Need to develop such systems, particularly for sites without proprietary anticoagulation management software
Use of nonstandard target INR ranges	Lower target INR ranges such as 1.5 to 2.0 remain in use, despite having been shown to produce harms without additional benefit	Finding effective ways to promote the use of standard rather than nonstandard target ranges
Timely follow-up after deranged INR values	Prompt follow-up after high (>4) or low (≤1.5) INR improves control	Clinicians may resist changing practice; patients may resist frequent follow-up
Patient education	Patient education may lack standardization and may have limited effectiveness.	Developing new and innovative ways to educate and re-educate patients about warfarin therapy
Patient adherence to therapy	Limited adherence to pill-taking, dietary consistency, on-time follow-up, and other matters	Need to identify and address various patient-level barriers to improved adherence
Anticoagulation clinic leadership	Each clinic needs strong leadership to ensure continuous quality improvement	Individuals may not feel empowered to identify and implement strategies to improve outcomes
Performance measurement	Anticoagulation therapy is clearly important enough to deserve a program of performance measurement	Performance measures have been developed, but still need to be used more widely, and may need to be amended over time in response to feedback

INR indicates international normalized ratio.

Any algorithm for warfarin dose management, whether paper-based or computer-based, needs to be introduced with a caveat, namely that the clinician must always have the power to override the algorithm. Any decision about warfarin dose changes must occur in the context of the visit, and some information that is divulged by the patient (for example, recent dietary intake) may well prompt a decision that is discordant with the algorithm.[7] However, both the Van Spall and Kim studies strongly suggest that clinicians managing warfarin should ask themselves whether they really have a compelling reason to deviate from the algorithm—and then ask again for good measure.

The present study also adds to a growing discussion about how to manage warfarin doses when the INR is only slightly out of range. In the past, several studies have suggested that dose changes are not necessary for mildly deranged INR, and in fact may begin a cycle of overcorrection and rebound that may worsen control.[8–9] Based on this limited evidence, the latest consensus guidelines for managing warfarin suggest not changing the dose when the INR deviates by ≤0.5 from the target range, and instead merely rechecking in 1 to 2 weeks.[10] Notably, a deviation of up to 0.5 is an even wider tolerance range than would be suggested by either of the previous studies.[8–9] With this issue in mind, Van Spall and colleagues examined whether their findings would also be true when the tolerance range was widened from 2.0 to 3.0 to 1.9 to 3.1, 1.8 to 3.2, 1.7 to 3.3, and 1.6 to 3.4. They found that TTR was higher with increased adherence to any of these ranges, but was best with the strict construction of the target range (ie, 2.0–3.0). In addition, only the strict construction predicted the primary combined end point in a statistically significant fashion. Thus, the findings of the present study cast at least some doubt on the idea of a widened tolerance range, within which slightly deranged INR values do not prompt a dose change. Ideally, a well-designed prospective study could address this issue more definitively. For now, although some clinicians may still opt to have a tolerance range, it may be prudent not to extend it beyond approximately 1.8 to 3.2,[8–9] as opposed to the much wider range of 1.5 to 3.5 recommended by the most recent guidelines.[10]

One noteworthy limitation of the present study stems from its origins in a clinical trial.[11] The patients represented in this study may have been unusually adherent to their medication, and gaps in INR monitoring were likely minimal. In a real-world setting, dose management may not predict 87% of site variation, and other issues, like gaps in INR monitoring, also may play an important role. Our group has shown that nonstandard target ranges, gaps in INR monitoring, and failure to recheck INR promptly after an out-of-range value are also strong predictors of site-level TTR.[12–14] Together, these 3 measures predicted 48% of TTR variation among sites of care in the Veterans Health Administration (our unpublished finding). It is likely, therefore, that although adherence to the algorithm examined by Van Spall and colleagues may be the single most important determinant of site-level TTR, it is not the only performance measure worth addressing. In fact, improving TTR is likely to require a multifactorial approach, as there are many related issues that contribute to TTR (Table).

Another limitation, mentioned above, is that the present study was not an attempt to actually implement the algorithm under study. Kim and colleagues successfully implemented a similar algorithm,[6] but they did so at a single site of care, which may not be representative of other sites. An important next step would be a prospective test of this algorithm in a real-world setting, preferably across an integrated health system. Such an effort would require great attention to the principles of implementation science to promote successful adoption of the algorithm.[15] In fact, we have recently begun such a study in the New England region of the Veterans

Health Administration. One challenge for our effort, and for any effort occurring in the real world, is that automated data may not reliably identify dose changes in warfarin, which is usually prescribed as use as directed. A need to rely on chart review to track adherence to the algorithm may hamper efforts to measure its uptake.

In summary, Van Spall and colleagues[4] have added several important new pieces of information to the literature. First, in combination with other studies,[6] the present study convincingly demonstrates that managing warfarin according to a standard algorithm can improve patient outcomes. Second, it should lay to rest any lingering doubts about whether TTR is truly in the causal pathway to adverse events. Finally, it suggests that changing the dose of warfarin for any out-of-range INR may in fact be best, although other studies have found differently,[8–9] and further evidence is needed. The study by Van Spall and colleagues certainly provides a powerful argument for greater adoption of any sort of system to promote standardized dose management for warfarin—either computer support when it is available, or paper-based algorithms if not. Improving outcomes for patients receiving warfarin will not be easy, but it may be easier than we think.

Summary. *Background:* Not all clinicians target the same International Normalized Ratio (INR) for patients with a guideline-recommended target range of 2–3. A patient's mean INR value suggests the INR that was actually targeted. We hypothesized that sites would vary by mean INR, and that sites of care with mean values nearest to 2.5 would achieve better anticoagulation control, as measured by per cent time in therapeutic range (TTR). *Objectives:* To examine variations among sites in mean INR and the relationship with anticoagulation control in an integrated system of care. *Patients/Methods:* We studied 103 897 patients receiving oral anticoagulation with an expected INR target between 2 and 3 at 100 Veterans Health Administration (VA) sites from 1 October 2006 to 30 September 2008. Key site-level variables were: proportion near 2.5 (that is, percentage of patients with mean INR between 2.3 and 2.7) and mean risk-adjusted TTR. *Results:* Site mean INR ranged from 2.22 to 2.89; proportion near 2.5, from 30 to 64%. Sites' proportions of patients near 2.5, below 2.3 and above 2.7 were consistent from year to year. A 10 percentage point increase in the proportion near 2.5 predicted a 3.8 percentage point increase in risk-adjusted TTR ($P < 0.001$). *Conclusions:* Proportion of patients with mean INR near 2.5 is a site-level 'signature' of care and an implicit measure of targeted INR. This proportion varies by site and is strongly associated with site-level TTR. Our study suggests that sites wishing to improve TTR, and thereby improve patient outcomes, should avoid the explicit or implicit pursuit of non-standard INR targets.

Keywords: ambulatory care, anticoagulants, medication therapy management, quality of healthcare, warfarin.

Millions of patients receive warfarin each year to prevent or treat thromboembolic disease. Better anticoagulation control (i.e. a greater percentage of time in therapeutic range [TTR]), can reduce the occurrence of adverse events [1–4]. Therefore, to improve patient outcomes, sites of care should develop systems to measure and improve TTR [5–7]. Ideally, we should measure not only intermediate outcomes (such as TTR), but also processes of care, because process deficiencies provide a prescription for remediation. Because the most useful process measures are 'tightly linked' to outcomes [8], it would be ideal to demonstrate which processes of care are associated with better anticoagulation control.

We have profiled 100 sites of care in an integrated healthcare system (the Veterans Health Administration, or VA) on TTR [9]. Having profiled sites on anticoagulation control (an intermediate outcome of care), we sought to determine which processes of care predict this outcome [8]. Several site-level processes of care are related to TTR, most notably follow-up intervals after out-of-range International Normalized Ratio (INR) values [10]. Another process measure likely to affect anticoagulation control is pursuit of a target INR range of 2–3 for most patients. Several high-quality randomized trials have demonstrated that aiming for a lower INR target range (such as 1.5–2) produces inferior protection from thromboembolism with no reduction in rates of major hemorrhage [11–16]. Despite the established value of the standard target range of 2–3 for patients with atrial fibrillation (AF) or venous thromboembolism (VTE) [5,17,18], some clinicians may continue to implicitly or explicitly aim for non-standard target ranges. Although these clinicians may believe that they can successfully keep patients within a very narrow target range such as 2–2.5, target ranges narrower than a full INR unit do not reduce the variability of INR [19].

One prominent study includes use of a standard target range of 2–3 for patients with AF among its quality measures [20]. However, in most large automated databases, we do not have direct access to the target range, complicating efforts to use this as a quality measure. In this study, we propose a new process of care measure for oral anticoagulation: the proportion of patients at a site, anticoagulated for AF or VTE, who achieve a mean INR of 2.3–2.7. We assert that this does not merely measure differences in INR variability among sites of care, but actually measures site-level propensity to target non-standard target ranges, because even patients with highly variable INR values will still tend to achieve a mean INR very close to what is being sought. We used a large database from the VA to address three main questions. (i) At which level of mean INR do patients record the highest TTR? (ii) Do sites of care vary in their propensity to aim for non-standard target ranges? (iii) Are these differences associated with site-level anticoagulation control? Demonstration of variability of process and a relationship with an intermediate outcome of care would provide strong support for measuring, and intervening to optimize, this new process measure.

Methods

Data

The database for this study has also been described elsewhere [9]. The Veterans AffaiRs Study to Improve Anticoagulation (VARIA) included all patients deemed to be receiving oral anticoagulation therapy from the VA between 1 October 2006 and 30 September 2008, based on the criteria described below. The study was approved by the Institutional Review Board of the Bedford VA Medical Center.

Patients

We included all patients who received warfarin from the VA during the 2-year study period (i.e. at least 30 days' worth dispensed by the pharmacy). We excluded patients whose primary indication to receive warfarin was valvular heart disease. Many such patients have a target INR range of 2.5–3.5 rather than the more standard 2–3, but it is not possible to determine with certainty which patients have the higher target range. Without specific knowledge of the target range, we cannot calculate TTR. For this study, we also excluded the inception period, or the first 6 months of warfarin therapy, a period when many patients may have erratic INR control and may spend much time below the target range.

Laboratory values and calculation of per cent time in range (TTR)

We included INR values within the VA system during times when a patient was 'on warfarin': that is, when a patient was either (i) in possession of warfarin or (ii) having INR tests at least every 42 days. We defined the period of warfarin possession as the duration of the most recent VA prescription for warfarin, plus 30 days. Because patients may be instructed to take half-doses of warfarin, we recognize that going more than 30 days beyond the end of a prescription does not necessarily indicate that warfarin therapy has stopped. We therefore also allowed a consistent pattern of INR measurements (i.e. every 42 days or less) to indicate that a patient was still being managed.

We excluded INR tests measured while the patient was hospitalized. Patients who are hospitalized may receive temporary parenteral anticoagulation or no anticoagulation, so low INR values while hospitalized may be intentional. We calculated TTR using Rosendaal's method [21], which uses linear interpolation to assign an INR value to each day between successive observed INR values. Gaps of 56 days or more between INR values are not interpolated. After interpolation, the percentage of time during which the interpolated INR values lie between 2.0 and 3.0 (from 0 to 100%) is calculated [21].

Sites of care

We included 100 VA sites of care, each of which includes a hospital, an outpatient care center and several outlying community-based clinics. Each site has a specialized anticoagulation clinic, which is usually run by clinical pharmacists under the supervision of a medical director[22]. Therefore, essentially all patients whose anticoagulation is managed in the VA are managed by specialized anticoagulation clinics. Most patients only visited one site of care, and their INR data were assigned to that site. If a patient visited more than one site (3% of patients), we partitioned their data by site.

While most INR values in the VA are processed via an automated laboratory, a few VA sites mostly or exclusively rely upon point-of-care (POC) testing. Our data do not specify which INR tests were obtained via POC. Home testing with POC devices is not covered by the VA, and therefore is extremely uncommon.

Risk adjustment model

We have previously described our risk adjustment model for TTR [9]. We considered many potential variables for inclusion in the model which were likely to impact TTR, including demographics, area-level poverty, driving distance to care, physical health conditions, mental health conditions, number of medications, and number of hospitalizations. Most variables were retained within the model, with the exception of several co-morbid conditions with small effect sizes. The model was derived and validated according to customary procedures, which included considerations of maximizing predictive ability, clinical credibility, and ease of use and understanding. This patient-level risk adjustment model for TTR has an R^2 of 13.3% when used with this dataset [9]. Table 1 contains all the variables in the model.

Table 1 Patient characteristics (n = 103 897)

Variable	Number (%), median (IQR) or mean (SD)
Female gender	1976 (1.9)
Median age (IQR)	72 (62–79)
Race/ethnicity	
Non-Hispanic white	88481 (85.2)
Non-Hispanic black	9572 (9.2)
Hispanic	3229 (3.1)
Asian	392 (0.4)
Native American	449 (0.4)
Other/unknown	1774 (1.7)
Median per cent poverty in zip code of residence (IQR)	10.7 (6.6–16.0)
Median distance from nearest VA facility in miles (IQR)	7.8 (3.7–16.5)
Primary indication for warfarin*	
Atrial fibrillation	66 756 (64.3)
Venous thromboembolism	28350 (27.3)
All others combined	8791 (8.5)
Physical co-morbid conditions	
Cancer (newly diagnosed)	7033 (6.8)
Chronic kidney disease	14581 (14.0)
Chronic liver disease	1228 (1.2)
Chronic lung disease	30 311 (29.2)
Diabetes	41 507 (40.0)
Epilepsy	2903 (2.8)
Heart failure	33 727 (32.5)
Hyperlipidemia	78 205 (75.3)
Hypertension	87 138 (83.9)
Mental co-morbid conditions	
Alcohol abuse	9583 (9.2)
Bipolar disorder	2359 (2.3)
Dementia	5491 (5.3)
Major depression	22 378 (21.5)
Substance abuse (non-alcohol)	4164 (4.0)
Median number of medications (IQR)	8 (6–12)
Hospitalized at least once	26 921 (25.9)
Anticoagulation control	
Per cent time in range (TTR), mean (SD)	61.6 (22.1)

IQR, interquartile range. *Patients whose main indication for anticoagulation was valvular heart disease or prosthetic heart valve were excluded from this study.

Dependent variable: site-level anticoagulation control

Our dependent variable was mean site risk-adjusted TTR (also known as observed minus expected, or O-E). First, for each patient, we calculated the observed TTR (O) and applied the risk adjustment model to calculate the expected TTR (E). Then, an observed minus expected (O-E) score was calculated for each patient. The mean O-E score for each site constituted its risk-adjusted TTR. We also calculated the mean O, E and O-E for each site of care.

Independent variable: site mean INR value

As explained above, we included all INR values that occurred when a patient was 'on warfarin' according to our definition, and that were within 56 days of another INR (a 'valid interval'). We limited this study to patients who had at least four valid intervals for calculating per cent time in therapeutic range (TTR) [21]. For this purpose, a valid interval consists of two INR values separated by 56 days or less, without an intervening hospitalization. In this way, we ensured that patients had sufficient INR values to reliably indicate their target INR. For each patient, we calculated his or her mean INR value over the 2-year study period. We also calculated separate mean INR values in years 1 and 2 of the study for patients who had at least four valid intervals in one year. We computed, for each site, the overall mean INR value, as well as the proportions of patients with a mean INR value < 2.3, 2.3–2.7 and > 2.7.

INR values may be measured several times in rapid succession when the INR is low or high. We were concerned that this phenomenon might impact our assessment of patient- or site-level mean INR values. We therefore computed an alternative version of our independent variable, omitting all INR values obtained within 7 days after the previous value. The results of our analyses were essentially unchanged.

Statistical analyses

We examined the baseline characteristics of patients in our database. We calculated unadjusted and risk-adjusted TTR for each patient and for each site of care. We characterized each patient's mean INR value, each site's mean INR value, and the proportion of patients at each site with a mean INR of 2.3–2.7. We examined the ability of patient-level mean INR value to predict unadjusted and adjusted TTR using ANOVA, linear regression and cubic smoothing splines [23]. We examined the relationship between site-level proportion of patients with mean INR 2.3–2.7 and site-level anticoagulation control using linear regression. All analyses were conducted using SAS, version 9.1 (SAS Corporation, Cary, NC, USA).

Results

Patients

Our database contained 103 897 patients who were experienced users of warfarin for indications ordinarily requiring a target INR range of 2–3 (i.e. not mechanical heart valves). Patient characteristics are shown in Table 1. The sample was mostly male (98%) and had a median age of 72 years (IQR 62–79). More than half of the patients were anticoagulated for AF (64%), with many of the others anticoagulated for VTE (27%). Patients had a substantial burden of chronic disease: 40% had diabetes, 32% had heart failure, 29% had chronic lung disease, and 14% had chronic kidney disease. Patients also had a substantial burden of mental health disorders: for example, 22% had major depression, and 9% carried a diagnosis of alcohol abuse. As might be expected with this burden of co-morbidity, patients received many medications (a median of eight) and 26% were hospitalized at least once during the study.

Overall anticoagulation control was fair for this population of experienced users of warfarin (mean TTR = 61.6%).

Mean INR values – patient level

Patients varied widely in their mean INR values. The mean of all INR values in the database was 2.42, but 10% of patients were below 2.00 and 10% were above 2.83, so extreme deviations were not uncommon. The maximum predicted TTR occurred at a mean INR value of 2.43. At this value, patients had a predicted TTR of 71%; for each deviation of 0.1 from this value, the predicted TTR was 3.9% lower ($P < 0.001$). However, this relationship was not symmetric, with greater decrements in TTR occurring below a mean INR of 2.43 than above it (Table 2). An ANOVA test, comparing deciles of patients with regard to mean INR values, demonstrated a similar phenomenon (Table 2). Anticoagulation control was generally excellent among patients with a mean INR between 2.3 and 2.7, but quite poor outside of this range.

Mean INR values – site level

There were 100 sites of care in the database. The number of patients per site ranged from 74 to 4371 (mean 1039 per site). Site TTR varied from a low of 43% to a high of 72%, and site risk-adjusted TTR varied from 18% below to 12% above predicted. Site mean INR varied widely, from 2.22 to 2.89. The median site had 34% of patients with a mean INR < 2.3, 48% of patients with a mean INR 2.3–2.7, and 16% of patients with a mean INR > 2.7. However, there was considerable variation in this regard; sites ranged from 30 to 64% of patients with a mean INR of 2.3–2.7 (Fig. 1). In a regression analysis, for every 10% of patients at a site with a mean INR of 2.3–2.7, site-unadjusted TTR was 4.4% higher, and site risk-adjusted TTR was 3.8% higher ($P < 0.001$ for both findings).

The proportion of patients at each site with a mean INR 2.3–2.7 was consistent between years: comparing FY07 with FY08, the coefficient of correlation was 0.78 ($P < 0.001$). Sites were also somewhat consistent regarding whether their patients achieved mean INR values above or below this desirable range. For example, regarding the proportion of patients with a mean INR below 2.3, sites varied from 19 to 62%. The coefficient of correlation between FY07 and FY08 regarding the proportion with mean INR below 2.3 was 0.45 ($P < 0.001$). Several sites had a consistent pattern of having many patients with low mean INR. For example, sites KM and GD had among the very highest proportion of patients with a low mean INR in both years (KM, 56% and 65%; GD, 55% and 60%). The correlation between years for the proportion with a high mean INR was also appreciable ($r = 0.35$, $P < 0.001$), but not as strong a relationship.

Discussion

We examined mean INR values at the patient level and the site of care level. We had three main findings: (i) site mean INR varied widely; (ii) proportion of patients near 2.5 varied widely by site, and proportions low, high and near 2.5 were stable across years; and (iii) a higher proportion near 2.5 was strongly associated with higher site-level TTR. Several related points remain speculation: (i) intentional pursuit of non-standard INR target ranges is the principal cause of variation in site-level mean INR; (ii) actively discouraging clinicians from adopting non-standard targets will increase TTR and reduce adverse events; (iii) it will be possible to induce clinicians to change their practise regarding INR target ranges; and (iv) discouraging non-standard targets will not harm certain classes of patients, such as the oldest old (age 80+).

We will soon launch an initiative to improve mean TTR in the VA from its current 58% to 70% [9], an improvement that could prevent thousands of adverse events [24]. In light of the present study, one strategy will be to discourage sites from pursuing non-standard target INR ranges. We hypothesize that decreased use of non-standard target ranges will increase the proportion of patients with a mean INR of 2.3–2.7, and that sites that change this parameter the most will increase TTR the most. In addition, by directly measuring outcomes among important subgroups of patients (e.g. the oldest old), we hope to provide reassurance that avoiding non-standard target ranges benefits them as well, or at least does not harm them. This forthcoming study will therefore address whether the proportion of patients whose mean INR is near 2.5 can serve as a useful process measure in anticoagulation care.

The finding that extremes of mean INR are associated with poor anticoagulation control at the patient level is not surprising. However, the finding that sites of care vary more

Table 2 Patient-level analysis of relationship between mean INR value and per cent time in therapeutic range (TTR). Patients are divided into deciles by mean International Normalized Ratio (INR) values. The range of mean INRs is given for each decile (n = 103 897)

Mean INR group	Lowest	2	3	4	5	6	7	8	9	Highest
Range of mean INR	< 2.00	2.00–2.16	2.16–2.25	2.25–2.33	2.33–2.40	2.40–2.48	2.48–2.56	2.56–2.66	2.66–2.83	> 2.83
Observed TTR	30.6%	57.4%	65.9%	68.8% A	70.6% B	70.9% B	70.8% B	69.1% A	64.7%	46.8%
Adjusted TTR	−28.4%	−3.7%	+4.1%	+6.6% C	+8.2% D	+8.5% D	+8.4% D	+6.9% C	+2.9%	−13.4%

Observed TTR is between 0 and 100%. Adjusted TTR measures the difference between observed and expected TTR. Expected TTR is calculated for each patient based on his or her demographics and co-morbid conditions. Positive values for adjusted TTR indicate that a patient's observed TTR exceeded the expected TTR. ANOVA tests are significant for comparisons of observed TTR and adjusted TTR ($P < 0.001$ for both). Groups designated by a common letter are not significantly different from one another by Tukey's *post hoc* test.

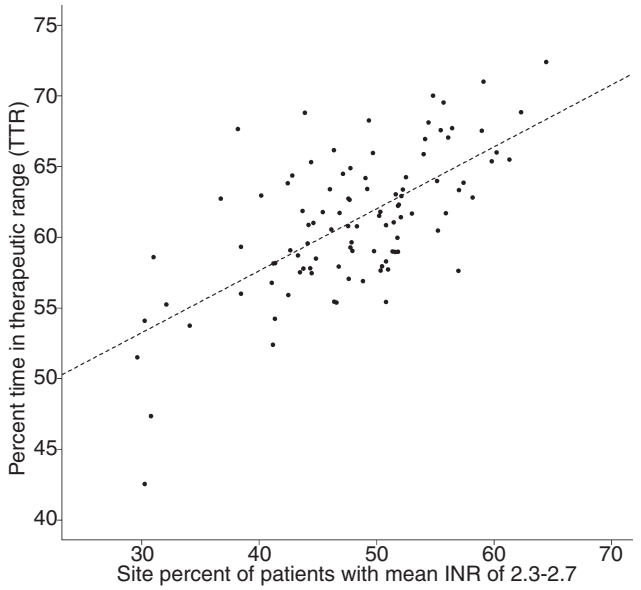

Fig. 1. Site-level per cent time in therapeutic range (TTR) plotted against site-level proportion of patients with mean INR of 2.3–2.7. (n = 100 sites).

than 3-fold regarding the proportion of patients with a mean INR below 2.3 suggests real differences in site-level practise. Our findings suggest that some sites routinely choose a guideline-concordant target range of 2–3 while others are likely to attempt to 'shade' patients below this range. This might take the form of an explicit designation of a non-standard target range (for example, 2–2.5) or an implicit tendency to aim for the lower end of a nominal target range of 2–3.

As discussed above, considerable work is needed to extend the results of this study and to clarify their implications. For now, however, we recommend that clinicians aim for standard target ranges, as are already recommended by prominent guidelines such as ACCP [5]. We are not advocating a target range of 2.3–2.7, or any other narrow range [19]. Clinicians should be equally satisfied with an INR of 2.1 or 2.9, provided the patient is under stable control. Rather, we recommend eliminating target ranges other than 2–3 and 2.5–3.5 [5,17,18,25,26].

Our study has important strengths, particularly the size and clinical detail of the database. However, we also acknowledge limitations. First, as stated above, we cannot know for sure why sites achieved such disparate mean INR values. While we suspect that it is a reflection of different styles of practise at each site, our observational database study is not equipped to confirm this suspicion. Second, we examined the impact of mean INR values on anticoagulation control, but did not examine the impact of mean INR values on adverse events. However, multiple studies have already linked TTR to adverse events [1–4], demonstrating the importance of pursuing a higher TTR both for populations and for individuals. In addition, multiple studies have also linked the pursuit of 'low' target INR ranges to inferior patient outcomes [11–15], as discussed above. Nevertheless, this study could have provided even more compelling evidence by directly linking site-level target ranges to site-level rates of adverse events. Unfortunately, we lack the data to directly examine adverse events with this dataset. In the future, we hope to examine this link more directly. Third, VA patients are mostly male and have higher rates of co-morbid illness, mental illness, substance abuse disorders and socioeconomic disadvantages than the general US population. This may have contributed to INR target range choices; for example, clinicians may justifiably fear hemorrhage in an alcoholic patient and therefore target a low INR value. However, these issues are unlikely to impact the underlying relationships we demonstrated between site-level mean INR values and site-level TTR. In addition, our risk-adjustment model should have accounted for the impact of these patient characteristics upon TTR, at least within the VA system [9].

In conclusion, 100 sites of care in the nation's largest integrated healthcare system varied considerably in their mean INR values and in the proportion of patients with a mean INR of 2.3–2.7. Our results suggest that pursuing standard INR target ranges (2–3 for most patients) could improve anticoagulation control, as measured by TTR. In a forthcoming intervention study, we plan to test this proposition by actively promoting the use of standard INR targets and observing the effects on TTR and patient outcomes.

RESEARCH ARTICLE

Organizational Characteristics of High- and Low-Performing Anticoagulation Clinics in the Veterans Health Administration

Adam J. Rose, Beth Ann Petrakis, Patricia Callahan, Scott Mambourg, Dimple Patel, Elaine M. Hylek, and Barbara G. Bokhour

Objective. Anticoagulation clinics (ACCs) can improve anticoagulation control and prevent adverse events. However, ACCs vary widely in their performance on anticoagulation control. Our objective was to compare the organization and management of top-performing with that of bottom-performing ACCs.

Data Sources/Study Setting. Three high outlier and three low outlier ACCs in the Veterans Health Administration (VA).

Study Design. Site visits with qualitative data collection and analysis.

Data Collection/Extraction Methods. We conducted semi-structured interviews with ACC staff regarding work flow, staffing, organization, and quality assurance efforts. We also observed ACC operations and collected documents, such as the clinic protocol. We used grounded thematic analysis to examine site-level factors associated with high and low outlier status.

Principal Findings. High outlier sites were characterized by (1) adequate (pharmacist) staffing and effective use of (nonpharmacist) support personnel; (2) innovation to standardize clinical practice around evidence-based guidelines; (3) the presence of a quality champion for the ACC; (4) higher staff qualifications; (5) a climate of ongoing group learning; and (6) internal efforts to measure performance. Although high outliers had all of these features, no low outlier had more than two of them.

Conclusions. The top-performing ACCs in the VA system shared six relatively recognizable characteristics. Efforts to improve performance should focus on these domains.

Key Words. Qualitative research, quality of health care, anticoagulants, pharmacists, organization and administration

Warfarin (Coumadin) is an oral anticoagulant given to millions of patients to treat or prevent blood clots. Warfarin requires routine blood tests to ensure that patients are sufficiently anticoagulated to prevent blood clots, but not so

thoroughly anticoagulated as to place them at excessive risk of bleeding. Warfarin can be difficult to manage, and clinicians must carefully monitor and adjust doses to keep the patients in the target range. Management in a dedicated anticoagulation clinic (ACC) can improve anticoagulation control (van Walraven et al. 2006). Veterans Health Administration (VA) medical centers are required to manage all patients receiving warfarin in an ACC, which is generally run by clinical pharmacists (Veterans Health Administration 2009).

Nevertheless, even among patients receiving treatment in an ACC, there is substantial variation in anticoagulation control (Rose et al. 2011a). Many patients have poor control (van Walraven et al. 2006; Rose et al. 2010), which increases rates of stroke, venous thromboembolism, major hemorrhage, and death (Veeger et al. 2005; White et al. 2007; Wallentin et al. 2010). Anticoagulation control can be measured by the percentage of time in therapeutic range (TTR) (Rosendaal et al. 1993). We have proposed using TTR as a quality measure (Rose et al. 2009). In our recent study, mean site TTR varied among 100 VA ACCs by more than 20 percent, a large and clinically important difference (Rose et al. 2011a).

We sought to understand this variation in performance using the positive deviance approach (Bradley et al. 2009). This approach emphasizes in-depth qualitative study of organizations with exceptionally high performance to understand the factors that contribute to their excellence (Peters and Waterman 1982; Spear and Bowen 1999; Gawande 2007). Qualitative methods are ideal for studying organizational culture, which can be difficult to characterize using quantitative methods (Sofaer 1999; Patton 2002). The Anticoagulation Forum has proposed nine key domains (Table 1) that are essential to establishing and maintaining a high-quality ACC (Garcia et al. 2008). We sought to explore these nine domains, while remaining open to others that would emerge through this qualitative study.

Table 1: Nine Recommendations for Optimal Anticoagulation Care as per the Anticoagulation Forum Consensus Statement (Garcia et al. 2008)

Domain	*Explanation*
1. Qualifications of personnel	ACC staff should be licensed health care professionals possessing core competency related to anticoagulation therapy.
2. Supervision	The ACC should have a well-defined relationship with responsible/referring health care providers (e.g., the primary care physician).
3. Care management and coordination	The ACC should have written policies and procedures that are approved by the clinic's medical director. An efficient system for scheduling and tracking patients should be utilized.
4. Documentation	The ACC should have an accurate system of documentation to ensure that clinically relevant data are available to staff at all times.
5. Patient education	The delivery of anticoagulation care should address the educational needs of patients and their caregivers.
6. Patient selection and assessment	Optimized anticoagulant therapy should be instituted only after careful consideration of the risk and benefit for an individual patient. The appropriateness of anticoagulation therapy should be periodically reviewed for each patient.
7. Laboratory monitoring	Optimized anticoagulation therapy should incorporate regular laboratory monitoring of anticoagulant effect, using either a high-quality laboratory or a well-maintained point of care device.
8. Initiation of therapy	The initiation of optimized anticoagulation therapy should use a systematic, evidence-based approach.
9. Maintenance of therapy	The delivery of optimized anticoagulation should use a systematic process for longitudinal patient assessment, adjustment of anticoagulant drug doses, scheduling of follow-up visits, and interruptions of therapy for elective procedures.

METHODS

Selection of Study Sites

Based on our rankings of risk-adjusted anticoagulation control at 100 VA sites (Rose et al. 2010, 2011a), we selected 3 of the top 10 and 3 of the bottom 10 sites, and obtained IRB approval from all study sites. Sites were not informed of their high or low outlier status. Although we selected sites based on their performance from October 2006 to September 2008 (the "measurement period"), site visits occurred between May 2010 and March 2011. We took care to identify personnel and organizational factors that had changed since the measurement period. To a large extent, these factors and personnel had not changed, but when they had, we viewed this as an additional opportunity to examine not only static models of high and low performance but also changes in performance. When conditions as we found them differed in important ways from what was present during the measurement period, we have noted this in the text.

Data Collection

Interviews. One author (A. J. R.) visited each study site for two working days. At each site, we sought to interview all staff members who work in the ACC or whose work impacts the ACC. All employees agreed except one, and all participants gave informed consent. Each participant was interviewed in private for 20–60 minutes using a semi-structured interview technique. Interview topics were based largely upon the Anticoagulation Forum recommendations (Garcia et al. 2008) and included ACC work flow, staffing, organization, and quality assurance efforts. We also asked about the clinic's patient population, the challenges of managing anticoagulation, and the participant's opinion of the clinic's performance. All interviews were audio-recorded and transcribed verbatim.

Observation. At each site, we observed approximately 4 hours of direct clinical care, which occurred face-to-face or by telephone. We observed delivery of care, work environment, work pace and flow, patient-provider interactions, and interactions among pharmacists and pharmacy technicians working in the ACC.

Documents. We obtained ACC-related documents, including ACC protocols, note and consult templates from the electronic medical record, training manuals for ACC staff, education materials for non-ACC staff, patient education materials, patient-provider treatment agreements, form letters sent to patients, quality assurance forms and reports, and screen shots of clinical management software used by the ACC.

Data Analysis

Using grounded thematic analysis, we coded interview transcripts, identifying broad "domains" of ACC organization and subtopics within each domain (Patton 2002). Having coded the interview transcripts, we added information gleaned from the field notes and the ACC documents. We synthesized the data from each site and produced a profile of each site's organization and management. As successive study sites were added, we used constant comparison to contrast our findings from various sites, noting similarities and differences between high- and low-performing sites. We made a conscious effort to note counterexamples, particularly positive aspects of bottom-performing sites and negative aspects of top-performing sites. We identified key features present or

absent at each site, noting relationships between these features and site performance. Finally, we performed internal member checking among our co-authors, many of whom have direct experience managing oral anticoagulation, to ensure that our findings resonate with anticoagulation practitioners.

RESULTS

The six sites we visited represented six different states and all geographic regions of the United States. Details about site performance are located in Table 2. Table 3 lists the job descriptions of the 55 interviewees.

We identified 11 domains related to site organization; six were related to site performance and five were unrelated (Table 4). Although high outliers had all six of the features related to performance, no low outlier had more than two of them. The important domains were (1) adequate (pharmacist) staffing levels and effective use of (nonpharmacist) support personnel; (2) innovations to standardize clinical practice around current evidence and guidelines; (3) the presence of a quality champion; (4) higher staff qualifications; (5) a climate of ongoing group learning; and (6) internal performance measurement.

Domain #1: Staffing

We observed, and were told by interviewees, that ACC staff at the low outlier sites had a rushed work pace and a chaotic work environment, whereas

Table 2: Three High Outlier and Three Low Outlier Sites, as Measured by Performance on Percent Time in Range (TTR), a Measure of Anticoagulation Control

Site Number	*Outlier Status*	*TTR, 2007–2008 (%)*
1	High	67
2	High	67
3	High	70
4	Low	52
5	Low	54
6	Low	54

Notes. Although Sites Were Selected for Inclusion Based on Risk-Adjusted TTR (Rose et al. 2011b), Unadjusted TTR Is Presented Here for Ease of Understanding. TTR was computed using the Rosendaal method (Rosendaal et al. 1993). TTR above 60 percent is generally considered adequate, whereas TTR above 70 percent is generally considered excellent.

staff at the high outliers worked at a comfortable pace in a well-organized environment. Based on expert opinion, consensus guidelines for organizing an ACC recommend a ratio of no more than 400 patients per pharmacist full-time equivalent (FTE) (Ansell et al. 2008). Details about staffing at our six study sites are in Table 5. In general, the adequacy of staffing was not fully characterized by the patient/FTE ratio but also depended on the effective integration of support staff into the ACC, the degree to which staff could focus on their ACC duties without other responsibilities, and avoiding an inappropriate reliance upon trainees (pharmacy residents) to provide manpower, as will be discussed below.

Pharmacists. Anticoagulation clinic staff at low outlier sites consistently reported being rushed due to inadequate staff allocations; we also observed this rushed work pace. In contrast, staff at high outliers only rarely reported mild issues with staffing related to vacations and sick leave. Understaffing at

Table 4: Summary of Six Anticoagulation Clinics on Six Domains Related to Site Performance and Five Domains Not Related to Site Performance

Key to table:
✓ = present during measurement period of 2007–2008.
No symbol = absent during measurement period of 2007–2008.
Key to domains:
Staffing: Sufficient staffing to handle workload without rushing.
Innovation: Innovations to encourage evidence-based practice.
Champion: Presence of one or more quality champions for the ACC.
Qualifications: Hiring residency-trained pharmacists.
Group learning: Creating a climate of ongoing group learning.
Measurement: Internal performance measurement.
Telephone clinic: Majority of patients managed via telephone rather than face-to-face.
Commitment: Demonstrated commitment to serving veterans.
Integration: Effectively leverages the advantages of membership in an integrated health system.
Patient selection: Selectively refusing to treat difficult or troublesome patients (gaming).
Tenure: Clinic established more than 20 years ago.

low outliers was manifested through frequently overbooked appointments, chaotic work days, and sagging morale. An interview with one pharmacist revealed the stress prevalent at the low outlier sites:

> Q: Are you pretty happy with how your job here is going?
> A: I'm overwhelmed…over the years, our numbers have grown … and no one has really looked at our workload and I think we're really stretched. (Pharmacist, Low Outlier)

A pharmacist at another low outlier suggested that being short-staffed may prevent them from following some patients as frequently as needed, a potentially serious issue with quality of care:

Table 5: Details for Clinic Staffing in Six VA ACCs

Panel Size		*FTE*	*Patient/ FTE Ratio*	*Support Staff*	*Details*
High outlier sites					
Site 1	550	1.5	375	Specially trained clerks	ACC providers have considerable time for administrative tasks, much of which is also devoted to the ACC
Site 2	1700	4	425	2 pharmacy technicians	Workflow is highly streamlined and is aided by clinical management software
Site 3	250	1.5	167	None	
Low outlier sites					
Site 4	600	2	300	None	Pharmacists not dedicated to ACC; distraction may reduce effectiveness
Site 5	1000	1	1000	None	Approximately 1 additional FTE of resident labor in ACC
Site 6	800	1.5	533	1 pharmacy technician	

Notes. Panel Sizes Were Determined from VA Automated Data (Rose et al. 2011b), whereas Pharmacist FTEs Assigned to the ACC during the Measurement Period (10/06-9/08) Were Determined through Interviews and Direct Observation. A Patient to FTE Ratio of No More Than 400 Is Generally Recommended by Consensus Guidelines (Ansell et al. 2008).
ACC, anticoagulation clinic; FTE, full-time equivalents (pharmacists, not counting support staff); VA, Veterans Health Administration.

> Sometimes we need closer follow-up, but we don't do closer follow-up 'cause we don't have enough help. So I think we're doing the best we can with what we've got. (Pharmacist, Low Outlier)

By contrast, ACC providers at the top sites had fewer patients per FTE, which was reflected in their work pace. One participant noted:

> I don't think we're capacity most days. I don't think we have 40 face-to-face visits most days, but that's good, because that allows us to see patients more frequently if necessary. There are still appointments left to see those patients without overbooking. (Associate Chief of Pharmacy, High Outlier)

Support Staff. Adequate staffing also relates to the role of support staff, individuals who work in the ACC but do not have the authority to prescribe warfarin. When present, pharmacy technicians were universally lauded as contributing to the smooth functioning of the ACC. For example, at one high outlier, four FTE of pharmacists were supplemented by two FTE of pharmacy technicians, who handle incoming calls, distribute workload, and mail letters,

thereby freeing the pharmacists to concentrate on higher level tasks, such as managing patients who are out of range. However, personnel other than pharmacy technicians can also provide effective support. At another high outlier, only the most experienced clerks are given special training and permission to schedule appointments for the ACC. Low outliers were generally characterized by ineffective approaches to support staffing: either untrained clerks or, at two sites, no support staff at all.

Dedicated Time for ACC Duties. At most study sites, ACC pharmacists had dedicated days when they staffed the ACC without other obligations. In contrast, at one low outlier, ACC pharmacists were simultaneously responsible for anticoagulation and other tasks related to primary care pharmacy. Pharmacists at this site were frequently interrupted from ACC duties to attend to non-ACC matters.

For example, we observed a pharmacist from this low outlier site treating a patient who had suffered a blood clot in the lung. The patient was hard of hearing, possibly suffered from dementia, lived in a trailer, and did not fully understand or accept the need for anticoagulation. The visit was interrupted six times by people walking into the room (often without knocking) to ask the pharmacist questions in her role as a primary care team member. Each interruption caused a loss of focus and momentum, and the overall effect was to prolong the visit and to transform an already difficult encounter into an almost insurmountable challenge.

Avoiding Inappropriate Use of Pharmacy Residents. At most of the sites we visited, pharmacy residents were in the ACC primarily to learn and were not expected to contribute greatly to staffing due to their inexperience and need to be supervised. However, at one low outlier site, residents were expected to be about as productive as the senior pharmacists. They handled about half of the workload of the ACC and we were explicitly told that they constituted an important part of the staffing plan. A pharmacy resident from this site, who had recently rotated through the ACC for a month, remarked:

> I feel like the pharmacy residents do a lot here … just because there are so many patients … I'm interviewing patients in 10 or 15 minute increments, very fast. (Pharmacy Resident, Low Outlier)

The fact that half the care at this site was delivered by pharmacy residents may have contributed to uneven quality of clinical management. A pharmacist at this site admitted that the quality of the pharmacy residents can vary from day to day and from month to month: "It's hit and miss with them." This does not suggest that these residents or their training are lacking, merely that they need to complete residency before so much can be expected of them.

Domain #2: Innovations to Encourage Uniform, Evidence-Based Practice

Top sites developed innovative ways for encouraging uniformity of practice. In general, the organizing principles for standardization were drawn from existing clinical guidelines about anticoagulation care, especially the American College of Chest Physicians (ACCP) guidelines for managing warfarin (Ansell et al. 2008). This domain, with its emphasis on the systematic pursuit of uniform, evidence-based practice, is also embodied in the Anticoagulation Forum Consensus Guidelines for organizing an ACC (Garcia et al. 2008). We noticed at least three examples of how sites pursued uniform, evidence-based practice: developing note templates as an aid to clinical reasoning and documentation, adopting new software packages to enhance workflow, and developing systems to reduce loss to follow-up.

Evidence-Based Note Templates. One way to reinforce evidence-based practice is to design note templates around it. Although all of the sites had note templates, some were especially effective at encouraging adherence to clinical guidelines. For example, one site's ACC Coordinator created a note to guide clinicians through the decision-making process of how to manage a temporary interruption of warfarin therapy for a procedure. Although this was a low outlier site, this note was introduced after the measurement period as part of an effort to improve the ACC.

> Previously … if we heard about a patient … stopping [warfarin] for a procedure we would kinda wait and see if somebody had the idea of using bridge. I standardized that process … [now] if we hear a patient's stopping Coumadin he's gonna do it through a standardized review process that's based strictly on the [ACCP] guidelines. I created a note template that quotes what the guidelines say … and then we walk 'em through the peri-procedure risk assessment note which gets documented in the medical record and is sent to the doctor. (Pharmacist, Low Outlier)

Adopting New Software to Aid Clinical Practice. One high outlier site used a software package to help streamline anticoagulation management. Participants commented, and we observed, that the software contributed to this site's ability to handle a large patient load without compromising quality. The software improved work flow, helped make sure patients were not lost to follow-up, and allowed for internal performance measurement with a minimum of effort. A low outlier site also started using this software package in 2010 (after the measurement period) with similar positive results.

Reducing Loss to Follow-Up. It is important not to lose ACC patients to follow-up, because without proper monitoring, patients may be at risk for serious adverse events. All six sites had various techniques to avoid losing patients—the most common was to limit warfarin prescriptions to a short period of time (often 30 days), to ensure that the patient must follow-up. However, some sites went farther. At one high outlier, the ACC Coordinator "runs the list" monthly to manually search for patients who have not been seen for over 30 days (a laborious process). The two sites that had adopted the new software package easily performed this task, because the software monitors this automatically. One low outlier had no system to prevent loss to follow-up:

> Actually we don't have a system in place for that. Now, if we could run our clinics quarterly or have some kind of computer program where if a person hasn't been to see us in say, two months, then we could follow it, but right now we don't have a way of tracking 'em down. (Pharmacist, Low Outlier)

Note that this pharmacist recognizes the potential for manually running the list or a "computer program," elements that are present at the high outlier sites.

Domain #3: Quality Champion

The best sites had one or more strong quality champions for the ACC, although this champion could occupy many different formal positions. At one high outlier, this champion was the Associate Chief of Pharmacy, also the ACC's founder. She wrote all the procedures for the ACC, trained her replacements, and continued to take a special interest in the ACC's performance. At another high outlier, this champion was the ACC Coordinator,

while at a third, the main quality champion for the ACC was the Chief of Pharmacy. In the following quote, a quality champion explains her role with regard to the ACC:

> I would say my main thing is to make sure that I really kinda do the quality aspect…make sure that the…care that we're providing is appropriate. That if we're gonna offer a program, that it's doing what it needs to do, and if it isn't then what do I need to do to fix it. (Chief of Pharmacy, High Outlier)

None of the low outliers had a quality champion. For example, one low outlier had a middle manager in the pharmacy department whose job was to oversee credentialing, peer reviews, academic pursuits, and quality assurance for pharmacists. However, he had almost no role with regard to the ACC pharmacists, because they were located in primary care rather than pharmacy. Instead, these pharmacists were supervised by the director of primary care, a physician. Although she has made her primary care clinic into a model of performance, she saw the pharmacists primarily in their role as supporting cast for the primary care clinic and was relatively unaware of the pharmacists as the central movers in managing anticoagulation. Thus, there were two people qualified to serve as the quality champion for the ACC (the pharmacy middle manager and the ACC medical director), but one was not given the authority to do so and the other did not see it as part of her job.

Domain #4: Staff Qualifications

Many pharmacists complete a 1-year residency after obtaining their PharmD degree. The purpose of residency is to gain a set of skills in a mentored setting, especially the ability to interact with patients to directly manage chronic conditions. All of the ACC pharmacists at the top outlier sites had completed residencies in pharmacy. In contrast, none of the pharmacists at two of the low outlier sites were residency trained.

We observed important differences between pharmacists with and without residency training. The residency-trained pharmacists had greater facility communicating with patients. The pharmacists that lacked residency training struggled to handle difficult situations, often despite years of experience. At one site, we did observe a nonresidency trained pharmacist who was instead completing a protracted apprenticeship in the ACC. This suggests that other kinds of training can also help pharmacists to achieve a similar degree of facility with the skills needed for direct patient management.

Domain #5: Climate of Group Learning

Clinicians frequently discuss difficult cases to solicit the opinions and insights of their colleagues. At the high outlier sites, such interactions were explicitly encouraged, and they occurred frequently:

> So it's good to have other people next to you in the room you can bounce ideas off of. (Pharmacist, High Outlier)

These interactions were largely absent from the low outlier sites; providers at these sites tended to practice without the benefit of their colleagues' opinions. When asked about how often she seeks advice from colleagues, this pharmacist said:

> Not very often. I would probably have to say less than once every 3 months. I would say we don't tend to collaborate a lot. (Pharmacist, Low Outlier)

We directly observed a marked contrast between low and high outliers with regard to the frequency and quality of discussions of difficult cases. The availability of colleagues for discussion at the high outlier sites seemed to contribute not only to the management of the case at hand but also to an atmosphere of learning from each other.

Domain #6: Internal Performance Measurement

The top-performing sites emphasized internal performance measurement. One high outlier manually collected data at every patient encounter (a laborious task) to be able to calculate and track percentage of lab values in range and rates of adverse events in their ACC. The Associate Chief of Pharmacy, when asked about the strengths of his site's ACC, demonstrated detailed awareness of its performance:

> About two-thirds of our patients on average are within the therapeutic range. Our no-show and cancelation rate typically combined is less than 12 to 15 percent … thromboembolism is usually less than two percent, and major bleeding is usually less than 5 percent. (Associate Chief of Pharmacy, High Outlier)

At other sites, anticoagulation software or regionally produced performance reports made performance measurement particularly easy to accomplish. One high outlier site began using such software well before our

measurement period. A low outlier site recently adopted the same software. The ACC coordinator at this site commented:

> When we started using software as of January 2010, we kinda changed our QA process. We were now able to calculate our TTR or actually get reports from that from the software … we look at … thrombotic events, bleeding events … patients lost to follow-up … When the software took over we started doing that more routinely … it's something that has become a part of our practice. (Pharmacist, Low Outlier)

Low outlier sites did not measure performance in 2007–2008, although two of them have begun doing so since then. At the third low outlier, the ACC medical director admitted that they do not yet measure ACC performance in a rigorous, proactive way. When asked about ACC performance, she appeared to be unprepared for the question and thus uncomfortable with the topic. She focused on one-time episodes such as complaints or adverse events as a way to measure quality:

> You mean in terms of bad outcomes with the patients or in terms of? [Clears throat] Yes we definite—that, I would know [Clears throat]. We do have adverse outcomes. It's something that we look at. So if … a patient comes in with [a critical degree of overanticoagulation] and nobody did anything about it, I would know about this … if there's an adverse occurrence, then I'm told about this. (ACC Medical Director, Low Outlier)

In the absence of quality measurement, ACC pharmacists at this site believed that their clinic was doing very well—but in fact, their TTR was among the lowest of any VA site. One pharmacist guessed that her patients spend 70 percent of time in range, whereas another guessed 75 percent. In fact, TTR at this site was closer to 55 percent, a large and clinically important difference.

Five Domains Not Related to ACC Performance

There were at least five domains that were not associated with ACC performance, although we had expected that they might be (Table 4).

1. We had expected to find that quality might vary due to the configuration of the ACC, that is, telephone versus face-to-face management of patients and the use of point-of-care (fingerstick) testing versus reliance upon venous blood samples. We observed highly variable

configurations of care among our six sites. For example, three sites had predominantly telephone clinics and three saw their patients face-to-face, but neither model was associated with high or low outlier status.

2. All sites, whether low or high outliers, exhibited a strong commitment to serving veteran patients. Staff went to great lengths to help patients, contacting them after hours when necessary and even assisting them with matters unrelated to anticoagulation.
3. The VA's integrated system of care, and particularly the electronic medical record, are thought to contribute to the VA's generally high performance (Longman 2007). However, we did not notice any differences among sites regarding the extent to which they utilized these advantages.
4. We had suspected that high outlier sites might achieve better performance in part by being more selective in the patients they agree to manage (gaming). However, all sites went to extraordinary lengths to manage even the most challenging patients.
5. We had expected that ACCs established long ago might perform better than those established recently; in fact, only one of our ACCs was established less than 10 years before our site visit, and it was a high outlier.

In addition to these five domains, it should be noted that the nine domains identified as important by the Anticoagulation Forum (Garcia et al. 2008) generally were not sufficient to separate high- and low-performing sites (Table 1). Exceptions included Item 3, where high outlier sites generally had better systems for tracking patients and preventing loss to follow-up, and aspects of some of the other items, in that high outliers achieved greater uniformity of practice. In most respects, however, high and low outliers fulfilled the Anticoagulation Forum recommendations equally.

DISCUSSION

In this study, we visited three of the best-performing and three of the worst-performing ACCs in the VA system. We sought to understand how elements of ACC organization and management related to these differences in site-level performance. We found that six critical domains separated high and low outlier sites. Although we had anticipated some of these domains, our

investigation revealed details that we had not anticipated. For example, while we had suspected that staff credentials might be important, we had assumed that all ACC pharmacists would be residency trained, and that those at the top sites would be distinguished by additional credentials. We discovered the importance of residency training through its absence among staff at some low outlier sites and its apparent impact on their fluency as clinicians.

We also found that the recommendations of the Anticoagulation Forum (Garcia et al. 2008) were not sufficient to separate high outliers from our three low outliers. To a large extent, all six study sites had met all of these criteria. It is apparent, therefore, that the pursuit of excellence in oral anticoagulation care will require a comprehensive program of quality measurement and quality improvement (Rose et al. 2009).

In a previous study, we examined many of the same domains, including staffing, presence of quality improvement programs, and training of ACC staff but were unable to link them to site-level performance (Rose et al. 2011b). The previous study relied upon a site-level questionnaire to gather data, but complex ideas like adequate staffing may not easily be encapsulated in a single number. In the present study, we examined not only the FTE ratio but also the context and configuration of care delivery, the workflow, and the importance of support staff in allowing pharmacists to focus on higher level tasks. The present study suggests that adequate staffing is indeed important but that a simple numerical ratio of pharmacists to patients may not fully capture all the data needed to understand this issue.

Anticoagulation clinics improve anticoagulation control and usually reduce adverse events compared with "usual care" (van Walraven et al. 2006; Ansell et al. 2008), but less is known about how ACC management improves these outcomes. Our study suggests that an ACC should be characterized by a core group of well-qualified and well-trained staff, dedicated time to focus on anticoagulation (without other responsibilities), development of innovations to improve care, opportunities to discuss difficult cases and learn from each other, internal performance measurement, and a quality champion, whose role it is to facilitate all of these other things. To the extent that our low outlier sites lacked these features, they did not fully embody the ideal of an ACC. It should not be surprising, therefore, to find that anticoagulation control at these low outliers was similar to what has been reported for non-ACC settings (van Walraven et al. 2006).

Our study also suggests that building time into schedules for the purpose of problem solving and knowledge sharing can increase the value created per

person. Discussion of difficult cases allows for group learning and may even encourage group solutions to frequently encountered problems. In contrast, while providers at low outlier sites may learn from challenging cases as individuals, such learning is unlikely to spur practice innovations. It may not be necessary to add additional people to set aside time for these activities; rather, by emphasizing these activities, an ACC can foster a climate of efficiency in which people simply accomplish more and do it better.

Insights gained from this study are not limited to ACCs alone. In fact, Curry et al. found remarkably similar themes that differentiated between hospitals ranking in the top and bottom 5 percent on risk-adjusted mortality after acute myocardial infarction (Curry et al. 2011). Thus, there may be considerable overlap between the ingredients of success in a large program (such as treatment of myocardial infarction) and a small program (such as management of anticoagulation).

This study has important strengths. Our in-depth observation allowed us to uncover previously unsuspected findings, as discussed above. However, some limitations should also be noted. First, we were unable to gain access to some of the worst-performing ACCs in the VA system, primarily because those sites did not have an IRB of record, and therefore could not participate in research. We might have gained further insight had we been able to visit low outlier sites with worse performance. Second, a considerable amount of time elapsed between our measurement period and our site visits. This was unavoidable because of the time needed to identify outlier sites and obtain IRB approvals. Third, due to time and resource constraints, we were only able to visit six sites. We might have learned more if we had visited additional sites. Fourth, we realize that local circumstances may contribute to some of the suboptimal features we observed, such as a heavy reliance on pharmacy residents, high patient-FTE ratios, or a lack of residency-trained pharmacists. Strategies for addressing local resource limitations are beyond the scope of our study. Finally, the site visitor was not blinded to outlier status, and the analysis of data was also not blinded. However, we consciously tried to note what was suboptimal about high outlier sites and what was good about low outlier sites.

In summary, we found that six domains of organization and management are related to ACC performance. Clinics have the potential to transform themselves, and their performance, by focusing on changing these six domains for the better. This study reminds us that excellence is within our reach if we focus on the most important determinants of performance.

ACKNOWLEDGMENTS

Joint Acknowledgment/Disclosure Statement: This study was funded by the VA Stroke Quality Enhancement Research Initiative (QUERI), Project RRP-10-054. Validating the Patient Safety Indicators in the Veterans Health Administration

Do They Accurately Identify True Safety Events?

Amy K. Rosen, PhD,†‡ Kamal M.F. Itani, MD,‡§‖ Marisa Cevasco, MD, MPH,§¶ Haytham M.A. Kaafarani, MD, MPH,#** Amresh Hanchate, PhD,*‡ Marlena Shin, JD, MPH,* Michael Shwartz, PhD,*†† Susan Loveland, MAT,* Qi Chen, MPH,*† and Ann Borzecki, MD, MPH†‡ ‡‡*

Background: The Agency for Healthcare Research and Quality (AHRQ) Patient Safety Indicators (PSIs) use administrative data to detect potentially preventable in-hospital adverse events. However, few studies have determined how accurately the PSIs identify true safety events.

Objectives: We examined the criterion validity, specifically the positive predictive value (PPV), of 12 selected PSIs using clinical data abstracted from the Veterans Health Administration (VA) electronic medical record as the gold standard.

Methods: We identified PSI-flagged cases from 28 representative hospitals by applying the AHRQ PSI software (v.3.1a) to VA fiscal year 2003 to 2007 administrative data. Trained nurse-abstractors used standardized abstraction tools to review a random sample of flagged medical records (112 records per PSI) for the presence of true adverse events. Interrater reliability was assessed. We evaluated PPVs and associated 95% confidence intervals of each PSI and examined false positive (FP) cases to determine why they were incorrectly flagged and gain insight into how each PSI might be improved.

Results: PPVs ranged from 28% (95% CI, 15%−43%) for Postoperative Hip Fracture to 87% (95% CI, 79%−92%) for Postoperative Wound Dehiscence. Common reasons for FPs included conditions that were present on admission (POA), coding errors, and lack of coding specificity. PSIs with the lowest PPVs had the highest proportion of FPs owing to POA.

Conclusions: Overall, PPVs were moderate for most of the PSIs. Implementing POA codes and using more specific ICD-9-CM codes would improve their validity. Our results suggest that additional coding improvements are needed before the PSIs evaluated herein are used for hospital reporting or pay for performance.

Key Words: patient safety, ICD-9-CM coding, criterion validation, adverse events, administrative data

(*Med Care* 2012;50: 74–85)

The Institute of Medicine (IOM) report *To Err is Human* [1] increased national concern and focus on patient safety, prompting demand for evidence-based measures that could be used with administrative data to identify patient safety events. The Agency for Healthcare Research and Quality (AHRQ) Patient Safety Indicators (PSIs), released in 2003, were developed in response to this demand and represent a significant contribution to the scientific detection of patient safety events. They are specifically designed to screen for potentially preventable adverse events occurring in the acute inpatient setting. Because they use administrative discharge data (known for its coding variability and inconsistency with respect to diagnoses and procedures), they were viewed as "indicators," rather than as definitive measures, intended for use in quality improvement initiatives, case-finding activities, and monitoring trends.[2]

Although the PSIs underwent a rigorous development process, in which face, content, and construct validity were assessed,[2] and several studies have subsequently evaluated predictive validity,[3–8] concerns about how well the indicators identify true events and accurately reflect hospital performance have heightened with increasing use in public reporting. The National Quality Forum (NQF) recently endorsed 10 PSIs as consensus standards,[9] and the Centers for Medicare & Medicaid Services (CMS) will soon be publicly reporting 6 individual PSIs and a PSI Composite measure on their Hospital Compare website and will be tracking these through their annual payment program.[10,11]

Given these concerns, AHRQ recently conducted the PSI Validation Pilot Project to assess the criterion validity, defined as the degree to which a measure generates data that agree with data from a "gold standard" approach to measuring the same characteristic, of 5 PSIs in a volunteer sample of nonfederal hospitals.[12–16] Validation of additional PSIs, in collaboration with AHRQ, was undertaken by UHC, an alliance of 113 academic medical centers and their affiliated hospitals. Positive predictive value (PPV), the proportion of flagged cases confirmed by chart review to have the PSI event, ranged from 32% for decubitus ulcer to 91% for accidental puncture or laceration.[12–17] These studies highlighted some of the limitations of conducting chart review (eg, unavailability of specific data elements; time intensiveness; poor documentation); they led to recommendations for coding changes to enhance the specificity and PPV of certain indicators[18] and they provided guidelines for use of individual PSIs in quality improvement, public reporting, or pay-for-performance initiatives.

Despite these pilot study results, knowledge about the criterion validity of the PSIs is still relatively limited. Understanding whether AHRQ's results are generalizable to other healthcare settings is particularly critical, as healthcare systems move increasingly toward public reporting of measures. Therefore, we undertook a study to assess the criterion validity of the PSIs in the Veterans Health Administration (VA). The VA is an ideal setting in which to do this. It has a comprehensive, clinically integrated electronic medical record (EMR), which enables centralized access to detailed clinical data and provides a reliable and efficient method for data collection. EMR data can be easily linked with VA discharge data, which are known to have a high level of data element completion and accuracy.[19,20] Further, the VA is strongly committed to making performance and quality data publicly available.[21,22] VA PSI rates will be reported on both the VA and CMS Hospital Compare websites in the near future (personal communication, Dr. Marta Render, 4/11). Finally, although the VA is dedicated to "accountability" through its transparency initiatives, it lacks financial incentives for "upcoding" of diagnoses, and has no penalties or rewards tied to PSI events.

The specific goals of this study were to: (1) assess the criterion validity, specifically the PPV of the PSIs, to determine whether PSI-flagged cases represented true adverse events compared with the gold standard of medical record abstracted data[23]; (2) determine reasons why flagged PSI cases did not represent true events; and (3) recommend modifications to the PSI algorithms to improve PPVs.

METHODS

Study Design and Data

This was a retrospective cross-sectional study using VA administrative and EMR data from VA fiscal year 2003 through 2007 (October 1, 2002 -September 30, 2007). We used hospital discharge information, including demographics, ICD-9-CM coded diagnoses and procedures, and discharge status from the VA's National Patient Care Database Patient Treatment File.[24] On the basis of prior work, we eliminated nonacute care as the PSIs were designed to screen for events in the acute-care setting.[25,26] We also used a previously developed algorithm to distinguish elective from nonelective (ie, urgent/emergent) admissions as VA data lack an admission type and this is required for the denominator of 3 surgical PSIs.[25] VistaWeb was used to access EMR data from all VA facilities.[27]

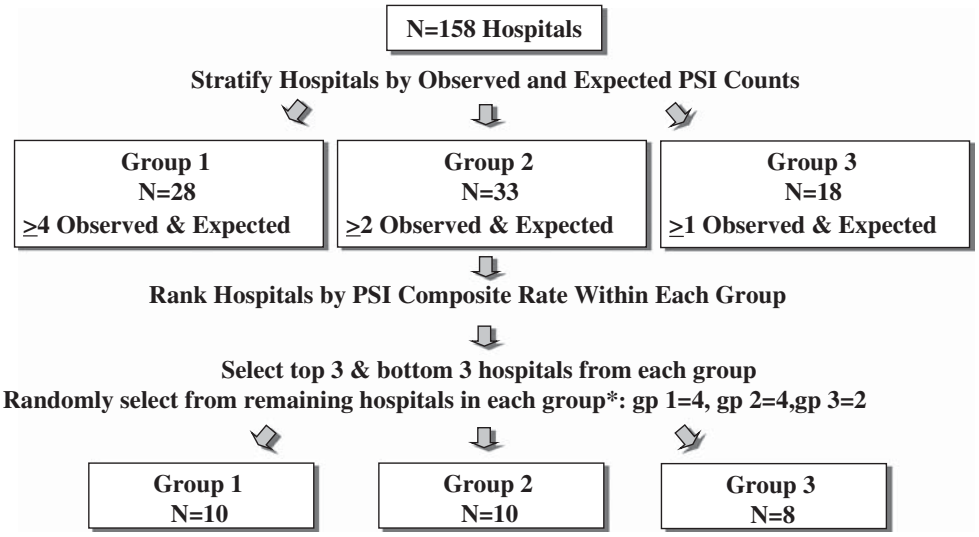
PSI Definitions

The PSIs are constructed as rates or proportions based primarily on relevant ICD-9-CM diagnosis and procedure codes. Each PSI is defined with both a numerator (complication of interest) and denominator (population at risk). We selected 12 of the 20 hospital-level PSIs for study based on their relevance to the VA population, observed VA rates, and their potential preventability. These included decubitus ulcer ("Ulcer"), foreign body left in during procedure ("Foreign Body"), iatrogenic pneumothorax ("Pneumothorax"), central venous catheter-related blood stream infections ("Infections"), postoperative hip fracture ("Fracture"), postoperative hemorrhage or hematoma ("Hemorrhage/Hematoma"), postoperative physiologic and metabolic derangement ("Derangement"), postoperative respiratory failure ("Respiratory Failure"), postoperative pulmonary embolism/deep vein thrombosis ("PE/DVT"), postoperative sepsis ("Sepsis"), postoperative wound dehiscence ("Dehiscence"), and accidental puncture or laceration ("Puncture/Laceration"). (See Appendix for complete definitions.) These PSIs have all been endorsed by the NQF as individual measures.[9] Pneumothorax, Dehiscence, Puncture/Laceration, PE/DVT, and Respiratory Failure will be posted by CMS as individual PSI measures, along with the PSI Composite measure, a combined measure of these 11 PSIs, with the exclusion of Foreign Body [28,29]

We excluded the 4 obstetric PSIs, 2 PSIs with extremely low frequencies (Complications of Anesthesia and Transfusion Reaction), plus 2 PSIs based on mortality (Death in Low Mortality DRGs and Failure to Rescue) because they measure how well hospitals treat complications rather than how well they prevent complications.[30]

Hospital Sampling

Criteria for hospital selection included: (1) obtaining a manageable number of hospitals for chart review; (2) selecting hospitals that represented a spectrum of PSI rates; and (3) ensuring that selected hospitals had an adequate number of PSI events available for chart abstraction. We first applied the AHRQ PSI software (v3.1a) to VA inpatient data to obtain hospital-level PSI counts and PSI composite scores; these were generated by the software.[28,29] Second, we grouped the 158 acute-care VA hospitals into 3 tiers based on their observed and expected PSI counts (Fig. 1). A facility's expected number of PSI events was calculated as the national VA PSI rate multiplied by the PSI denominator of that specific facility. The first tier included hospitals with ≥ 4 observed and expected safety-related events for each PSI, whereas the second and third tiers had ≥ 2 and ≥ 1



Note that Foreign Body and Postoperative Hip Fracture are excluded from the PSIs selected to identify the sample of hospitals. Observed counts are the number of flagged cases per PSI. Expected counts are the number of expected cases per PSI. A facility's expected number of PSI events was calculated as the national VA PSI rate multiplied by the PSI denominator of that specific facility. Our final hospital sample included 28 hospitals (10 in Group 1, 10 in Group 2, and 8 in Group 3). From each of the 28 hospitals, we selected 4 cases per PSI, for a total of 112 cases per PSI.

FIGURE 1. Hospital sampling strategy.

observed and expected events, respectively. Hospitals with < 1 observed or expected safety-related event were excluded, yielding a sample of 79 hospitals. Third, within each tier, we ranked hospitals by the PSI composite measure and included the top 3 and bottom 3 hospitals. Fourth, we randomly selected from the remaining hospitals within each tier to obtain a sample of 28 hospitals. Finally, to assure balanced geographical representation, 3 hospitals were replaced by the next hospital in rank.[31]

Case Identification

Four flagged medical records per PSI were randomly selected from each of the 28 hospitals. On the basis of previously reported PPV estimates, 112 cases per PSI, as available, were selected to ensure reasonably narrow PPV confidence intervals (CI range, 10%−20%).[32]

Medical Record Abstraction

Two trained nurse abstractors reviewed EMRs using standardized data abstraction instruments and guidelines adapted from AHRQ-developed tools[33] or developed de novo if there were no existing tools. Medical records were reviewed for: (1) the occurrence of a safety-related event; (2) demographics, comorbidities, and risk factors; (3) clinical circumstances surrounding the safety-related event; and (4) patient outcomes.

To ensure consistency of abstracted information, we examined interrater reliability (IRR). Two nurses reviewed approximately 10% of the medical records of each PSI. IRR was measured as the percentage of agreement across all questions on each abstraction instrument. Identical records were abstracted in groups of 5 until ≥ 90% agreement was obtained; thereafter, they abstracted different records. Study physicians reviewed questions on which nurses disagreed, with resulting instrument revisions and/or guideline clarifications as appropriate, and also reviewed cases for clarification as needed throughout the abstraction process. Additional IRR assessment was performed on 5 charts toward the end of the abstraction process to check for abstractor reliability drift; subsequent IRR testing revealed ≥ 90% agreement for all PSIs.

Analyses

To determine whether our sample's PSI rates were representative of overall VA hospital PSI rates, we calculated PSI observed and risk-adjusted rates using the PSI software. Next, we categorized flagged cases as either true positives (TPs) or false positives (FPs) based on the application of AHRQ's definition of each PSI and chart-abstracted information. FPs were cases flagged by the PSI software that failed to meet the clinical intent of the indicator. To assess criterion validity, we calculated the PPV of each PSI and associated 95% CIs. PPV was calculated by dividing TPs by the number of flagged cases. We also examined FPs in detail to determine why they were flagged and gain insight into how the PSI might be improved. This included classifying reasons for FP occurrence, such as whether FPs resulted from inappropriate coding or coding limitations. All statistical analyses were performed using SAS version 9.1 (SAS Institute Inc., Cary, NC).

TABLE 1. Rates of Selected Patient Safety Indicators in Our Sample of Hospitals and in All VA Hospitals

PSI No.	Name	Observed Rates in 28 Selected Hospitals	Observed Rates in All VA Hospitals	Risk-adjusted Rates in 28 Selected Hospitals	Risk-adjusted Rates in All VA Hospitals
3	Decubitus Ulcer	15.86	16.41	17.46	17.9
5	Foreign Body Left in During Procedure	0.14	0.12	—+	—+
6	Iatrogenic Pneumothorax	0.68	0.64	0.94	0.90
7	Central Venous Catheter-related Bloodstream Infections	2.21	1.98	2.06	1.89
8	Postoperative Hip Fracture	0.40	0.39	0.61	0.59
9	Postoperative Hemorrhage or Hematoma	3.77	3.89	2.99	3.03
10	Postoperative Physiologic and Metabolic Derangements	2.14	2.15	0.62	0.59
11	Postoperative Respiratory Failure	13.55	14.17	11.06	11.19
12	Postoperative Pulmonary Embolism or Deep Vein Thrombosis	11.43	11.86	10.12	10.39
13	Postoperative Sepsis	6.50	6.67	8.03	7.92
14	Postoperative Wound Dehiscence	6.43	6.18	4.16	3.94
15	Accidental Puncture or Laceration	3.98	3.08	6.61	5.60

Rates are reported per 1000 discharges at risk using PSI software version 3.1a (October 1, 2002-September 30, 2007). Risk adjustment was performed using the AHRQ risk-adjustment software which includes 27 comorbidities, age, sex, and modified DRGs. + PSI 5 is not risk adjusted per PSI software.

RESULTS

Observed PSI rates ranged from 0.14 (Foreign Body) to 15.86 (Ulcer) per 1000 eligible discharges in our 28-hospital sample (Table 1). Ulcer and Respiratory Failure were the most commonly flagged PSIs (15.86 and 13.55, respectively per 1000 discharges). Risk adjustment had a noticeable impact on some of the indicators. Risk-adjusted rates were lower than observed rates for 6 of the PSIs, whereas some risk-adjusted rates were slightly higher than observed, particularly for Ulcer and Sepsis. Given the comparability of observed and risk-adjusted rates between the 2 groups, our hospital sample appeared to be representative of all VA hospitals with respect to PSI rates.

Table 2 displays the PPVs and estimated 95% CIs for selected PSIs and the percentage of cases that were present on admission (POA). PPVs varied considerably, ranging from a low of 28% (95 CI, 15%−43%) for Fracture to a high of 87% (95 CI, 79%−92%) for Dehiscence. Although there were some relatively low PPVs, particularly for Fracture and Ulcer, most PPVs were relatively moderate, ranging from 43% (95% CI, 34−53%) for PE/DVT to 75% (95% CI, 66%−83%) for Hemorrhage/Hematoma. Notably, the PPVs of 2 indicators, Dehiscence and Puncture/Laceration, were relatively high (87% and 85%), respectively, demonstrating good predictive ability.

Many PSIs occurred before the index hospitalization. Overall, 17% of flagged cases were POA, with a range from 0% (Respiratory Failure and Dehiscence) to 59% (Ulcer). POA was also a major reason for flagged cases being deemed as FPs (42% of all FPs were due to POA). For example, among FP cases of Ulcer, 83% were POA; other PSIs with relatively high POA percentages among their FPs included: Fracture (73%), Foreign Body (56%), and Derangement (47%). Because the PSIs with the lowest PPVs also had the highest proportion of FPs owing to POA, we explored the impact on PPV by eliminating POA cases. As expected, the PPVs for these PSIs increased substantially compared to those of other PSIs.

Of the 1266 abstracted cases, 41% were FPs. We categorized reasons for the occurrence of FPs among the 12 PSIs (Table 3). In addition to POA, miscoding and lack of coding specificity were important reasons for mis-flagging cases, accounting for 28% and 16% of FPs, respectively. Individual manuscripts describing the clinical findings of 10 of these PSIs are currently in press.[31,34–40]

We use 1 PSI, PE/DVT, to illustrate the reasons for FPs. Miscoded cases represent those that resulted in a flagged PSI owing to being assigned an incorrect diagnosis or procedure code based on the documentation available in the chart. Among PE/DVT's FPs, there were 24 miscoded cases. These included cases of arterial (not venous) thrombosis, superficial (not deep) vein thrombosis, and cases where a postoperative PE/DVT workup was negative or PE/DVT was a "rule-out" diagnosis. Lack of coding specificity refers to flagged cases that were coded correctly; however, the codes were not specific enough to distinguish between a true PSI event and a nonevent. For example, 14 cases of PE/DVT occurred after admission but before the index procedure. Although these cases were appropriately coded as PE/DVTs, the codes were not specific to "postoperative" events.[31] Two other cases in this category were coded correctly as "thrombophlebitis" events, but because some of the ICD-9-CM codes included in the PSI algorithm do not distinguish superficial phlebitis (eg, inflammation of the superficial veins) from true deep vein thromboses (which is the clinical intent of this PSI), these 2 cases were flagged as PE/DVT events.[31]

There were other less frequent reasons for the occurrence of FPs, some of which were more important with respect to specific PSIs. Three PSIs (Respiratory Failure, Derangement, and Sepsis) required a code for admission type to identify cases that were more likely to be

TABLE 2. Positive Predictive Values and Percentage of Cases That Were Present on Admission Among All Flagged Cases and False Positives by Selected Patient Safety Indicators in the VA

PSI No.	PSI Name	Sample (n)	PPV (%) (95% CI)	POA (%) in All Flagged Cases	POA (%) in False Positives	Sample w/o POA (n)	PPV w/o POA (%) (95% CI)
3	Decubitus Ulcer	112	30 (22–40)	59	83	46	74 (59–86)
5	Foreign Body Left in During Procedure	93	46 (36–55)	30	56	65	66 (53–77)

7	Central Venous Catheter-related Bloodstream Infections	112	38 (29–47)	19	30	91	46 (36–57)
8	Postoperative Hip Fracture	46	28 (15–43)	52	73	21	62 (38–82)
9	Postoperative Hemorrhage or Hematoma	112	75 (66–83)	8	32	103	82 (73–89)
10	Postoperative Physiologic and Metabolic Derangements	119	63 (54–72)	18	47	98	77 (67–85)
11	Postoperative Respiratory Failure	112	67 (57–76)	0	0	112	67 (57–76)
12	Postoperative Pulmonary Embolism or Deep Vein Thrombosis	112	43 (34–53)	14	25	96	50 (40–60)
13	Postoperative Sepsis	112	53 (42–64)	14	30	96	61 (51–71)
14	Postoperative Wound Dehiscence	112	87 (79–92)	0	0	112	87 (79–92)
15	Accidental Puncture or Laceration	112	85 (77–91)	5	35	106	90 (82–95)

The number displayed is the number of cases in our sample that were flagged for each of these PSIs. For Postoperative Physiologic and Metabolic Derangements, we flagged 119 cases rather than 112 to ensure that we had an adequate number of diabetes patients who developed abnormalities of glucose control to review in addition to those discharges who developed acute kidney injury requiring dialysis. We were not able to flag 112 cases for Foreign Body and Postoperative Hip Fracture because they were relatively rare events. Parentheses contain 95% confidence intervals (CIs). Positive predictive value (PPV) represents the proportion of true positive cases divided by the number of flagged cases. POA indicates present on admission.

preventable. Misidentification of nonelective admissions as elective accounted for a high percentage of the FP cases for these PSIs, particularly Respiratory Failure and Derangement, (62% and 45% of FPs, respectively).[36,38] A remote or previous history of the PSI before admission was another reason for FPs, particularly for PE/DVT (16% of FPs). Also important for determining if a case was an FP or not was whether the PSI event was related to surgery. Similar to PE/DVT, both Fracture and Sepsis had PSI events that occurred during admission but before surgery (15% and 13%, respectively), and were therefore not related to the index surgery/procedure.

DISCUSSION

This study explored the criterion validity of selected PSIs in the VA. Specifically, we characterized one aspect of criterion validity, PPV, for 12 PSIs that were designed to detect complications that are potentially preventable through good care. Given increasing national focus on improving safety, accurate identification of safety events is critical for guiding improvement efforts. Our overall findings suggest that the original intent of the PSIs, as screening tools to detect potential safety events, may still be the most appropriate use of the PSIs, given the coding inaccuracies and limitations we encountered.

We had several specific study findings. First, consistent with the literature,[26,41–44] we found that PSI rates were generally low; 2 PSIs were relatively rare (Foreign Body and Fracture), with rates less than 1.0 per 1000 discharges. Despite the overall low incidence of individual PSI rates, some PSIs, such as Ulcer (even with POA codes) and Respiratory Failure, had fairly substantial rates, suggesting clinical areas for targeting and opportunities for hospital improvements. As in earlier VA studies, risk adjustment had varying effects on individual PSIs[26,43] in some cases, risk-adjusted rates increased by up to 10%, whereas in others, risk-adjusted rates decreased by up to 35%.

Second, despite evidence on the accuracy and completeness of VA data,[19,20] all of the PSIs misidentified true events to some extent, with considerable PPV variation across PSIs. This variation was likely due to coding inaccuracies or limitations (eg, differences in hospital coding practices, lack of POA codes, lack of precise or meaningful codes, poor documentation). We generally found moderate PPVs for most of the PSIs, ranging from 43% to 75%. Dehiscence had the highest PPV (87%), possibly for 2 reasons: first, wound dehiscence is more likely to occur within the immediate postoperative period compared with other PSIs; and second, in contrast to other PSIs that had high percentages of cases that were POA but were missing POA codes, Dehiscence had no FPs that were due to POA cases.[40]

Our PPV results were generally comparable to those of other non-VA and VA studies[3,12–16,45–47]; for example, for

TABLE 3. Reasons for False Positives by Selected Patient Safety Indicators in the VA

PSI No.	PSI Name	No. FPs	Reasons for Exclusions, n (%)

FPs indicates false positive cases; POA, present on admission. The categories of miscoding and nonelective admission are mutually exclusive; other categories may overlap so that the numbers in the column do not necessarily match up with the number of FPs for each PSI; for example, most of the overlap is between cases that occurred during the admission but before surgery and those included under lack of coding specificity. "Other" category includes events that were intentional (eg, a patient with a single kidney underwent a necessary nephrectomy resulting in a need for dialysis and was flagged as PMD), documentation errors (eg, a patient who had diabetic ketoacidosis incorrectly noted as a complication in a discharge summary by a physician, flagged as PMD), postoperative complications that were incidental to surgery (eg, using the PMD example, a patient developed kidney failure from underlying liver problems but it occurred after having a minor surgical procedure, a mouth biopsy under local anesthetic.) These may also overlap with other categories.

PE/DVT, the AHRQ and UHC studies reported PPVs of 47% and 44%, respectively,[15] whereas Henderson et al[45] reported a PPV of 55% compared with our PPV of 43%. A previous VA study compared 5 surgical PSIs with chart-abstracted data obtained from the VA National Surgical Quality Improvement Program (NSQIP), a program designed to promote quality improvement through dissemination of risk-adjusted surgical outcomes to VA facilities.[46] Notably, our PPVs were higher for Sepsis (53% vs. 45%), Dehiscence (87% vs. 72%), and PE/DVT (43% vs. 22%) than those found in the earlier VA study, possibly owing to differences in methodologies and abstraction tools used in the 2 studies, plus definitions of adverse events. Further, that study matched only about 50% of PSI-flagged hospitalizations with NSQIP surgical cases because of NSQIP's exclusion criteria. Nonetheless, there are enough similarities between the various PSI validation studies to suggest that the shortcomings of the PSIs are more inherent to coding-related issues and practices, rather than specific to any 1 study.

Third, there were several reasons for the occurrence of FPs; the 3 most common reasons included diagnoses that were POA, miscoding, and lack of coding specificity. The impact of POA codes on the PSIs is not unique to the VA. A recent AHRQ study found that including POA information reduced the overall number of identified PSI cases by approximately 50%.[48] The effect was especially striking for Ulcer, where as few as 11% of originally flagged cases of Ulcer remained after inclusion of POA codes, followed by Fracture and PE/DVT, where as few as 21% and 43%, respectively, of originally flagged cases remained.[48] The recent CMS mandate to collect POA codes in all Inpatient Prospective Payment System hospitals should help mitigate this issue.[49] Although the VA lags behind the private sector in implementing this policy, it is currently collecting POA codes at the hospital level. Once these codes are incorporated into administrative databases, they will help improve the PPVs of many of the PSIs, particularly those with the highest proportions of FPs owing to POA. Even for PE/DVT, cases that are POA or have a history of PE/DVT would be dropped, potentially increasing the PPV by as much as 13%, albeit decreasing the number of cases flagged.

Another large group of FPs was miscoded cases. As illustrated by PE/DVT, the inability to distinguish the type and nature of the thrombosis was a common reason for miscoding, both in our study and in others.[15,31,45] Lack of coding specificity was also an important reason for FPs among selected PSIs. For the postoperative PSIs, current ICD-9-CM codes do not adequately distinguish the timing of the PSI event (ie, before, during, or after surgery). In addition, the codes may not match up with clinical criteria or nomenclature applied by physicians when documenting patients' diagnoses.[15] For example, at the time of our study, there were no existing codes

that would allow one to distinguish upper extremity from lower extremity DVTs, a distinction that is meaningful for prevention. To remedy some of these specificity issues, AHRQ proposed several coding structure revisions to the ICD-9-CM Coordination and Maintenance Committee, one of which, a new code specifically for upper extremity DVTs, has been approved.[18] Although miscellaneous coding errors and poor physician documentation may still remain as issues, these changes should improve both the codes and coding guidelines for PE/DVT.[14]

General coding changes to improve the inaccuracies and limitations in the ICD-9-CM coding structure, such as implementation of a "timing" code for diagnoses, would help to improve the PPVs of all selected PSIs. Improving the validity of all the PSIs could also be facilitated by standardizing coding practices, such as relying more on evidence-based clinical criteria for diagnostic coding, as well as educating and training medical coders to improve both general and specific coding practices related to adverse event reporting. Providers could assist in this latter process by ensuring that relevant complications are well documented in the discharge summary and that "rule-out" diagnoses are replaced by more precise diagnoses once appropriate tests have been performed. Incorporation of an admission type code denoting an emergent versus elective admission into VA administrative databases would help to improve the PPVs of the 3 PSIs requiring this code in the VA. However, even in UHC member hospitals that code data with respect to admission status, inaccurate admission status coding was still the most frequent reason for FPs,[13] occurring in 5% of Respiratory Failure cases. Nonetheless, these recommendations should be useful in leading to real improvements in quality rather than simply to changes in documentation/coding practices.[13]

Our study has several strengths worth highlighting. Our 28 hospitals were drawn from a nationally representative sample of VA acute-care hospitals. Unlike most other validation studies that relied on paper charts,[12–16,45] we had access to a centralized EMR. This was useful in streamlining the abstraction process and facilitating accurate information retrieval through automated text searching for adverse events and preventing misinterpretation of data owing to poor text legibility. Study clinicians were available to clarify clinical questions throughout the abstraction process, which also helped to maximize the accuracy and reliability of our findings. Finally, we examined agreement between the 2 nurses at different time points, achieving a high level of abstractor agreement at each review.

There were also some limitations. We were not able to report other aspects of criterion validity, namely specificity, sensitivity, or negative predictive value of the PSIs; this was beyond the study's scope and resources. In addition, our sample sizes were small, preventing us from examining whether there was variation in coding accuracy across hospitals.

Although not a specific study goal, we attempted to determine the preventability of the TP cases in our clinically detailed manuscripts.[31,36–40] However, we were unable to determine the actual number of cases associated with quality of care problems given the retrospective nature of the study, lack of evidence-based processes of care for some of the PSIs, information missing from the EMR (such as anesthesia reports), and the lack of control groups. As such, we are limited in concluding whether or not the PSIs, which should in theory be preventable if appropriate perioperative and in-hospital care are provided, do in fact, identify cases that represent true deficiencies in the quality of care and that can lead to or inform meaningful quality improvements.

In conclusion, the PSIs appear to be useful tools for screening, case-finding, and quality improvement. Given the relatively moderate PPVs found, and the need for information on potential preventability and how often true events are missed, we believe it is premature to use the PSIs for public reporting or pay-for-performance. Further, without standardized surveillance systems in place to identify and track safety events nationally, higher PSI rates may be more a marker of improved screening practices or coding differences rather than quality of care.[50] Nonetheless, the PSIs are a step in the right direction, and it is still important to understand what the indicators detect and whether care could be improved.

ACKNOWLEDGMENTS

We are indebted to the following individuals and groups for their assistance in writing the original PSI proposal, participation in the project, guidance and support on all clinical and methodological aspects of the PSIs, and interest in improving the PSIs to make them well-validated and acceptable performance measures: Hillary Mull, MPP, VA Boston Healthcare System; David McClusky, MD, Atlanta VA Medical Center; Andrew Cowan, MD, VA Boston Healthcare System; Kathleen Hickson, RN, MA, VA Boston Healthcare System; Sally MacDonald, RN, Bedford VA Medical Center; Dijon Fasoli, PhD, RN, Bedford VA Medical Center; Julie Lynch, RN, MBA, Bedford VA Medical Center; Kristine Ruggiero, RN, Bedford VA Medical Center; Edward Dunn, MD, ScD, Lexington VA Medical Center; Shibei Zhao, MPH, Bedford VA Medical Center; Arlene Ash, PhD, University of Massachusetts Medical School; Patrick Romano, MD, MPH; UC Davis School of Medicine; Garth Utter, MD, MSc, UC Davis School of Medicine; Patricia Zrelak, PhD, CNRN, CNAA-BC, UC Davis School of Medicine; Jeffrey Geppert, JD, Battelle; Mamatha Pancholi, AHRQ; PSI Validation Study Steering Committee (Leonard Pogach, MD; Anna Alt-White, PhD, RN; William Gunnar, MD; Vickie Montague, RN; Carol Bills, RN, Peter Almenoff, MD; Brian Carney, MD; Allen Gifford, MD; Mary Roseborough, RN); and Joanne Cuny, RN, MBA, AMA.

Indicator	Definition	Numerator	Denominator
PSI 3. Decubitus Ulcer	Cases of decubitus ulcer per 1000 discharges with a length of stay greater than 4 days	Discharges with ICD-9-CM code of decubitus ulcer in any secondary diagnosis field among cases meeting the inclusion and exclusion rules for the denominator	All medical and surgical discharges 18 y and older defined by specific DRGs. Exclude cases: With length of stay of less than 5 days With ICD-9-CM code of decubitus ulcer in the principal diagnosis field or in a secondary diagnosis field if present on admission, if known. MDC 9 (Skin, Subcutaneous Tissue, and Breast) MDC 14 (pregnancy, childbirth, and puerperium) with any diagnosis of hemiplegia, paraplegia, or quadriplegia With an ICD-9-CM diagnosis code of spina bifida or anoxic brain damage With an ICD-9-CM procedure code for debridement or pedicle graft before or on the same day as the major operating room procedure (surgical cases only) Admitted from a long-term care facility (SID Admission Source = 3) Transferred from an acute care facility (SID Admission Source = 2)
PSI 5. Foreign Body Left in During Procedure	Discharges with foreign body accidentally left in during procedure per 1000 discharges	Discharges with ICD-9-CM codes for foreign body left in during procedure in any secondary diagnosis field per among cases meeting the inclusion and exclusion rules for the denominator	All medical and surgical discharges, 18 y and older or MDC 14 (pregnancy, childbirth, and puerperium), defined by specific DRGs. Exclude patients with ICD-9-CM codes for foreign body left in during procedure in the principal diagnosis field or secondary diagnosis present on admission, if known
PSI 6. Iatrogenic Pneumothorax	Cases of iatrogenic pneumothorax per 1000 discharges	Discharges with ICD-9-CM code of 512.1 in any secondary diagnosis field among cases meeting the inclusion and exclusion rules for the denominator	All medical and surgical discharges 18 y and older defined by specific DRGs. Exclude cases: With ICD-9-CM code of 512.1 in the principal diagnosis field or secondary diagnosis present on admission, if known. MDC 14 (pregnancy, childbirth, and puerperium) With an ICD-9-CM diagnosis code of chest trauma or pleural effusion With an ICD-9-CM procedure code of diaphragmatic surgery repair With any code indicating thoracic surgery or lung or pleural biopsy or assigned to cardiac surgery DRGs
PSI 7. Central Venous Catheter-related Bloodstream Infections* *Patient Safety Indicators Technical Specifications Version 4.2–2010 (Formerly named "Selected Infections Due to Medical Care," Version 3.1)	Cases of ICD-9-CM codes 99662 or 9993 or 99931 per 1000 discharges.	Discharges with selected infections defined by specific ICD-9-CM codes any secondary diagnosis field among cases meeting the inclusion and exclusion rules for the denominator. For discharges before October 1, 2007: *ICD-9-CM Hospital-associated Infection diagnosis codes*: 99662-Due to other vascular device, implant and graft 9993-Other infection.For discharges on or after October 1, 2007: *ICD-9-CM Central Line-associated Bloodstream Infection diagnosis codes*: 99931-Infection due to central venous catheter	All surgical and medical discharges, 18 y and older or MDC 14 (pregnancy, childbirth, and puerperium), defined by specific DRGs or MS-DRGs. Exclude cases: With principal diagnosis of selected infections or secondary diagnosis present on admission With length of stay less than 2 days With any diagnosis or procedure code for immunocompromised state With any diagnosis of cancer
PSI 8. Postoperative Hip Fracture	Cases of in-hospital hip fracture per 1000 surgical discharges with an operating room procedure.	Discharges with ICD-9-CM code for hip fracture in any secondary diagnosis of field among cases meeting the inclusion and exclusion rules for the denominator.	All surgical discharges 18 y and older defined by specific DRGs and an ICD-9-CM code for an operating room procedure.

(*continued*)

TABLE. (*continued*)

Indicator	Definition	Numerator	Denominator
			Exclude cases: With ICD-9-CM code for hip fracture in the principal diagnosis field or secondary diagnosis present on admission, if known Where the only operating procedure is hip fracture repair Where a procedure for hip fracture repair occurs before or on the same day as the first operating room procedure *Note: If day of procedure is not available in the input data file, the rate may be slightly lower than if the information was available* With diseases and disorders of the musculoskeletal system and connective tissue (MDC 8) With principal diagnosis (or secondary diagnosis present on admission, if known) of seizure, syncope, stroke, coma, cardiac arrest, poisoning, trauma, delirium and other psychoses, or anoxic brain injury With any diagnosis of metastatic cancer, lymphoid malignancy or bone malignancy, or self-inflicted injury MDC 14 (pregnancy, childbirth, and puerperium)
PSI 9. Postoperative Hemorrhage or Hematoma	Cases of hematoma or hemorrhage requiring a procedure per 1000 surgical discharges with an operating room procedure.	Discharges among cases meeting the inclusion and exclusion rules for the denominator with either of the following: ICD-9-CM codes for postoperative hemorrhage in any secondary diagnosis field and a code for drainage of hematoma in any procedure code field ICD-9-CM codes for postoperative hematoma in any secondary diagnosis field and a code for postoperative control of hemorrhage in any procedure code field.	All surgical discharges 18 y and older defined by specific DRGs and an ICD-9-CM code for an operating room procedure. Exclude cases: With preexisting condition (principal diagnosis or secondary diagnosis present on admission, if known) of postoperative hemorrhage or postoperative hematoma Where the only operating room procedure is postoperative control of hemorrhage or drainage of hematoma Where a procedure for postoperative control of hemorrhage or drainage of hematoma occurs before the first operating room procedure *Note: If day of procedure is not available in the input data file, the rate may be slightly lower than if the information was available.* MDC 14 (pregnancy, childbirth and the puerperium)
PSI 10. Postoperative Physiologic and Metabolic Derangements	Cases of specified physiological or metabolic derangement per 1000 elective surgical discharges with an operating room procedure.	Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM codes for physiologic and metabolic derangements in any secondary diagnosis field. Discharges with acute renal failure (subgroup of physiologic and metabolic derangements) must be accompanied by a procedure code for dialysis (3995, 5498).	All elective* surgical discharges age 18 and older defined by specific DRGs and an ICD-9-CM code for an operating room procedure. *Defined by admit type. Exclude cases: With preexisting condition (principal diagnosis or secondary diagnosis present on admission, if known) of physiologic and metabolic derangements or chronic renal failure With acute renal failure where a procedure for dialysis occurs before or on the same day as the first operating room procedure *Note: If day of procedure is not available in the input data file, the rate may be*

(*continued*)

TABLE. (*continued*)

Indicator	Definition	Numerator	Denominator
			slightly lower than if the information was available With both a diagnosis code of ketoacidosis, hyperosmolarity, or other coma (subgroups of physiologic and metabolic derangements coding) and a principal diagnosis of diabetes With both a secondary diagnosis code for acute renal failure (subgroup of physiologic and metabolic derangements coding) and a principal diagnosis of acute myocardial infarction, cardiac arrhythmia, cardiac arrest, shock, hemorrhage, or gastrointestinal hemorrhage MDC 14 (pregnancy, childbirth and puerperium)
PSI 11. Postoperative Respiratory Failure	Cases of acute respiratory failure per 1000 elective surgical discharges with an operating room procedure.	Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM codes for acute respiratory failure (518.81) in any secondary diagnosis field (After 1999, include 518.84). OR Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM codes for reintubation procedure as follows: (96.04) One or more days after the major operating room procedure code (96.70 or 97.71) Two or more days after the major operating room procedure code (96.72) zero or more days after the major operating room procedure code.	All elective* surgical discharges age 18 and over defined by specific DRGs and an ICD-9-CM code for an operating room procedure. *Defined by admit type. Exclude cases: With preexisting (principal diagnosis or secondary diagnosis present on admission, if known) acute respiratory failure With an ICD-9-CM diagnosis code of neuromuscular disorder Where a procedure for tracheostomy is the only operating room procedure or tracheostomy occurs before the first operating room procedure *Note: If day of procedure is not available in the input data file, the rate may be slightly lower than if the information was available.* MDC 14 (pregnancy, childbirth, and puerperium) MDC 4 (diseases/disorders of respiratory system) MDC 5 (diseases/disorders of circulatory system)
PSI 12. Postoperative Pulmonary Embolism or Deep Vein Thrombosis	Cases of deep vein thrombosis (DVT) or pulmonary embolism (PE) per 1000 surgical discharges with an operating room procedure.	Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM codes for deep vein thrombosis or pulmonary embolism in any secondary diagnosis field.	All surgical discharges age 18 and older defined by specific DRGs and an ICD-9-CM code for an operating room procedure. Exclude cases: With preexisting (principal diagnosis or secondary diagnosis present on admission, if known) deep vein thrombosis or pulmonary embolism where a procedure for interruption of vena cava is the only operating room procedure Where a procedure for interruption of vena cava occurs before or on the same day as the first operating room procedure *Note: If day of procedure is not available in the input data file, the rate may be slightly lower than if the information was available.* MDC 14 (pregnancy, childbirth and puerperium)
PSI 13. Postoperative Sepsis	Cases of sepsis per 1000 elective surgery patients with an operating room procedure and a length of stay of 4 days or more.	Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM code for sepsis in any secondary diagnosis.	All elective* surgical discharges age 18 and older defined by specific DRGs and an ICD-9-CM code for an operating room procedure.

(*continued*)

TABLE. (*continued*)

Indicator	Definition	Numerator	Denominator
			*Elective-Admission type # is recorded as elective (Admission Type = 3). Exclude cases: With preexisting (principal diagnosis or secondary present on admission, if known) sepsis or infection With any code for immunocompromised state or cancer MDC 14 (pregnancy, childbirth, and puerperium) With a length of stay of less than 4 days
PSI 14. Postoperative Wound Dehiscence	Cases of reclosure of postoperative disruption of abdominal wall per 1000 cases of abdominopelvic surgery.	Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM code for reclosure of postoperative disruption of abdominal wall (54.61) in any procedure field.	All abdominopelvic surgical discharges age 18 and older. Exclude cases: Where a procedure for reclosure of postoperative disruption of abdominal wall occurs before or on the same day as the first abdominopelvic surgery procedure *Note: If day of procedure is not available in the input data file, the rate may be slightly lower than if the information was available* Where length of stay is less than 2 days With immunocompromised state MDC 14 (pregnancy, childbirth, and puerperium)
PSI 15. Accidental Puncture or Laceration	Cases of technical difficulty (eg, accidental cut or laceration during procedure) per 1000 discharges.	Discharges among cases meeting the inclusion and exclusion rules for the denominator with ICD-9-CM code denoting technical difficulty (eg, accidental cut, puncture, perforation, or laceration) in any secondary diagnosis field.	All medical and surgical discharges age 18 y and older defined by specific DRGs. Exclude cases: With ICD-9-CM code denoting technical difficulty (eg, accidental cut, puncture, perforation, or laceration) in the principal diagnosis field or secondary diagnosis present on admission, if known MDC 14 (pregnancy, childbirth, and puerperium)

Examining the Impact of the AHRQ Patient Safety Indicators (PSIs) on the Veterans Health Administration

The Case of Readmissions

Amy K. Rosen, PhD,† Susan Loveland, MAT,* Marlena Shin, JD, MPH,* Michael Shwartz, PhD,*‡ Amresh Hanchate, PhD,*† Qi Chen, MPH,*§ Haytham M.A. Kaafarani, MD, MPH,‖¶ and Ann Borzecki, MD, MPH†§#*

Background: By focusing primarily on outcomes in the inpatient setting one may overlook serious adverse events that may occur after discharge (eg, readmissions, mortality) as well as opportunities for improving outpatient care.

Objective: Our overall objective was to examine whether experiencing an Agency for Healthcare Research and Quality Patient Safety Indicator (PSI) event in an index medical or surgical hospitalization increased the likelihood of readmission.

Methods: We applied the Agency for Healthcare Research and Quality PSI software (version 4.1.a) to 2003–2007 Veterans Health Administration inpatient discharge data to generate risk-adjusted PSI rates for 9 individual PSIs and 4 aggregate PSI measures: any PSI event and composite PSIs reflecting "Technical Care," "Continuity of Care," and both surgical and medical care (Mixed). We estimated separate logistic regression models to predict the likelihood of 30-day readmission for individual PSIs, any PSI event, and the 3 composites, adjusting for age, sex, comorbidities, and the occurrence of other PSI(s).

Results: The odds of readmission were 23% higher for index hospitalizations with any PSI event compared with those with no event [confidence interval (CI), 1.19–1.26], and ranged from 22% higher for Iatrogenic Pneumothorax (CI, 1.03–1.45) to 61% higher for Postoperative Wound Dehiscence (CI, 1.27–2.05). For the composites, the odds of readmission ranged from 15% higher for the Technical Care composite (CI, 1.08–1.22) to 37% higher for the Continuity of Care composite (CI, 1.26–1.50).

Conclusions: Our results suggest that interventions that focus on minimizing preventable inpatient safety events as well as improving coordination of care between and across settings may decrease the likelihood of readmission.

Key Words: patient safety, readmissions, adverse events, coordination of care

(*Med Care* 2013;51: 37–44)

Despite improvements in patient safety resulting from the Institute of Medicine report "To Err is Human,"[1] shortcomings in patient safety remain a major concern. Only 36% of safety-related hospital measures (eg, postoperative complications) improved at a rate >5% per year, compared with 84% of non–safety-related measures (eg, measures of effectiveness, timeliness, and patient centeredness).[2] Although tracking safety event trends is complicated, standardized measures such as the Agency for Healthcare Research and Quality (AHRQ) Patient Safety Indicators (PSIs) have helped identify hospitalizations with potentially preventable adverse events (AEs), hospital variation in the safety of care,[3–6] and the consequences of AEs [eg, excess mortality, length of stay (LOS), and costs] during hospitalization.[7–9]

Nevertheless, by focusing excessively on outcomes in the inpatient setting one may overlook serious AEs among inpatients that may manifest after discharge,[10,11] important postdischarge safety events,[12,13] and opportunities for improvement in postdischarge patient care.[11,14] Recent studies have expanded on earlier work linking PSI events with in-hospital adverse outcomes,[7–9] attributing postdischarge outcomes, such as readmissions, to PSI events that occurred during the index admission.[10,11] In 1 study of adult surgery patients treated in nonfederal hospitals, the 30-day readmission rate increased by 44% when a PSI event occurred during the index admission.[11] Another study of privately insured adult surgery patients suggested that PSI events in the index admission were responsible for 11% of all deaths and 2% of all readmissions at 90 days.[10]

ISSN: 0025-7079/13/5101-0037

We build on the sparse literature in this area by examining whether the occurrence of a PSI event in the index hospitalization increases the likelihood of readmission in the Veterans Health Administration (VA). The VA is the nation's largest integrated health care system, currently offering a full continuum of care to approximately 8 million veterans.[15] We also expand the previous focus from surgical cases only to both medical and surgical cases, making our findings particularly timely given the recent posting of VA 30-day readmission rates for pneumonia, heart failure (HF), and acute myocardial infarction on the Centers for Medicare and Medicaid Services Hospital Compare website.[16,17] Readmissions have emerged nationally as an important outcome measure, as they occur frequently (all-cause readmission rates range from 13% to 20%),[14,17] account for substantial costs (estimates as high as $25 billion per year have been reported),[18] and reflect poor quality of care during the index hospitalization, breakdown in continuity of care, poor discharge planning, or the occurrence of an AE in the index hospitalization.[11,14,19]

Although a recent systematic review of the literature on readmission prediction models suggests that patient-level factors, such as sociodemographic and clinical variables, are strongly associated with readmission risk, it also noted that the lack of hospital-level and system-level factors (including the quality of inpatient care) limits the models' ability to predict readmission.[20] By examining whether a PSI event in the index hospitalization increases the likelihood of readmission, we may be able to improve the ability of the models to target those at high risk of readmission and thus facilitate the design of transitional care interventions.

Our specific objectives were to: (1) compare demographic and clinical characteristics of index hospitalizations with and without PSIs; (2) examine 30-day "all-cause" readmission rates for index hospitalizations with and without PSIs; (3) assess whether experiencing a PSI event in the index hospitalization affects the reason for readmission; and (4) examine the likelihood of 30-day readmission on the basis of the type of PSI event that occurred in the index hospitalization.

METHODS

Data Sources

Our primary source of inpatient data was the VA Patient Treatment File, an administrative database that contains information on all veterans discharged from VA acute-care facilities, such as demographics, principal and secondary diagnoses, and surgical procedures.[21] Because the PSIs were designed to screen for patient safety events in acute-care hospitals, as in a previous work, we eliminated the nonacute portion of care, creating a hospital discharge file containing only acute care.[22] We linked the Patient Treatment File data to dates of death from the VA Vital Status File to obtain information on deaths within 30 days after discharge. Study approvals were received from the relevant Institutional Review Boards.

Sample

Our initial sample (n = 2,332,794) comprised all acute-care discharges from VA hospitals from fiscal years 2003 to 2007 (October 1, 2002 through September 30, 2007). Similar to the Centers for Medicare and Medicaid Services' Hospital Compare methodology, we combined hospitalizations in which the subsequent admission was on the same or next day after the prior discharge.[23] There were a total of 60,032 admissions that were combined with a preceding discharge, which reduced the final sample to 2,272,762 discharges. For these aggregated hospitalizations, admission attributes (eg, principal diagnosis) came from the first hospitalization and discharge attributes (eg, discharge location) came from the last hospitalization.

We defined an index hospitalization as the first hospitalization that occurred on or after October 1, 2002 (the first day of the study period) or 31 days or more after the index discharge. Thus, patients could have multiple index hospitalizations (it is noteworthy that 55% had only 1 index hospitalization over the 5 y). Consistent with other studies[11,14,23] we excluded index hospitalizations in which the patient left against medical advice (n = 32,980) or was transferred to a non-VA hospital (n = 14,807). We also excluded index hospitalizations documented as occurring after the patient's date of death (n = 3,899) (ie, data errors) or discharged after August 9, 2007 (n = 60,809), ensuring that any index hospitalization occurring toward the end of our data would have a large enough window after discharge to capture a readmission. This cutoff date, 51 days before the last day of the fiscal year 2007, accounted for the 30-day span from discharge to potential readmission as well as the readmission's LOS (95% of all hospitalizations had a LOS <21 d).

As final steps, we eliminated index hospitalizations that died in-hospital (n = 58,767), and excluded 290 hospitalizations that did not meet eligibility criteria for any of the PSIs used in the study (eg, obstetric discharges). We also retained the readmission information associated with all index hospitalizations to examine reasons for readmission. However, for hospitalizations with multiple readmissions occurring <30 days apart, we kept only the first readmission, excluding 31,696 subsequent readmissions.

This yielded a final sample of 1,807,488 index hospitalizations and 262,026 readmissions for study. We divided the index hospitalizations into 2 groups for analytical purposes: index hospitalizations with a PSI event(s) (n = 27,958) and those without a PSI event(s) (n = 1,779,530).

The PSIs

The PSIs were designed specifically to capture potentially preventable events that represent compromised patient safety in the acute-care setting, such as complications after surgeries, procedures, or medical care. The original 20 hospital-level PSIs resulted from a 4-step process including literature review, evaluation of candidate PSIs by clinical panels, consultation with coding experts, and empirical analyses.[24] The PSI software uses secondary diagnoses, procedures, and other hospital discharge information to flag hospitalizations for potential safety-related events. The PSIs are calculated as rates, defined with a numerator (complication of interest) and denominator (population at risk). Currently there are 17 PSIs, 7 relevant to surgical discharges

only, 8 to both medical and surgical discharges, and 2 to obstetric discharges.[25]

We excluded the following PSIs from all analyses: 2 obstetric PSIs as they are not relevant to the VA population; 2 PSIs related to in-hospital mortality: PSI #2 (Death in Low Mortality DRGs) and PSI #4 (Complications in Surgical Inpatients); and PSI #16 (Transfusion Reaction) which is very rare. Three PSIs, PSI #8 (Postoperative Hip Fracture), PSI #3 (Pressure Ulcer), and PSI #5 (Foreign Body Left in During Procedure), were used in aggregated PSI measures only (described below)—the former 2 because they are present on admission about 70% of the time[26] and therefore are not associated with care in the index hospitalization, and the latter because it is relatively rare.[27] This yielded 9 PSIs for individual analyses (see Table, Supplemental Digital Content 1, http://links.lww.com/MLR/A354 for PSI definitions).

Four aggregated PSI measures were used for analyses. The first measure was designed to capture "any PSI event" (yes/no) and contained the 9 individual PSIs plus PSIs #3, #5, and #8. Three PSI composite measures, developed in previous work to compensate for the relatively low rates of individual PSIs, were also included in analyses.[28] These measures, empirically derived through factor analyses and clinical judgment, grouped individual PSIs into clinically meaningful categories. The "Continuity of Care" composite contained PSIs that reflect continuity of care and medical management of high-risk patients in the perioperative setting: PSI #10 (Postoperative Physiologic and Metabolic Derangements), PSI #11 (Postoperative Respiratory Failure), and PSI #13 (Postoperative Sepsis). The "Technical Care" composite included PSIs reflecting technical skill–based care: PSI #5 (Foreign Body Left in During Procedure), PSI #9 (Postoperative Hemorrhage or Hematoma), PSI #14 (Postoperative Wound Dehiscence), and PSI #15 (Accidental Puncture or Laceration). The "Mixed" composite included both surgical and medical PSIs: PSI #6 (Iatrogenic Pneumothorax) and PSI #7 (Central Venous Catheter-related Bloodstream Infections), PSI #8 (Postoperative Hip Fracture), and PSI #12 (Postoperative Pulmonary Embolism/Deep Vein Thrombosis).

Because the PSIs were developed and tested using hospital discharge abstracts from AHRQ's HCUP State Inpatient Databases, they require UB-92 (1992 Uniform Bill) data elements from hospital claims,[22] some of which are missing from VA databases. Consequently, we used previously developed algorithms to calculate certain variables, such as principal procedure, that were not readily available from the data.[29]

Outcome Measure

The primary outcome measure was a 30-day all-cause readmission, defined as a readmission occurring for any diagnosis within 30 days of an index discharge.

Analyses

Analyses were performed by applying the PSI software (version 4.1a) and the statistical analysis system (SAS, version 9.1.3) to our dataset. We ran descriptive statistics, *t* tests, and χ^2 tests as appropriate, to compare demographic and clinical characteristics, as well as rates of readmission, between index hospitalizations with and without any PSI event. We also explored whether having any PSI event in the index hospitalization (prior PSI event) was related to the reason for readmission, defined by the principal diagnosis or the primary cause of readmission.[21] To provide a more meaningful description of the reason for each readmission, we grouped the principal diagnosis of the readmission associated with each index hospitalization into a discrete category using the clinical classification software (CCS), a tool developed by AHRQ for clustering patient diagnoses and procedures into a manageable number of clinically meaningful categories.[30]

As a final step, we developed separate logistic regression models to predict the likelihood of 30-day readmission for any PSI event, selected PSIs, and each of the 3 PSI composite measures, controlling for age, sex, 27 comorbidities that are included in the AHRQ comorbidity software,[31] and the occurrence of any other PSI(s). To explore the impact of multiple PSIs, we ran a logistic regression model among hospitalizations with at least 1 PSI, and included a variable indicating 2 or more PSIs. Odds ratios and 95% confidence intervals (CIs) were calculated for each of the 13 models. As a sensitivity analysis to account for the potential correlation among repeated hospitalizations for the same patient, we reran the logistic regression models nesting hospitalizations within patients; to account for any changes in readmissions over time, we included dummy variables for "year."

RESULTS

Characteristics of Index Hospitalizations

As shown in Table 1, our sample was predominantly male, with a mean age of 64.8 years (SD = 12.9) and LOS of 6.6 days (SD = 35.4). Compared with index hospitalizations without any PSI event, those with any PSI event were slightly older (67.8 vs. 64.8 y, respectively), had much longer LOS (24.2 vs. 6.3 d), were more likely to be hospitalized for a surgical rather than a medical inpatient stay (62.1% vs. 37.9%), and were more likely to die within 30 days after discharge (9.4% vs. 3.4%). Hospitalizations with any PSI event also had higher rates of HF and renal failure compared with hospitalizations without events (10.4% vs. 6.9% and 8.1% vs. 6.1%, respectively). In addition, readmission rates were higher for index hospitalizations with any PSI event compared with those without an event (18.6% vs. 14.4%, respectively) ($P < 0.0001$ for all listed comparisons).

Rates of readmission were consistently higher for index hospitalizations with selected PSIs and PSI composites compared with hospitalizations without these events (Table 2). Differences in readmission rates were greatest for index hospitalizations with and without Postoperative Physiologic and Metabolic Derangements (23.8% vs. 11.4%, respectively). Among composites, the largest difference in readmission rates was for index hospitalizations with and without the Continuity of Care composite (18.7% vs.

TABLE 1. Selected Demographic and Clinical Characteristics of Index Hospitalizations Discharged Alive With and Without Any PSI Event (Fiscal Years 2003–2007)*

	Total Index Hospitalizations	Index Hospitalizations With Any PSI Event†	Index Hospitalizations Without Any PSI Event
N (%)	1,807,488 (100%)	27,958 (2%)	1,779,530 (98%)
Age, mean (SD)	64.8 (12.9)	67.8 (12.2)	64.8 (12.9)
Male (%)	96.4%	97.2%	96.4%
Length of stay (d), mean (SD)	6.6 (35.4)	24.2 (48.7)	6.3 (35.1)
Death within 30 d after discharge, N (%)	63,452 (3.5%)	2613 (9.4%)	60,839 (3.4%)
No. comorbidities, mean (SD)	1.9 (1.4)	2.0 (1.4)	1.9 (1.4)
Diabetes, N (%)	517,485 (28.6%)	8020 (28.7%)	509,465 (28.6%)
Heart failure, N (%)	125,857 (7.0%)	2901 (10.4%)	122,956 (6.9%)
Renal failure, N (%)	110,273 (6.1%)	2255 (8.1%)	108,018 (6.1%)
Valvular disease, N (%)	37,759 (2.1%)	832 (3.0%)	36,927 (2.1%)
Hypertension, N (%)	952,525 (52.7%)	12,766 (45.7%)	939,759 (52.8%)

Paralysis, N (%)	46,614 (2.6%)	809 (2.9%)	45,805 (2.6%)
Liver disease, N (%)	75,650 (4.2%)	1064 (3.8%)	74,586 (4.2%)
Alcohol/drug abuse, N (%)	161,347 (8.9%)	1958 (7.0%)	159,389 (9.0%)
30-day readmission,‡ N (%)	262,026 (14.5%)	5193 (18.6%)	256,833 (14.4%)
Medical DRGs, N (%)	1,367,079 (75.6%)	10,599 (37.9%)	1,356,480 (76.2%)
Surgical DRGs, N (%)	440,403 (24.4%)	17,359 (62.1%)	423,044 (23.8%)

*All results significant at $P < 0.0001$.

†Any PSI event includes the following PSIs: PSI #3 Pressure Ulcer, #5 Foreign Body Left in During Procedure, #6 Iatrogenic Pneumothorax, #7 Central Venous Catheter-related Bloodstream Infections, #8 Postoperative Hip Fracture, #9 Postoperative Hemorrhage or Hematoma, #10 Postoperative Physiologic and Metabolic Derangements, #11 Postoperative Respiratory Failure, #12 Postoperative Pulmonary Embolism or Deep Vein Thrombosis, #13 Postoperative Sepsis, #14 Postoperative Wound Dehiscence, and #15 Accidental Puncture or Laceration.

‡All-cause readmissions within 30 days from the index discharge.

DRGs indicates diagnosis-related groups; PSI, Patient Safety Indicator.

11.3%, respectively) (all comparisons were significant at $P < 0.0001$).

We explored differences in the top 10 reasons for readmission among index hospitalizations with and without any prior PSI event. Although the causes of readmission, as illustrated by CCS categories, were generally similar between the 2 groups (Table 3), there were some differences in prevalence rates for specific CCS categories. For example, "complications of surgical procedures or medical care" and "complication of device" were the top reasons for readmission (6.5% and 5.0% of readmissions, respectively) among hospitalizations with any prior PSI event; both of these occurred less frequently among those without any prior PSI event (4.8% and 2.8%, respectively). Similarly, although pneumonia and urinary tract infections were among the top reasons for readmission for hospitalizations with any prior PSI event (4.7% and 4.2%, respectively), these were not as frequent among those without any prior PSI event (3.7% and 2.4%, respectively) (all comparisons were significant at $P < 0.0001$). Moreover, although septicemia (another potentially hospital-related infection) occurred in 4.0% of readmissions associated with index hospitalizations that had any prior PSI event, it was not among the top 10 reasons for readmission in hospitalizations that did not have any prior PSI event.

The odds of readmission were 23% higher for index hospitalizations with any PSI event compared with those with no event (CI, 1.19–1.26) (Table 4). The odds of readmission were higher for all selected PSIs except Accidental Puncture or Laceration, ranging from 22% higher for Iatrogenic Pneumothorax (CI, 1.03–1.45) to 61% higher for Postoperative Wound Dehiscence (CI, 1.27–2.05). This suggests that index hospitalizations with a particular PSI, such as Postoperative Wound Dehiscence, had a greater likelihood of readmission than index hospitalizations that did not have that individual PSI (although they could have had other PSIs in the index hospitalization). For the composites, the odds of readmission ranged from 15% higher for the Technical Care composite (CI, 1.08–1.22), compared with those without any of the PSIs comprising this composite, to 37% higher for the Continuity of Care composite (CI, 1.26–1.50). Interestingly, among those with at least 1 PSI event, the odds of readmission were 1.15 (CI, 1.02–1.31) for those that had 2 or more PSI events. Nesting hospitalizations within patients, and including dummy variables for time, had no impact on results.

DISCUSSION

A few recent studies provide some empirical evidence that PSI events can increase the risk of readmission.[10,11] We explore this relationship in the VA health care system, which has a state-of-the-art electronic medical record system and a strong commitment to providing high-quality care and improving discharge planning.[32,33,34] Compared with other studies, our study population is broader, and we examine the types of PSIs associated with the greatest likelihood of readmission. Our study is also one of the first to ascertain whether experiencing a PSI event in the index hospitalization is associated with the risk of readmission.

TABLE 2. Readmission Rates for Index Hospitalizations With and Without Selected PSI Events (Fiscal Years 2003–2007)*

PSIs	Index Hospitalizations With Selected PSI Events (N)	30-Day Readmissions† (N)	%	Index Hospitalizations Without Selected PSI Events (N)	30-Day Readmissions (N)	%
PSI #6 Iatrogenic Pneumothorax	883	159	18.0	1,715,423	245,536	14.3
PSI #7 Central Venous Catheter-related Bloodstream Infections	2254	459	20.4	1,098,790	147,620	13.4
PSI #9 Postoperative Hemorrhage or Hematoma	1519	285	18.8	428,528	48,230	11.3
PSI #10 Postoperative Physiologic and Metabolic Derangements	593	141	23.8	257,062	29,183	11.4
PSI #11 Postoperative Respiratory Failure	2642	470	17.8	169,806	16,815	9.9

†All-cause readmissions within 30 days from the index discharge.

‡The Technical Care composite includes PSIs reflecting technical skill–based care: PSIs #5 Foreign Body Left in During Procedure, #9 Postoperative Hemorrhage or Hematoma, #14 Postoperative Wound Dehiscence, and #15 Accidental Puncture or Laceration.

§The Continuity of Care composite includes PSIs reflecting continuity of care and medical management of high-risk patients in the perioperative setting: PSIs #10 Postoperative Physiologic and Metabolic Derangements, #11 Postoperative Respiratory Failure, and #13 Postoperative Sepsis.

‖The Mixed composite includes a mix of surgical and medical PSIs: PSIs #6 Iatrogenic Pneumothorax and #7 Central Venous Catheter-related Bloodstream Infections, #8 Postoperative Hip Fracture, and #12 Postoperative Pulmonary Embolism or Deep Vein Thrombosis.

PSI indicates Patient Safety Indicator.

Our study has several important findings. First, our results are consistent with the literature suggesting the potential impact of safety-related events on increased risk of readmission and other outcomes.[4,8–11,22] Second, despite the relatively low prevalence of individual PSIs, index hospitalizations with selected PSIs had significantly higher readmission rates than those without PSIs. In some instances, the odds were almost double. Having multiple PSI events increased the odds even more. Readmission rates were also higher for index hospitalizations with PSI composites compared with those without the composites, and, similar to other studies, for index hospitalizations with any PSI event compared with those with no event.[10,11] The risk of readmission was about 60% higher for index hospitalizations in which a Postoperative Hemorrhage or Hematoma or Postoperative Wound Dehiscence occurred compared with those in which these particular PSIs did not occur. In contrast, Friedman et al[11] found the highest risk of 30-day readmission among patients who had a Postoperative Pulmonary Embolism/Deep Vein Thrombosis or Accidental Puncture or Laceration in the index admission, whereas Encinosa and Hellinger[10] found the highest risk of 90-day readmission among patients with PSIs related to infections (PSIs #7 and #13), Postoperative Physiologic and Metabolic Derangements, and Postoperative Respiratory Failure. Differences in study methods, patient populations, readmission definitions, and random variation may explain the impact of different PSIs in each study.

Third, we found that the occurrence of any PSI event in the index hospitalization was reflected in the reason for readmission. In general, index hospitalizations with any prior PSI event had a greater likelihood of readmission for complications related to surgical or medical care or implanted devices, or for acute problems such as infections that might be hospital acquired, compared with those without any prior PSI event. It is noteworthy that index hospitalizations without any prior PSI event were likely to be readmitted for exacerbations of chronic conditions, such as HF.

Our findings suggest that 1 way to reduce readmissions is to target and minimize potentially preventable AEs that occur in hospitals. The establishment of surgical checklists, training of staff in patient safety, hospital-wide efforts to reduce hospital-acquired infections, and developing incentives to improve care are just a few examples of possible steps hospitals can take to reduce readmissions.[35] Moreover, early follow-up and monitoring of surgical discharges may help prevent continuation of in-hospital complications into the postdischarge period and detect delayed complications early.[13]

Index hospitalizations with PSIs reflecting continuity of care had a higher likelihood of being readmitted than hospitalizations that did not have these PSIs. This composite comprises the same PSIs that had the greatest impact on likelihood of readmission in Encinosa and Hellinger's[10] study, providing further empirical support for the validity of this composite construction. As readmissions are sometimes thought of as "missed opportunities to better coordinate care,"[19] our results provide additional evidence that interventions to improve coordination of care across inpatient

TABLE 3. Top 10 Reasons for Readmission Among Index Hospitalizations With and Without Any Prior PSI Event*

	Readmissions After Index Hospitalizations With Any PSI Event (n = 6231)			Readmissions After Index Hospitalizations Without Any PSI Event (n = 255,791)

settings and between the inpatient and outpatient settings are important in reducing readmission rates.[36–38] In addition, patients at high risk of readmission, such as those with PSIs reflecting continuity of care, may be a good subset to target during and after hospitalization.

Our study has several important strengths. Unlike previous cross-sectional studies in this area that examined surgical cases only,[10,11] we used 5 years of VA nationwide data, and included both medical and surgical discharges, providing an opportunity to examine PSI events and readmissions on a large population of patients. Use of composite measures helped ensure adequate statistical power to test the association between PSIs and readmissions. The consistency of our results with those of the private sector[10,11] provides increased evidence of the impact of the PSIs on readmissions.

There were also some limitations. We lacked clinical data for risk adjustment, thereby limiting the ability to ascertain patients' severity of illness. We lacked current data; however, PSI and readmission rates have remained relatively stable over time, suggesting that use of more recent data

would not have affected our results.[39–42] In addition, use of administrative data is always subject to coding inaccuracies. For example, some PSI events were likely to be present on admission, and some of the conditions that were incorporated as comorbidities could have been complications of care.[26,43] However, several recent studies show that a number of the PSIs (including those with the highest impact on readmissions in our study) have moderate to good positive predictive ability based on chart review.[44–47] In addition, we did not examine organizational-level factors potentially associated with readmissions, because our primary focus was on the relationship between PSIs and readmissions. Future studies should examine their impact on readmissions. Finally, we could not establish causality between PSIs and readmissions because unobserved patient or provider factors could affect both measures, nor could we determine whether readmissions were clinically related to the index hospitalization, planned, or potentially preventable.

The relative lack of direct financial incentives in the VA compared with the private sector may result in less pressure to decrease readmission rates in the VA. However, the VA operates in an increasingly budget-constrained environment, and the public reporting of VA readmission rates should increase pressure to better understand the causes of readmissions and to develop interventions to reduce them. Although previous studies have linked readmissions with the quality of inpatient care during the index hospitalization,[48,49] our study suggests that focusing on AEs that occur during the index hospitalization provides another important way of viewing readmission as an indicator of quality of care. Thus, efforts to reduce readmissions should also incorporate quality improvement initiatives targeted at minimizing and preventing inpatient AEs.

Choices in the use of ICD-9 codes to identify stroke risk factors can affect the apparent population-level risk factor prevalence and distribution of CHADS2 scores

Abstract: While developed for managing individuals with atrial fibrillation, risk stratification schemes for stroke, such as CHADS2, may be useful in population-based studies, including those assessing process of care. We investigated how certain decisions in identifying diagnoses from administrative data affect the apparent prevalence of CHADS2-associated diagnoses and distribution of scores. Two sets of ICD-9 codes (more restrictive/ more inclusive) were defined for each CHADS2-associated diagnosis. For stroke/transient ischemic attack (TIA), the more restrictive set was applied to only inpatient data. We varied the number of years (1-3) in searching for relevant codes, and, except for stroke/TIA, the number of instances (1 vs. 2) that diagnoses were required to appear. The impact of choices on apparent disease prevalence varied by type of choice and condition, but was often substantial. Choices resulting in substantial changes in prevalence also tended to be associated with more substantial effects on the distribution of CHADS2 scores.

Keywords: Stroke, atrial fibrillation, risk stratification, CHADS2, ICD-9-CM codes

Introduction

Atrial fibrillation (AF) is a risk factor for ischemic stroke, but among patients with AF, the level of risk for an individual patient varies according to other clinical characteristics [1-5]. Several risk stratification schemes have been developed for assessing the relative risk of stroke in patients with non-valvular AF [2-8], and such information may help clinicians in making more informed decisions regarding clinical management. While these risk stratification schemes were developed for use in individual patients, they may also be useful in population-based studies [9-14]. For individual patients, chart reviews to obtain prior and current medical conditions are typically used for identifying characteristics associated with increased risks of stroke. However, for assessing relative risks for large cohorts of patients, administrative data is often more feasible.

There is disagreement on which risk stratification scheme provides the most useful information in patients with AF. We have chosen to focus on the CHADS2 because its elements (age and diagnoses) are often available in large administrative databases [6]. (Some risk stratification schemes use data that is less commonly available in such databases, such as systolic blood pressure or heart size measurements from echocardiograms [3-5].) In the CHADS2 scheme, a score is created by adding one point for each of the elements of Congestive heart failure (CHF), Hypertension, Age ≥75 or Diabetes, and two points for prior Stroke or transient ischemic attack (TIA) [6]. In the initial validation of CHADS2 in Medicare beneficiaries, a chart review was used to identify the presence of hypertension, a history of stroke or TIA and, for most of the cohort, diabetes [6]. However, International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9) codes were

used to identify "recent" CHF exacerbations associated with hospitalizations. ICD-9 codes were also used to identify the presence of diabetes for some of the patients. In a subsequent study comparing the CHADS2 to other risk adjustment schemes, any history of CHF was substituted for recent exacerbations [8].

Since the initial validation of CHADS2, a number of population-based studies have defined the elements of the CHADS2, in whole or in part, by the use of ICD-9 diagnosis codes [9-12]. However, in defining the various elements of the CHADS2, there have been differences among studies in the specifications of sets of ICD-9 codes associated with each condition, the number of times that a code was required to be present or the use of inpatient vs. outpatient datasets from which codes are extracted. Furthermore, there has been variation in the time interval used in searching for such codes.

Studies that have focused on validating sets of ICD-9 codes to represent the types of clinical conditions associated with the CHADS2 scheme have reported differences in sensitivity and specificity based on similar types of choices [15-19]. Use of ICD-9 codes to identify stroke has been particularly difficult in regard to identifying code sets that have both high sensitivity and specificity [19-21]. Therefore, among investigators who have used ICD-9-based datasets in defining CHADS2 scores, variation in codes to identify CHADS2 conditions is probably not surprising.

Differences in choices regarding how ICD-9 codes are used to identify the clinical conditions associated with CHADS2 could also impact the distribution of CHADS2 scores at the population level. This, in turn, could affect statistical associations and conclusions. The purpose of this study was to assess how different sets of ICD-9 codes as well as other decisions (such as the number of times a code appears and the time over which the presence of codes is searched) affect the apparent prevalence of CHADS2-associated conditions and the distribution of CHADS2 scores in a population of patients with non-valvular AF.

Methods

Datasets

Department of Veterans Affairs (VA) national datasets encompassing outpatient visits and/or acute inpatient hospitalizations were used to determine the presence of certain ICD-9 codes, as further specified below.

Population

Patients with "non-valvular" AF were identified from among those cared for in the VA during fiscal year (FY) 2007 (October 2006 through September 2007). Diagnoses for AF were based on having two or more inpatient or outpatient ICD-9 codes of 427.31 separated by at least 60 days. Patients were excluded if there was a history of valvular heart disease manifested by mitral stenosis or certain types of prior cardiac valve surgery [22], as indicated by the following ICD-9 diagnostic or procedure codes: 394.0, 394.2, 396.0, 396.1, 396.8, V42.2, V43.3, 35.10 to 35.14 or 35.20 to 35.28. These exclusion diagnoses were based on outpatient or inpatient records in the three years prior to the initial diagnosis of AF identified in FY2007.

ICD-9 definitions for CHADS2 components

A number of reports in the literature that incorporate CHADS2 scores have defined the presence of CHF, hypertension, diabetes or stroke/TIA using sets of ICD-9 codes [9-12]. Other reports, not involved with CHADS2, have studied ICD-9 code sets for these conditions in comparison to chart reviews [15, 16, 18, 19]. "Core" sets of codes often include 428.x for CHF, 401.xx-405.xx for hypertension and 250.x for diabetes. Additional codes for each condition, typically associated with other comorbidities or complications, have been used by some investigators. For example, the set for CHF has included 398.91, 402.01, 402.11, 402.91, 404.01, 404.11, 404.03, 404.13, 404.91, 404.93, that for hypertension has included 437.2, and that for diabetes has included 357.2, 362.0 and 366.41 [10, 19]. While it did not seem likely that use of these additional codes would identify a substantial number of additional patients with the relevant condition, we investigated this issue by specifying "more restrictive" and "more inclusive" code sets, as indicated in **Table 1**.

Compared to the other CHADS2 conditions, the use of ICD-9 codes to identify patients with prior ischemic stroke or TIA is more problematic. Because the CHADS2 scheme includes any prior history of ischemic stroke or TIA, it becomes

Table 1. ICD-9 codes used to define more restrictive and more inclusive sets associated with the CHADS2 conditions. TIA: transient ischemic attack

CHADS2 condition	More restrictive set	More inclusive set
Congestive heart failure	428.x	428.x, 398.91, 402.01, 402.11, 402.91, 404.01, 404.11, 404.03, 404.13, 404.91, 404.93
Hypertension	401.x, 402.x, 403.x, 404.x, 405.x	401.x, 402.x, 403.x, 404.x, 405.x, 437.2
Diabetes	250.x	250.x, 357.2, 362.0, 366.41
Stroke and TIA	433.x1,* 434.x1,* 435.x*	433.x1, 434.x1, 435.x, 436, 438.x

*Assessed using only inpatient data

important to search for records indicating prior in addition to acute events. Validation studies in the literature have typically assessed the codes associated with acute strokes associated with hospitalizations, and even in that setting, it has been difficult to identify code sets that have both good sensitivity and specificity [20, 21]. Using one year of inpatient records, Birman-Deych reported use of an ICD-9 code set that achieved a sensitivity of 58% for detecting acute or prior strokes, but patients in the cohort were selected based on a hospitalization for AF [19]. In attempting to identify any history of an ischemic stroke or TIA in a population that includes individuals without hospitalizations within a specified span of data, it would seem important to include outpatient records. However, we are not aware of published studies that have reported on systematic validation of outpatient ICD-9 codes for either acute or prior strokes (or TIAs). While we included outpatient codes in our more inclusive code set, as indicated below, we recognize that the accuracy of such codes is unknown at this time.

For the more restrictive code set for stroke/TIA, we included ICD-9 codes 433.x1 and 434.x1 identified from acute inpatient records, as these codes have been found to have high specificity and positive predictive value [20]. Also included in the restrictive set is 435.x for TIA. We accepted these codes in any position in the list of discharge diagnoses.

For the more inclusive code set, we included codes that appeared in either acute inpatient or in outpatient records. In addition to 433.x1, 434.x1 and 435.x, we included codes 436 and 438.x. Investigators who have defined CHADS2 using ICD-9 codes have often included code 436 ("Acute, but ill-defined, cerebrovascular disease") in identifying stroke [9-12], although it had a positive predictive value of only 48% in VA inpatient datasets [20]. We included ICD-9 code 438.x ("Late effects of cerebrovascular disease") in an effort to detect previous strokes [11, 19]. One potential issue is whether, in the outpatient setting, prior strokes are being coded with 438.x or with one of the codes more typically associated with acute events. Yiannakoulias et al found that in certain outpatient facilities in the province of Alberta, Canada, ICD-9 codes 435.x, 436 and 438.x were the most common of those for cerebrovascular disease [23]. However, there were substantial differences among the facilities in which of these codes predominated. For example, at some facilities, 438.x predominated, while at others, it was 436. While the actual medical conditions were not determined by chart review, the authors suggested that such wide variation in coding was unlikely to be explainable by differences in disease prevalence.

There was a change in the definition of ICD-9 code 436 beginning in October 2004 that was intended to remove the words "stroke" and "cerebrovascular accident" (CVA) from its description and to re-index those terms to other codes [24, 25]. However, it is unclear how this has changed coding practices in either the inpatient or outpatient setting, and some reference documents have continued to include, for certain sub-entries, the terms "stroke" and "CVA" in association with code 436 [26, 27]. Therefore we counted its presence in periods after September 2004 as part of the more inclusive code set. V12.54 is a current code for indicating prior stroke or TIA without residual sequelae, but was not relevant to this study as it was not an official code until Oct. 1, 2007.

In searching for relevant ICD-9 codes for each of the CHADS2 conditions, we assessed the effect

Table 2. Prevalence (%) of Components of CHADS2 by ICD-9 set (restrictive/inclusive), number of diagnoses required and lookback period. TIA: transient ischemic attack

Component Variant	Lookback Period					
	1 year		2 years		3 years	
	2 diagnoses	1 diagnosis	2 diagnoses	1 diagnosis	2 diagnoses	1 diagnosis
Congestive Heart Failure						
More Restrictive	17.2	24.5	21.7	28.2	23.7	30.3
More Inclusive	17.3	24.7	21.9	28.4	23.9	30.5
Hypertension						
More Restrictive	61.6	76.9	73.7	81.6	77.0	83.8
More Inclusive	61.6	76.9	73.7	81.6	77.0	83.8
Diabetes						
More Restrictive	30.2	34.3	32.7	35.5	33.4	36.1
More Inclusive	30.4	34.4	32.8	35.6	33.4	36.2
Stroke and TIA						
More Restrictive	N/A	0.6	N/A	1.0	N/A	1.3
More Inclusive	N/A	9.6	N/A	11.7	N/A	13.1

of looking back 1, 2 and 3 years ("lookback" times) prior to the initial diagnoses of AF in FY2007. Also, for diagnoses involving CHF, hypertension and diabetes, we explored the effect of requiring only 1 vs. 2 diagnoses during each of the relevant "lookback" times.

Statistical methods

We used descriptive analyses to indicate the prevalence of disease as a percent of all individuals in the cohort. In addition, we assessed the distribution of the CHADS2 scores (0, 1, 2, or 3+) as a percent of all scores in the cohort for each of the choices related to ICD-9 code sets, number of diagnoses and years of lookback.

Results

A total of 126,167 individuals met the study criteria for non-valvular AF. Their mean age was 74.0, and 98.4% were male. **Table 2** shows the prevalence of the individual conditions that comprise the CHADS2 as a function of the ICD-9 code set (more restrictive vs. more inclusive), the number diagnoses required (1 vs. 2) and the number of "lookback" years used in assessing for the presence of diagnoses (1, 2 or 3).

For CHF, hypertension and diabetes, the additional codes in the more inclusive set made relatively little difference, as expected, in the calculated disease prevalence. However, the requirement of having at least two diagnoses substantially decreased the apparent prevalence for all three conditions, especially with only a one year lookback, although the effect was greater for CHF and hypertension in comparison to diabetes. For Stroke/TIA, there was a substantial difference in the calculated prevalence of disease between the more restrictive and more inclusive code sets, mainly due to the inclusion in the more inclusive code set of diagnoses drawn from outpatient datasets. A majority of such outpatient codes were for 436, and there was also a substantial prevalence of 438.x and 435.x, whereas there were relatively few 433.x1 and 434.x1.

For all four of the condition categories, the number of years of lookback also had a substantial effect on the calculated disease prevalence. On a relative basis, the difference was most pronounced for stroke/TIA. Diabetes showed the least change as a function of years of lookback, perhaps because diabetes is so often a focus of office visits.

Table 3 shows the distribution of CHADS2 scores as function of ICD-9 criteria, number of diagnoses required and years of database lookback. In this case, the more restrictive and more inclusive categories include the corresponding code sets for each of the four conditions. There were moderate differences in the CHADS2 distribution between the more restrictive and more inclusive categories, mainly due to the prevalence differences for stroke/TIA. The effect of the more restrictive/ more inclusive categories was greater for the higher CHADS2 scores.

Varying the number of required diagnoses and

Table 3. Distribution of CHADS2 (%) scores by ICD-9 set (restrictive/inclusive), number of diagnoses required, and lookback period

CHADS2 Variant	1-Year Lookback Value of CHADS2				2-Year Lookback Value of CHADS2				3-Year Lookback Value of CHADS2			
	0	1	2	3+	0	1	2	3+	0	1	2	3+
More restrictive												
2 diagnoses*	12.1	32.7	36.5	18.7	8.4	27.5	39.8	24.3	7.5	25.9	40.0	26.5
1 diagnosis	6.8	26.2	40.5	26.5	5.5	23.9	40.4	30.2	5.0	22.7	40.0	32.3
More Inclusive												
2 diagnoses*	11.4	30.0	33.7	24.9	7.8	25.0	35.9	31.3	7.0	23.3	35.5	34.2
1 diagnosis	6.4	24.2	37.1	32.3	5.2	21.7	36.2	36.8	4.6	20.5	35.5	39.4

*Except for stroke/transient ischemic attack, which uses 1 diagnosis

the number of years of database lookback both had substantial effects on the distribution of the CHADS2 scores. As expected, there was a decrease in those with scores of 3+ when two diagnoses were required. Similarly, the number of patients with CHADS2 scores of 0 was substantially higher with one year compared to three years of lookback, and there was a corresponding decrease in the percentage of those with scores of 3+ with one compared to three years of lookback. For the more restrictive code sets, use of two diagnoses over one year was associated with 12.1% of patients with CHADS2 score of 0, compared to 5% when one diagnosis was required over three years.

Discussion

Because the more inclusive sets of ICD-9 codes for hypertension, CHF and diabetes differed from the more restrictive sets only by inclusion of codes that indicate certain complications or comorbidities, it is not surprising that there were only small differences in prevalence between these sets. However, for these same conditions, the requirements based on the number of years of lookback and number of diagnoses required both had more substantial effects on disease prevalence. The extent of these differences may vary among different healthcare systems and their associated administrative datasets.

For stroke and TIA, there were also substantial differences in apparent disease prevalence as a function of the number of years of lookback. There were also large relative differences in disease prevalence between more restrictive and more inclusive code sets. For the more inclusive code set, the increased prevalence was mainly due to the inclusion of codes in the outpatient setting, including those more typically associated with acute events. However, it is possible that in many cases of "acute" codes, the intent was to indicate a prior stroke or TIA. To the extent that prior strokes or TIAs were being diagnosed, the relative contribution of such data to the overall prevalence of stroke/TIA might be expected to have a larger effect in VA datasets compared to those of some other healthcare systems. This hypothesis is based on a report that most patients dually eligible for VA care and Medicare receive their initial care for acute strokes in non-VA hospitals, and such acute events would not typically be included in the VA acute hospitalization files [28]. As previously noted, we are not aware of any validation studies in the outpatient setting for using ICD-9 codes to identify stroke/TIA, and chart reviews were not part of this study. Therefore, the relative accuracy of different outpatient codes to identify stroke/TIA is unknown, and further studies in this area are warranted. However, the apparent prevalence of stroke/TIA of 13.1% using three years of data is similar to other studies that have determined the prevalence of these conditions in patients with AF [29, 30].

Consistent with the effect on disease prevalence, choices studied in this report regarding identification of conditions from ICD-9 codes also had a substantial effect on the distribution of the CHADS2 scores. Reports in the literature that have assessed CHADS2 scores based on ICD-9 codes have varied in these parameters, and this may affect comparison among studies [9-12].

Even in our "more inclusive" set of codes for stroke/TIA, we did not include such codes as 433.x0 or 434.x0 since these codes have been found to have poor positive predictive value for

stroke, although they may indicate other manifestations of cerebrovascular disease [20]. We also did not assess variation of disease prevalence or CHADS2 distribution as a function of the position of a particular diagnosis (i.e. primary vs. anywhere in the record). Such an assessment would likely have resulted in further variation in the observed parameters. For those ICD-9 codes identified from outpatient records, we included all outpatient services (including laboratory, radiology, etc) and not just face-to-face clinical encounters. This may also have affected the relative prevalence of these codes.

There are several additional issues that may limit the generalizability of our findings. The VA population in our cohort was 98.4% male, and the VA population tends to have a higher prevalence of comorbidities than non-VA populations. Also, as previously noted, a substantial percentage of patients dually eligible for VA care and Medicare receive initial care for strokes outside the VA. Therefore, the presence of outpatient codes suggestive of stroke/TIA may have had a greater influence on apparent disease prevalence compared to other health care systems. In addition to care for stroke, many VA patients receive at least some routine outpatient care outside the VA, and the VA datasets may therefore not reflect some comorbidities not addressed at VA clinic encounters. Regarding outpatient diagnoses, the VA uses an electronic medical record (EMR) to document care. The EMR's characteristics and the methods by which providers choose ICD-9 codes using this EMR may result in different distributions of codes compared to those found in other healthcare systems. Because of the presence of these issues, the actual numbers in this report derived from VA datasets are likely to be different in other systems of care. Although specific numbers may vary, it seems likely that in other healthcare systems, decisions in identifying CHADS2 conditions using ICD-9 codes can similarly affect calculated disease prevalence and distribution of scores.

Our goal in this report was not to define "optimal" algorithms to identify the presence of the various conditions associated with CHADS2 from administrative data, but rather to demonstrate the variation that can occur in the observed prevalence of these conditions as a function of choices made in their identification. While the CHADS2 often is used on an "n" of 1 basis for the clinical care of patients who might be at increased risk of stroke, the intent of this paper is to show the effect of different choices regarding use of ICD-9 codes in deriving the CHADS2 scores for application in population-based studies and not for individual patients.

Researchers performing population-based studies based on ICD-9 codes identified in administrative datasets should be aware of how choices in specifying components of stroke risk stratification schemes, such as the CHADS2, affect the distribution of risk scores. Further studies would be useful to assess how such choices affect the accuracy of administrative diagnostic codes for different healthcare systems. In particular, validation studies are needed regarding the accuracy of outpatient ICD-9 codes to indicate prior strokes and TIAs.

Evidence-based design: part of evidence-based medicine?

Richard Saitz

10.1136/eb-2012-100934

Editor, *Evidence-Based Medicine*

In this issue of *Evidence-Based Medicine*, Shepley and Watson push the envelope of evidence-based medicine and healthcare.[1] Their *Perspective* emphasises that health professionals and designers (eg, architects) should collaborate to create healthcare facilities, and that such collaboration should lead to better staff, patient and family outcomes. But is this just 'knowledge-based gibberish' as a writer has misguidedly lamented in a news article that describes the misuse of the term evidence-based?[2] Is this just another example of a field wanting to claim the lofty mantle of having evidence to support its actions? I do not think so.

Healthcare facility construction is costly, and effects on clinical outcomes could include important benefits and risks for many. The most obvious examples would be infections from poor ventilation or from construction that leads to practitioner behaviours that increase such risks (eg, no sinks near exam rooms). Shepley and Watson note psychological outcomes too. In the USA, the Joint Commission accredits healthcare facilities and maintains standards for them, including requirements for the physical facilities themselves.[3]

Shepley and Watson's *Perspective* and the importance of design for healthcare outcomes beg another question: Are facility standards evidence-based?

Shepley and Watson point out that there are papers published in the peer-reviewed literature on the topic, and that there are research-based standards, and they lament the lack of medical-designer collaborations. Their review stops after counting articles, describing authorship (few medical/design collaborations) and providing case examples. But what of study design? What level of evidence is desired and feasible for evidence-based (healthcare facility) design (EBD)? To what extent should such decisions be subjected to randomised trials, n=1 trials, and even systematic reviews? Surely these are possible for some relevant questions, though likely difficult or impossible for others.

It seems clear that the location and logistics of healthcare delivery can impact important health outcomes. EBD seems to be in its infancy, and will no doubt face serious challenges, but it also seems worthy of serious consideration as healthcare continues to strive to become more evidence-based.

Competing interests None.

Screening and brief intervention (SBI): has it hit the tipping point?

Richard Saitz*

In 1961, Chafetz [1] reported the results of a randomized trial of brief advice by a psychiatrist to patients with alcoholism in the Massachusetts General Hospital (MGH) emergency department (ED); 42% of patients in the advice arm reported to an alcohol clinic versus only 1% in the control group. Fifty years later, in the Liberty Hotel, the same space as the former Charles Street Jail in Boston where there was a "drunk tank" and across from that same MGH ED, over 200 researchers and clinicians gathered to present over 100 abstracts and plenary sessions on screening and brief intervention (SBI). In those 50 years, thousands of patients participated in randomized trials of SBI; the US Institute of Medicine (in 1990) encouraged identification and intervention for unhealthy alcohol use for people across the spectrum from risky use through dependence; the World Health Organization validated assessment tools and showed SBI's effectiveness in primary care settings; and the US Substance Abuse and Mental Health Services Administration allocated substantial funding for SBI for both alcohol and other drugs across many general health settings.

Research presented at the September 2011 International Network on Brief Interventions for Alcohol and Other Drugs (INEBRIA) conference in Boston was from around the globe, covered alcohol and other drugs, crossed a variety of health settings and practitioners, and showed the sophistication that has been reached in the field. Research discussed when, where, and for whom SBI has or might not have efficacy, how to implement SBI programs, adaptations of SBI, costs and effectiveness, and many other topics. Nonetheless, despite the excitement, breadth, and sophistication, the fact remains that few patients eligible for SBI receive the service, and, as a result, opportunities to improve health and save health care costs are missed. Most people with alcohol and drug use disorders receive no treatment.

At least in some cases, SBI is ready for dissemination. And, with solid evidence available, health reforms promised in the US and elsewhere, and an international discussion taking serious shape regarding the integration of care for medical, mental health, and substance use conditions, SBI may have reached a tipping point for dissemination and implementation as well as for small- and large-scale studies of remaining efficacy and effectiveness questions.

The editors of ASCP invited INEBRIA attendees and presenters to submit their studies for peer review and possible publication. The initial core of this thematic series, "Screening and brief intervention for unhealthy alcohol and other drug use," is the result of that call for papers, a seed that we expect will grow as the SBI literature continues to become more robust. Papers will cover a range of topics from what the efficacy of SBI really is, to effectiveness in people with mental health and drug use conditions, to adolescent SBI, to health professional attitudes towards SBI, to SBI implementation research and even to state-of-the-art SBI research protocol design, among others. We hope this series begins a long and serious conversation.

Science to improve care for people affected by unhealthy alcohol and other drug use

Richard Saitz* and Jeffrey Samet

Why *Addiction Science & Clinical Practice?*

The last 20 years have brought two major changes in the field of addiction. First, the US Institute of Medicine (IOM) encouraged recognition of a spectrum of alcohol and other drug use that affects health and is not limited to those with the highest severity [1]. Unhealthy use (the spectrum from use that risks consequences through addiction [2]) among those without addiction is much more common than addiction itself. The second major shift also began in the 1990s with an emphasis on addiction as a chronic illness [3,4] and on unhealthy use as a health condition.

Although drug and excessive alcohol use clearly have social and other environmental determinants and consequences, there is little doubt that health care should play a major role in addressing them. In the health-care sector, attention to unhealthy substance use cannot be limited to highly specialized care settings; most patients with these conditions appear in general health settings where such problems are all too often ignored. In 2006, the IOM urged improvements in the quality of care for substance use conditions [5]. Responding to that report is a major impetus for the establishment of *Addiction Science & Clinical Practice (ASCP)*. We see this focus as unique among journals that address addictions.

History of *ASCP*

Addiction Science & Clinical Practice was founded in 2002 by the National Institute on Drug Abuse (NIDA), an agency of the US National Institutes of Health and the largest funder of drug-abuse research in the world. In 2011, NIDA discontinued ownership of the journal and transferred editorial control to us. We hope to see all of their subscribers and authors continuing the dialogue they established so well. Under NIDA's stewardship, *ASCP* excelled at bringing researchers and clinicians together to better translate science into practice and back again–to blend the two by publishing reviews and roundtables. We aim to take the next steps in this thematic direction: to serve as a forum for clinically relevant research and perspectives that contribute to improving the quality of care (prevention and treatment) for people with unhealthy alcohol, tobacco, or other drug use and addictive behaviors across a spectrum of clinical settings–from emergency departments to prisons, from primary-care offices to the Internet, and from general hospitals to specialty care programs.

A modern publishing model for *ASCP*

To achieve these aims, we have moved firmly into the cutting edge of 21st-century publishing practices by teaming with BioMed Central. Although some feel tied to print publications, we realize that, in 2012, most scientific reading occurs online. We are interested in having a broad reach and large impact, and online open-access journals are best able to meet these goals. In this publishing model, authors pay the costs to publish their work, which funders of research recognize as legitimate and expected. For an initial period, we are grateful to have support from NIDA that allows us to defray those costs for authors.

With BioMed Central as publisher, *ASCP* continues to be listed in Medline, to have articles deposited in national and international repositories, and to make our content freely and permanently available around the globe at no charge. Articles will be published immediately upon acceptance and listed in PubMed shortly thereafter. Because they are widely indexed, articles in *ASCP* are easily and freely discoverable through Internet search engines. We seek to have an impact beyond the usual calculations of citations; we want our articles to benefit people receiving care.

Building blocks

We appreciate the contributions of our exceptional group of Associate Editors and world-class Editorial Board who represent a range of disciplines (e.g., psychiatry, internal

medicine, psychology), research approaches (e.g., clinical trials, health services, behavioral sciences), and countries and offer their expertise on a variety of substances (e.g., alcohol, drugs, tobacco).

We look forward to reviewing your quality work and appreciate in advance your willingness to peer review submissions that, in some dimension, will improve the quality of health care for individuals with unhealthy substance use. It is with great humility and honor that we accept the task of providing thoughtful, timely, and responsive reviews for all submissions to *ASCP* as it embarks on its next phase. We know all the articles we publish will benefit from the wisdom, creativity, and hard work of our international, multidisciplinary substance use research colleagues.

Acknowledgements
The Editors acknowledge the superb efforts of Donna Vaillancourt, Managing Editor, in the preparation of this editorial for publication and in the launch of ASCP.

nature genetics

Meta-analyses identify 13 loci associated with age at menopause and highlight DNA repair and immune pathways

To newly identify loci for age at natural menopause, we carried out a meta-analysis of 22 genome-wide association studies (GWAS) in 38,968 women of European descent, with replication in up to 14,435 women. In addition to four known loci, we identified 13 loci newly associated with age at natural menopause (at $P < 5 \times 10^{-8}$). Candidate genes located at these newly associated loci include genes implicated in DNA repair (*EXO1*, *HELQ*, *UIMC1*, *FAM175A*, *FANCI*, *TLK1*, *POLG* and *PRIM1*) and immune function (*IL11*, *NLRP11* and *PRRC2A* (also known as *BAT2*)). Gene-set enrichment pathway analyses using the full GWAS data set identified exoDNase, NF-κB signaling and mitochondrial dysfunction as biological processes related to timing of menopause.

Menopause is the cessation of reproductive function of the human ovaries. This life stage is associated with one of the major hormonal changes of women, characterized by a decline in secretion of estrogen, progesterone and, to a lesser degree, testosterone. It influences a woman's well-being and is associated with several major age-related diseases including cardiovascular disease, breast cancer, osteoarthritis and osteoporosis[1]. Ovarian aging is reflected by the continuous decline of the primordial follicle pool, which is established during fetal life, subsequently leading to endocrine changes owing to loss of the negative feedback from ovarian hormones on the hypothalamic-pituitary axis. In addition to follicle loss, oocyte quality diminishes with increasing age, which is believed to be due to greater meiotic nondisjunction[2]. Oocyte quality may be controlled at the time germ cells are formed during fetal life, but it may also reflect accumulated damage during reproductive life and/or age-related changes in granulosa cell–oocyte communication[3]. Although both oocyte quantity and quality decline with increasing age, it is unclear whether they are controlled by the same mechanisms and whether they decline in parallel.

The average age at natural menopause in women of Northern European descent is 50–51 years (range 40–60 years)[4]. Heritability estimates from twin and family studies for age at natural menopause range from 44% to 65% (refs. 5–8). Thus far most genetic association studies regarding age at menopause have focused on candidate genes[9] from the estrogen pathway[10,11] or vascular components[12,13]. Recently, two GWAS have newly identified five loci associated with age at natural menopause on chromosomes 5, 6, 13, 19 and 20 (refs. 14,15). These loci, however, explained <1.5% of the phenotypic variation of age at natural menopause, suggesting that additional loci of small effect will probably be discovered in larger samples. Therefore, we conducted a two-stage GWAS of women of European ancestry, combining the women from the two previous GWAS[14,15] with new participants for a total of 38,968 women from 22 studies in the discovery stage, and 14,435 women from 21 studies in the replication stage.

RESULTS

In our discovery stage of 38,968 women with natural menopause aged 40–60 (**Supplementary Tables 1** and **2**), we identified 20 regions with SNPs meeting the genome-wide significance criterion $P < 5 \times 10^{-8}$ (**Fig. 1**). Four of these loci confirmed earlier reports of associations on chromosomes 5, 6, 19 and 20 (refs. 14,15; regions 5b, 6a, 19a and 20, respectively, in **Table 1**) and 16 loci were previously unidentified. We did not confirm one reported association on chromosome 13 (13q34, rs7333181, $P = 0.12$). The overall genomic inflation factor was 1.03 (**Fig. 1**, inset; SNP with lowest P value from each region, **Table 1**). There was no between-study effect heterogeneity across discovery studies ($P > 0.05/20 = 0.0025$) for the 20 SNP associations presented. Within the Framingham Heart Study group, we tested for differences in effect size for the 20 SNPs in retrospectively and prospectively collected menopause age, and found no significant differences (data not shown). The effect sizes ranged from 0.17 years (8.7 weeks) to nearly 1 year (50.5 weeks) per each copy of the minor allele. We computed the effect sizes for dichotomized age at natural menopause in women from the Women's Genome Health Study (WGHS). For early menopause, we compared women with age at menopause <45 ($N = 745$) to those with age at menopause >45. For late menopause, we compared women with age at menopause >54 ($N = 1,632$) to those with age at menopause <54. The estimated odds ratios for early menopause for the menopause-decreasing allele ranged from 1.01 to 2.03. The estimated odds ratios for late menopause for the menopause-decreasing allele ranged from 0.52 to 0.96 (**Supplementary Table 3**). The top SNPs in regions 2c, 5a and 19b were >400 kb but <1 Mb from the top SNP in another region on the same chromosome. The top SNP in each of these primary regions had low linkage disequilibrium (LD; $r^2 < 0.5$) with the top SNP in the nearby region. To determine whether these associations were independent, we carried out a conditional association analysis in the discovery study samples with the most significant SNP from each of the primary 17 regions included as covariates in the analysis. For regions 5a and 19b (rs890835 and rs12461110, respectively), the effect estimates in the conditional analysis were unchanged compared

A full list of authors and affiliations appears at the end of the paper.

Received 21 July 2011; accepted 2 December 2011; published online 22 January 2012; doi:10.1038/ng.1051

with in the discovery analysis (differences of 0.3% and 4%, respectively), and the *P* values were genome-wide significant. However, for region 2c, the effect size was ~12.5% lower in the conditional analysis than in the initial analysis, and the SNP *P* value was no longer genome-wide significant ($P = 9.8 \times 10^{-7}$; **Table 1**), suggesting that the association with rs7606918 is not independent of the rs1018348 region 2b association. We attempted replication only for the 19 SNPs that represented independent regions that reached genome-wide significance ($P < 5 \times 10^{-8}$), thus we did not pursue replication of rs7606918.

Replication

We used 21 studies contributing 14,435 women for replication of the 19 SNPs that defined the independent genome-wide significant regions from stage 1. We defined age at natural menopause using the same criteria as in the discovery studies (**Supplementary Table 1**). Of these studies, 17 ($n = 6,639$) were included in *in silico* replication (**Supplementary Table 2**); an additional 4 studies ($n = 7,796$) contributed *de novo* genotypes for the 19 SNPs (**Supplementary Table 2**; effect sizes and *P* values for replication and combined meta-analysis of discovery and replication samples, **Table 1**). There was no evidence for effect heterogeneity among the replication studies (**Table 1**). We also tested for heterogeneity between the *in silico* and *de novo* genotyped studies, and found no evidence for heterogeneity of effect (data not shown), suggesting that for the significant SNPs, the genotype imputation methods did not lead to significantly different effect size estimates than would have been obtained from direct genotyping. Of the 19 SNPs, 17 were genome-wide significant and had lower *P* values in combined meta-analysis of the discovery and replication samples. Regions 5a and 13a showed no evidence of association in the replication samples ($P > 0.50$) and were not genome-wide significant in combined discovery and replication meta-analysis. Four of the 17 replicated regions have been reported previously; thus our analysis identified 13 regions newly associated with age at natural menopause on the basis of genome-wide significant discovery with replication. In the combined discovery and replication meta-analyses, the effect estimates ranged from 8.2 to 49.3 weeks per minor allele. The estimated proportion of variance explained by the 17 replicated SNPs in the four replication studies with *de novo*–genotyped SNPs varied from 2.5% (Osteos) to 3.7% (EPOS and BWHHS) to 4.1% (PROSPECT-EPIC).

We used the largest study contributing data to our discovery GWAS (WGHS, $n = 11,379$) to explore whether substantial SNP-SNP interactions are present among the 17 replicated SNPs. We tested all 136 pairs of SNPs and found no evidence for interaction (all $P > 0.01$).

Roles of genes at or near newly identified loci

All but two of the replicated SNPs are intronic or exonic to known genes (**Table 2**). The top SNPs in regions 6b, 12, 19b and 20 are missense polymorphisms. Three of the four have been predicted to have damaging protein function by SIFT[16], and one by PolyPhen2 (ref. 17). Using dbSNP and LocusZoom[18], we identified the genes underlying the newly identified top regions. We used SCAN (see URLs) to identify all genes with SNPs that are in LD ($r^2 > 0.5$) with our SNPs (**Table 2**). We identified all SNPs with $r^2 \geq 0.8$ with our top SNPs and used several databases to determine whether the SNPs are associated with expression (**Table 2**).

The strongest new signal was on chromosome 4 (region 4, rs4693089; $P = 2.4 \times 10^{-19}$). The SNP is located in an intron of *HELQ*, which encodes the protein HEL308, a DNA-dependent ATPase and DNA helicase[19]. The second strongest new signal was on chromosome 12 (region 12, rs2277339; $P = 2.5 \times 10^{-19}$). This SNP is a nonsynonymous variant in exon 1 of *PRIM1*. The top SNP was significantly associated with expression of *PRIM1* in visual cortex, cerebellum and prefrontal cortex (**Table 2**).

Several other previously unidentified signals are located in introns of genes for which mouse models exist. These were region 8 in *ASH2L* (rs2517388; $P = 9.3 \times 10^{-15}$), region 15 in *POLG* (rs2307449; $P = 3.6 \times 10^{-13}$) and region 1b in *EXO1* (rs1635501; $P = 8.5 \times 10^{-10}$). *ASH2L* encodes a trithorax group protein, and is involved in X chromosome inactivation in women[20]. *POLG* encodes the catalytic subunit of mitochondrial DNA polymerase, the enzyme responsible for replication and repair[21] of mitochondrial DNA. *EXO1* is a member of the RAD2 nuclease family of proteins, which is involved in DNA replication, repair and recombination, and the top hit is in LD ($r^2 = 0.83$) with a functional polymorphism in *EXO1* that affects a transcription factor–binding site in the promoter. Region 11 (rs12294104; $P = 1.5 \times 10^{-11}$) is near and in LD ($r^2 = 0.92$) with SNPs in *FSHB*. Transcription of *FSHB* limits the rate of production of the heterodimeric follicle-stimulating hormone (FSH), a key pituitary gland–expressed hormone that stimulates maturation of follicles. Region 19a (rs11668344; $P = 1.5 \times 10^{-59}$) is in tight LD with SNPs in *IL11*; this cytokine stimulates the T cell–dependent development of immunoglobulin-producing B cells.

The top SNPs in two other previously unknown regions are nonsynonymous coding variants. Region 6b, rs1046089 ($P = 1.6 \times 10^{-16}$), is in exon 22 of *PRRC2A* and was associated with expression of several transcripts in the human leukocyte antigen (HLA) region in several tissues (**Table 2**). Region 19b, rs12461110 ($P = 8.7 \times 10^{-10}$) is in exon 5 of *NLRP11*. *PRRC2A* encodes HLA-B associated transcript 2 and has several microsatellite repeats. *NLRP11* encodes the nucleotide-binding domain and leucine-rich repeat–containing (NLR) family pyrin domain–containing 11 protein, which is implicated in the activation of proinflammatory caspases[22].

Of the remaining five new regions, the top SNPs for regions 1a, 2a, 2b and 13b are located in introns. These were rs4246511 in *RHBDL2* (0.24 years per minor allele, $P = 9.1 \times 10^{-17}$), which is thought to function as an intramembrane serine protease; rs2303369 in *FNDC4*, which encodes fibronectin type III domain–containing 4 ($P = 2.3 \times 10^{-12}$);

rs10183486 in *TLK1* ($P = 2.2 \times 10^{-14}$), a nuclear serine-threonine kinase that is potentially involved in the regulation of chromatin assembly; and rs4886238 in *TDRD3* ($P = 9.5 \times 10^{-11}$). *TDRD3* is a binding partner for *FMR1*, which has been associated with primary ovarian insufficiency (POI). The top SNP in the final newly identified region, 16, is within 60 kb of three genes, *TNFRSF17*, *GSPT1* and *RUNDC2A*. It is in LD ($r^2 > 0.5$) with SNPs in these three genes and four others (rs10852344; $P = 1.0 \times 10^{-11}$; **Table 2**).

Pathway analyses

We used three independent pathway-based methods to identify connections among our single-marker associations and link them with broader biological processes. Although all three approaches (ingenuity pathway analysis (IPA, see URLs), MAGENTA[23] and GRAIL[24]) are based on published data, thus linking the gene products of our top hits to each other in functional pathways, each uses a substantially different methodology and uses different aspects of our results as input. Thus, we expect complementary results from the three approaches.

We used IPA (see URLs) to identify potential biological pathways common to the 17 replicated SNPs. On the basis of the genes physically nearest the 17 loci, we identified four major functional networks applying direct interactions only (**Supplementary Table 4**). Network 1, related to lipid metabolism, molecular transport and small molecule biochemistry, contained 14 of the genes nearest the menopause loci ($P = 1 \times 10^{-30}$). Central to this network is the *HNF4A* gene, which has a role in diabetes. Network 2, containing 12 of the input genes, relates to cell cycle, cell death and cancer ($P = 1 \times 10^{-24}$). The *ESR1* gene is central in this network, suggesting that genes in this network influence or are influenced by estrogen signaling. Network 3 is also partially related to cell death, and includes TNF and NF-κB ($P = 1 \times 10^{-19}$). Network 4 relates to infection mechanism, DNA replication, recombination and repair and gene expression ($P = 1 \times 10^{-12}$). Notably, several of the input genes included in network 1 (*EXO1* and *HELQ*) and network 2 (*UIMC1*, *FANCI* and *TLK1*) are also involved in DNA repair mechanisms.

We used gene set enrichment analysis (GSEA) implemented in MAGENTA[23] to explore pathway-based associations using the full GWAS results. Three pathways reached study-wide significance (false discovery rate (FDR) < 0.05), exoDNase ($P = 0.0005$), NF-κB signaling ($P = 0.0006$) and mitochondrial dysfunction ($P = 0.0001$; **Supplementary Table 5**).

Finally, we used the GRAIL method of literature-based pathway analysis[24] to explore the connections between genes near our top SNPs. Genes are considered related if they share informative words. GRAIL scores for genes associated with three of the replicating genome-wide significant SNPs were significant, *EXO1*, *FKBPL* and *BRSK1*. When we applied this method to a deeper set of 66 SNPs from the discovery meta-analysis with significance meeting FDR < 0.05, 12 genes had significant GRAIL scores: *EXO1*, *MSH6*, *PARL*, *RHBDL2*, *FKBPL*, *TP53BP1*, *TLK1*, *RAD54L*, *CHEK2*, *H2AFX*, *APEX1* and *REV3L*. *BRSK1* was also borderline significant with GRAIL FDR = 0.06.

Candidate genes

Within the discovery GWAS, 18,327 SNPs were within 60 kb of the start and end of transcription of 125 candidate genes selected because of a reported relationship with ovarian function (**Supplementary Table 6**). After multiple testing correction, 101 SNPs in or near five of the candidate genes (*DMC1*, *EIF2B4*, *FSHB*, *POLG* and *RFPL4A*) were significantly associated with age at natural menopause. SNPs in or near four of these genes were already identified as genome-wide significant (*EIF2B4*, region 2a; *RFPL4A*, region 19b; *POLG*, region 15; and *FSHB*, region 11). For the other gene, *DMC1*, the most significant SNP was rs763121, with nominal $P = 1.6 \times 10^{-7}$ ($P = 0.0009$ corrected for candidate gene SNP analyses); age at natural menopause was lower by ~0.18 years per copy of the minor allele. *DMC1* encodes a protein that is essential for meiotic homologous recombination and is regulated by *NOBOX*, mutations in which can cause POI[25–27].

Pleiotropy of primary hits

We examined overlap of our significant regions against published GWAS results for other traits (GWAS catalog; see URLs). Twelve menopause loci were within 1 Mb of a previously published genome-wide significant SNP, but most of the colocalized SNPs were in low LD ($0 < r^2 < 0.21$) with our SNP in the region (**Supplementary Table 7**). The exception was at the *GCKR* locus on chromosome 2. Region 2a (rs2303369) was correlated ($r^2 \approx 0.5$) with four different SNPs reported to influence kidney function, type 2 diabetes, continuous glycemic traits, as well as serum albumin, C reactive protein, serum urate, and triglycerides. These results increase the observed clustering of signals in complex trait genetics, whilst also adding to the increasing pleiotropy observed at the *GCKR* locus.

DISCUSSION

In this large two-stage GWAS, we confirmed four established menopause loci and identified and replicated 13 loci newly associated with age at natural menopause. Of these 17 hits, all but two are intronic or exonic to known genes. For associated SNPs in GWAS, on average 40% are intergenic, whereas only 2% of our hits are intergenic. Furthermore, we found twice the nonsynonymous top hits typically observed in GWAS (24% versus 12%; ref. 28). The 17 replicated loci function in diverse pathways including hormonal regulation, immune function and DNA repair. Together, they explained 2.5–4.1% of the population variation in menopausal age in independent replication samples. Biological pathway analysis of the genetic associations with age at natural menopause in this study using distinct algorithms and databases were in close agreement in emphasizing general biological pathways for mitochondrial function, DNA repair, cell cycle and cell death and immune response.

Aging is thought to result from the accumulation of somatic damage[29]. Analysis of gene expression patterns in aging organs, such as heart and brain, identified changes in genes involved in inflammatory response, oxidative stress and genome stability[30], processes also identified in analysis of age-related changes in mouse oocytes, including changes in mitochondrial function[31]. Comparisons of lifespans across species show that longevity and DNA repair function are generally related[32]. This notion is reinforced in the Werner and Bloom syndromes, which involve genome instability due to mutations in 3′→5′ DNA helicases of the RecQ family members, and are characterized by both premature aging and premature menopause[33]. Similarly, an increase in meiotic errors is associated with an age-related decline in oocyte quality, compounding progress toward menopause owing to follicle depletion[34].

In biological pathway analysis, seven candidate genes identified by proximity to the 17 genome-wide significant associations with age at natural menopause are related to DNA damage repair and replication (*EXO1*, *HELQ*, *UIMC1*, *FAM175A*, *FANCI*, *TLK1*, *POLG* and *PRIM1*; **Supplementary Table 4**). The protein encoded by *UIMC1* physically interacts with BRCA1 and estrogen receptor α and is thought to recruit BRCA1 to DNA damage sites and to initiate checkpoint control in the G2/M phase of the cell cycle. PRIM1 (primase) is involved in DNA replication by synthesizing RNA primers for Okazaki fragments during discontinuous replication[35]. A mutation in *POLG* can segregate with POI[36]. *Polg* knock-in mice show lower lifespan, premature aging

and lower fertility compared with wild type[37]. *FANCI*, another gene at the same locus adjacent to *POLG*, is a member of the Fanconi anemia complementation group. Fanconi anemia is a recessive disorder characterized by cytogenetic instability and defective DNA repair. Fanconi anemia patients experience irregular menstruation with menopause occurring around age 30 (ref. 38). The functional polymorphism correlated to our top hit in *EXO1* is associated with longevity in female centenarians[39]. Male and female *Exo1* knockout mice are sterile because the gene is essential for male and female meiosis[40]. In addition to the GWAS regions in or near genes associated with early menopause, we investigated a panel of candidate genes identified before the study, and found a SNP near the meiotic recombination gene *DMC1* to be significantly associated with age at menopause. How the DNA repair pathways contribute to menopause remains unclear. With altered DNA repair mechanisms, damage could accumulate, rendering poor-quality oocytes for selection. In contrast, the number of damaged follicles may increase with aging, leading to a greater rate of follicle loss through atresia. The top hit in this study, a nonsynonymous SNP in *MCM8*, was not included in the IPA results, probably because the exact function of this protein is still unknown. The MCM family, however, is a key component of the prereplication complex, and its main function is to restrict DNA replication to one round per cell cycle[41].

The pathway analyses highlighted additional candidate genes with functions in DNA repair, but with subgenome-wide levels of significance for association with age of natural menopause. These 12 candidates (**Supplementary Table 5**) included the gene encoding Werner helicase (WRN), mutations in which cause Werner syndrome, a classic progeria with advanced aging phenotype and ovarian aging[42]. Estrogen can enhance WRN expression, preventing cell senescence, suggesting that WRN is involved in menopause[43]. The identification of DNA repair as one of the biological pathways involved in menopause may also explain the association between smoking and an earlier age at menopause. Damage caused by smoking activates several different DNA repair mechanisms. Indeed, a polymorphism in *Exo1*, one of our top loci, is associated with colorectal adenomas in smokers only[44]. Additional studies are needed to determine whether smoking status modifies the association between age at natural menopause and polymorphisms in DNA repair genes, as has been observed for various cancers.

Pathway-based analysis indicated that genes related to autoimmune disease also influence age at natural menopause. This link has not been reported before, however, in a proportion (2–10%) of women with POI, ovarian autoimmunity can have a role[45]. POI is frequently associated with additional autoimmune diseases, such as type 1 diabetes mellitus[46]. The top SNP in region 19a is near *IL11*, which binds the interleukin 11 (IL-11) receptor α chain. Female mice with null mutations in *Il11ra* are infertile owing to defective uterine decidualization, the process necessary for successful embryo implantation[47]. *NLRP11* (region 19b) is a member of the NLRP family of genes, which have important roles in the innate immune system and reproductive system. Several NLRP genes show an oocyte-specific expression pattern[46], whereas *NLRP5* has been implicated in POI, and serves as an autoantigen in a mouse model of autoimmune POI[48,49]. Many autoimmune conditions are associated with a particular HLA type, but no such association has been reported for POI[50,51]. One of our top menopause associations (rs1046089) is a missense substitution in *PRRC2A* (HLA-B-associated transcript), which is in the HLA class III complex on chromosome 6 and has been associated with type I diabetes mellitus and rheumatoid arthritis. Multiple phenotypes have been associated with *PRRC2A* SNPs in GWAS, including BMI, neonatal lupus, HIV control and height (**Supplementary Table 7**), but the SNPs have low correlation with our top hit. Expression data for rs1046089 show that the polymorphism was associated with altered expression of HLA-DRB4 in monocytes and HLA-DQA1 in lymphoblastoid cell lines (**Table 2**). Thus, this gene is a candidate for a proinflammatory component to oocyte depletion that affects menopause age. Indeed, the enrichment of genes involved in NF-κB signaling (*TNF*, *TNFRSF17* and *CSNK2B*) in biological pathway analysis suggests that susceptibility to inflammation, which often accompanies immunosenescence in aging, may also affect ovarian aging. The finding that the innate immune response can be upregulated in response to DNA damage[52] suggests that interplay between the two main pathways we identified (DNA repair and inflammation) may contribute to variation in age at natural menopause.

Three of the 17 regions can be linked to hormonal regulation, an additional route to follicle pool exhaustion. The top SNP in region 11 (rs12294104) is in high LD with SNPs in *FSHB* ($r^2 = 0.92$, **Table 2**), which limits the rate of production of FSH, a key pituitary gland–expressed hormone that stimulates maturation of follicles. FSH-deficient female mice are infertile[53]. Transgenic mice that overexpress FSH show premature infertility owing to postimplantation reduction of embryo-fetal survival[54]. FSH concentrations rise in women approaching menopause; this might be related to a decrease in growing follicles[55]. Mutations in *FSHB* cause hypogonadism and primary amenorrhea in women[56] and lead to greater FSH concentrations and infertility in males compared with wild type[57]. The latter observation is due to a promoter polymorphism that may be causal[58] and is in LD ($r^2 = 0.7$) with our most significant SNP. Although *STAR*, which encodes steroidogenic acute regulatory protein (StAR), was not the nearest gene to the top SNP in region 8 (rs2517388), its functional role in cleavage of cholesterol to pregnenolone in response to tropic hormones makes it a probable functional candidate, and our top SNP is in high LD with SNPs in that gene ($r^2 = 0.81$, **Table 2**). Pregnenolone is a precursor for several steroid hormones, such as estrogen and progesterone, and mutations in the *STAR* gene are associated with congenital lipoid adrenal hyperplasia and POI[59]. Furthermore, *STAR* is a target of FOXL2, for which truncating mutations are preferentially associated with POI[60]. Similarly, *BCAR4*, which encodes the breast cancer antiestrogen resistance 4 protein, is the best candidate gene near region 16. *BCAR4* is expressed only in placenta and oocytes and may have a role in hormonal stimulation in the ovary. In breast cancer treatment, tumors highly expressing *BCAR4* are more resistant to tamoxifen treatment[61], reinforcing the role of *BCAR4* in transduction of hormonal signals.

In summary, our findings demonstrate the role of genes that regulate DNA repair and immune function, and genes affecting neuroendocrine pathways of ovarian function in regulating age at menopause, indicating that the process of aging is involved in both somatic and germ line aging.

We expect that several additional common variants with small effects on age at natural menopause are yet to be identified, and that many of them are in genes in pathways identified in this study. Sequencing and exome chip studies to determine whether low-frequency and rare variants of large effect also contribute to age at natural menopause are underway or being planned in many of the cohorts involved in this GWAS. A collaboration of several consortia is examining the contribution of common genetic variants to age at natural menopause in African-American women, and could allow researchers to determine whether the genetic variation that affects age at natural menopause in African-American women is the same or substantially different from that for women of primarily European descent. We are now conducting a study of women with POI to determine whether variants associated with age at natural menopause

within the normal range of age 40–60 also contribute to disease conditions related to the early-menopause phenotype.

ONLINE METHODS

Discovery. Age at natural menopause was defined as age at last menstrual period that occurred naturally with at least 12 consecutive months of amenorrhea. This analysis included women with natural menopause aged 40–60. Women of self-reported non-European ancestry were excluded, as were women with menopause owing to hysterectomy and/or bilateral ovariectomy, chemotherapy or irradiation, if validated by medical records, and women using HRT before menopause. Most cohorts collected age at natural menopause retrospectively; in the Framingham Offspring, the Atherosclerosis Risk in Communities Study (ARIC), Nurses Health Study (NHS) and WGHS studies, some women became menopausal under study observation. Study-specific questions, mean age at menopause and age at interview are in **Supplementary Table 1**. Genotyping and imputation information for discovery cohorts are in **Supplementary Table 2**. Descriptions of each study are in **Supplementary Note**. For all studies participating in the meta-analyses, each participant provided written informed consent. The Institutional Review Board at the parent institution for each respective cohort approved the study protocol.

Replication. A total of 14,435 women from 21 studies meeting the same inclusion and exclusion criteria as the women in discovery analysis were included in replication analysis. The women had mean and s.d. of age at natural menopause similar to the discovery set (**Supplementary Table 1**). Genotyping and imputation methods for the *in silico* replication cohorts are in **Supplementary Table 2**. Genotyping information for the studies that genotyped the SNPs *de novo* is in **Supplementary Table 2**. Descriptions of each study are in **Supplementary Note**.

The 19 independent genome-wide significant SNPs were tested for association with age at natural menopause using linear regression models. Meta-analysis inverse variance weighted meta-analysis of the studies was done with METAL using genomic control[62]. A SNP within a study was omitted if the minor allele frequency was <1% or imputation quality score was <0.2. The discovery meta-analysis included 2,551,160 autosomal SNPs and 38,968 samples.

Expression quantitative trait locus analysis. For each of the genome-wide significant menopause SNPs (**Table 1**), all proxy SNPs with $r^2 > 0.8$ were determined in HapMap CEU release 22. Each SNP and its proxies were searched against a collected database of expression quantitative trait locus (eQTL) results, including the following tissues: fresh lymphocytes[63], fresh leukocytes[64], leukocyte samples in individuals with Celiac disease[65], lymphoblastoid cell lines (LCLs) derived from asthmatic children[66], HapMap LCLs from three populations[67], HapMap CEU LCLs[68], fibroblasts, T cells and LCLs derived from cord blood[69], peripheral blood monocytes[70,71], $CD4^+$ lymphocytes[72], adipose and blood samples[73], brain cortex[70,74], brain regions including prefrontal cortex, visual cortex and cerebellum (three large studies; V.E., unpublished data), cerebellum, frontal cortex, temporal cortex and caudal pons[75], prefrontal cortex[76], liver[77] and osteoblasts[78]. The collected eQTL results met criteria for statistical significance for association with gene transcript levels as described in the original papers. eQTL findings for replicated GWAS SNPs are summarized in **Table 2**.

Conditional analysis. On each chromosome, SNPs of the lowest *P* value that met genome-wide significance were identified. Genome-wide-significant SNPs >250,000 bp and <1 Mb apart that also had pairwise HapMap CEU LD values of $r^2 < 0.5$ were considered potentially independent regions. Potential independent regions that were within 1 Mb of a second region with a more significant *P* value were tested for independence using conditional analysis. In this analysis, the most significant SNP in the most significant region on each chromosome was used as a covariate in a genome-wide analysis. The second region on the chromosome was then retested for independent association.

Pathway analyses. IPA Knowledge Base 8.8 (see URLs) was used to explore the functional relationship between proteins encoded by the 17 replicated menopause loci. The IPA Knowledge Base contains millions of findings curated from the literature. All reference genes ($n = 61$) within 60 kb potentially encoded by the 17 loci (**Table 2**) were entered into the Ingenuity database. Fifty-one genes were eligible for pathway analysis. These eligible 'focus genes' were analyzed for direct interactions only. Networks were generated with a maximum size of 35 genes and molecular relationships between genes or gene products were graphically represented. Proteins are depicted as nodes in various shapes representing functional class of protein. Lines depict the biological relationships between nodes. To determine the probability that the analyzed gene would be found in a network from Ingenuity Pathways Knowledge Base owing to random chance alone, IPA applies a Fisher's exact test. The network score or *P* value represents the significance of the focus gene enrichment. Enrichment of focus genes to diseases and functional categories was also evaluated in the IPA Knowledge Base. The *P* value, determined by a right-tailed Fisher's exact test, considers the number of identified focus genes and the total number of molecules known to be associated with these categories in the IPA knowledge database.

MAGENTA was used to explore pathway-based associations in the full GWAS data set. MAGENTA implements a GSEA-based approach that has been described[23]. Briefly, each gene in the genome is mapped to a single index SNP of the lowest *P* value within a 110 kb–upstream, 40 kb–downstream window. This *P* value, representing a gene score, is then corrected for confounding factors such as gene size, SNP density and LD-related properties in a regression model. Genes within the HLA region were excluded from analysis owing to difficulties in accounting for gene density and LD patterns. Each mapped gene in the genome is then ranked by its adjusted gene score. At a given significance threshold (95th and 75th percentiles of all gene scores), the observed number of gene scores in a given pathway, with a ranked score above the specified threshold percentile, is calculated. This observed statistic is then compared with 1,000,000 randomly permuted pathways of identical size. This generates an empirical GSEA *P* value for each pathway. Significance was determined when an individual pathway reached FDR <0.05 in either analysis (**Supplementary Table 5**). In total, 2,580 pathways from Gene Ontology, PANTHER, KEGG and Ingenuity were tested for enrichment of multiple modest associations with age at natural menopause.

GRAIL is designed to provide evidence for related biological function among a set of candidate genes. The method is based on connections between gene names and informative words extracted from PubMed abstracts by automated language processing techniques. Genes are considered related, and achieve a high similarity score, if they share informative words. For this analysis, the input for GRAIL was a list of candidate SNPs associated with age at natural menopause. From among candidate genes mapping near the candidate SNPs, GRAIL identifies genes with associated informative words that are significantly similar to informative words from other candidate genes. Genes with significant similarity scores are thus consistent with the set of candidate genes as a whole in having greater sharing of informative words than would be expected by chance, suggesting shared biological functions or even biological pathways. GRAIL was first applied to the lead SNPs from each of the replicating genome-wide significant loci using the 2006 edition of the database of genes and informative words. Separately, GRAIL was applied to a list of 66 SNPs, one from each locus that had at least one SNP meeting a FDR threshold of 0.05 from the QVALUE software in R[79]. For meta-analysis of age at natural menopause, the FDR < 0.05 threshold implied $P < 2.8 \times 10^{-5}$.

Candidate gene analysis. We explored the association of natural age of menopause with 125 candidate genes selected because of a reported relationship with ovarian function, including animal models in which gene mutations affect ovarian function ($n = 37$), human studies of menopause or isolated POI ($n = 48$), syndromes including ovarian failure ($n = 4$) or genes expressed in the ovary or female germ cells ($n = 38$; **Supplementary Table 6**). For each gene, the start and end of transcription was defined by the transcripts that span the largest portion of the genome. NCBI36/hg18 positions taken from the UCSC genome browser were used to define gene and SNP locations. Using the correlation measured from a set of ~850 independent Framingham Heart Study participants, we computed the effective number of independent SNPs for each chromosome[80], and used the total (5,774) in a Bonferroni correction for multiple testing.

Pleiotropy of primary hits. Allelic pleiotropy was explored by comparing genome-wide-significant menopause signals to the online catalog of published GWAS (GWAS catalog; see URLs). All reported associations that reached $P < 5 \times 10^{-8}$ and were within 1 Mb of the menopause signal were considered. LD estimates between the SNP pairs were assessed using HapMap (CEU, release 27). Results are in **Supplementary Table 7**.

ABSTRACT

We tested whether friends' and family members' cardiovascular health events and also their own aspirin use are associated with the likelihood that an individual takes aspirin regularly. Analyses were based on longitudinal data on 2724 members of the Framingham Heart Study (based in Massachusetts, U.S.A.) who were linked to friends and family members who were also participants in the same study. Men were more likely to take aspirin if a male friend had recently been taking aspirin, and women were more likely to take aspirin if a brother had recently been taking aspirin. Men were also more likely to take aspirin if a brother recently had a cardiovascular event, and women were more likely to take aspirin if a female friend recently experienced a cardiovascular event. Aspirin use is correlated with the health and behavior of friends and family. These findings add to a growing body of evidence which suggests that behavioral changes that promote cardiovascular health may spread through social networks.

Introduction

A large body of evidence shows that aspirin reduces cardiovascular events for patients with and without histories of cardiovascular disease (CVD) (Berger et al., 2006; Campbell, Smyth, Montalescot, & Steinhubl, 2007; Eidelman, Hebert, Weisman, & Hennekens, 2003; Farley, Dalal, Mostashari, & Frieden, 2006). However, several national studies reveal that aspirin is underutilized (Pignone, Anderson, Binns, Tilson, & Weisman, 2007; Stafford, 2000). Increases in aspirin use have been slow given its efficacy, and rates remain low, particularly among outpatients (Stafford & Radley, 2003). Using the 2003 Behavioral Risk Factor Surveillance Survey, Ajani, Ford, Greenland, Giles, and Mokdad (2006) report adjusted aspirin prevalence rates of 69.3% and 32.7% for individuals with and without CVD. They also find less aspirin use among women than men (adjusted prevalence for women was 34% and for men 38.5%).

Given that aspirin is inexpensive, available without a prescription, and its health benefits have been relatively widely publicized (e.g., industry-initiated advertising campaigns), much of the variation in aspirin use is likely to be determined by factors outside of the clinical setting. While having had a conversation with one's doctor about aspirin is an important determinant of aspirin use in national samples (Brown et al., 2002; Pignone et al., 2007), discrepancies between medical records and self-reports suggest than many people take aspirin on their own initiative without their doctor's knowledge (Brown et al., 2002).

It seems reasonable to suppose that having a member of one's social circle (i.e., an "alter") experience a cardiovascular event and/or begin taking aspirin is likely to affect an individual's (i.e., an "ego") aspirin use. Health behaviors and risk factors (e.g., obesity, smoking) may be "socially contagious," and the chances that one changes his/her own behavior are increased if a member of one's social network recently began behaving differently (e.g., with respect to diet, exercise, smoking, or drinking) (Christakis & Fowler,

doi:10.1016/j.socscimed.2011.12.033

2007, 2008; Rosenquist, Murabito, Fowler, & Christakis, 2010). Aspirin-use may have a comparable dynamic of social diffusion. Having a friend or family member experience a cardiovascular event and/or begin taking aspirin may increase an ego's odds of aspirin-use by increasing his/her awareness of CVD and aspirin prophylaxis. Alters' events and aspirin-use could also raise ego's subjective assessment of personal cardiovascular risk and improve his/her attitudes toward aspirin use. This work departs from prior work in that it evaluates both the similar behaviors in alters (aspirin use) and also events occurring in alters (e.g., cardiovascular illness) with respect to how they affect ego.

Methods

The Framingham Heart Study Social Networks Study

The Massachusetts, U.S.A. Framingham Heart Study (FHS) began in 1948 with an Original Cohort of 5209 adults. In 1971, the FHS added an Offspring Cohort comprised of 5124 adult children of the Original Cohort and their spouses. In 1994, a minority oversample of 508 people known as the "Omni Cohort" was empaneled. Beginning in 2002, 4095 adults having at least one parent in the Offspring Cohort enrolled in the Third Generation Cohort, along with 103 parents of the Third Generation Cohort participants who were not previously enrolled in the Offspring Cohort. As a means of following participants, the FHS collected regular contact information for participants' close friends and family members. Since the FHS cohorts are family-based and participants are drawn primarily from the Framingham, Massachusetts area, many of the friends and family members that were listed as contacts are also participants in FHS. Connecting participants (i.e., egos) at each wave to their contacts who were also participants (i.e., alters) gives researchers longitudinal data on a network of social connections among participants. Combining these network data with data from periodic physical exams and questionnaires allows us to test how alters' recent events and behaviors impact egos.

The Framingham Heart Study protocol is reviewed by the Boston University Medical Center Institutional Review Board and participants signed written informed consent. Our project was additionally reviewed by the Harvard Medical School Institutional Review Board.

Study sample

Longitudinal data for our analysis come from physical exams and questionnaires performed during three-year periods centered at 1985, 1989, 1992, 1997, and 1999. We limit our analysis to egos who are likely candidates for aspirin prophylaxis—that is, women age 55–70 and men ages 45–79. All egos are from the Framingham Offspring Cohort, while alters may be in any of the Framingham cohorts. In this analysis, we include three types of intimate peer relationships: spousal relationships, sibships, and friendships. We select these relationship types because we expect egos to be more sensitive to events/behaviors among alters they identify with and feel close to. An insufficient number of observations and events made it impossible to examine gender-stratified parent–child relationships.

In the data for our analysis, information on egos' and alters' health events, behaviors, and social ties are time-varying across waves. If a respondent lists a friend as a contact in one wave, but not in the next wave, that tie is dissolved and is not included in subsequent waves. If an alter dies between the last and current wave, we include information about the health events leading to his/her death in the current wave, but that tie will be dissolved and is not included in all subsequent waves. Examining ego-alter ties across all waves, 32% of the observations are spousal ties, 58% are sibling ties, and 11% are friendships.

Study variables

The dependent variable for this analysis is a dichotomous indicator for whether ego is taking aspirin on a daily basis at the time of the current wave. The key predictors of interest are whether alter was taking aspirin on a daily basis at the last wave and whether alter had a cardiovascular event between the last and current waves. Specific cardiovascular events included in the alter event measure are: myocardial infarction, angina pectoris, coronary insufficiency, stroke, intermittent claudication, and death from CVD or stroke.

We include a lagged version of the dependent variable as a predictor to adjust for whether ego was taking aspirin at the last wave. We also adjust for whether ego has ever had his/her own cardiovascular event prior to the current wave. The measure of ego's prior events includes: myocardial infarction, angina pectoris, coronary insufficiency, stroke, and intermittent claudication. Other control variables are ego's age, education, marital status, and survey wave.

Statistical analysis

The longitudinal logistic regression model employed in our analysis can be written as:

$$\ln\left(\frac{Y^e_{it}}{1-Y^e_{it}}\right) = \alpha + \beta_1 X^a_{1ir(t,t-1)} + \beta_2 X^a_{2ir(t-1)} + \beta_3 X^e_{3i(t-1)} + \beta_4 X^e_{4it} + \beta_5 X^e_{5it} + \beta_6 X_{6t} + e_{irt}$$

where the superscript e indicates a variable measuring an ego characteristic and a superscript a indicates a variable measuring an alter characteristic. The subscript i refers to individual ego, i, the subscript r refers to relationship, r, with a given alter, and the subscript t refers to a given wave at time t. Y^e_{it} is the dichotomous dependent variable indicating whether ego used aspirin at the current wave. $X^a_{1ir(t,t-1)}$ is a dichotomous variable indicating whether alter experienced a cardiovascular health event between the last wave $(t-1)$ and the current wave (t). $X^a_{2ir(t-1)}$ is a dichotomous variable indicating whether alter was taking aspirin at the last wave. $X^e_{3i(t-1)}$ is a dichotomous measure of whether ego was taking aspirin at the last wave. X^e_{4it} is a dichotomous measure of whether ego had a cardiovascular health event at any time prior to the current wave. X^e_{5it} reflects the set of controls for ego's characteristics (e.g., age, education, marital status). X_{6t} reflects the set of controls for survey wave. And, finally, e_{irt} is an error term specific to each ego-alter pair at a given wave. To account for clustered error terms resulting from ego-alter pairings and multiple observations of the same egos across waves, we use generalized estimating equations with an independent working correlations structure (Hardin & Hibe, 2002).

After presenting a model for all ties combined, we stratify the analysis according to ego's sex, the sex-composition of the tie (i.e., two males, two females, or a male and female), and the type of relationship (i.e., spouses, siblings, and friendships). Aspirin-use is lower among women than men, and evidence of the preventative benefits of aspirin is somewhat more controversial for women than men (Ajani et al., 2006; Mulrow & Pignone, 2005). We further expect that people may be more likely to identify with and take behavioral cues from same-gender alters, and that alter's influence on ego may differ depending on the type of relationship they share (i.e., spouses, siblings, friends).

Table 1
Characteristics of egos and alters in sample.

	Total sample	Male egos	Female egos
Ego Aspirin Use at Current Wave	22.98%	25.45%	19.35%
Alter Aspirin Use at Last Wave	20.03%	18.24%	22.66%
Ego Aspirin Use at Last Wave	19.64%	20.98%	17.67%
Alter CV Event between Last and Current Wave	5.23%	4.29%	6.62%
Ego CV Event Prior to Current Wave	12.88%	15.04%	9.70%
Ego Female	40.46%		
Ego Age (average)[a]	61.279 (7.838)	59.333 (8.339)	64.144 (5.978)
Ego Education			
High School Degree	53.99%	47.89%	62.97%
Associates Degree	8.93%	9.69%	7.81%
Bachelor Degree	15.04%	17.14%	11.97%
Masters/Doctorate Degree	10.74%	15.16%	4.23%
None of the Above	11.30%	10.13%	13.01%
Ego Married	85.60%	90.12%	78.96%
N (Ego-Alter Pair Observations)	19,849	11,818	8031

[a] Standard deviations for ego age in parentheses.

Since siblings are, roughly speaking, equally likely to be male as female, there are comparable numbers of same-sex and mixed-sex sibling pairs and we present estimates separately for sister pairs, brother pairs, and brother–sister pairs. Friendships, on other hand, are much more likely to same-sex than mixed-sex, and we do not have sufficient observations to present separate mixed-sex friendship estimates. We, therefore, present estimates for all friendships combined and then present separate estimates for the subset of same-sex friendships. We conducted all the analysis using STATA SE 10 software.

Results

As shown in Table 1, about 25% of male and 19% of female egos were using aspirin on a daily basis in a given wave. Looking at male and female egos combined in the first column of Table 1, about 20% of their alters were using aspirin daily at the last wave and about 5.2% had a cardiovascular event between the previous and current waves. Table 2 presents odds ratios and 95% confidence intervals from our first regression model including all relationship types and both male and female egos. Older egos, male egos, and egos who had a prior cardiovascular event were more likely to take aspirin regularly. In line with widely documented trends, ego's odds of aspirin use were also higher at more recent waves (Stafford, 2000). Ego's marital status and education, however, were not significantly associated with his/her aspirin use in this sample.

In Table 2, ego's odds of daily aspirin use were 12% higher if alter used aspirin daily at the last wave. On the other hand, there was no significant association between alter's recent cardiovascular events and ego's aspirin use. However, this reflects the overall association for all ego-alter pairs and we expect associations may vary according to ego's gender, relationship type, and the gender composition of the relationship. Tables 3 and 4 replicate the basic model presented in Table 2 stratified according to each of these factors.

In Table 3, male egos' aspirin-use was not associated with their wives' aspirin-use or cardiovascular events. Their aspirin use also did not appear to be sensitive to their sisters' aspirin-use or events. On the other hand, male egos were about 41% more likely to use aspirin if their brothers had a cardiovascular event since the last wave. Brothers' earlier aspirin use, however, was not associated with ego's aspirin use. Men's aspirin-use was about 48% higher if a male friend was using aspirin at the last wave. Men's aspirin-use may also be higher if a male friend had a recent cardiovascular event, but this odds ratio of 1.71 should be interpreted cautiously since the lower bound for the 95% confidence interval is 1.00.

Whereas male egos' aspirin-use was not associated with their sisters' aspirin-use, Table 4 shows that female egos were about 35% more likely to take aspirin if their brother used aspirin at the last wave. Brothers' recent cardiovascular events, however, were not

All Friends ($N = 838$)	1.73	(0.74, 4.05)	0.66	(0.40, 1.11)
Same-sex Friends ($N = 740$)	2.85	(1.27, 6.37)	0.77	(0.45, 1.31)

*Although not included in the interests of space, models for each relationship type include all control variables listed in Table 2 (except Ego Female).

associated with women's aspirin use. Women's odds of aspirin use did not appear to be sensitive to their sisters' aspirin use or health events. Women were more than twice as likely to use aspirin if a female friend recently had a cardiovascular event. However, female friends' recent aspirin use was not associated with women's aspirin use. Women's odds of aspirin use may also be positively associated with their husband's recent aspirin use, however this odds ratio of 1.30 should be interpreted cautiously since the lower bound for the 95% confidence interval is 1.00.

Discussion

Persons in this study were more likely to take aspirin regularly if a friend or family member took aspirin. A growing body of literature shows that behavioral changes that promote cardiovascular health may spread through social networks (Christakis & Fowler, 2007, 2008; Rosenquist et al., 2010). The above results add to this literature by providing preliminary evidence that another important cardiovascular health behavior—regular aspirin use—may also be shaped by how members of one's network behave.

Another contribution of this analysis is the examination of alters' cardiovascular events. This approach has both conceptual and methodological advantages compared to prior work. Conceptually, it broadens the scope of what sorts of inter-personal effects might be relevant to individual and public health. Methodologically, it is advantageous because, when considering the effect of an alter event on an ego behavior, it may reduce concern about confounding (since it is a bit harder to imagine factors that are associated with alter events and ego behaviors than it is to imagine factors that are associated with the same behavior in both egos and alters).

While alters' cardiovascular events were not associated with ego's behavior when looking at average effects among all pairs in Table 2, we did find significant associations among certain subgroups. Men were more likely to take aspirin if their brothers recently had a cardiovascular event, and women were more likely to take aspirin if a same-sex friend recently suffered an event. There has been very little research into how people may learn about their own cardiovascular risk and possibly take cues from their friends or family members' health problems (Khwaja, Sloan, & Chung, 2006). Models and theories of behavioral change posit that health behavior depends on how people perceive their health risk and where they fall on a continuum of "readiness to change" (Prochaska & Velicer, 1997). Having a friend or family member go through an experience like a myocardial infarction or stroke may be an important catalyst on the path toward healthier behaviors and better cardiovascular health.

Because aspirin-use is lower among women than men, and evidence of the benefits of aspirin is somewhat more controversial for women than men (Ajani et al., 2006; Mulrow & Pignone, 2005), we stratified the above models according to ego's sex and the sex-composition of the relationship. While the above analysis does not allow us to draw clear conclusions about sex differences in the spread of aspirin-use through social networks, there are suggestive findings. It is notable, for instance, that only male alters, not female alters, appeared to shape ego's aspirin use. Men's aspirin use was associated with their male friends' aspirin use. Women's aspirin use was associated with their brother's aspirin use. Female alters' (i.e., wives, sisters, female friends) aspirin use, on the other hand, was not significantly associated with ego's aspirin use in any of our stratified models. This greater sensitivity to male alter's aspirin use may result from several different factors including higher rates of aspirin use among men, different perceptions of cardiovascular risk for men and women (Frijling et al., 2004), and gender inequalities in the inter-personal dynamics of ego-alter relationships.

Our analysis also points to possible sex differences in sensitivity to alters' cardiovascular events. Associations between ego's aspirin use and alters' cardiovascular events occurred only within same-sex relationships (i.e., brother pairs for men and same-sex friendships for women). There was no association between the ego's aspirin use and the alter's cardiovascular events within mixed-sex pairs. Although several factors may contribute to this pattern, people probably identify more strongly with, and take more health cues from, people of the same sex.

When interpreting the results of our study, it is important consider the role that subjects' doctors may have played in their behavior. One possible explanation for associations between ego's and alter's aspirin use is that they both have the same physician who encouraged aspirin use. In our study sample, we were able to identify ego-alter pairs who shared the same doctor and adjust our estimates for this potential confounder. Associations between ego's and alter's aspirin use were quite robust to this adjustment and it does not appear that shared doctors can account for our results (see Table S1 in the online data supplement). Unfortunately, our data do not allow us to know whether egos who were influenced by alters' aspirin use involved their doctors in their aspirin use decisions (e.g., when an ego learns of an alter's aspirin use, does she then turn to her physician for advice about aspirin prophylaxis?).

In an effort to focus our study on egos who are likely candidates for aspirin prophylaxis, we analyzed women ages 55–70 and men ages 45–79. We believe this broad, demographically-based definition of an aspirin use risk group is appropriate given that we are examining how people make choices about aspirin use outside of clinical settings. Further, because clinical recommendations regarding regular aspirin use were being developed over the period in our study (i.e., 1971–1998), it is important that we capture a broad segment of the general population.

It should be kept in mind, however, that influences of alters' behaviors and health may operate differently on egos with specific clinical risk factors (e.g., those based on blood pressure, cholesterol, diabetes, etc.). We found consistent results when we replicated our main analysis for the subset of egos with prior cardiovascular events and/or elevated 10-year coronary heart disease risk scores (based on Wilson et al., 1998). However, when we limited the sample further to include only egos with prior cardiovascular events, we no longer found a significant association between egos' and alters' aspirin-use. Interpreting this non-significance is difficult, though, because relatively few egos had prior cardiovascular events, raising concerns about sparse data and large standard errors (these results are presented in the online data supplement). Further research, preferably with larger samples, is needed to know whether individuals at higher risk for cardiovascular disease are more or less sensitive to the health and behaviors of their friends and family. This study makes no suggestions related to clinical guidelines or about who should take regular aspirin doses. Rather, our results document how social networks are correlated with whether or not an individual adopts a regular aspirin regimen, regardless of specific clinical risk factors.

This work has a few notable limitations. It does not randomize individuals into social networks, thus leaving open the possibility that these results may in part reflect homophily-driven selection bias on the basis of unobserved traits (e.g., avidity for drugs) that influence the use of aspirin over time. For instance, we can imagine that individuals with similar tastes, health knowledge, or physical resilience may be more likely to form relationships. Shared leisure time activities, as well as similar sociodemographic positions (e.g., educational backgrounds or professions), may increase the chances that people with underlying tendencies toward aspirin-use meet and form relationships. While observational data can never overcome all concerns about unmeasured confounding, the Framingham

Heart Study Social Networks Study, which is longitudinal and provides several control variables, gives us more leverage on causality than is usually possible with non-experimental data. Most notably, our data allow us to adjust for egos' prior aspirin use and cardiovascular events. Also, as has been widely noted, the Framingham Heart Study sample is somewhat homogenous and does not have a significant percentage of underrepresented minorities.

Because of differences in how questions about aspirin use were asked in earlier and later waves of the Framingham Heart Study, our dependent variable captures daily aspirin use, but does not detect less frequent regular aspirin doses (e.g., taking aspirin every other day). Furthermore, with these data, we can measure egos' aspirin use only every four years or so. Lower levels or shorter-term changes in egos' aspirin use are, therefore, not detected in our study. This may mean that we fail to capture some variation in egos' aspirin use, which would imply our estimates may fall on the conservative side.

Because our dataset captures a limited number of relationship ties, we were unable to stratify the data in certain ways, and there were several questions about heterogeneity across subgroups that we were not able to test. For instance, after stratifying by sex and relationship type, we did not have a sufficient number of observations to test whether associations differed depending on whether ego had cardiovascular disease and/or had taken aspirin previously. It should be kept in mind that the above results reflect average associations for a general population. It remains possible that associations between egos' aspirin use and alters' aspirin use/events may differ when distinguishing between further subgroups. Finally, the analyses comparing results across different types of relationships and exposures are exploratory. We did not have prior hypotheses about effect sizes for different types of relationships or exposures. These results should not be interpreted as evidence of differences in causal effects across groups/exposures. Since there is very little existing research into peer influences in drug-taking behavior, we believe that this type of exploratory analysis provides a useful first step in understanding how networks may shape pharmacotherapy. In this case of an exploratory analysis, it is not clear whether Bonferroni adjustments for multiple hypothesis testing are appropriate; nevertheless, we note that all Bonferroni-adjusted p-values in our analysis were greater than 0.05.

Across a broad swathe of behaviors, people are influenced by those around them. Pharmacotherapy is a behavior, and so we should not be surprised by the fact that people's drug-taking behavior is related to the behavior of those around them, and to the events occurring in those around them. Similar to the person who might stop smoking when his friend gets lung cancer, a person whose friend, sibling, or spouse has a myocardial infarction may be more inclined to take aspirin because he/she now has a palpable demonstration of the occurrences the aspirin is intended to prevent, rather than an abstract admonition. Likewise, those whose friends are taking aspirin might follow suit for a variety of reasons, including the basic realization that taking aspirin is not hard at all. People are connected, and so their health is connected.

Association of Female Reproductive Factors with Body Composition: The Framingham Heart Study

Subbulaxmi Trikudanathan, Alison Pedley, Joseph M. Massaro, Udo Hoffmann, Ellen W. Seely, Joanne M. Murabito, and Caroline S. Fox

Division of Endocrinology, Metabolism, and Diabetes (S.T., E.W.S., C.S.F.), Department of Medicine, Brigham and Women's Hospital, and Department of Radiology (U.H.), Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts 02115; National Institutes of Health (A.P.), Bethesda, Maryland 20892; Framingham Heart Study (J.M.Ma., J.M.Mu., C.S.F.), Framingham, Massachusetts 01702; Department of Mathematics and Statistics (J.M.Ma.), Boston University, Boston, Massachusetts 02215; Section of General Internal Medicine (J.M.Mu.), Department of Medicine, Boston University School of Medicine, Boston, Massachusetts 02118; and Center for Population Studies (C.S.F.), National Heart, Lung, and Blood Institute, Bethesda, Maryland 20824

Background: Identifying reproductive risk factors in women offers a life course approach to obesity and cardiovascular disease prevention. The association of female reproductive factors with measures of regional body fat distribution has not been comprehensively studied.

Methods: We examined the association of female reproductive factors (age at menarche, parity, age at natural menopause, menopausal status) in association with body composition data from women who participated in the Offspring and the Third Generation Framingham Heart Study cohorts. Visceral adipose tissue (VAT) and sc adipose tissue (SAT) were measured volumetrically by multidetector computerized tomography. We modeled the relationship between each fat depot and female reproductive factors after adjusting for various factors such as age, smoking status, alcohol intake, physical activity index, hormone replacement therapy, and menopausal status.

Results: Earlier age at menarche was associated with increased body mass index (BMI), waist circumference (WC), VAT, and SAT ($P < 0.0001$). This association of earlier menarche with adiposity measures was attenuated after adjusting for BMI (all $P > 0.70$). We observed no association between parity and all parameters of adiposity measurements (all $P > 0.24$). Similarly, age at natural menopause was not associated with measures of body composition. Despite higher mean BMI among the post- (BMI 27.3 kg/m^2) compared with the premenopausal women (BMI 25.9 kg/m^2) in an age-matched analysis, mean VAT was not different between the two groups ($P = 0.30$).

Conclusions: Earlier menarche is associated with overall obesity but not with VAT or SAT after accounting for measures of generalized adiposity. Parity and menopausal age were not associated with adiposity measures. Although postmenopausal women had increased BMI, VAT, and SAT, the association was predominantly due to age. **(*J Clin Endocrinol Metab* 98: 236–244, 2013)**

Cardiovascular disease (CVD) is the leading cause of death in women in the United States (1). Women, when compared with men, may manifest their clinical disease later in life (2) and tend to have less adverse CVD risk factor profiles (3), rendering standard risk prediction algorithms less reliable in women (4). The life course approach allows us to understand the association of female reproductive factors on CVD risk from childhood to later adult life. Female reproductive factors may provide a life course approach to understand-

Abbreviations: BMI, Body mass index; CT, computed tomography; CVD, cardiovascular disease; DXA, dual-energy x-ray absorptiometry scan; FHS, Framingham Heart Study; MDCT, multidetector computed tomography; SAT, sc adipose tissue; VAT, visceral adipose tissue; WC, waist circumference.

ing and predicting CVD risk in women at their preclinical stage (5–7).

Although there is accumulating evidence regarding the importance of understanding CVD outcomes related to female reproductive factors, including age at menarche, parity, and age at menopause, less is known regarding their determinants. Generalized obesity is a key risk factor that is associated with several reproductive factors, including age at menarche (8, 9), parity (10), and age at menopause (11). However, the association of body fat distribution and female reproductive factors has been less well characterized. Regional fat distribution, particularly visceral adipose tissue (VAT), is thought to be a unique pathogenic fat depot. VAT has been shown to be associated with hypertension (12), diabetes, insulin resistance (12), and dyslipidemia (13). Understanding whether body fat distribution is associated with female reproductive factors may provide insight into the potential mechanisms linking them to CVD and its risk factors.

Thus, the goal of this study was to examine whether measures of regional body fat distribution, including VAT and sc adipose tissue (SAT) are associated with age of menarche, parity, age of menopause, and menopausal status. We hypothesized that visceral adiposity is associated with earlier menarche, greater parity, and earlier menopause independent of body mass index.

Materials and Methods

Study sample

Participants for the present study were drawn from a subset of women (n = 1638) who participated in the multidetector computed tomography (MDCT) substudy of the Framingham Heart Study (FHS) from 2002 to 2005. These participants were part of the FHS Offspring and Third Generation cohorts. Women aged 40 yr or older, weighing less than 160 kg [owing to weight restrictions for computed tomography (CT) scan machine], and not pregnant, were included in the MDCT substudy (14). All participants in the FHS Offspring and Third Generation cohort underwent a contemporaneous research clinical visit (Offspring examination 7, 1998–2001; Third Generation examination 1, 2002–2005). During this clinic visit, a physical examination along with laboratory analyses was performed. Covariate data were taken from the contemporaneous examination for both cohorts. In addition, the Offspring cohort underwent examinations approximately every 4 yr from study inception in 1971 and reproductive history was updated at each attended examination.

The study protocol was approved by the institutional boards of the Boston University Medical Center and Massachusetts General Hospital. Written consent was obtained from all participants.

Assessment of female reproductive factors

The physician-administered standardized medical history portion of the FHS research examinations included questions on reproductive history. At Offspring examination 2 (1978–1981) and the Third generation examination 1, female participants were asked age at the start of menses and also asked, "How old were you at the time of your first menstrual period (menses)?" Responses were recorded in years. At the Third generation examination 1, women were asked about the number of live births. At all Offspring examinations and at Third generation examination 1, women were asked whether their periods stopped for 1 yr or more and if yes, the cause and age, when periods stopped was recorded. Only women who reported natural menopause were included. Women who reported cessation of menstrual periods due to hysterectomy and/or removal of both ovaries, chemotherapy, radiation, and other causes were excluded. Additionally, women who reported the use of hormone replacement therapy before the cessation of menses were excluded because it can lead to the misclassification of age at menopause.

Adiposity measurements

MDCT participants underwent an eight-slice CT scan of the abdomen in a supine position (Lightspeed Ultra; General Electric, Milwaukee, WI). Twenty-five consecutive 5-mm-thick slices were obtained covering 125 mm above the level of S1. Volumes of SAT and VAT were evaluated as described previously (14). Interreader reproducibility was high, with interclass correlations of 0.992 for VAT and 0.997 for SAT (15). Body mass index (BMI) and waist circumference (WC) were measured at the index examination. BMI was defined as weight (in kilograms) divided by square of height (in meters). WC was measured by trained technicians using a tape measure at the level of the umbilicus with the participant standing erect and arms hanging to the sides.

Covariate assessment

Covariates were ascertained during the contemporaneous FHS examination. Current smokers (as standardized across the Framingham Heart Study) were defined as women who smoked at least one cigarette per day for the year preceding the examination. Alcohol use (as standardized across Framingham Heart Study) was characterized in women as seven or more drinks per week. Physical activity was measured by a questionnaire that recorded the average number of sleep hours and activity hours (sleep, sedentary, slight, moderate, and heavy activity) (16). Physical activity index, a composite score was calculated by adding the weighted time spent in each activity as described in our prior studies (16). At Third generation examination 1, all women were asked, "Have you taken hormone replacement therapy?" The age at which hormone replacement therapy was started and duration of therapy were also noted. Use of estrogen or hormone replacement therapy was also collected in the Offspring examinations. Available data from 592 postmenopausal Offspring women showed 21% currently using estrogen (122 of 592 women). Of those women on estrogen, 55% were also on progesterone.

Statistical analyses

We performed three separate analyses for each female reproductive factor with additional analyses for menopausal status.

Age at menarche

Of the 1638 women in the FHS MDCT substudy, 1622 had both VAT and SAT data available. Age at menarche was available for 1544 women. Of these, 1456 women (41% from Offspring cohort and 59% from Third Generation cohort) had complete covariate and outcome (BMI and WC) information. The accuracy of recall for age at menarche in adulthood has been well documented in several studies (17, 18).

Age at menarche was categorized per 1 yr starting from 9 yr up to 14 yr. Those with ages at menarche at 15 yr old or older were grouped together. The primary analysis incorporated all of the data in continuous form using individual years of age and collapsing at the extremes of age. Women who attained menarche at less than 9 yr of age were excluded from the study. Separate multivariable linear regression models were created to examine the association of continuous age at menarche (exposure) with each measure of adiposity (including BMI, WC, VAT, and SAT as the outcome variables). Covariates included in the primary analyses were age at CT scan, cohort (Offspring *vs.* Third Generation), smoking, alcohol intake, hormone replacement therapy, physical activity, and menopausal status. In secondary analyses, to adjust for overall adiposity, BMI was added to the model as a covariate. To reinforce the analyses, we performed step-wise selection model (with entry and stay cutoff of $P = 0.15$) to determine which of the body composition variables were most associated with age at menarche. All the covariates in the primary analyses were forced into the model after which BMI, WC, VAT, and SAT were allowed to compete and the covariate with the highest partial R-square entering first. We also performed backward elimination (with a stay cutoff of $P < 0.15$). In the backward elimination, all variables were put in and the variable with the lowest partial correlation was removed and the model refit.

Parity

Detailed data on parity was only available in the Third Generation data set. Overall, 900 women in the MDCT substudy were in the Third Generation cohort. All 900 had VAT and SAT data. Of these, 898 women had parity information and 870 women had complete covariate information, resulting in a final sample size of 868 women.

Parity was categorized as no, one, two, three, and four or more live births. Multivariable linear regression models with parity as the exposure and adiposity measures (BMI, WC, VAT, and SAT) as the outcome were performed, adjusting for age at CT scan, smoking, alcohol intake, hormone replacement therapy, physical activity, and menopausal status. In secondary analyses, we additionally adjusted for BMI.

Age at menopause

Of the 1622 women in the FHS MDCT substudy with VAT and SAT data available, across both the Offspring and Third Generation cohorts, 652 women experienced natural menopause. Women with missing age at natural menopause (n = 7), women reporting estrogen use before cessation of menstrual periods (n = 21), and women with primary ovarian insufficiency (natural menopause age <40 yr, n = 28) were excluded. Of the remaining 596 women with body composition measures, 522 had complete covariate and outcome information. Age at menopause was categorized as follows: 40–45, 46–47, 48–49, 50–51, 52–53, and more than 54 yr. Because we had too many individual ages and thus for logistical reasons, we simplified them to age categories. We collapsed the age categories at the extremes into 40–45 yr and 54 yr old or older. Multivariable linear regression models were performed, with age at menopause as the exposure and adiposity measures (BMI, WC, VAT, and SAT) as the outcome. We adjusted for age at CT scan, cohort (Offspring *vs.* Third Generation), smoking, alcohol intake, hormone replacement therapy, and physical activity. In second-order models, we additionally adjusted for BMI. We report our results as least square means and *P* values comparing differences across the groups as obtained from multivariable linear regression models.

Menopausal status

To examine pre- *vs.* postmenopausal body composition, we used two complementary analyses designed to examine the association of menopausal status above that of age. Some previous studies (19, 20) have reported that aging may contribute to body adiposity irrespective of menopausal status.

First, we performed an analysis of the overall sample of women from the Offspring and Third Generation cohort (n = 1280). Of these, 1271 women had age at CT and outcome data and were used for the unmatched model. Of these women, 681 were premenopausal and 590 women were postmenopausal. We modeled measures of body composition (BMI, WC, VAT, and SAT) as a function of menopausal status (before *vs.* after menopause). We used an unadjusted model examining crude differences in adiposity between pre- and postmenopausal women; and additionally adjusted for age at CT scan.

In a secondary, supportive sensitivity analysis, we performed a matched analysis of pre- and postmenopausal women matched by cohort and age at CT scan. Eighty-five pairs were identified matched on age at natural menopausal (63 in Third Generation cohort and 22 in Offspring). Premenopausal women within the same cohort were randomly matched to another postmenopausal woman with the same age at CT. Given that many of the postmenopausal women were older at the time of the CT than women who were premenopausal, the sample was significantly reduced from 1271 to the 85 pairs. We performed paired *t* tests of the differences in body composition and conditional logistic regression models predicting postmenopausal status from VAT and SAT. This conditional model included adjustments for smoking and alcohol intake.

Results

Association between age at menarche and body fat distribution

Cross-sectional characteristics of the study sample by categories of age at menarche are presented in Table 1. In the multivariable linear regression analysis examining the association between age at menarche and body composition (Table 2), we observed an inverse association between menarcheal age and adiposity as measured by BMI, WC, VAT, and SAT (all $P < 0.0001$). For each 1-yr increase in menarche age, VAT was 61.0 cm^3 lower. However, upon adjustment for BMI in the above model, our results were attenuated (β-coefficient 2.78 cm^3, $P = 0.74$). These re-

[a] Defined as more than seven drinks per week.

sults were confirmed using stepwise regression and backward elimination models. We also found the overall model R^2 was 4.37% with a partial R^2 from BMI of 2.87%. BMI had the largest partial R^2 of all model terms and accounted for more 65% of the total variation explained by the model.

Parity and body fat distribution

Supplemental Table 1, published on The Endocrine Society's Journals Online web site at http://jcem.endojournals.org, contains the descriptive data for 868 women according to their parity status. Table 3 shows the multivariable linear regression model for body composition across various categories of parity. Associations between adiposity measures (BMI, WC, VAT, and SAT) and parity did not reach statistical significance in our study (all $P > 0.24$). For example, for every incremental increase in parity by 1 live birth, VAT was 23.1 cm^3 higher, although this association was not significant ($P = 0.24$).

Age at natural menopause and body fat distribution

Supplemental Table 2 depicts the demographic characteristics of the cohort by categories of age at menopause. BMI ($P = 0.5$), WC ($P = 0.5$), VAT ($P = 0.7$), and SAT ($P = 0.8$) were not associated with categorized menopausal age (Table 4, Supplemental Fig. 1). The adjusted means for VAT in women with menopause age between 48 and 49 yr was 1469 cm^3. VAT was higher for women who had menopause earlier than 48 yr and later than 50 yr, although these trends were not significant ($P = 0.7$). We also performed quadratic model predicting adiposity measures from age at menopause and did not find any relationship with the squared terms.

Menopausal status and body fat distribution

In unadjusted models, postmenopausal women had higher levels of BMI, WC, VAT, and SAT (all $P < 0.0001$, Table 5), which were attenuated upon age adjustment ($P > 0.16$). One notable exception was SAT, which continued to be higher in post- *vs.* premenopausal women (3289.8 *vs.* 2876.2 cm^3) after age adjustment ($P = 0.007$).

To disentangle the associations of chronological age and compare the association of menopausal status alone, additional testing was carried out. We performed an age-matched analysis of pre- and postmenopausal pairs; sample characteristics are displayed in Table 6. The mean difference between the age at CT scan and age at menopause was 2.8 yr (range 2–11 yr). As expected, VAT and SAT

were slightly higher in post- (VAT: 1251.2 cm^3; SAT: 3213.3 cm^3) *vs.* premenopausal women (VAT: 1123.4 cm^3; SAT: 2872.1 cm^3). However, this difference was not statistically significant ($P = 0.3$ for VAT, $P = 0.19$ for SAT).

Discussion

Principal findings

We observed that earlier age at menarche was associated with increased BMI, WC, VAT, and SAT, although this association was attenuated after adjusting for BMI. Our study did not identify an association between parity and BMI, WC, VAT, and SAT. Similarly, age at natural menopausal was not associated with measures of body composition. We noted that postmenopausal women had increased BMI, WC, VAT, and SAT when compared with premenopausal women; however, this was mostly explained by increased ages among postmenopausal women.

Menarche and body composition

In our study earlier age at menarche was associated with BMI, WC, VAT, and SAT. However, VAT was not associated with earlier menarche after adjusting for BMI. These findings suggest that earlier menarcheal age is associated with generalized but not regional body fat depots.

These findings are consistent with other longitudinal and cross-sectional studies that have shown that early menarche is associated with increased BMI and WC (21, 22). For example, in the European Prospective Investigation into Cancer and Nutrition study (22), per older year of age at menarche, generalized and central adiposity (as measured by waist circumference) was lower. Similarly, the BioCycle study used dual-energy x-ray absorptiometry scan (DXA) to measure total body fat in 253 healthy premenopausal women and found that earlier age of menarche (≤12 yr) was associated with increased BMI and percent total body fat (23). The findings from our study advance the current literature in important ways. Our study used a multidetector CT scan to examine VAT in a large number of women in a contemporary setting. We observed from our data that early age at menarche was associated with generalized adiposity rather than VAT.

Disentangling the associations of childhood adiposity on earlier menarcheal age and subsequent risk for adulthood obesity is challenging. We acknowledge the complex interaction between body fat and puberty (24, 25). Epidemiological studies, including the Bogalusa Heart Study (8), have noted that childhood obesity is associated with both earlier menarcheal age and adulthood obesity. Because childhood obesity influences the timing of menarche, it remains unclear whether childhood obesity simply tracks across to adult obesity (26). Furthermore, many genetic variants associated with the timing of menarche are in or near genes associated with childhood and adulthood BMI, energy homeostasis, and body weight regula-

tion (27). For example, *LIN28B* is associated with earlier age at menarche and prolonged increase in BMI in women across adolescence and midadulthood (28). Thus, an important limitation of our study is the lack of data on childhood adiposity, which may confound the association of age at menarche with general adiposity observed in our study.

Parity and body composition

In contrast to much of the prior literature (10, 29, 30), we observed no association between parity and measures of adiposity. However, our findings are supported by results from the Stockholm Pregnancy and Women's Nutrition study. In the Stockholm Pregnancy and Women's Nutrition study, 563 Swedish women were followed up at 1 and 15 yr after the first delivery with questionnaires and anthropometric measurements. At the end of 15 yr, approximately 39% of the women became overweight (BMI > 25 kg/m^2). No difference were noted in terms of parity (2.4 ± 0.8 *vs.* 2.4 ± 0.9 children) between the group that became overweight *vs.* the group that remained normal weight, respectively (31). However, weight gain during pregnancy and high weight retainers at the end of the first year had a greater BMI at 15 yr follow-up. The findings observed by the Coronary Artery Risk Development in Young Adults Study showed that considerable weight gain (3–6 kg) and increased WC (3–6 cm) occurred in women who were overweight before childbirth. In this study, excess weight gain was not associated with higher-order births among parous women. However, increased WC was noted in parous women when compared with nonparous women (5–6 cm, $P < 0.001$) (32).

TABLE 6. Cross-sectional characteristics by menopausal status using an age-matched analysis of 85 pre- and postmenopausal pairs

	Premenopausal	Postmenopausal

Data are presented as mean (±SD), for categorical data, percentage (n).

[a] Defined as more than seven drinks per week.

[b] $P = 0.30$ on paired *t* test.

[c] $P = 0.19$ on paired *t* test.

Two studies have specifically focused on parity and visceral adiposity. In a cross-sectional study, 170 nonsmoking Caucasian women underwent DXA and CT scan to assess total body fat and intraabdominal adiposity (33). Parity was associated with VAT ($P = 0.02$) but not with percent body fat ($P = 0.68$), waist circumference ($P = 0.16$), or SAT ($P = 0.98$). Potential reasons for the disparate results from our study could be their relatively small sample size and inclusion of only nonsmokers; several cross-sectional studies have noted that smokers have lower body weight than nonsmokers (34). Our study sample included smokers with a higher prevalence of smoking among nonparous women and women with lower-order births. Current smoking was adjusted for in this analysis.

In the second study (4), 122 premenopausal women had total body fat measured by DXA and VAT measured by CT scan over a 5-yr period. Of these 122 women, only 14 had at least one interim birth. There was no change in total body fat over the 5-yr period for one interim birth *vs.* no interim births (2.7 *vs.* 3.7 kg, $P = 0.55$). However, a larger gain in VAT was observed among women who had at least one interim birth (27.1 *vs.* 9.2 cm^2, $P < 0.01$) (35). Differences with our study include the longitudinal design and the short interval between childbirth and assessment of VAT. It may be plausible that parity does not affect long-term gain in VAT as observed in our study.

Age at menopause and body composition

We did not identify robust associations between menopausal age and BMI, WC, VAT, and SAT. Although there is a large body of literature on menopausal status and body weight, very few studies (11, 36) have examined the as-

sociations of age at menopause and body weight. In a Japanese study (n = 1022), pre- and postmenopausal BMI were studied in three groups of women, depending on the age at the time of menopause (<45 yr, 45–50 yr, > 50 yr). No differences in the BMI were observed among the groups both during early postmenopause and late postmenopause (36). There is a paucity of studies exploring the association of age at the time of menopause with body fat depots.

Menopausal status and body composition

Further analysis to dissect the associations between age and menopausal status in the present study revealed that postmenopausal women had increased BMI, WC, VAT, and SAT compared with premenopausal women, but this association was largely attributable to the age. These findings underscore the important role of aging and the selected indices of body composition.

Several studies have explored the association of chronological aging *vs.* menopause-related changes in the body composition of women (19, 37–39). In the Study of Women's Health Across the Nation study, a cross-sectional study of a large multiethnic cohort of middle-aged women, after adjusting for chronological age, no differences were seen in the BMI between premenopausal women and women who reported natural menopause (40). Similarly, Wing *et al.* (41) prospectively studied 484 middle-aged women over 3 yr and noted a 2.25-kg increase in weight during follow-up; however, this weight was similar among control women who remained premenopausal during the follow-up.

Some studies have evaluated longitudinal changes in body composition among perimenopausal women using imaging techniques. An observational longitudinal study followed up 103 healthy premenopausal women over 4 yr. All women gained SAT over time; however, only women who transitioned through menopause demonstrated a significant increase in VAT (42). In another study, intraabdominal fat by CT scan significantly increased by 21% across menopausal transition (43). However, in this study, no age-matched controls were used. Thus, it remains unclear whether these findings were due to aging (43). In the present work, we have attempted to disentangle the associations of aging compared with menopause transition. In doing so, we show that post- compared with premenopausal women have higher levels of SAT, but levels of VAT are similar. Our results suggest that much of the differences in body composition between pre- and postmenopausal women may be due to aging.

Implications

The overarching aim of our study was to use a life course approach to explore the association of female reproductive factors and body composition. The findings from our study suggest that early menarche in women may be an opportune moment to advocate lifestyle measures to prevent adult obesity. Our study notes that parity and age at menopause *per se* may not be suitable determinants for predicting obesity. However, further studies are necessary to test whether female reproductive factors can be used to target lifestyle interventions in high risk women to prevent the metabolic complications of obesity and CVD.

Strengths and limitations

The strengths of our study include the large population-based cohort without ascertainment for obesity-related conditions. All clinical risk factors were assessed by a study physician. Clinical characteristics were carefully measured and standardized. A highly reproducible MDCT scan was used for accurately measuring visceral adiposity. Limitations of our study include the observational and cross-sectional nature of the data, obscuring our ability to comment on temporality and causality. The study sample was comprised of predominantly Caucasians; thus, the findings may not be generalizable to other ethnic groups. Data on birth weight, prior growth parameters, age at adrenarche, and thelarche were not recorded in this study. Other reproductive factors such as gestational weight gain, polycystic ovarian syndrome, gestational diabetes, and preeclampsia were not examined in this study.

Conclusions

Earlier age at menarche is associated with overall adiposity but is not specific to VAT or SAT. Parity and age at menopause were not associated with parameters of central or generalized adiposity. However, postmenopausal women had higher levels of adiposity, which appears to be predominantly due to age.

Abstract

Background: Ongoing conflict in the Darfur region of Sudan has resulted in a severe humanitarian crisis. We sought to characterize the nature and geographic scope of allegations of human rights violations perpetrated against civilians in Darfur and to evaluate their consistency with medical examinations documented in patients' medical records.

Methods and Findings: This was a retrospective review and analysis of medical records from all 325 patients seen for treatment from September 28, 2004, through December 31, 2006, at the Nyala-based Amel Centre for Treatment and Rehabilitation of Victims of Torture, the only dedicated local provider of free clinical and legal services to civilian victims of torture and other human rights violations in Darfur during this time period. Among 325 medical records identified and examined, 292 (89.8%) patients from 12 different non-Arabic-speaking tribes disclosed in the medical notes that they had been attacked by Government of Sudan (GoS) and/or Janjaweed forces. Attacks were reported in 23 different rural council areas throughout Darfur. Nearly all attacks (321 [98.8%]) were described as having occurred in the absence of active armed conflict between Janjaweed/GoS forces and rebel groups. The most common alleged abuses were beatings (161 [49.5%]), gunshot wounds (140 [43.1%]), destruction or theft of property (121 [37.2%]), involuntary detainment (97 [29.9%]), and being bound (64 [19.7%]). Approximately one-half (36 [49.3%]) of all women disclosed that they had been sexually assaulted, and one-half of sexual assaults were described as having occurred in close proximity to a camp for internally displaced persons. Among the 198 (60.9%) medical records that contained sufficient detail to enable the forensic medical reviewers to render an informed judgment, the signs and symptoms in all of the medical records were assessed to be consistent with, highly consistent with, or virtually diagnostic of the alleged abuses.

Conclusions: Allegations of widespread and sustained torture and other human rights violations by GoS and/or Janjaweed forces against non-Arabic-speaking civilians were corroborated by medical forensic review of medical records of patients seen at a local non-governmental provider of free clinical and legal services in Darfur. Limitations of this study were that patients seen in this clinic may not have been a representative sample of persons alleging abuse by Janjaweed/GoS forces, and that most delayed presenting for care. The quality of documentation was similar to that available in other conflict/post-conflict, resource-limited settings.

Funding: This study was funded by Physicians for Human Rights with support from the Open Society Foundations and the Sudan Aid Fund of the Community Foundation of Western Massachusetts. ACT received salary support through the Robert Wood Johnson Health & Society Scholars Program. MAE received salary support through Physicians for Human Rights, the Open Society Foundations, the Sudan Aid Fund of the Community Foundation of Western Massachusetts, the Scholar Rescue Fund of the Institute for International Education, and the Robert F. Kennedy Center for Justice and Human Rights, as well as in-kind support from the Harvard Humanitarian Initiative. No funding bodies had any role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Competing Interests: Six of the study authors are currently affiliated with organizations that advocate for the prevention of mass atrocities, protection of internationally guaranteed rights, and/or prosecution of those who violate human rights: the Amel Centre for Treatment and Rehabilitation of Victims of Torture (MAE), Physicians for Human Rights (MAE, SC, SS, MH, VI), the Harvard Humanitarian Initiative (MAE), the Francois-Xavier Bagnoud Center for Health and Human Rights at the Harvard School of Public Health (JL), and the Human Rights Center at the University of California at Berkeley (VI). From 2004 to 2009, one of the study authors (MAE) served as medical director of the clinic from which the data were obtained. All authors have declared that no financial conflicts of interest exist.

Introduction

In the Darfur region of western Sudan, ongoing conflict between Arabic-speaking and non-Arabic-speaking tribes [1,2] has reached crisis proportions since the Government of Sudan (GoS) first initiated its military response to organized armed groups opposing the GoS [2]. In addition to targeting armed rebel forces in its response, however, the GoS has also been accused of targeting non-Arabic-speaking civilians, namely members of the Fur, Masalit, and Zaghawa tribes [3,4]. By the end of 2007, more than 2.4 million refugees from the violence, or nearly one-third of the population [5], had fled to camps for internally displaced persons (IDPs) within Darfur or to similar refugee camps in neighboring Chad [6], thus creating a severe humanitarian disaster.

Prior research has focused on generating accurate mortality estimates to inform policy and programming [7–13], with recent studies estimating 200,000–300,000 deaths directly and indirectly attributable to the conflict in 2003–2005 alone [14,15]. The reported systematic, repeated, targeted assaults on non-Arabic-speaking civilians, large-scale disruption of rural livelihoods, and deliberate consignment to conditions conducive to death have prompted observations that these could constitute acts of genocide [4,5,16–19]. Following a United Nations–appointed Commission of Inquiry and an International Criminal Court (ICC) investigation, the Pre-Trial Chamber I of the ICC issued arrest warrants for allegedly responsible authorities, including two arrest warrants for Sudanese President Omar Hassan Ahmad Al Bashir (''Al Bashir'') on the grounds of crimes against humanity (March 4, 2009) [20,21] and genocide (July 12, 2010) [22].

Despite investigations into the violence in Darfur, little research to date has been able to make use of Sudanese documents to substantiate victims' or observers' claims of violence amounting to war crimes, crimes against humanity, or genocide. GoS forces were implicated in the Atrocities Documentation Survey [5,23–25]. Arab Janjaweed (''men with guns on horses or camels'') militias, which originated as Libyan proxy militias in the Chadian civil war and have been suspected of collaborating with GoS forces [2], have been implicated in reports of sexual violence described by Darfuri women now living in IDP camps [26]. The systematic destruction of livelihoods, which under certain circumstances can be considered an act of genocide [17,27,28], has also been described. However, a critical limitation of prior studies is their reliance on self-report data gathered from victims living in refugee camps outside of Sudan. One team of investigators attempted to conduct interviews at IDP camps within Darfur but was refused access by the GoS [17,27]. With unique access to medical records of clinical encounters in Darfur, we undertook this study to characterize the nature and geographic scope of alleged abuses against civilians in Darfur and to substantiate the allegations with forensic review and analysis of the medical evidence.

Methods

Ethics Statement

As this was a retrospective analysis of de-identified medical records, informed consent was not obtained. All study procedures were approved by the Harvard School of Public Health Office of Human Research Administration as well as an independent ethics review board convened for this research project by Physicians for Human Rights. Given that the medical records used in the analysis were de-identified, this research project was assessed to represent minimal risk to Amel Centre patients. The ethics review board was guided by the relevant process provisions of Title 45 of the US Code of Federal Regulation and the Declaration of Helsinki as revised in 2000 [29] and was composed of individuals with expertise in forensic medicine, public health, bioethics, and international health and human rights research.

Study Population and Setting

Data for this study consisted of 325 de-identified medical records of all initial visits (i.e., excluding follow-up visits) of patients seen for treatment at the Amel Centre for Treatment and Rehabilitation of Victims of Torture, in Nyala, South Darfur, from its opening on September 28, 2004, through December 31, 2006. Records for 2007–2009 could not be retrieved because of ongoing security concerns (as described in more detail below). With funding from the European Commission, the United Nations High Commissioner for Refugees, the US Agency for International Development, and the United Nations Development Programme, the Amel Centre was the only dedicated local non-governmental provider of free clinical and legal services to any civilian victim of torture or other human rights violations. The Amel Centre received referrals from volunteers placed in three large IDP camps near Nyala (Dreig, Otash, and Kalma) but accepted civilian clients from all over Darfur. Aside from the free services, and transportation to and from the IDP camps, patients were not given additional incentives or benefits.

The Amel Centre's initial staff in the Nyala office consisted of one general medicine doctor (M. A. E.), one junior doctor, one psychosocial worker, and two lawyers. Their training on the treatment of victims of torture and sexual violence was facilitated by the Sudan Organisation Against Torture and was consistent with the *Manual on Effective Investigation and Documentation of Torture and Other Cruel, Inhuman or Degrading Treatment or Punishment* (''Istanbul Protocol'') [30–32]. The paper-based record-keeping system was similar to other prototypical clinics operating in conflict zones. Although examining clinicians typically conversed with patients in the patients' language of choice (typically Fur, Zaghawa, or Dago), notes documenting the encounters were written in English. A standardized medical record form was used, but few fields specified closed-ended responses (e.g., ''name,'' ''date of birth,'' ''date of detention''). The content of the clinical encounter, and therefore the bulk of the medical record documentation, was driven by patients' concerns. A network of volunteer physicians and social workers provided specialty care, and all women who disclosed that they had been sexually assaulted were referred to a gynecologist for evaluation. The laboratories associated with the network were able to implement all necessary blood, urine, stool, serological, and pregnancy tests but did not have the capacity for deoxyribonucleic acid analysis. After the initial visit, follow-up visits were provided to assess symptomatic improvement and provide longer term physiotherapy where indicated. The care provided and coordinated by the Amel Centre was delivered under difficult and often dangerous field conditions. After the ICC issued the first arrest warrant for Al Bashir [21], the Sudanese Ministry of Humanitarian Affairs ordered the Amel Centre, along with two other local and 13 foreign aid groups, to cease operations [33]. The three clinicians formerly on staff are now living abroad. Prior to fleeing the country, they preserved hard copies of the medical records for 2004–2006 and sent them out of the country.

Data Collection

Amel Centre clinicians generated the medical records for the purposes of clinical care and internal record-keeping. We sought

to abstract the data both accurately and in such a way as to capture the main themes identified in the records. Guided by prior research [34–41], we created a list of different types of abuses that may be considered evidence of torture and/or other human rights violations, as well as symptoms potentially reported by patients and signs potentially documented by examining clinicians. Then we developed a medical record abstraction tool that included lists of standardized names (e.g., tribes and rural council areas) and response options to guide efficient abstraction of data (Text S1).

Data were abstracted by one of the authors (A. C. T.) from the demographic, incident, and clinical care components of the Amel Centre's general medical records. Although the general medical records may have noted the presence of diagnostic or laboratory testing, or specialty medical records, access to these raw data elements unfiltered by the examining clinicians (e.g., diagnostic imaging or laboratory reports) were not available for our analysis. We collected data on patient socio-demographic characteristics, alleged abuses, and the harms reportedly resulting from the abuses. To assess the reliability of the data abstraction tool for coding the key variables on alleged abuses, we randomly selected 20 medical records for independent coding by two other study authors (M. A. E. and S. S. C.) as well as for wider discussion by the research team. Inter-rater agreement exceeded 0.70 on the coding of most of these variables. The abstraction tool was further refined through an iterative process to ensure that the variables were clearly defined and could be applied consistently to the data. With regards to content validity, the 20 records were carefully reviewed to ensure that all potential categories were represented. Data from the remaining 305 medical records were then abstracted by a single author (A. C. T.).

Medical Opinions on Alleged Abuses

Two study authors with extensive medical experience in the evaluation and treatment of survivors of torture and other forms of physical and psychological abuse (S. S. C. and V. I.) independently reviewed each medical record, blinded to each other's assessments. First, they determined whether the medical record contained sufficient detail to enable an informed opinion about the consistency of the documented signs and symptoms with the record of alleged abuses in the medical notes. Second, among the cases that did contain sufficient detail, they assessed the extent to which the recorded signs and symptoms were consistent with the alleged abuses described in the medical record. Consistency was scored using a five-point Likert-type scale: "not related to alleged abuse," "not consistent with," "consistent with," "highly consistent with," and "virtually diagnostic of." These evaluations were based on the Istanbul Protocol [30–32] and other conventions for the evaluation of survivors of torture and other human rights abuses [42–45].

Statistical Analysis

Data were entered into Excel (version 12.0, Microsoft) and then exported to Stata (version 11.0, StataCorp) for analysis. We characterized socio-demographic, incident, and clinical variables with medians and inter-quartile ranges. Inter-rater agreement was assessed using the kappa statistic [46]. The locations of alleged attacks were mapped to the longitude and latitude [47–49] of the administrative center, principal town, or largest secondary town of the rural council area where they were reported to have taken place. ArcGIS (version 9.2, Esri) was used to generate a continuously variable proportional circle map, with circle sizes classified into seven categories using the Fisher-Jenks algorithm [50].

Results

Characteristics of Amel Centre Patients

We obtained medical records for all 325 patients presenting for care at the Amel Centre from September 28, 2004, to December 31, 2006. Summary statistics are presented in Table 1. Most patients were brought in by friends or relatives (54.2%) or by staff or volunteers (28.0%). Median age was 35 y, with a range of 4–82 y. Thirty patients (9.2%) were under the age of 18 y. Men comprised the majority of patients (252 [77.5%]). Approximately one-half (49.5%) of the men and boys were younger than 36 y of age. Most patients were married (76.3%). All self-identified as Muslim. The sample included patients from 14 different non-Arabic-speaking tribes, and members of the Fur, Zaghawa, and Dago tribes accounted for nearly 90% of patients. Only two (0.6%) patients were from Arab tribes. Most (84.9%) lived in South Darfur, where the Amel Centre was located.

Patterns and Geographic Scope of Alleged Abuses

The attacks documented in the patients' records occurred between 2002 and 2006, with a peak frequency in March 2005. Characteristics of these incidents are displayed in Table 2. Between the date of the incident and the date of presentation at the Amel Centre, a median of 101 d had elapsed (inter-quartile range, 22–365 d). Approximately one-third (36.6%) of patients presented to the Amel Centre within 6 wk of the alleged incident.

Alleged attacks on individuals and villages recorded in the patients' records took place in 23 rural council areas (out of 65 total) throughout Darfur (Figure 1). Of the total, 281 (86.5%) occurred in South Darfur, 35 (10.8%) occurred in West Darfur, and eight (2.5%) occurred in North Darfur. Approximately one-third (35.1%) of the attacks disclosed by patients were also described by at least one other Amel Centre patient. Many villages were repeatedly attacked, with five villages reportedly attacked a total of 41 times during the study period: Marla was attacked 13 times during a 12-mo period from December 2004 to December 2005; Adwa, ten times (October 2003–November 2005); Labado, seven times (March 2004–December 2005); Bendisi, six times (August 2003–Dececember 2004); and Mukjar, five times (August 2003–August 2004). In addition, 46 (14.2%) patients disclosed that they had been attacked in the vicinity of an IDP camp: 16 (34.8%) of these attacks occurred inside the camp, 15 (32.6%) occurred a median of 3 km outside the camp, six (13.0%) occurred an unspecified distance outside the camp, and nine (19.6%) occurred within the general vicinity of a camp but the exact location was unspecified.

Two hundred ninety-three (90.1%) patients described their perpetrators as GoS and/or Janjaweed forces; of these, 48 (16.4%) stated that GoS and Janjaweed forces attacked in concert (Table 3). Thirty-two (9.9%) patients disclosed that they had been attacked by rebel soldiers, bandits, community authorities, or other community members. Among those attacked by GoS and/or Janjaweed, 292 (99.7%) patients were from 12 different non-Arabic-speaking tribes, and only one (0.3%) was from an Arab tribe. Thirty-two (9.9%) patients disclosed to the examining clinician that a military commander was present during the attack. Nearly all (98.8%) attacks occurred in the absence of active armed conflict between GoS/Janjaweed forces and rebel groups. The examining clinician noted when patients speculated as to reasons for the attack: 60 (18.5%) patients stated that they were targeted because the attackers suspected them of being rebels, and 58 (17.9%) stated that they were targeted because of their racial or tribal identity.

Table 1. Characteristics of patients presenting for care at the Amel Centre for Treatment and Rehabilitation of Victims of Torture in Nyala, South Darfur.

Patients' medical records described a wide range of alleged abuses, including beatings (161 [49.5%]), gunshot wounds (140 [43.1%]), destruction or theft of private property (121 [37.2%]), involuntary detainment (97 [29.9%]), and being bound with rope, chains, or other material (64 [19.7%]) (Table 4). GoS forces were described as accounting for more than one-half of custody-related incidents (61 [59.8%]), whereas Janjaweed forces were alleged to have accounted for most incidents involving physical assault (148 [50.7%]), sexual assault (28 [62.2%]), and destruction or theft of private property (77 [63.6%]). In addition to the abuses patients personally experienced, the medical records for this group of

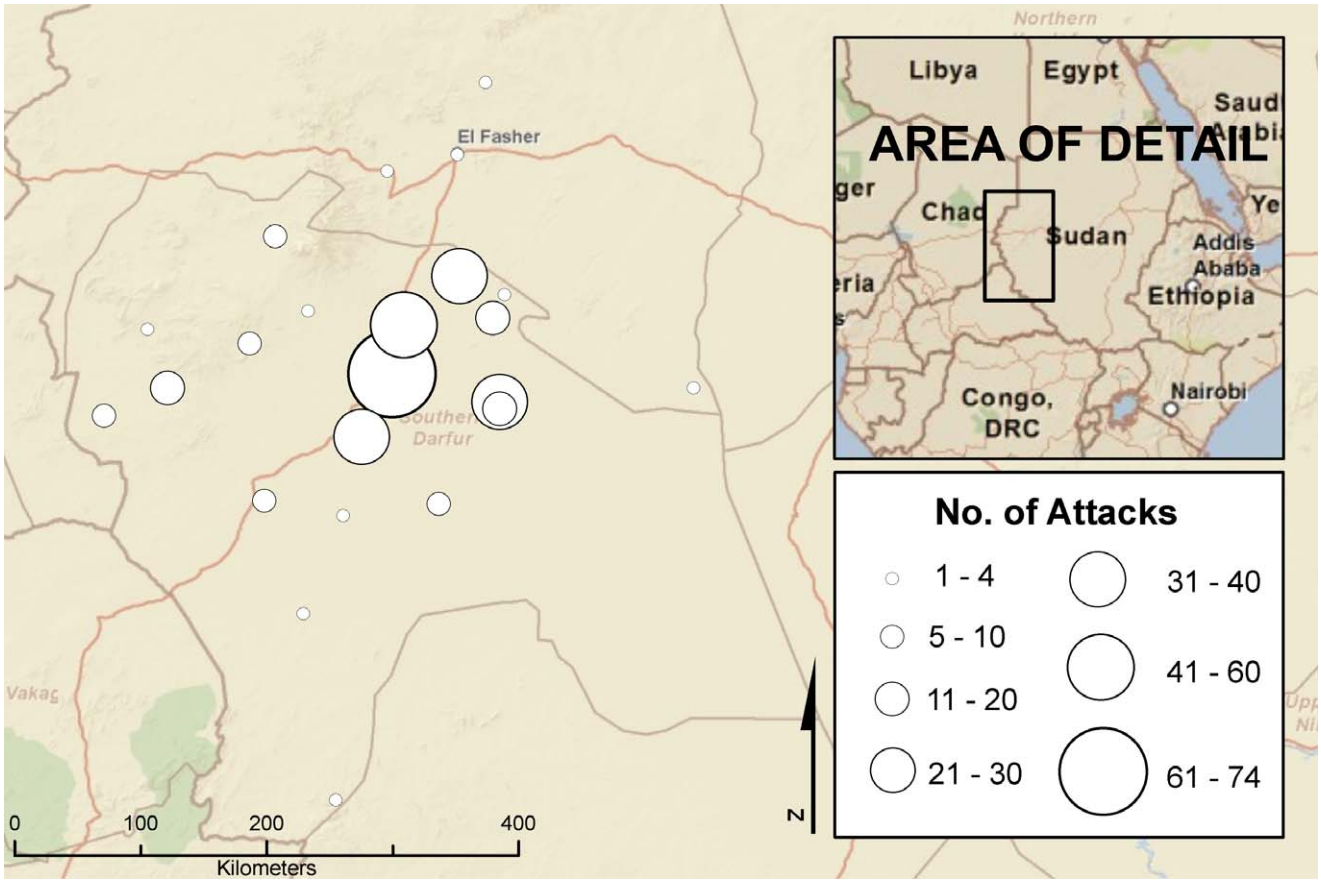

Figure 1. Geographic pattern of attacks reported by patients, 2002–2006. The largest circle corresponds to the town of Nyala, where the Amel Centre was located. patients also collectively describe that they witnessed the killing of 948 other persons.

Consistency between Allegations of Abuse and the Signs and Symptoms Described in the Medical Records

The signs and symptoms most frequently documented in the medical records were chronic pain (194 [59.7%]), wounds or scars (167 [51.4%]), functional disabilities (e.g., contractures causing restricted grasp) (65 [20.0%]), and bone fractures (55 [16.9%]) (Table 5). There was 96.3% agreement ($\kappa = 0.92$) between the medical reviewers on whether the medical records contained sufficient detail to enable an informed opinion about the consistency of the recorded signs and symptoms with the allegations documented in the medical record. More than one-third (127 [39.1%]) of the medical records were assessed by at least one reviewer to lack sufficient detail (i.e., documentation was incomplete) to enable him or her to render an informed judgment about consistency. Of the 198 (60.9%) records that were considered sufficiently detailed by both reviewers, the medical reviewers agreed that the recorded signs and symptoms were either consistent with (101 [51.0%]), highly consistent with (81 [40.9%]), or virtually diagnostic of (5 [2.5%]) the alleged abuses. There were no cases in which the reports of medical examinations were considered not consistent with, or unrelated to, the recorded allegations. In only 11 (3.4%) cases did the medical reviewers disagree in their consistency scorings, for an excellent inter-rater agreement overall ($\kappa = 0.89$).

Approximately one-half (36 [49.3%]) of all women presenting to the Amel Centre disclosed that they had been sexually assaulted. One-half of sexual assaults on women were recorded as having occurred in close proximity to an IDP camp, with nine (25.0%) recorded as having occurred in the general vicinity of the camp and nine (25.0%) having occurred within 3 km of the camp. The majority (31 [86.1%]) of sexual assaults on women involved rape or gang rape. Among these, five (16.1%) women disclosed they had become pregnant as a result of the alleged rape; no follow-up information was available on the remainder. Nine men also disclosed that they had been sexually assaulted, including one who had been raped. Twenty-five (55.6%) medical records of sexual assault victims were considered by the medical reviewers to be sufficiently detailed in recorded signs and symptoms to enable him or her to render an informed judgment about consistency. Of these, the medical reviewers agreed that the medical evidence was consistent with (14 [56.0%]), highly consistent with (9 [36.0%]), or virtually diagnostic of (1 [4.0%]) the alleged sexual assault. There were no cases in which the medical findings were considered not consistent with, or unrelated to, the alleged sexual assault. The reviewers disagreed about the scoring for one (4.0%) case, for an excellent inter-rater agreement on sexual assault findings overall ($\kappa = 0.92$).

Discussion

We analyzed the medical records of 325 consecutive patients who were seen for care at the Amel Centre in Nyala, Darfur, between September 28, 2004, and December 31, 2006, with the aim of assessing the consistency between the recorded allegations of abuse and the signs and symptoms noted in the medical record. Our findings show that in all of the medical records that contained sufficient detail, the medical evidence was considered to be at least consistent with (if not highly consistent with or virtually diagnostic of) the human rights violations disclosed by the patients. There were no cases in which the reports of medical examinations were considered not consistent with, or unrelated to, the recorded allegations. Most of the abuses described in the medical records—which included beatings, killings, sexual assault, torture, and involuntary detainment—were allegedly perpetrated by GoS and Janjaweed forces and were described as having occurred throughout Darfur, with five villages attacked a total of 41 times during the study period. The spatial distribution of reported incident locations in our data suggests, at a minimum, that the attacks were widespread. However, our lack of a representative population-based sample makes it difficult for us to generalize about the full extent or population incidence of attacks. Many patients reported attacks by GoS and Janjaweed forces acting in concert. In some cases, patients disclosed to the examining clinician the names of specific victims, perpetrators, or military commanders, and this information was noted in the medical record. Fewer than 1% of patients reported observing the perpetrators to be in active armed conflict with rebel or other groups. Although the medical reviewers had no way to corroborate the identities of the perpetrators, these findings are consistent with prior research implicating GoS forces in the perpetration of human rights violations upon non-Arabic-speaking civilians in Darfur [24,25].

Nearly one-half of women presenting for care disclosed that they had been sexually assaulted. The use of sexual violence in armed conflict has been recognized as a means of not only demoralizing individual victims but also destabilizing their families and terrorizing communities [51–56]. Rape and other forms of sexual violence have been recognized as war crimes and crimes against humanity [57], as well as instruments of genocide [55,58]. Moreover, one-half of these assaults were described as having occurred in close proximity to an IDP camp. These data are consistent with prior reports of rapes occurring near IDP camps [26,55,59], as well as previous work documenting that violence was responsible for a substantial proportion of deaths among persons settled (i.e., not in the villages or in flight) in IDP camps in West Darfur [11]. Collectively, these data raise questions about the security provided to persons living in IDP camps, notably women, who must frequently venture outside the camp to gather firewood for fuel [27]. The Inter-Agency Standing Committee has issued guidelines that suggest several minimum prevention and response interventions that could be implemented with regards to security mechanisms instituted in areas of close proximity to IDP camps.

In contrast to prior studies' reliance on self-report of refugees living outside of Darfur [17,24,25,27,28], our data are based on unusual access to medical records of clinical encounters in Darfur maintained by local clinicians directly responsible for treatment and record-keeping. Medical forensic experts reviewed and analyzed the signs and symptoms described in the medical records and evaluated their consistency with the alleged abuses documented in the medical notes. Less than two-thirds of the records were detailed enough for the forensic reviewers to substantiate the patients' claims of abuse, a finding that is not surprising given that the Amel Centre medical records were not intended for research purposes. In a similar study in which third-party experts assessed the official medical evaluations of forensic experts working for the Mexican Procuraduría General de la República (Office of the Attorney General), in 18 of 39 cases (46%) their assessments were indeterminate because of insufficient documentation to corroborate alleged torture and ill treatment [60]. Their findings are consistent with ours and highlight the potential value of using clinical information to corroborate allegations of abuse. In our study, among the medical records that contained sufficient detail, all were assessed to be at least consistent with (if not highly consistent with or virtually diagnostic of) the allegations. These data substantially enhance the credibility of the patients' claims of abuse. Importantly, however, the medical records provided the forensic reviewers with no data that could be used to corroborate either claims of assailant identities or claims of genocidal intent.

Limitations

Interpretation of our findings is subject to a number of limitations. First, we used a discrete, comprehensive sample of patients, but it was not systematic. During this time period, the Sudanese Criminal Procedure Act required all injury or trauma victims to file a report with the police in order to obtain a medical evidence form ("Form 8"), without which they were legally not permitted to receive treatment from an authorized medical officer [55,61–63]. In practice the police were known to deny the Form 8

Table 4. Types of abuses disclosed by patients.

Type of Abuse	Affiliation of Alleged Perpetrator(s)	
	GoS and/or Janjaweed ($n=293$)	Other/Unknown ($n=32$)
Attacks involving heavy weapons	33 (11.3%)	2 (6.3%)
Ground explosives (bombing, grenades)	2 (0.7%)	
Attack by aircraft or helicopter	18 (6.1%)	1 (3.1%)
Attack by land cruiser	24 (8.2%)	1 (3.1%)
Physical assault	264 (90.1%)	28 (87.5%)
Blunt trauma (beating, whipping)	145 (49.5%)	16 (50.0%)
Gunshot wound	125 (42.7%)	15 (46.9%)
Burns or electric shocks	21 (7.2%)	
Stretch injury (hanging, suspension)	19 (6.5%)	
Genital trauma	10 (3.4%)	
Sexual assault	39 (13.3%)	6 (18.8%)
Forced undressing	12 (4.1%)	1 (3.1%)
Insertion of foreign object into anus/vagina	3 (1.0%)	
Attempted rape	5 (1.7%)	
Rape	15 (5.1%)	1 (3.1%)
Rape by more than a single perpetrator	12 (4.1%)	4 (12.5%)
Humiliation or psychological manipulation	70 (23.9%)	3 (9.4%)
Verbal abuse	32 (10.9%)	1 (3.1%)
Verbal abuse involving racial slurs	6 (2.1%)	
Forced performance of humiliating/taboo acts	7 (2.4%)	
Verbalized threats of death	43 (14.7%)	2 (6.3%)
Custody-related violations	95 (32.4%)	7 (21.9%)
Involuntary detainment	90 (30.7%)	7 (21.9%)
Bound with rope or other apparatus	60 (20.5%)	4 (12.5%)
Crowded, unhygienic conditions	43 (14.7%)	
Deprived of food/water or medical care	32 (10.9%)	1 (3.1%)
Sensory deprivation	25 (8.5%)	
Destruction or theft of private property	115 (39.3%)	6 (18.8%)

Table 5. Common symptoms and signs documented in patient medical records.

Type of Symptom or Sign	Number (Percent)
Pain (non-pelvic)	194 (59.7%)
Wounds or scars	167 (51.4%)
Functional disability	65 (20.0%)
Broken or fractured bones	55 (16.9%)
Weakness	38 (11.7%)
Pelvic pain	34 (10.5%)
Insomnia	32 (9.9%)
Numbness	23 (7.1%)
Swelling	18 (5.5%)
Headache	14 (4.3%)

doi:10.1371/journal.pmed.1001198.t005

to members of non-Arabic-speaking tribes, so this legal requirement represented a substantial hurdle, and in many cases a complete barrier, to accessing health care services. Consistent with this, patients in our sample presented for care a median of 101 d after the abuses leading to their need for treatment. Furthermore, the majority of patients seen were men, highlighting the issue of women's lack of adequate access to care and their overall limited public mobility in this setting. These barriers are of particular salience with regards to cases of sexual violence [61], where victims may fear reprisals, blame, and other psychosocial consequences of disclosure [5,26,59,64–68]. A second limitation relates to the delay in presentation for care. Although physical and psychological sequelae may persist for years and even for the duration of a victim's lifetime, some symptoms and disabilities may resolve or diminish over time [42–45,69]. Despite their training and experience, Amel Centre staff could have under-detected and therefore under-documented some symptoms, especially those concerning sensitive topics (e.g., sexual violence, psychological distress) that might not be spontaneously disclosed. More generally, the medical chart review literature is characterized by under-documentation of signs and symptoms [70–73], so we

would expect this limitation to generically apply in any setting. Third, because these data were not collected in a research setting, in most if not all cases, the same individual documented both the allegations of abuse and the results of the medical examination. The examining clinician's prior knowledge of the nature of the allegations could have biased the completeness of the documentation with regards to signs and symptoms observed. Fourth, few rape cases were scored by our medical forensic experts as virtually diagnostic of the alleged assault. Amel Centre protocol directed all female rape victims to a gynecologist for evaluation [74]. However, these records were unavailable for analysis because they could not be secured and sent out of the country prior to the clinicians' fleeing the country (as described above). Fifth, we were unable to include information on victims who were killed, so it may be more appropriate to regard our data as underestimating the true severity of atrocities inflicted upon non-Arabic-speaking civilians living in this region. Sixth, Amel Centre staff were routinely subject to surveillance, detainment, and interrogation by GoS forces [75,76]. With increasing frequency in 2009, Amel Centre staff were detained, interrogated, tortured, and accused of collaborating with the ICC. Upon Al Bashir's indictment, they were advised to flee the country. Because of ongoing security concerns, we could not obtain the records for 2007–2009 to analyze for this study. This limitation underscores that the Amel Centre clinicians provided medical and legal services under dangerous working conditions. Health care workers in other settings have faced similar challenges [77], further emphasizing the need for international support for the protection of health professionals working under similar circumstances.

In summary, despite these unavoidable limitations, our study of non-Arabic-speaking civilian patients who visited the Amel Centre in Nyala, Darfur, between 2004 and 2006 found that in all of the medical records that contained sufficient detail, the recorded medical evidence was considered at least consistent with the alleged incidents of torture and other human rights violations. There were no cases in which the reports of medical examinations were considered not consistent with, or unrelated to, the recorded allegations. The widespread, organized, and sustained pattern of attacks documented in our study indicates that the actions of Janjaweed and GoS forces may constitute war crimes, crimes against humanity, and/or possibly acts of genocide.

Editors' Summary

Background. Conflict in the Darfur region of Sudan between Arabic- and non-Arabic-speaking tribes over the past decade has resulted in a severe humanitarian crisis. According to the United Nations, more than 2.7 million people have fled from their homes to camps for internally displaced persons (IDPs) or to refugee camps in neighboring Chad, and up to 300,000 people have died from war, hunger, and disease since the conflict started. The origins of this conflict go back many years, but in 2003, organized rebel forces began attacking government targets, accusing the Government of Sudan (GoS) of oppressing black Africans in favor of Arabs. In response, the GoS attacked the rebel forces, but some observers allege it also targeted non-Arabic-speaking civilians, in contravention of international laws of war. Observers have also accused the GoS of having links with the Janjaweed militias, nomadic Arabs who attack settled black farmers, although the GoS denies any such links. Indeed, reports of systematic, targeted assaults on non-Arabic-speaking civilians, of large-scale disruption of rural livelihoods, and of deliberate consignment to living conditions likely to cause death have prompted some observers to accuse the GoS of genocide (violent crimes committed against a national, ethnical, racial, or religious group with the intention of destroying that group) and the International Criminal Court to issue arrest warrants for the allegedly responsible authorities.

Why Was This Study Done? Most investigations of claims of violence against civilians in Darfur have relied on self-reported data gathered from people living in refugee camps outside Sudan. Because these data could be biased, in this cross-sectional study (a study that characterizes a population at a single point in time), the researchers investigate the nature and geographic scope of alleged abuses against civilians in Darfur and endeavor to substantiate these allegations by analyzing the medical records of patients attending the Amel Centre for Treatment and Rehabilitation of Victims of Torture in Nyala, South Darfur. Opened in 2004, this center provided free clinical and legal services to civilians affected by human rights violations. Its staff fled in 2009 because of increasingly dangerous working conditions; the medical records used in this study were sent out of Sudan before the staff fled.

What Did the Researchers Do and Find? Between September 28, 2004, and December 31, 2006, 325 patients were seen at the Amel Centre. According to their medical records, 292 patients from 12 different non-Arabic-speaking tribes alleged that they had been attacked by GoS or Janjaweed forces in rural areas across Darfur. Nearly all the patients reported that they had been attacked in the absence of active armed conflict between GoS/Janjaweed forces and rebel groups. Half of them claimed that they had been beaten, two-fifths reported gunshot wounds, a third reported destruction or theft of property, and nearly a third reported involuntary detainment. Half of the 73 women seen at the center disclosed that they had been sexually assaulted, often near IDP camps. Only 198 medical records contained sufficient detail to enable the researchers to determine whether the documented medical evidence was consistent with the alleged abuses. However, in all these cases, the researchers judged that the medical evidence was consistent with, highly consistent with, or virtually diagnostic of the alleged abuses.

What Do These Findings Mean? These findings provide credible medical evidence that is consistent with torture and other human rights violations being inflicted on non-Arabic-speaking civilians in Darfur from 2004 to 2006. These findings cannot be used to estimate the population incidence of attacks on civilians or to corroborate claims of assailants' identities or of genocidal intent. Moreover, their accuracy may be affected by several limitations of this study. For example, during the study period, only patients who obtained a medical evidence form from the police were permitted to receive treatment from an authorized medical officer; obtaining such a form likely represented a considerable hurdle to accessing health care services. Nevertheless, the widespread, organized, and sustained pattern of attacks documented in this study is consistent with the possibility that the actions of Janjaweed and GoS forces during the conflict in Darfur may constitute war crimes, crimes against humanity, and/or acts of genocide. Importantly, these findings also highlight the need to provide adequate protection for health professionals working in countries affected by internal conflicts.

(*Received 22 March 2011; final version received 16 November 2011*)

The study aim was to assess whether hepatitis C virus (HCV) was associated with painful symptoms among patients with HIV. Using data from a prospective cohort of HIV-infected adults with alcohol problems, we assessed the effects of HCV on pain that interfered with daily living and painful symptoms (muscle/joint pain, headache and peripheral neuropathy). Exploratory analyses assessed whether depressive symptoms and inflammatory cytokines mediated the relationship between HCV and pain. HCV-infected participants ($n = 200$) had higher odds of pain that interfered with daily living over time (adjusted odds ratio [AOR] 1.43; 95% CI: 1.02–2.01; $p = 0.04$) compared to those not infected with HCV. HIV/HCV co-infected participants had higher odds of muscle or joint pain (AOR 1.45; 95% CI: 1.06–1.97; $p = 0.02$) and headache (AOR 1.57; 95% CI: 1.18–2.07; $p < 0.01$). The association between HCV and peripheral neuropathy did not reach statistical significance (AOR 1.33; 95% CI: 0.96–1.85; $p = 0.09$). Depressive symptoms and inflammatory cytokines did not appear to mediate the relationship between HCV and pain. Adults with HIV who are also co-infected with HCV are more likely to experience pain that interfered with daily living, muscle or joint pain, and headaches compared to those not co-infected. Research is needed to explore the association between HCV infection and pain, and to determine whether HCV treatment is an effective intervention.

Keywords: pain; hepatitis C; cytokines; symptoms; peripheral neuropathy

Introduction

Pain is a common condition in HIV-infected patients. A nationally representative survey conducted in 1996 reported that 67% of HIV-infected persons in the United States had experienced pain in the previous 4 weeks (Dobalian, Tsao, & Duncan, 2004). Pain is among the most common of symptoms reported by HIV-infected patients, and is strongly correlated with quality of life and psychological distress (Breitbart et al., 1998; Vogl et al., 1999). Substance abuse and unhealthy alcohol use, which commonly occur in the context of HIV-infection (Samet, Phillips, Horton, Traphagen, & Freedberg, 2004), may represent maladaptive coping responses to pain (Brennan, Schutte, & Moos, 2005; Holahan, Moos, Holahan, Cronkite, & Randall, 2001). A better understanding of the etiology of pain in HIV-infected individuals is needed to effectively prevent and treat pain in this population.

A co-morbidity whose contribution to pain among HIV-infected persons has been relatively unexplored is infection with hepatitis C virus (HCV). Chronic HCV infection has been associated with painful diagnoses such as peripheral neuropathy, arthritis, and arthralgias (Cacoub et al., 2000), as well as generalized pain in quality of life studies (Spiegel et al., 2005). Individuals with HCV have been noted to have a high prevalence of chronic pain and treatment for pain (Silberbogen, Janke, & Hebenstreit, 2007; Whitehead et al., 2008), and a study of substance users found that those who were HCV-infected were more likely to have persistent pain compared to those who were uninfected (Caldeiro et al., 2008). The majority of injection drug users are infected with HCV (Garfein, Vlahov, Galai, Doherty, & Nelson, 1996; Lorvick, Kral, Seal, Gee, & Edlin, 2001; Murrill et al., 2002; Thomas et al., 1995), and 15–30% of HIV-infected individuals are co-infected with HCV because of the shared risk factor of injecting drugs (Sulkowski & Thomas, 2003). Injection drug use (IDU) has been associated with greater pain in some studies of HIV-infected individuals (Del Borgo et al., 2001; Dobalian et al., 2004; Martin, Pehrsson, Osterberg, Sonnerborg, & Hansson, 1999; Riley et al., 2003), and underlying HCV infection may be an unrecognized contributory factor.

A number of causal mechanisms can be hypothesized to explain an association between HCV and pain. Depression, which is a known risk factor for pain in patients with (Richardson et al., 2009; Riley et al., 2003; Tsao, Dobalian, & Naliboff, 2004) and without HIV(Bair, Robinson, Katon, & Kroenke,

http://www.tandfonline.com

2003), is a common co-morbidity among patients with HCV (Dwight et al., 2000; el-Serag, Kunik, Richardson, & Rabeneck, 2002; Fontana et al., 2002; Golden, O'Dwyer, & Conroy, 2005; Lee, Jamal, Regenstein, & Perrillo, 1997). Among HIV-infected patients, co-infection with HCV has been shown to be independently associated with depressive symptoms (Libman et al., 2006). HCV may cause a cytokine-induced depression; a small study demonstrated correlations between plasma levels of interleukin-1β (IL-1β) and tumor necrosis factor-α (TNF-α) and depressive symptoms (Loftis, Huckans, Ruimy, Hinrichs, & Hauser, 2008). Researchers have also suggested that HCV may predispose to chronic pain conditions such as fibromyalgia through a cytokine-mediated pathway (Thompson & Barkhuizen, 2003).

The primary aim of this study was to evaluate whether HCV status was associated with pain that interfered with daily living and painful symptoms in a cohort of HIV-infected adults with alcohol problems. A secondary aim was to explore whether depressive symptoms and serum levels of the inflammatory cytokines TNF-α, IL-6, and IL-10 mediated the relationship between HCV infection and pain.

Materials and methods

Design

Data were obtained from a prospective, observational cohort study (HIV-Longitudinal Interrelationships of Viruses and Ethanol [HIV-LIVE]), in which assessments occurred at 6-month intervals over a maximum of 48 months.

Subjects

Recruitment occurred from a previous cohort study, an intake clinic for HIV-infected patients, HIV primary care and specialty clinics at two hospitals, homeless shelters, drug treatment programs, subject referrals, and flyers. Enrollment occurred between August 2001 and July 2003. Eligibility criteria were as follows: (1) documented HIV antibody test by ELISA and confirmed by Western blot; (2) two or more affirmative responses to the CAGE alcohol screening questionnaire, or physician investigator diagnosis of alcoholism; and (3) ability to speak English or Spanish. Exclusion criteria included: (1) scoring <21 on the 30-item Folstein Mini-Mental State Examination (i.e., cognitive impairment); and (2) inability to provide informed consent. The Institutional Review Boards of Boston Medical Center and Beth Israel Deaconess Medical Center approved this study. Informed consent was obtained from each patient and the protocol conforms to the ethical guidelines of the 1975 Declaration of Helsinki.

Outcomes

The primary outcome was any pain interference with daily life, which was measured using a single question from the SF-12 (Ware, Kosinski, & Keller, 1996): "During the past 4 weeks, how much did pain interfere with your normal work (including housework)?" Pain interference was defined as any response other than "not at all." Secondary outcomes were musculoskeletal pain, headache, and peripheral neuropathy. These symptoms were measured using the HIV Symptom Index (Justice et al., 2001). This index is a validated 20-question inventory of symptoms common in the setting of HIV infection which assesses their frequency and consequences in the prior month. The questions asked: "How much have you been bothered by each of the following symptoms: 1) muscle aches or joint pain; 2) headache; and 3) pain, numbness or tingling in the hands and feet (peripheral neuropathy)?" Headache, muscle/joint pain, and peripheral neuropathy were defined as a response other than "I do not have this symptom." The primary and secondary outcomes were assessed at baseline and each follow-up visit.

Independent variables

The main independent variable was chronic HCV infection, as defined as a positive HCV antibody result confirmed with detectable HCV RNA level on polymerase chain reaction (PCR) testing. Participants who were HCV antibody-positive and HCV RNA-negative were considered not to have chronic HCV infection (i.e., they had cleared their infection either spontaneously or through treatment). HCV status was assessed only at baseline. Covariates included in the analyses were age, sex, race (black vs. non-black), current marital status (married vs. not married), current smoking, past 6 months homelessness past 6 months any IDU, past month any heavy alcohol use, low CD4 count (<200 cells/μL), HIV viral load (detectable vs. undetectable), HIV medication use in the past 6 months, depressive symptoms, and baseline serum levels of inflammatory cytokines TNF-α, IL-6, and IL-10. Hazardous alcohol use was defined as: (1) drinking greater than 14 standard drinks per week, or greater than 4 drinks in a day, for men; or (2) drinking greater than 7 drinks per week or greater than 3 drinks in a day for women (Saitz, 2005). Depressive symptoms were measured using the Center for Epidemiologic Studies Depression Scale (CES-D), and a threshold of ≥ 23 was used to define

substantial depressive symptoms (Golub et al., 2004). The cytokines TNF-α, IL-6, and IL-10 were chosen based on prior research demonstrating that (1) serum levels are significantly different in the setting of HCV infection compared to controls (Jacobson Brown & Neuman, 2001); and (2) they play a potential role in the pathogenesis of central pain conditions and chronic pain (Jacobson Brown & Neuman, 2001; Uceyler & Sommer, 2008; Verri et al., 2006; Watkins, Hutchinson, Milligan, & Maier, 2007). TNF-α and IL-6 were measured using Bio-Rad Luminex Flow Cytometry (Millipore) and IL-10 was measured using Chemiluminescent ELISA (R&D Systems). Laboratory testing was conducted at the University of Vermont's Laboratory for Clinical Biochemistry Research.

Statistical analyses

Chi-square and Student's *t*-tests were used to compare baseline characteristics of subjects with and without chronic HCV infection. General estimating equations (GEE) logistic regression was used to calculate odds ratios and 95% confidence intervals for each pain outcome. The GEE approach was used to account for the correlation from using repeated observations from the same subject over time. An exchangeable working correlation structure was used, and empirical standard errors are reported for all analyses. Collinearity of covariates was assessed by calculating the correlation between independent variables, and no pair of variables had a Spearman correlation >0.40. A two-tailed p-value <0.05 was considered statistically significant for all hypothesis testing. Final models were adjusted for all covariates. Covariates except for age, sex, and race were all modeled as time-dependent. Based on the approach described by Baron and Kinney (1986), exploratory analyses were performed to assess whether depressive symptoms and serum levels of cytokines TNF-α, IL-6, and IL-10 mediated the association between HCV infection and pain outcomes. As such, models that included and excluded depressive symptoms and inflammatory cytokines were compared to assess whether HCV coefficient estimates were attenuated by inclusion of the potential mediators. All subjects had data on depressive symptoms, however, only 309 had data on IL-6 and 343 had data on TNF-α and IL-10 due to insufficient serum sample for testing. Indicator variables were used to create a category for missing values for inflammatory cytokines, so that the same subset of respondents was examined in each analysis. All statistical analyses were conducted using SAS version 9.2 (SAS Institute, Inc., Cary, NC, USA).

Results

Of the 400 participants in the HIV-LIVE cohort, 397 had been tested for HCV RNA and were included in the analysis. Of the 397 HIV-infected subjects, 200 (50.4%) were found to have detectable HCV RNA and were considered to be co-infected. Participants who were HCV-infected were more likely to be older, homeless, have recently used injection drugs, diabetes, and have substantial depressive symptoms (Table 1). At baseline, the prevalence of having pain that interfered with daily living, muscle or joint pain, headache, and peripheral neuropathy was higher among HIV-infected participants who were co-infected with HCV compared to those who were not. HCV-infected participants were also significantly more likely to have baseline levels above the median for IL-6 and IL-10.

The median follow-up was 23.7 months (IQR: 12.2–31.7 months); the median number of follow-up assessments was 6 (IQR: 4 to 7). Analyses of longitudinal data included 2371 observations from 397 subjects. Results from final GEE logistic regression models (adjusted for time, age, sex, black race, marital status, homelessness, smoking, hazardous alcohol use, IDU, low CD4 count, detectable HIV viral load, use of HIV medications, and additional adjustment for diabetes for peripheral neuropathy outcome) are presented in row 1 of Table 2. Participants who were HCV-infected had significantly higher odds for experiencing pain that interfered with daily living over time (adjusted odds ratio [AOR] 1.43; 95% CI: 1.02–2.01) compared to those who were not HCV-infected. Likewise, HCV-infected participants were more likely to experience muscle or joint pain (AOR 1.45; 95% CI: 1.06–1.97) and headache (AOR 1.57; 95% CI: 1.18–2.07) over time compared to those who were not HCV-infected. The relative odds for HCV associated with peripheral neuropathy, while also greater than 1, did not reach statistical significance (AOR 1.33; 95% CI: 0.96–1.85).

The additional adjustment for substantial depressive symptoms somewhat attenuated the OR for HCV for all four pain outcomes (Table 2), suggesting that some of the association between HCV and pain may be explained by a greater burden of depressive symptoms in that group. However, the degree of attenuation was low ($<10\%$ in all models) suggesting depression is not a mediator of the relationship between HCV and pain. In the multivariate models, depressive symptoms were strongly associated with pain interference (AOR 1.99; 95% CI: 1.60–2.48; $p<0.01$), muscle or joint pain (AOR 2.35; 95% CI: 1.88–2.93; $p<0.01$), headache (AOR 2.25; 95% CI: 1.86–2.71; $p<0.01$), and

Table 1. Baseline characteristics of HIV-infected participants with and without HCV.

	HCV negative	HCV positive

**Use in the past month.

peripheral neuropathy (AOR 1.54; 95% CI: 1.27–1.87; $p < 0.01$), and therefore, depressive symptoms may be a weak confounder. Levels of IL-6, IL-10, and TNF-α, however, were not significantly associated with any pain outcomes in multivariate models, and adjustment for these factors did not substantially impact the HCV effect in any model.

Discussion

In this cohort of HIV-infected persons with alcohol problems, co-infection with HCV was found to be associated with greater odds of experiencing pain that interfered with daily living, as well as symptoms of muscle or joint pain and headache. Although pain has been demonstrated to affect the majority of HIV-infected persons (Dobalian et al., 2004; Hewitt et al., 1997; Vogl et al., 1999), the mechanisms that underlie pain in this population are relatively poorly understood. Co-infection with HCV may be an overlooked and potentially modifiable risk factor for pain.

Substance use, and in particular IDU, has been associated with increased risk for pain at baseline and over time in HIV-infected patients (Del Borgo et al., 2001; Dobalian et al., 2004; Martin et al., 1999; Richardson et al., 2009; Riley et al., 2003; Tsao, Dobalian, & Stein, 2005). A study by Tsao et al. (2005) demonstrated that HIV-related disease burden mediated the association between illicit drug use and pain in a longitudinal cohort of HIV-infected persons. However, no published studies to date have examined the specific contributions of HCV co-infection to pain among persons living with HIV infection. Because HCV is strongly associated with IDU and has weaker associations with other drug use (Armstrong et al., 2006). it may be contributing to associations between substance use and pain observed in other studies. Our findings suggest that HCV may independently contribute to pain in HIV-infected patients. As prior studies have demonstrated the relative safety and efficacy of anti-HCV therapy among individuals with HIV (Carrat et al., 2004; Torriani et al., 2004), the potential to modify or prevent painful symptoms may provide additional motivation for addressing HCV in co-infected patients.

Our results demonstrating an association between HCV infection and muscle and joint pain are consistent with background studies in HIV-uninfected populations. Quality of life studies using the SF-36 have demonstrated greater bodily pain among patients who are HCV-infected versus HCV-uninfected (Spiegel et al., 2005). Clinical manifestations of HCV include extra-hepatic painful conditions. In a large

series of HCV-infected subjects, the prevalence of arthralgias and neuropathy was found to be 19% and 9%, respectively (Cacoub et al., 2000). A study of chronic liver disease patients found that HCV-infected patients had a higher relative odds for musculoskeletal pain compared to uninfected patients (Barkhuizen et al., 1999). To our knowledge, however, no prior studies have reported an association between HCV and headache. There is evidence, however, that HCV can be neuroinvasive (Laskus et al., 2005), and a large body of research demonstrates links between HCV and neurocognitive dysfunction (Perry, Hilsabeck, & Hassanein, 2008). The fact that HCV was associated with pain at multiple sites could suggest that infection with HCV affects one's overall tolerance of pain. Studies of pain tolerance using experimental techniques such as cold-pressor test have found differences in pain thresholds between opioid dependent former injection drug users and controls (Compton, Charuvastra, Kintaudi, & Ling, 2000; Compton, Charuvastra, & Ling, 2001; Doverty et al., 2001). It is conceivable that HCV status could, in part, be responsible for these differences.

We explored whether depressive symptoms and increased levels of inflammatory cytokines were mediators of the relationship between HCV and pain. Adjustment for depressive symptoms did not substantially attenuate the effects of HCV suggesting it is not a mediator. Results of the exploratory analyses also did not support that higher baseline levels of inflammatory cytokines were part of the causal pathway between HCV and pain. However, caution must be taken with interpreting these results as there were a number of limitations to the analyses. We measured serum levels of inflammatory cytokines at baseline only, and it is possible that changes in cytokine levels over time might better correlate with pain. Second, serum cytokine levels might not reflect the relevant physiologic pathway as cytokine expression can occur in other compartments (cerebrospinal fluid, peripheral blood mononucleocytes) (Loftis, Huckans, & Morasco, 2010).

There are additional limitations to this study. The main study outcome was based on a single question on the SF-12 questionnaire that reflected pain over the past 4 weeks. There was no information on pain severity, duration, or treatment available for analysis. Our findings could be related to undertreatment of pain among HCV-infected persons. Prior research has suggested that HIV-infected injection drug users are less likely to have pain effectively treated than those who do not use injection drugs (Breitbart et al., 1997). It is also possible that providers who care for patients with HCV infection may be reluctant to prescribe certain pain medications because of concerns about potential hepatotoxicity. The study was conducted on a population of HIV-infected adults with alcohol problem, which may affect the generalizability of its findings. However, given the prevalence of past alcohol problems among HIV-infected individuals, up to 40% in some studies (Samet et al., 2004), these findings would still be of importance even if not more broadly applicable. There may be other unmeasured confounders such as stress or anxiety associated with HCV infection that were not addressed in the analysis.

In summary, this study of HIV-infected adults with alcohol problems found that participants who were co-infected with HCV were more likely to experience pain that interfered with daily living,

muscle or joint pain, and headaches over time compared to those who were HCV-negative. Given that pain is a common morbidity among HIV-infected patients, more research is needed to explore the association between chronic HCV infection and pain in this population, and whether HCV treatment improves pain.

A Randomized Controlled Trial of a Goals-of-Care Video for Elderly Patients Admitted to Skilled Nursing Facilities

Angelo E. Volandes, M.D.,[1,2] Gary H. Brandeis, M.D.,[3] Aretha Delight Davis, M.D., J.D.,[1,4] Michael K. Paasche-Orlow, M.D., M.A., M.P.H.,[3] Muriel R. Gillick, M.D.,[1,5] Yuchiao Chang, Ph.D.,[1,2] Elizabeth S. Walker-Corkery, M.P.H.,[2] Eileen Mann, R.N., M.S.N.,[1,2] and Susan L. Mitchell, M.D., M.P.H.[1,6]

Abstract

Objective: To determine the impact of a video on preferences for the primary goal of care.
Design, subjects, and intervention: Consecutive subjects 65 years of age or older ($n=101$) admitted to two skilled nursing facilities (SNFs) were randomized to a verbal narrative (control) or a video (intervention) describing goals-of-care options. Options included: life-prolonging (i.e., cardiopulmonary resuscitation), limited (i.e., hospitalization but no cardiopulmonary resuscitation), or comfort care (i.e., symptom relief).
Main measures: Primary outcome was patients' preferences for comfort versus other options. Concordance of preferences with documentation in the medical record was also examined.
Results: Fifty-one subjects were randomized to the verbal arm and 50 to the video arm. In the verbal arm, preferences were: comfort, $n=29$ (57%); limited, $n=4$ (8%); life-prolonging, $n=17$ (33%); and uncertain, $n=1$ (2%). In the video arm, preferences were: comfort, $n=40$ (80%); limited, $n=4$ (8%); and life-prolonging, $n=6$ (12%). Randomization to the video was associated with greater likelihood of opting for comfort (unadjusted rate ratio, 1.4; 95% confidence interval [CI], 1.1–1.9, $p=0.02$). Among subjects in the verbal arm who chose comfort, 29% had a do-not-resuscitate (DNR) order (κ statistic 0.18; 95% CI–0.02 to 0.37); 33% of subjects in the video arm choosing comfort had a DNR order (κ statistic 0.06; 95% CI–0.09 to 0.22).
Conclusion: Subjects admitted to SNFs who viewed a video were more likely than those exposed to a verbal narrative to opt for comfort. Concordance between a preference for comfort and a DNR order was low. These findings suggest a need to improve ascertainment of patients' preferences.
Trial Registration: Clinicaltrials.gov Identifier: NCT01233973.

Introduction

Elderly patients admitted to skilled nursing facilities (SNFs), are at a vulnerable point in their medical care.[1] These patients are recuperating from an acute illness and often have underlying complex chronic medical conditions. At the same time, SNF providers are likely to be unfamiliar with these patients' medical history and values. The hazards resulting from discontinuity of care between the hospital and SNF setting are well-described.[2–5]

Emerging health policy initiatives are increasingly focused on reducing avoidable, costly and burdensome rehospitalizations of older patients, particularly when patients' primary goal of care is comfort.[6,7] Optimizing advance care planning by ascertaining the patient's care preferences presents a key opportunity to promote goal-directed care that avoids unwanted and costly treatments.[8]

Over the last decade, an expanding body of evidence suggests that video decision aids help patients make better informed decisions by clarifying treatment options for a variety of life-limiting conditions including cancer and advanced dementia.[9–13] Video enhances communication beyond the usual *ad hoc* verbal approaches to advance care planning by providing realistic and standardized depictions of treatment options. To date, video support tools for advance care planning have not been studied in the post-acute care setting

where vulnerable older patients are often required to make value-laden decisions about treatment options.

To address this gap, we conducted a pilot randomized controlled trial of using a goals-of-care video for elderly patients admitted to a SNF after an acute hospitalization. We hypothesized that compared to subjects randomized to a verbal description of the goals of care, those viewing the video decision aid would be more likely to opt for treatments that align with comfort as the primary goal of care. An additional aim was to examine the correlation between a stated preference for comfort with the presence of a do-not-resuscitate (DNR) order in the medical record.

Methods

Subjects

The protocol was approved by the Partners Institutional Review Board and all subjects provided written informed consent. Subjects were recruited from a consecutive sample of patients admitted from acute hospitals to one of two SNFs in the greater Boston area. Both SNFs were located within nursing homes; one facility had 164 beds and the other had 190 beds.

Recruitment occurred between July 1, 2010 and February 28, 2011. At the time of admission, all patients who were 65 years of age or older and English-speaking were identified by the SNF admitting clerk and given a flier outlining the study. Patients were then asked by a SNF staff member (e.g., nurse or social worker) if they were interested in participating in the study. The final eligibility of patients who expressed a willingness to participate was then determined by a research assistant based on an assessment of their cognitive status performed within 72 hours of SNF admission. Patients were excluded if they had a Short Portable Mental Status Questionnaire (SPMSQ) score of less than 7.[14]

Design

All interviews were conducted in-person by one of two members of the research team (either A.E.V. or E.M.). Subjects underwent a baseline interview within 72 hours of admission to ascertain age, self-reported race, gender, religion, educational status, marital status, self-rated health status (excellent, very good, good, fair, or poor), and self-reported completion of advance directives (designated health care proxy or living will).

Immediately after the baseline interview, subjects were randomized into one of two decision-making modalities: (1) listening to a verbal narrative describing potential goals of care (control group) or (2) viewing a 6-minute video visually depicting treatments comprising the various potential goals of care (intervention group). We used simple randomization at each site based on a computer-generated scheme. Individual assignments were concealed in numbered envelopes. At the end of the trial, the randomization order of subjects was checked against the computer-generated list.

The video and verbal narratives were presented to the subjects in a quiet room in the SNF by a trained member of the research team who followed a structured script. Subjects randomized to the verbal control group were read a description of the three goals of medical care framework (life-prolonging care, limited medical care, and comfort care) developed in our previous work.[12,13,15,16] This framework was generated from a review of the advance care planning literature, and consultations with geriatric, critical care, palliative care, health literacy, and decision-making experts. Early versions of the framework were tested and validated with elderly subjects.[12,13,15,16]

The first option presented, life-prolonging care, was described as aiming to prolong life using all available medical care, and includes cardiopulmonary resuscitation and treatments in the intensive care unit. The second option presented, limited medical care, was described as aiming to maintain physical and mental functioning. It includes treatments such as hospitalization, intravenous fluids, antibiotics, but excludes cardiopulmonary resuscitation and treatments in the intensive care unit. The third option presented, comfort care, was described as aiming to maximize comfort and to relieve pain. It includes oxygen and analgesics, but excludes intravenous therapies and hospitalization unless necessary to provide comfort.

Subjects randomized to the intervention group viewed the video decision aid, shown on a portable computer. The 6-minute video depicts the three categories of medical care using the same definitions used in the verbal narrative, but includes visual images of the typical treatments comprising each goal. For example, life-prolonging care images includes: an intensive care unit with a ventilated patient being tended to by respiratory therapists; a simulated code on a mannequin with clinicians conducting cardiopulmonary resuscitation and intubation; and vasopressors administered through a venous catheter. Visual images to depict limited medical care include: a patient getting antibiotics via a peripheral intravenous catheter; scenes from a typical medical ward service; and a patient wearing a nasal cannula for oxygen delivery. The video depiction of comfort care includes: a patient on home hospice care receiving pain medications; a patient with a nasal cannula for oxygen at home; and, a medical attendant assisting a patient with self-care.

The development of the video decision aid followed a systematic approach, starting with a review of the advance care planning literature. The video's design, content, and structure were reviewed and edited for appropriateness and accuracy by geriatricians, critical care intensivists, palliative care physicians, and decision-making experts using an iterative process. The video was filmed without the use of prompts or stage directions to convey a candid realism in the style known as cinema verite.[17,18] All filming and editing was done by the investigative team (A.E.V. and A.D.D.) following previously published filming criteria.[19]

After exposure to either the verbal narrative or video, subjects were asked to select which level of care they would prefer if their medical condition worsened while at the SNF. Specifically, they were asked: "Imagine that you became very ill and in need of medical treatment, which general approach of medical care would you want provided: life-prolonging care, limited care, or comfort care?" Subjects unable to select a level of care were considered "uncertain."

For those subjects randomized to the video group, a four-point scale was used to assess perceived value of the video by asking subjects whether they were comfortable watching the video, whether they would recommend it to others, and whether they found the video helpful in their understanding of the goals-of-care options. Subjects who stated they did not

find the video helpful were asked to comment why, which was transcribed by the interviewer.

Last, a chart abstraction by the research assistant was performed immediately after exposure to the verbal or video narratives to ascertain whether or not the patient had a DNR order.

Statistical analysis

All subject characteristics and outcomes were described using proportions for categorical variables, and means and standard deviations (SD) for continuous variables. The primary outcome was a preference for comfort care (versus life prolongation, limited care or uncertain) as the goal of care and compared between the two groups using the exact χ^2 test. Additional analyses were conducted between subject characteristics (age, gender, education, marital status, health status, presence of advance directive, race, and randomization arm) and desire for comfort care for the entire cohort (i.e., both arms of the study). Rate ratios (RR) and 95% confidence interval (CI) were used to summarize the associations.

Finally, κ statistics were used to summarize the agreement between stated preferences for comfort and the presence of a DNR order in the medical record among the subjects in the intervention and control groups. A two-sided p value < 0.05 was considered statistically significant for all analyses.

With a target of 50 patients in each group, the power of the study was estimated to be 90% to detect a 30% difference in the preference for comfort care between the two groups. Data were analyzed and the randomization table was prepared using SAS software, version 9.2 (SAS Institute Inc., Cary, NC).

Results

Subject flow

A total of 155 consecutive English-speaking patients 65 years or older admitted to the two SNFs were approached to participate in the study, of whom 102 (66%) agreed to participate. Patients who declined did not differ significantly from the recruited subjects in terms of age, gender, or race. The most common reason given for not participating was lack of interest. Of the 102 patients expressing interest in the study, 1 patient was excluded because her SPMSQ score was less than 7, resulting in a total of 101 study subjects. A total of 51 subjects were randomized to the verbal control group, and 50 subjects were randomized to the video intervention group (Fig. 1). Baseline characteristics of the subjects are shown in Table 1.

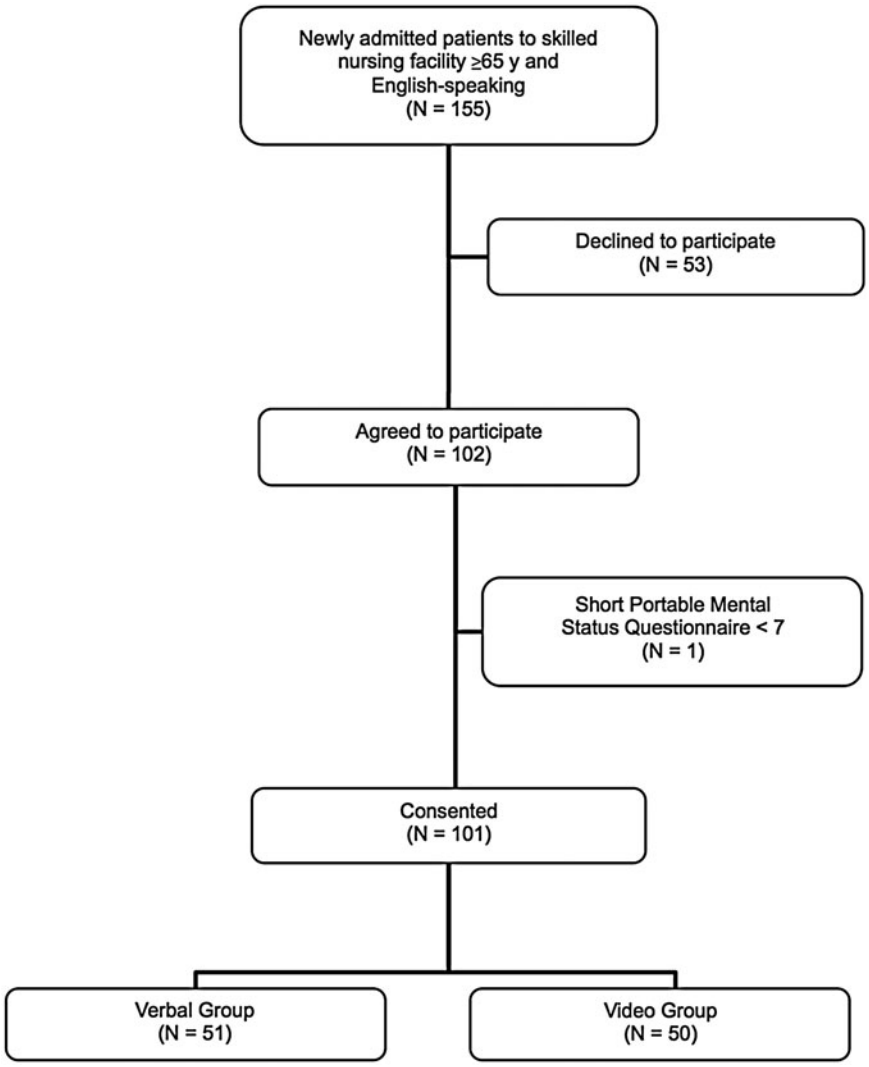

FIG. 1. Flow diagram of study and subjects' flow.

Outcomes

Among the 51 subjects receiving the verbal narrative, 29 (57%) preferred comfort care, 4 (8%) chose limited care, 17 (33%) desired life-prolonging care, and 1 (2%) was uncertain. Among the 50 subjects receiving the video decision aid, 40 (80%) chose comfort care, 4 (8%) chose limited care, and 6 (12%) desired life-prolonging care (Fig. 2). The proportion of subjects opting for comfort care was significantly higher in the intervention group ($p = 0.02$).

Subjects randomized to the video group had a greater likelihood of opting for comfort care (versus other responses; RR 1.4; 95% CI 1.1 to 1.9). None of the other subject characteristics were significantly associated with a preference for comfort care (Table 2).

In the verbal group, 28 of the 29 subjects who chose comfort care had a code status documented in their medical record. Only 8 of these 28 subjects (29%) had a DNR order in their medical record (κ statistic 0.18; 95% CI–0.02 to 0.37). In the video group, among the 40 subjects who chose comfort care, only 13 (33%) had a DNR order in their medical record (κ statistic 0.06; 95% CI–0.09 to 0.22). The video decision aid was highly acceptable to subjects in the intervention group: 45 of 50 (90%) subjects said they were "very comfortable" or "somewhat comfortable" viewing the video; 43 (86%) said they would "definitely" or "probably" recommend the video to others. Of the 50 subjects who viewed the video, only 4 (8%) found the video "not helpful." All 4 subjects who did not find the video helpful stated that they had already made their decisions previously and did not find viewing the video additionally helpful. There were no adverse events in either group.

Discussion

Elderly subjects transitioning from an acute hospital stay to a SNF who view a video decision support tool for advance care planning are more likely to state comfort as a goal of care compared to those who listen to a verbal description about medical options. However, only about a third of subjects in both arms of the study who stated that they preferred comfort-oriented measures had a DNR order documented in their record. Thus, while a video decision aid increased the expressed desire for comfort care, our findings suggest a need to better translate those preferences into a written order to limit treatment.

As the first known randomized controlled trial of a video support tool to help determine the goals of care among elderly patients transitioning from an acute hospital to a SNF, this study supports and extends prior research about video decision-making tools in seriously ill patients.[12,13,15,16] In our previous work in advanced dementia and advanced cancer, video decision aids elicited preferences for comfort-oriented care, but these studies were conducted in outpatient settings and with patients who were making hypothetical decisions. Our current study extends this earlier work by showing the efficacy of the video for elderly patients in a clinical environment during periods of serious illness and transitioning across health care settings.

Delivery of medical care to patients that is consistent with their stated preferences is a critical consideration to providing high-quality medical care. The main finding in this study in a SNF is consistent with all earlier trials of video support tools for life-limiting conditions: subjects exposed to the video compared to a verbal narrative are more likely to opt for comfort-focused care (vs. life-prolonging or limited medical care). Our prior work also found that video decision support tools improve patient knowledge about their condition and treatment options, and reduce disparities among patients due poor health literacy.[12,13,20] Federal and state bodies will soon legislate the development of decision aids to assist patients and their families facing complex health care decisions.[21] Our work supports this initiative and may inform the type of decision support tools selected for further development and implementation.

Our findings show a lack of correlation between documented DNR status and stated preferences for comfort-oriented care regardless of decision-making modality. This suggests that in practice, more attention needs to be placed on providing patients and their families with opportunities to fully discuss preferences and to ensure these preferences are reflected in medical orders, especially during a vulnerable period as elderly patients transition between the hospital and post-acute care settings.[22–25] Ideally, an out-of-hospital DNR form would be completed that can travel with patients across sites.

Our study has several important limitations. First, the research staff collecting data were not blinded to randomization, which could introduce bias into our findings. Previous randomized studies of interventions aimed at improving end-of-life decision-making have seldom been blinded because limiting the number of interviewers eases the burden on

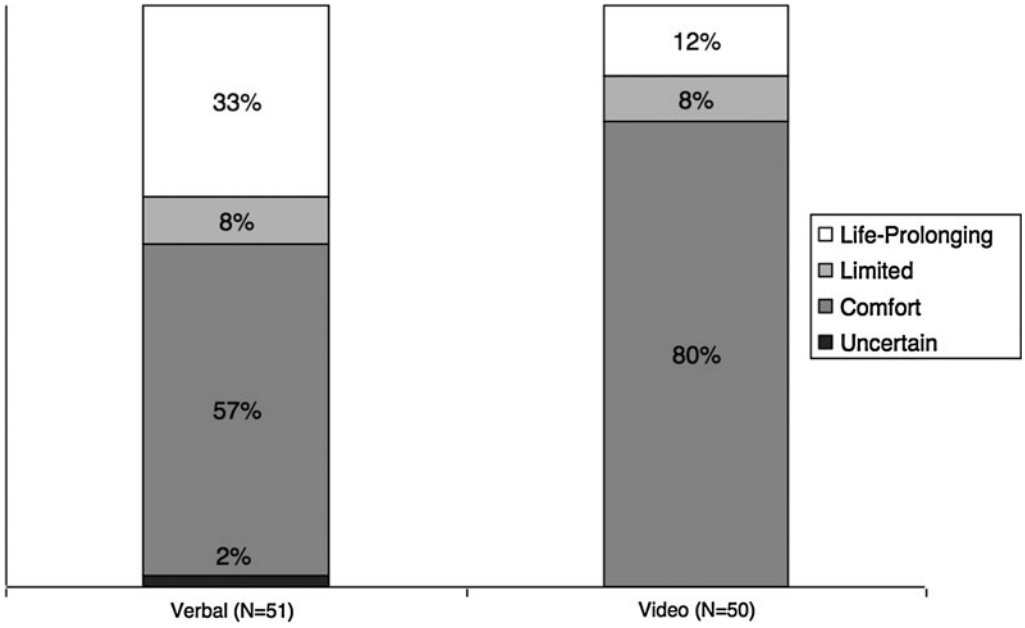

FIG. 2. Subjects' preferences for their goals of care.

subjects of addressing difficult subject matter.[26,27] We attempted to reduce the influence of this potential bias by using structured interviews and data collection instruments.

Second, one third of eligible subjects declined to participate in the study, although they did not differ significantly from the recruited subjects in terms of age, gender, or race. Third, videos can be manipulated to favor a particular perspective. Our study used one video exploring the goals of care. We did not assess responses to different videos altering the races and characteristics of the patients in the video. However, the video

was evaluated by experts in a range of fields to ensure that it does not present a biased perspective or to otherwise try to influence subjects to choose a specific option. Fourth, we did not incorporate the video into clinical care by informing patients' physicians of their preferences and then following patients longitudinally to determine whether the video support tool had an effect on their advance care planning or actual clinical outcomes over time. This would be an ideal subsequent study to our present pilot study. Finally, our sample was limited to two SNFs in the Boston area. Thus, our findings might not be generalizable to elderly patients in other geographic areas or health care settings.

Discharge from an acute hospital stay to the post-acute care setting is a challenging and critical time of transition for older patients. Upon admission to a SNF, the patient's health status is often tenuous, and elucidation of their goals of care is needed to align ongoing treatments with patient preferences, and to help avoid unwanted and costly interventions for those whose goal of care is comfort. Our findings suggest that video decision aids may be a feasible and effective approach towards addressing this need in the setting of a SNF. However, our findings also demonstrate that ascertainment of goals of care may not be enough, as steps must also be taken to translate those wishes into a medical order (e.g., DNR orders).

In summary, elderly patients often face complex decision-making as they transition from the acute hospital setting to the SNF setting. To secure high-quality medical care at this juncture, patients must be informed about their options regarding end-of-life goals of care. Education of patients using video decision aids offers a more concrete portrait of potential goals of care compared to verbal discussions. As health care organizations look for innovative tools to inform patients at the end of life and to deliver high-quality medical care that is consistent with patient preferences, video decision aids may provide a useful tool. Future initiatives to improve ascertainment of patients' goals-of-care preferences should also include activities to improve the alignment between patient preferences, medical orders documenting patient goals-of-care, and the care that is delivered.

Methadone Dose, Take Home Status, and Hospital Admission Among Methadone Maintenance Patients

Alexander Y. Walley, MD, MSc, Debbie M. Cheng, ScD, Courtney E. Pierce, MPH, Clara Chen, MHS, Tiffany Filippell, MD, Jeffrey H. Samet, MD, MA, MPH, and Daniel P. Alford, MD, MPH

Objectives: Among patients receiving methadone maintenance treatment (MMT) for opioid dependence, receipt of unobserved dosing privileges (take homes) and adequate doses (ie, ≥ 80 mg) are each associated with improved addiction treatment outcomes, but the association with acute care hospitalization is unknown. We studied whether take-home dosing and adequate doses (ie, ≥80 mg) were associated with decreased hospital admission among patients in an MMT.

Methods: We reviewed daily electronic medical records of patients enrolled in one MMT program to determine receipt of take-home doses, methadone dose 80 mg or more, and hospital admission date. Nonlinear mixed-effects logistic regression models were used to evaluate whether take-home doses or dose 80 mg or more on a given day were associated with hospital admission on the subsequent day. Covariates in adjusted models included age, sex, race/ethnicity, human immunodeficiency virus status, medical illness, mental illness, and polysubstance use at program admission.

Results: Subjects (n = 138) had the following characteristics: mean age 43 years; 52% female; 17% human immunodeficiency virus–infected; 32% medical illness; 40% mental illness; and 52% polysubstance use. During a mean follow-up of 20 months, 42 patients (30%) accounted for 80 hospitalizations. Receipt of take homes was associated with significantly lower odds of a hospital admission (adjusted odds ratio [AOR] = 0.26; 95% confidence interval [CI], 0.11-0.62), whereas methadone dose 80 mg or more was not (AOR = 1.01; 95% CI, 0.56-1.83).

Conclusions: Among MMT patients, receipt of take homes, but not dose of methadone, was associated with decreased hospital admission. Take-home status may reflect not only patients' improved addiction outcomes but also reduced health care utilization.

Key Words: dose, hospital admission, methadone maintenance treatment, take-home status

(*J Addict Med* 2012;6: 186–190)

Methadone maintenance treatment (MMT) in the United States is provided in federally regulated clinics that typically operate separate and in-parallel to mainstream medical care. Although methadone dosing should be individualized, as methadone metabolism exhibits individual variability (Lugo et al., 2005), higher doses are more effective than lower doses at retaining patients in treatment (Peles et al., 2010), diminishing craving, providing opioid blockade, and thus minimizing illicit opioid use and decreasing injection frequency (National Consensus Development Panel on Effective Medical Treatment of Opiate, Addiction, 1998; Strain et al., 1999; Faggiano et al., 2003; Center for Substance Abuse Treatment, 2005). National surveys of MMT programs have shown that the average methadone dose has been increasing since the 1980s and programs with higher average doses are more likely to be accredited by the Joint Commission (D'Aunno and Pollack, 2002; Pollack and D'Aunno, 2008). Thus, sufficiently high methadone dose may be one marker of MMT quality.

A "take home" is a dose of methadone given to the patient to take unobserved at home in place of requiring a return to the clinic a subsequent day for observed dosing. Contingent take-home doses are offered as rewards to patients with regular clinic attendance, counseling attendance, and abstinence from illicit drug use as measured typically by urine toxicology tests (Center for Substance Abuse Treatment, 2005). With adherence to MMT program expectations, take-home doses may increase up to a maximum of 6 or 13 consecutives doses, so eligible patients present to clinic every 1 or 2 weeks. Thus, contingent take-home dosing results from and reenforces success in MMT and is another potential marker of MMT quality. In a cohort study, it has been associated with longer retention in treatment and survival (Peles et al., 2011). Controlled studies have demonstrated that contingent take-home dosing increases abstinence from heroin and cocaine use (Chutuape et al., 1999, 2001) and increases counseling attendance (Kidorf et al., 1994).

As easily measurable markers of treatment adequacy and treatment success, methadone dose and take-home status may also reflect improved health care utilization. Patients receiving adequate methadone dosing and who have treatment success may be less likely to use acute hospital services, as they may be more capable of self-management (ie, attending to their medical needs). Addiction treatment generally is associated with decreased utilization of acute hospital services and, in some cases, lower overall costs (Laine et al., 2001, 2005; Weisner et al., 2001; Parthasarathy et al., 2003; Friedmann et al., 2006; Gourevitch et al., 2007). However, it is not clear which aspects of MMT are associated with improved medical care utilization.

In the setting of national health reform and the prospect of parity for the treatment of substance use disorders, the impact of MMT on the broader health system should be of interest to policymakers, providers, and patients. The determination of factors that reflect effective MMT will assist with evaluating health system outcomes. In this study, we reviewed the MMT and hospital electronic medical records (EMRs) of patients to determine longitudinally whether an association exists with hospital admission and 2 easily accessible clinical factors: (1) methadone dose and (2) take-home status.

METHODS

Study Design and Population

We conducted a retrospective medical record review of patients in the Boston Public Health Commission (BPHC) MMT program from February 1, 2006, to March 30, 2008. Only those individuals who met the following criteria were eligible for analysis: (1) enrolled in MMT on March 30, 2008; (2) received primary medical care from Boston Medical Center (BMC), an affiliated but physically and institutionally distinct medical center; and (3) had provided an active 2-way release of information with a BMC primary care physician. The release permitted ongoing exchange of medical information between the BPHC MMT program and providers at BMC for the purpose of clinical care coordination. This release was typically initiated at enrollment in MMT. For the purposes of the study, we linked patient data between the MMT program and the hospital. Investigators did not have direct contact with any study subjects as this study was a retrospective review of medical record data and therefore did not obtain any informed consents. This study was reviewed and approved by the institutional review board of Boston University and BMC, on behalf of the BPHC.

Data Collection and Measures

Outcomes

The primary outcome of the study was hospital admission (yes vs no) on a given day. To document hospital admissions, the medical record reviewers recorded start and end dates for each hospitalization listed in the MMT EMR from February 1, 2006, to March 30, 2008. The MMT nursing staff was informed by either hospital staff or the patient upon return about any hospitalization that resulted in a missed methadone dose. The nursing staff documented the dates, diagnoses, and locations of these hospitalizations in the MMT EMR after direct communication with the hospital staff. Forty-four of 55 hospitalizations (80%) reported to have occurred at BMC were confirmed in the BMC EMR. Periods when patients had no opportunity to receive take homes were excluded from analyses. These periods included the first 90 days of program admission, days incarcerated, and days hospitalized. Periods of known pregnancy were recorded and excluded because of expected hospitalizations during this time (pregnancy complications or child birth).

Independent Variables

There were 2 main independent variables in the study: methadone dose ($\geq$80 mg vs $<$80 mg) and receipt of take home (yes vs no) on a given day. Methadone dose and take-home status were extracted from the MMT EMR for each day the subject was enrolled from February 1, 2006, to March 30, 2008. Take homes are the primary incentive MMT programs use for positive reinforcement for patients who are succeeding in treatment and are granted after at least 90 days of complete methadone dosing attendance, counseling attendance, and no evidence of any illicit substances as determined by urine drug testing. Daily methadone doses were categorized as 80 mg or greater or less than 80 mg. This categorization was based on previous studies that demonstrated that doses 80 mg or more were associated with improved treatment outcomes (Strain et al., 1999). Both methadone dose and take-home status were modeled as time-dependent variables.

Covariates

From the BPHC EMR, reviewers recorded age, sex, race/ethnicity, and polysubstance use at the time of MMT admission. Race/ethnicity categories included 3 mutually exclusive categories—non-Hispanic white, non-Hispanic black/African American, and Hispanic. Subjects were categorized with polysubstance use if alcohol, cocaine, or benzodiazepine (nonprescribed) use was noted at methadone program admission. From the BMC EMR, we also recorded the active co-occurring medical and mental health conditions. Subjects were categorized as having medical illness if they had any of the following diagnoses documented: chronic obstructive pulmonary disorder, diabetes, renal disease, hypertension, cancer, pancreatitis, or hypercholesterolemia. Human immunodeficiency virus (HIV) status was documented and included as a covariate separately from other medical conditions. Subjects were categorized as having mental illness if they had a mood, thought, or anxiety disorder documented.

Analysis

Descriptive statistics of all subject characteristics at study entry were obtained and stratified by take-home status (ever vs never) and dose status (always $\leq$ 80 mg vs ever $\geq$ 80 mg). We used nonlinear mixed-effect logistic regression models to evaluate whether receipt of take homes or high-dose methadone were associated with a hospital admission on the following day. The mixed-effects regression model was used to incorporate multiple observations available from the same individual (eg, subjects could have repeated hospitalizations) in the analysis while controlling for the correlation within individuals to obtain proper estimates of variability. The

primary analysis included both independent variables in the same adjusted model. Because some previous studies define 60 mg of methadone as "high dose" (Faggiano et al., 2003), we repeated the model, using a definition of 60 mg or higher in a sensitivity analysis. Covariates in the adjusted model included age, sex, race/ethnicity, HIV status, chronic medical illness, mental illness, polysubstance use, length of time in treatment before study enrollment, and time since baseline. To minimize the potential for collinearity, we assessed correlation between pairs of independent variables and verified that no pair of variables included in the same regression model was highly correlated (ie, $r > 0.40$). Analyses were conducted using 2-sided tests and a significance level of 0.05. All analyses were performed using SAS software version 9.1 (SAS Institute Inc., Cary, North Carolina).

RESULTS

Of the 365 patients enrolled in the MMT program, 71 (19%) had no release signed for communication with a primary care physician and 128 (35%) had a signed release, but not with a physician at the affiliated medical center. Of the remaining 166 subjects screened, 28 were excluded because they had been enrolled in MMT less than 90 days as of March 30, 2008. Hence, 138 of the 365 patients (39%) were ultimately found eligible and included in study analyses (Figure 1).

The following were patient characteristics at study entry: mean age of 43 years; 52% female; 49% white, 29% black or African American, and 22% Hispanic; 17% HIV-infected; 32% chronic medical illness; 40% mental illness; and 52% polysubstance use. Table 1 details patient characteristics overall and stratified by both take-home status and methadone dose ($\geq$80 mg or $<$80 mg). Among the study patients, 52% had at least 1 documented take home during the follow-up period and 75% had at least 1 documented methadone dose of 80 mg or more. Those patients who ever received take homes were less likely to have polysubstance use at baseline, were older, and had more follow-up months during the study and more months in treatment before the study. Those patients with a dose always 80 mg or less were less likely to have mental illness or polysubstance use and had fewer follow-up months during the study. Among the 138 subjects, the total number of eligible observed days in MMT was 83,149 and the mean duration of follow-up time was 20 months. Of the 80 hospital admissions among 42 (30%) subjects, 9 (11%) admissions were among subjects with take homes and 50 (62.5%) admissions were among subjects with 80 mg or more of methadone. The overall hospitalization rate was 0.35 hospitalizations per person-year of eligible treatment days.

In models adjusted for age, sex, race/ethnicity, mental and medical illness, HIV infection, and polysubstance use, receipt of take homes was associated with significantly lower odds of a hospital admission (odds ratio = 0.26; 95% confidence interval [CI], 0.11-0.62), whereas dose of 80 mg or more was not (odds ratio = 1.01; 95% CI, 0.56-1.83) (Table 2). In a sensitivity analysis, methadone dose of 60 mg or more was also not significantly associated with hospital admission. In both models, medical illness was associated with increased odds of hospital admission. Common hospitalization diagnoses were typical for that seen in an urban hospital and are listed in Table 3.

DISCUSSION

Among MMT patients with established medical care, those who demonstrated treatment success in MMT as defined by achieving unobserved dosing privileges (ie, take home doses) had one quarter the odds of hospital admission

compared with those not receiving take-home doses. Thus, achieving take-home doses represented not only substantial addiction treatment success but also a marked decreased risk of medical hospitalization during this period. Although this analysis does not determine whether take-home status directly reduces hospitalization or is a marker of other unmeasured factors, it does account for other known predictors of hospital admission, including age, HIV infection, chronic medical illnesses, and mental illness.

We found no evidence that the dose of methadone was associated with decreased hospitalization. The observed lack of association between doses greater than 80 mg and hospitalization suggests that the benefits of a higher dose do not include decreased hospital admissions.

The Office of National Drug Control Policy 2010 Strategy highlights increasing quality and performance within addiction treatment as a key objective and using quality and performance measures to improve addiction treatment (Office of National Drug Control Policy, 2010). The treatment of opioid dependence with pharmacotherapy (eg, MMT) is one of the 11 evidence-based practices identified by the National Quality Forum and cited by the Office of National Drug Control Policy for widespread adoption. Providing pharmacotherapy for opioid dependence should include demonstrating treatment quality and performance. Hospitalization is an important outcome to consider because of both health and cost implications. Adequate MMT dosing is already recognized as a measure of MMT effectiveness in that lower doses result in poorer addiction treatment outcomes (National Consensus Development Panel on Effective Medical Treatment of Opiate, Addiction, 1998; Strain et al., 1999; Faggiano et al., 2003; Center for Substance Abuse Treatment, 2005). Take-home status has been less studied, but by definition it is a marker of treatment success, because abstinence from drugs, participation in counseling, and daily dosing are required to receive take homes. However, whether or not such success extends to utilization of medical resources has not been examined in previous studies. By demonstrating an association between take-home status

and hospitalization, an important medical and health system cost outcome, this study supports consideration of take-home status as a useful performance measure reflecting direct benefit to individual patients and the wider health care system.

This study's strengths included the use of the daily MMT program EMR, which allowed us to determine each patient's methadone dose, take-home status, and hospitalization status for every day they were enrolled in MMT during the study period. By including subjects with a documented primary care physician and a signed release of information, our sample allowed for documentation of medical problems through the EMR at the affiliated medical center. Although this inclusion criterion limited the proportion of eligible patients included in the analysis and limits the generalizability of our findings, it is unlikely that this would bias the results, because engagement in primary care likely decreases acute care utilization. This study was also limited by the nature of retrospective design and focus on a single clinic. However, because MMT is subject to federal regulations, there are substantial similarities from clinic to clinic.

CONCLUSIONS

Among MMT patients, receipt of take homes, but not dose of methadone, was significantly associated with reduced medical hospitalizations. Thus, take-home status reflects not only patients' improved addiction outcomes but also reduced health care utilization. Given that this characteristic is easy to measure, clinically important and had cost implications, it should be further considered as a useful quality and performance measure for MMTs. Furthermore, intervention studies that seek to increase take-home status among MMT patients should evaluate health care utilization outcomes.

ACKNOWLEDGMENTS

The authors thank the staff at the Opioid Treatment Program, Boston Public Health Commission, for their support and cooperation during this study. This project was funded in part by the National Institute on Drug Abuse R25-DA13582. Parts of this work were presented at the Society of General Internal Medicine annual meeting May 13-16, 2009, and the College on Problems in Drug Dependence annual meeting June 24, 2009.

1. Introduction

Integration of substance use treatment and medical care has long promised to enhance the care of patients with alcohol and drug abuse, and related medical conditions (Samet, Friedmann, & Saitz, 2001). In 2006, the Institute of Medicine called for normalization of collaboration and coordination among health care providers that serve patients with medical, mental health and substance use disorders (Committee on Crossing the Quality Chasm, 2006). The integration of these services could improve the quality and efficiency of care by diagnosing and treating more than one condition at once. Integration can be *good for patients* with more than one condition, because it allows for "one stop shopping" resulting in fewer visits to fewer places for care. The potential for longitudinal relationships to develop over time may result in increased understanding and trust, essential components in effective care for substance use disorders. Integration can also be *good for providers* because it facilitates team-based care where no individual provider takes on the full burden of a patient's multiple conditions, but the work is shared among multiple disciplines. Communication and collaboration can be a daily part of the team culture, eliminating an extra step to coordinate care.

In the fall of 2011, *JSAT* recruited the co-chairs of the Substance Abuse Interest Group of the Society of General Internal Medicine, Dr. Jeanette Tetrault and Dr. Alexander Walley, to serve as guest editors of a special issue to advance the science in this area. A call for submissions was issued in January 2012. Original research addressing the focus of the special issue received *JSAT*'s standard peer review: two experts and an editor assessed each paper's pertinence and scholarly merit. The papers included in this special issue address a range of topics and settings that are relevant to the integration of medical care and substance use treatment.

This diverse group of articles demonstrates that interventions for the detection and management of substance-related disorders can reach patients in medical settings. The converse is also true: the integration of medical care into specialty addiction treatment improves the effectiveness of care for substance-related medical conditions such as hepatitis C and HIV. Some important themes that emerge from this collection of papers enhance our understanding as to when and how these integrated models work. Several of the articles address the challenges of delivering high-quality interventions in medical settings. Others address the critical issue of complex comorbidity, as screening in medical settings will detect patients with substance use and co-occurring medical and psychiatric conditions for whom adequate treatment will require more than brief intervention. Fortunately, effective models exist for delivering care to patients with comorbid needs, of which some examples appear in this issue. Finally, this collection demonstrates the potential of pharmacotherapy as a tool for the innovative treatment of more severe substance use problems by medical providers.

2. Delivering high-quality care in integrated medical settings

2.1. Quality of brief interventions delivered in medical settings

Screening, Brief Intervention, and Referral to Treatment (SBIRT) programs have received nationwide attention and a growing body of literature describes successful ways to implement SBIRT in clinical settings (Substance Abuse & Mental Health Services Administration, 2012). Brief interventions (BI) for at-risk alcohol use have proven

efficacy in a variety of clinical settings (Academic, 2007; Babor et al., 2007; Estee, Wickizer, He, Shah, & Mancuso, 2010; Fleming, Barry, Manwell, Johnson, & London, 1997) and BI delivered in the emergency department can reduce both drinking outcomes and health care-related cost (D'Onofrio, Pantalon, Degutis, et al., 2008; Gentilello, Ebel, Wickizer, Salkever, & Rivara, 2005; Havard, Shakeshaft, & Sanson-Fisher, 2008). BI is a "teachable skill" that can be readily integrated into existing graduate medical education curricula (Bernstein, Bernstein, Feldman, et al., 2007; D'Onofrio, Nadel, Degutis, et al., 2002; Ryan, Martel, Pantalon, et al., 2012; Tetrault, Green, Martino, et al., 2012); however, no formal assessment tool exists to measure the degree to which practitioners adhere to the key components of BI. Pantalon et al., 2012 describe the development and psychometric testing of a tool to measure practitioner adherence to a type of brief intervention called the Brief Negotiation Interview (BNI) (Pantalon). The BNI Adherence Scale was originally used in the context of a randomized clinical trial of BNI for hazardous drinking in the emergency department. Through review of 342 audio-taped patient encounters in the emergency department, the authors found that the BNI Adherence Scale had excellent internal consistency and good-to-excellent inter-rater reliability. The authors conclude that this tool can serve as a measure of the integrity of BI delivery in randomized clinical trials and as an integral component of BI skills-based teaching exercises allowing trainers to provide structured feedback to trainees. Further research is needed in more diverse populations to understand its application in practice. However, as the field of integrated medical and addiction care matures, standardized assessments will be essential to efforts to improve the quality of brief interventions.

2.2. Quality of chronic disease management for alcohol and other drug treatment in primary care

Although alcohol and other drug (AOD) dependence are increasingly recognized as chronic conditions, treatment of these disorders often remains stuck in an acute-care paradigm (Friedmann, Lemon, Stein, & D'Aunno, 2003). Implementing a chronic disease management approach to treatment of AOD dependence has the potential to improve addiction outcomes and patient satisfaction by providing flexible, patient-centered, longitudinal care (Samet et al., 2001; McKay, 2009). Support for chronic disease management (CDM) models for addiction treatment exists; however, no formal assessment exists to measure the quality of CDM for AOD. Visit frequency and timing-based measures have classically been considered quality assessments in this area (McCorry, Garnick, Bartlett, Cotter, & Chalk, 2000), whereas consideration of addiction outcomes has less commonly been considered. As such, Kim et al., 2012 investigated the relationship between quality of CDM measures for AOD dependence and addiction outcomes using data from a randomized clinical trial of access to primary care-based CDM for AOD dependence. Visit frequency, based on engagement in the CDM clinic, was not associated with abstinence or addiction severity while self-reported perception of receipt of chronic disease care, regardless of the source of care, was associated with abstinence and alcohol addiction severity. This work supports the efforts to integrate primary health care, mental health services and addiction treatment while showing that the quality of the CDM provided needs to be considered. Specifically, as we continue to understand and implement integrated medical systems, patient perception of receipt of quality CDM may be a key factor associated with improved disease-specific outcomes.

2.3. The potential of technology to improve the delivery of screening and brief intervention in medical settings

Several barriers exist to implementing behavioral health screening and interventions in emergency department settings, such as time, provider constraints, lack of provider training, and incomplete knowledge of area referral and follow-up resources (Delgado, Acosta, Ginde, et al., 2011). Using computer interfaces and other technology to deliver substance use screening and intervention has been proposed to perform these services, bypassing individual practitioner time and expertise and allowing modifiable messages based on patient responses. Choo et al, 2012. explored the accessibility and interest in technology-based substance use health information among patients with alcohol and drug use presenting to the emergency department and the barriers to using such technology. The results of this study suggest that although access to technology was high, interest in receiving health information via technology ranged from 41 to 46% among patients misusing drugs and alcohol. Barriers included concerns over confidentiality—especially among patients with drug misuse, complexity of use and time. Technology will undoubtedly play a key role in the implementation of integrated health care delivery systems. It is clear, however, that confidentiality concerns must be addressed if integrated health care settings are to realize the full potential of technology for screening and intervention.

2.4. Quality of behavioral health integration in medical care

Health care reform has provided much impetus for comprehensive and integrated care, including integration of mental health and substance use services into primary care settings (Humphreys & McLellan, 2011). Federally Qualified Health Centers (FQHCs) will play a central role in these efforts, especially for patients with substance use disorders. McGovern et al., 2012 describe the development and feasibility of an organizational measure, the Dual Diagnosis Capability in Health Care Settings (DDCHCS) index, to assess the level of behavioral health integration in FQHCs. Prior work has established the utility of the Dual Diagnosis Capability in Addiction Treatment and the Dual Diagnosis in Mental Health Treatment to inform policy makers and researchers in efforts toward integrated care delivery (McGovern, Lambert-Harris, McHugo, Giard, & Mangrum, 2010). After establishing DDCHCS feasibility and reliability, the authors utilized this measure to assess 13 FQHCs on level of behavioral health and substance use integration. They found that 3 of 13 FQHCs met standards to be dual diagnosis capable and were more likely to be integrated in behavioral health rather than addiction treatment services. Significant variation was noted in center staffing, treatment practices and program milieu. Although designed to assess feasibility and field testing of the DDCHCS, this study suggests that further work is needed to enhance the capability of FQHCs to deliver integrated health care to the large population of patients with substance use disorders who will become insured with the Medicaid expansion under the Affordable Care Act.

3. Meeting the challenge of substance use and co-occurring disorders

3.1. Screening and brief intervention for alcohol use uncovers drug and mental health issues

The American College of Surgeons mandates that trauma centers have alcohol screening and brief intervention services integrated into their programs. However, screening for alcohol use may uncover other problems, such as problem drug use and mental illness. Among a cohort of 878 injured trauma survivors, Zatzick et al., 2012 identify a high rate (74%) of illegal drug or alcohol problems and 25% with post-traumatic stress disorder (PTSD). Among the 166 (19%) patients who received the brief intervention for alcohol, 70% had a concomitant illegal drug use or PTSD. So, while alcohol screening and brief intervention are mandated, it uncovers substantial other substance use and mental health issues, which these programs do not typically address. This finding demonstrates that integration to improve quality and efficiency can yield further challenges in the real world. The authors suggest stepped-care interventions as a potential solution,

where the intervention adapts based on the individual's co-morbidities. Whether stepped-care interventions will work awaits further study.

3.2. Integrated models facilitate treatment of HIV and hepatitis C in addiction treatment settings

Methadone maintenance treatment for opioid dependence in the United States requires daily face-to-face dosing at the beginning of treatment, with the possibility of earning take-home doses up to once every 2 weeks. This regular patient–provider contact creates the opportunity to deliver observed medical treatment for co-morbid medical conditions. Two articles in this issue describe methadone clinic-based treatment programs that seek to improve adherence to medication treatment, one offering directly observed HIV medication dosing, the other offering concurrent group treatment for hepatitis C infection. In both models, patients and providers chose to extend the duration of the integrated care intervention beyond the study period to cover the course of medical treatment. Sorensen et al. report on the implementation of a directly administered anti-retroviral therapy program among 24 HIV-infected methadone patients. They found improved HIV viral suppression and high rates of adherence to HIV treatment. Initially intended as a 24-week pilot that would include a planned step-down in intensity, at 48 weeks 38% of the patients were still receiving daily directly administered treatment because the treatment providers and patients were not willing to transition the patients to lower intensity. This small study suggests that directly administered HIV treatment in methadone programs is feasible, popular among patients and staff, and improves HIV outcomes.

Stein et al., 2012 describe the novel implementation of a concurrent hepatitis C infection group treatment program among 42 opioid dependent patients, most of whom were receiving methadone maintenance at multi-disciplinary drug treatment center. Concurrent group treatment included weekly group meetings for patients who initiated and continued through treatment together, experiencing the same treatment milestones together. Groups were co-led by a medical provider and peer educator and included elements of a traditional medical visit such as checking vital signs, administering pegylated interferon injections and provision of prescriptions during the group visit. This treatment program achieved treatment success rates comparable to previously published randomized clinical trials (Jacobson, McHutchison, Dusheiko, et al., 2011; Litwin, Harris, Nahvi, et al., 2009; Poordad, McCone, Bacon, et al., 2011; Rumi, Aghemo, Prati, et al., 2010; von Wagner, Huber, Berg, et al., 2005). This program, like that of Sorensen et al. above, was extended beyond the initially-intended 12 weeks to the full treatment duration (up to 48 weeks) because almost all patients wanted to continue group treatment. This study shows the promise of group medical treatment for hepatitis C within addiction treatment settings. It merits further study in controlled trials with more diverse addiction treatment populations —including those on buprenorphine maintenance treatment.

3.3. Primary care models can integrate addiction and medical care for HIV and hepatitis C

Office-based opioid dependence treatment with buprenorphine is effective in primary care settings (Fiellin, Pantalon, Chawarski, et al., 2006). Clinical guidelines mandate that counseling be available, yet how much counseling should delivered and by whom is not clear (Sullivan, Barry, Moore, et al., 2006). Tetrault et al., 2012 report the results of a randomized controlled trial of 15-minute physician-delivered counseling (PM) every other week compared to PM plus an additional 45-minute nurse-delivered counseling every week for opioid dependent patients initiating buprenorphine/naloxone treatment in an HIV primary care clinic. No differences in addiction or HIV-related outcomes were demonstrated. However, patients in both groups had improved control of their HIV when taking buprenorphine/naloxone. This study provides further confirmation that buprenorphine/naloxone treatment integrated into an HIV clinic has multiple benefits for opioid-dependent, HIV-infected patients, regardless of the level of counseling available.

For treatment of hepatitis C infection, achieving the success rates found in clinical trials in less selected, more diverse urban populations has been challenging (Feuerstadt, Bunim, Garcia, et al., 2010). Initiation of hepatitis C treatment in real-world patients is a challenge because of the subacute presentation, competing priorities, numerous relative contraindications, and the length, complexity, and side effects of the medication. Islam et al., 2012. describe an Australian effort to increase uptake of hepatitis C treatment through screening and facilitated referral from an integrated primary care and syringe access program. Of 143 patients with confirmed hepatitis C infection, 67% were referred to specialty care and 48% attended at least one appointment, but only 7.5% initiated hepatitis C treatment. This study shows that a primary care model integrated into a syringe access program can facilitate an appointment with a specialist, but treatment initiation remains low. In order to treat more of those at highest risk for hepatitis C infection—people who inject drugs—innovative and integrated programs are needed that build on the experience of Islam et al., 2012.

3.4. Buprenorphine/naloxone for co-occurring chronic pain and opioid dependence

Caring for patients with chronic pain and opioid dependence is challenging because opioid treatment both reduces the pain and has the potential to worsen addiction (Barry, Irwin, Jones, et al., 2010). Pade et al., 2012 describe the concomitant treatment of chronic pain and opioid dependence with buprenorphine/naloxone within a primary care-based co-occurring disorders clinic at the Albuquerque Veteran Affairs Medical Center. The clinic provided team-based primary care, opioid dependence treatment and psychiatric evaluation for patients with chronic pain and opioid dependence. Patient retention was high and pain scores improved in pre–post analyses. While chronic pain is a relative contraindication for buprenorphine treatment because of its partial agonist ceiling effect, this study supports the use of buprenorphine/naloxone by a primary care-based multi-disciplinary care team as a well-tolerated alternative to full opioid agonists for many patients with chronic pain and opioid dependence. Further research should focus on buprenorphine dose ranging and standardization of pain outcomes and may ultimately determine whether buprenorphine/naloxone should be considered as a first-line treatment for patients with chronic pain at high risk for opioid dependence and/or overdose.

4. Realizing the potential of addiction pharmacotherapy

When medications are prescribed for substance use disorders, these conditions unavoidably become medicalized. The people with substance use disorders become patients, as a prescriber now must be involved in the care. Side effects and drug interactions need to be monitored. The study by Pade et al., 2012 described above demonstrated how integration of treatment for both medical and substance use conditions occurs by co-locating the care, but also can hinge on the innovative use of medications to treat two problems at the same time. Two other studies in this issue describe pharmacotherapy innovations within integrated treatment models.

4.1. Buprenorphine/naloxone by mobile medical van

Schwarz et al., 2012 describe the delivery of buprenorphine/naloxone treatment for opioid dependence among a population that was not been included in prior randomized controlled trials. They report on Project BEST (Buprenorphine Entry into Substance Abuse Treatment), a mobile medical van-based program linked to a syringe

access program that brought medical care and buprenorphine/naloxone treatment for opioid dependence into four impoverished neighborhoods in New Haven, CT. Patients retained on buprenorphine/naloxone for more than 1 week had fewer emergency department visits that those retained less than 1 week, but hospitalizations and lengths of stay did not differ. Although not a conclusive trial, this study demonstrates that retaining patients in community-based, medication-oriented addiction care might reduce utilization of emergency care.

4.2. Extended-release naltrexone for alcohol dependence delivered in primary care

Extended-release naltrexone (XR-NTX) is FDA-approved for the treatment of alcohol dependence and opioid dependence. It is typically dosed monthly via a medical provider-delivered injection. Lee et al. (2010) previously demonstrated a 56% treatment completion rate and improved drinking outcomes at 12 weeks using XR-NTX in a primary care clinic with physician-delivered medical management counseling. The current study describes extended follow-up (Lee). Of 40 patients who completed the initial 12-week study, 19 (48%) continued treatment for a median of 38 weeks with persistently low levels of drinking. Of the original 72 patients who entered the original study, 7 (10%) completed the full 15 months of treatment. Thus, in this real world primary care-based study, a small group did continue to benefit from long-term XR-NTX. Further research should focus on improving retention and developing alternative strategies for those patients who are less successful.

5. Conclusions

As the implementation of health care reform progresses with conceptual support for the integration of the screening and treatment of substance use disorders and medical conditions, this special issue of the *Journal of Substance Abuse Treatment* offers multiple examples of innovative care models that put the concept of integration into practice. These papers examine important issues underlying the quality of substance use intervention delivery in medical settings; detection and co-management of co-morbidities that may be uncovered when integrated care is delivered; and innovative pharmacotherapy strategies. Integration is a key feature of health system reform that promises to improve the access, quality and value of care for all patients, but especially those with co-occurring substance use, mental health and medical disorders. Hopefully, the insights from this collection will inform this important work.

Genetic, Physiological, and Lifestyle Predictors of Mortality in the General Population

Stefan Walter, MA, MSc, MPH, Johan Mackenbach, MD, PhD, Zoltán Vokó, MD, PhD, Stefan Lhachimi, MPP, MSc, M. Arfan Ikram, MD, PhD, André G. Uitterlinden, PhD, Anne B. Newman, MD, MPH, Joanne M. Murabito, MD, ScM, Melissa E. Garcia, MPH, Vilmundur Gudnason, MD, PhD, Toshiko Tanaka, PhD, Gregory J. Tranah, PhD, Henri Wallaschofski, MD, Thomas Kocher, MD, Lenore J. Launer, PhD, Nora Franceschini, MD, MPH, Maarten Schipper, PhD, Albert Hofman, MD, PhD, and Henning Tiemeier, MD, PhD

Objectives. We investigated the quality of 162 variables, focusing on the contribution of genetic markers, used solely or in combination with other characteristics, when predicting mortality.

Methods. In 5974 participants from the Rotterdam Study, followed for a median of 15.1 years, 7 groups of factors including age and gender, genetics, socioeconomics, lifestyle, physiological characteristics, prevalent diseases, and indicators of general health were related to all-cause mortality. Genetic variables were identified from 8 genome-wide association scans (n = 19 033) and literature review.

Results. We observed 3174 deaths during follow-up. The fully adjusted model (C-statistic for 15-year follow-up [C_{15y}] = 0.80; 95% confidence interval [CI] = 0.75, 0.77) predicted mortality well. Most of the additional information apart from age and sex stemmed from physiological markers, prevalent diseases, and general health. Socioeconomic factors and lifestyle contributed meaningfully to mortality risk prediction with longer prediction horizon. Although specific genetic factors were independently associated with mortality, jointly they contributed little to mortality prediction (C_{15y} = 0.56; 95% CI = 0.55, 0.57).

Conclusions. Mortality can be predicted reasonably well over a long period. Genetic factors independently predict mortality, but only modestly more than other risk indicators. (*Am J Public Health.* 2012;102:e3–e10. doi:10.2105/AJPH.2011.300596)

In the 20th century, life expectancy at birth increased from 50 years to over 80 years in Western countries.[1] Demographers repeatedly predicted that it had reached a ceiling, but life expectancy in record countries continues to rise by an average of 3 months each year.[2] Although epidemiological research has identified numerous predictors of mortality, information about their comparative effect sizes and long-term predictive power is sparse. Prior research has often been limited by a short period of follow-up, a limited set of covariates, or a focus on cause-specific mortality. Only a few studies have evaluated the potential for explaining mortality from a broader perspective by jointly analyzing demographic characteristics, lifestyle factors, and indicators of health and disease.[3–7] It is still unclear whether genetic information can be used to predict mortality, but recent advances in genomic technology allow for the inclusion of genetic markers in the prediction of mortality.

We combined traditional indicators of mortality risk with genetic factors, derived from a meta-analysis of 8 genome-wide association studies and the literature, and associated them with mortality over 15 years of follow-up. Our aims were twofold: first, to identify independent determinants of mortality by analyzing 162 a priori identified risk factors; second, to provide information on the independent and combined potential of genetic markers in predicting mortality.

METHODS

The Rotterdam Study is a population-based prospective cohort initiated in 1990. It was designed to investigate risk factors for diseases in 7983 participants aged 55 years or older in the Ommoord district of Rotterdam, The Netherlands.[8,9] In the initial and subsequent investigation waves, trained research assistants collected data on health, medication use, medical and family history, and lifestyle factors in extensive home interviews. Participants subsequently visited the research center for clinical examinations, with a special emphasis on imaging and on collecting and storing biospecimens to facilitate in-depth molecular and genetic analyses. Data analyzed in this study concern 5974 participants with genetic information available from the first wave of the Rotterdam Study.

Predictors

We organized baseline data into related groups: age and gender, genetics, socioeconomics, lifestyle, physiology, diseases, and general health. We hypothesized a priori that genetics, socioeconomics, and lifestyle were associated with long-term health effects, whereas physiology, disease, and general health were more likely associated with short-term mortality.[10] Overall, we analyzed 162 risk indicators in this study: 69 previously studied risk factors for mortality and 93 single nucleotide polymorphisms (SNPs).

To study possible genetic risk factors of mortality, we used the genetic data of 19 033 participants (women = 55%) aged 55 years and older from 8 discovery cohorts of European ancestry. These people were participants not of the Rotterdam Study but of the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE), of which the Rotterdam Study is a part.[11] We identified the top 50 loci from the meta-analysis of genome-wide association studies on time to death. In addition, we used 43 SNPs that mapped to genes from a seminal review.[1] For the analysis, we extracted all SNPs from the imputed gene information of the Rotterdam Study, except for apolipoprotein E (*APOE*), which we genotyped directly.[12]

TABLE 1—Descriptive Statistics (Unadjusted and Completely Adjusted Models) and Association to 15-Year Mortality: The Rotterdam Study, 1990–2009

Variable	Baseline, Mean ±SD or No. (%)	Univariate		Final Model	
		RR (95% CI)	*P*	RR (95% CI)	*P*
Age, y	69.43 ±9.10	1.12 (1.11, 1.12)	< .001	1.09 (1.08, 1.10)	< . 001

Note. Chr = chromosome; CI = confidence interval; CVA = cardiovascular accident; GWA = genome-wide association; RR = relative risk. Total number of participants was 5974. The table shows all variables significant in the final model. Variables included in the full model but not included in this table are the following: socioeconomics: education, social class, occupation, insurance, living circumstance, death of spouse; lifestyle: alcohol consumption in g/day, fruit consumption in g/day, vegetable consumption in g/day; physiology: waist circumference, high density lipoprotein cholesterol, bone mineral density of lumbar spine, bone mineral density of femoral neck; general health: specialist visit within the last month, number of specialist visits in the last year, general practitioner visit within the last month, number of general practitioner visits in the last year, hospitalization within the last year, falls in the previous month, activities of daily living; disease: gout, vertebral fracture, cardiovascular accident, transient ischemic attack, hip fracture, coronary operation.
[a]Values represent the frequency of allele 1.

Information about cohort characteristics, genotyping, and imputation of the discovery set is presented in Tables A and B (available as a supplement to the online version of this article at http://www.ajph.org).

We included the following variables describing the socioeconomic status of the study population: education, employment status, monthly income, social class (derived from occupation of head of the household), health insurance status, number of children, whether living independently or in a nursing home, whether living with a partner, and death of spouse.[8,9] We included the following indicators of lifestyle: riding a bike, alcohol consumption, smoking, energy intake, and fruit and vegetable consumption.[13,14]

We assessed physiological characteristics in terms of body weight, body mass index, waist circumference, hip circumference, waist-to-hip ratio, sitting systolic and diastolic blood pressures, leukocyte count, erythrocyte sedimentation rate, albumin level, total cholesterol level, high-density lipoprotein cholesterol, creatinine, uric acid, serum C-reactive protein, postload insulin, bone mineral density of the femoral neck and lumbar spine, and atherosclerotic plaques. We assessed all physiological variables using standard medical, laboratory, and imaging procedures as described previously.[15–20]

On the basis of self-report, investigations at the baseline center visit, medical record information, and drug utilization, we defined the following prevalent diseases: diabetes, left ventricular hypertrophy, atrial fibrillation, hypertension, hip fracture, peripheral artery disease, myocardial infarction, heart failure, dementia, gout, Parkinson's disease, stroke, transient ischemic attack, cancer, cognitive function (Mini-Mental State Examination), and coronary operation.[21–27]

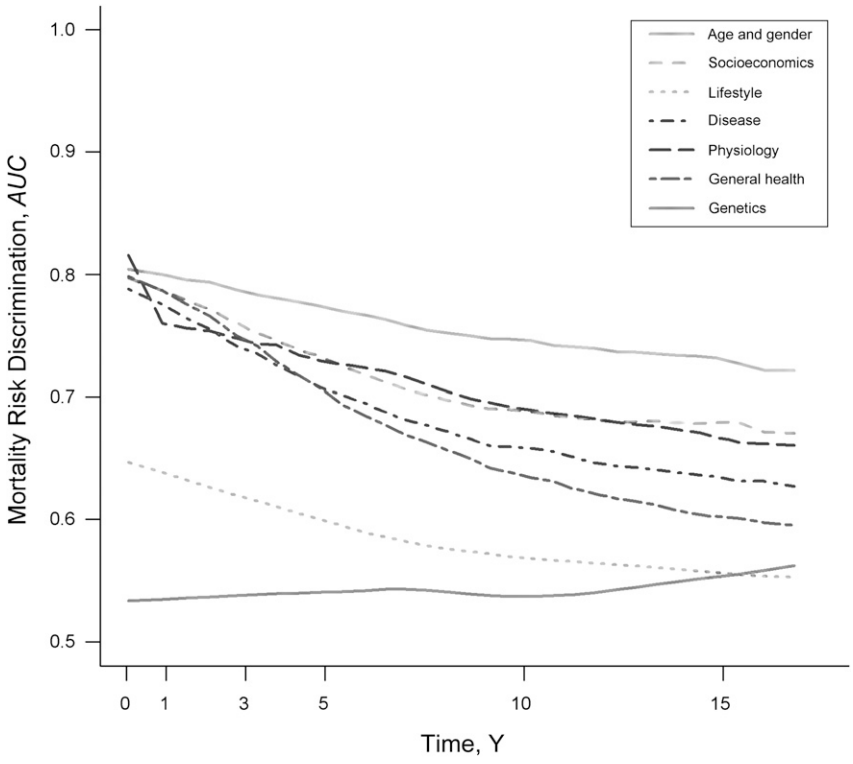
General health included the following: activities of daily living[28] and instrumental activities of daily living,[29] health care utilization, self-perceived comparative health, accidental falls, shortness of breath, past serious illness and hospitalization, unintentional weight loss, and self-reported memory complaints.

Outcome

The outcome measure was time to death from any cause. All participants of the Rotterdam Study were under continuous surveillance; general practitioners' and hospital records, as well as death certificates from the municipality, were used to identify participants who died before January 1, 2009. The median follow-up was 15.1 years (range = 0.05–19.50).

Statistical Analysis

We used SAS 9.2 (SAS Institute Inc, Cary, NC) and the PROC MI procedure to impute to 5 complete data sets. We set the maximum missingness for analysis of the data at 30% a priori. The percentage of missing information is reported in Table C (available as a supplement



Note. AUC = area under the curve.

FIGURE 1—Time-dependent receiver-operating characteristic curves for prediction of mortality for different groups of variables: The Rotterdam Study, 1990–2009.

to the online version of this article at http://www.ajph.org). Other than age, all continuous variables were standardized to facilitate the comparison of effect sizes. The estimates represent the effect of a change of 1 standard deviation.

We analyzed the risk indicators and their association with mortality with Cox proportional hazard models. We calculated unadjusted hazard ratios and the confidence intervals of each, and subsequently optimized the predefined groups separately, adjusting for age and gender within each group, by means of stacked imputed backward regression, with $P = .2$ as the exclusion threshold.[30] Finally, we combined all remaining variables in a final model using backward regression. We also used least absolute shrinkage and selection operator (LASSO) penalized regression as implemented in R (R Development Core Team, Vienna, Austria) in the package "penalized" to validate the results from backward regressions.[31,32] We evaluated the proportional hazard assumption using Schoenfeld residuals.[33] Variables that did not fulfill the proportional hazards assumption in the imputed datasets were modeled with piecewise constant Heaviside functions.[34] We considered $P < .05$ from 2-sided tests as statistically significant.

We used time-dependent receiver operating characteristic (ROC) curves to compare the predictive performance of the different variable groups over time.[35] ROC curves describe the relationship between sensitivity (true positive rate) and 1 − specificity (false positive rate) for all possible cutoffs of a marker to distinguish between high-risk participants and low-risk participants. We also computed the C-index, the probability that a participant who dies on any given day during a specified time interval has a higher predictive score than one who survives beyond that day. For this part of the analysis, we accounted for residual time dependency using Schoenfeld smoothing.[35] We estimated confidence intervals using cross-validation in 500 bootstrap samples.

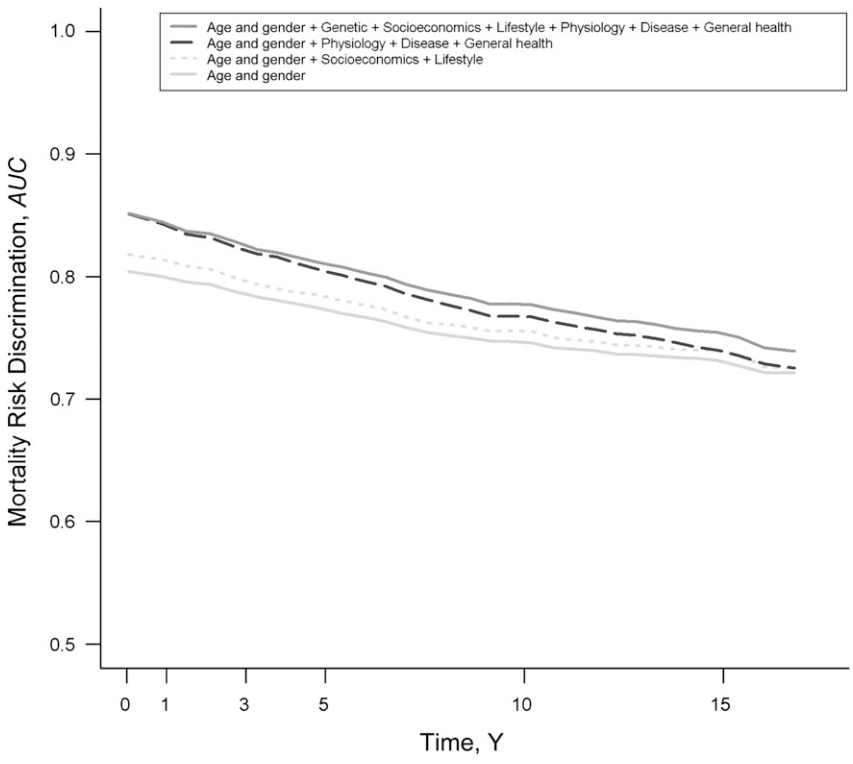
RESULTS

At baseline, participants were on average 69 years of age (range = 55–99 years; Table 1) and 59% were female. Of the 5974 participants, 3174 died (mortality rate = 4.2 per 100 person-years) during the follow-up period. From 162 a priori identified risk factors of mortality (supplemental Table C), backward regression retained 108 variables independently in the final model. Of these, 36 were significantly related to mortality ($P < .05$) as independent risk factors (Table 1). Age (hazard ratio [HR] = 1.09; 95% confidence interval [CI] = 1.08, 1.10) and female gender (HR = 0.71; 95% CI = 0.62, 0.81) were strongly associated with mortality (Table 1).

Of the candidate genes, a priori identified in the literature, *APOE,* insulin-like growth factor 1 receptor (*IGF1R*), and Werner syndrome, RecQ helicase-like (*WRN*) were significant and independent predictors of mortality. From the 50 independent loci, identified from the meta-analysis of 8 discovery genome-wide association studies on time to death, 2 SNPs in the neighborhood of tripartite motif-containing 32 (*TRIM32*) and methionine adenosyltransferase II, β (*MAT2B*) were associated with mortality.

Social class and living in serviced housing were independently associated with risk of death. Smoking status and pack-years as well as energy intake were also associated with mortality. The physiological measures blood pressure, body mass index, and waist circumference, and, in particular, the risk indicators assessed in blood (such as erythrocyte sedimentation rate, leukocytes, creatinine, C-reactive protein, and total cholesterol) or with imaging (such as bone mineral density of the femoral neck and aortic calcification) were all independently related to mortality. Diabetes, cardiac diseases, Parkinson's disease, cancer, and cognitive function remained independently associated with death. Self-perceived comparative health was a good indicator of mortality risk, as were unintentional weight loss and serious illness in the past 5 years.

The predictive power of the variable groups is best explained in 2 ways. First, Figures 1 and 2 show the development of predictive quality



Note. AUC = area under the curve.

FIGURE 2—Time-dependent receiver-operating characteristic curves for prediction of mortality for age and gender and differently combined models: The Rotterdam Study, 1990–2009.

over time. For each point during follow-up, the graphs depict the respective time-dependent area under the curve of a given variable group. Next, Table 2 quantifies the predictive quality for 5 specific prediction intervals (1, 3, 5, 10, and 15 years).

Figure 1 shows that over time, all variable groups except genetic risk markers exhibited decreasing ability to predict death. Figure 1 and Table 2 also demonstrate that prediction based solely on age and gender consistently outperformed all other groups of variables (C-statistic for 15-year follow-up [C_{15y}] = 0.76; 95% CI = 0.75, 0.77; Table 2). Physiological risk and socioeconomic characteristics each predicted mortality equally well over 15 years (each $C_{15y} = 0.72$; 95% CI = 0.71, 0.73). Although of significantly less predictive quality, the C-index of genetic risk markers was still better than chance ($C_{15y} = 0.56$; 95% CI = 0.55, 0.57).

Figure 2 shows the performance of the age- and gender-adjusted model compared with the fully adjusted model ($C_{15y} = 0.80$; 95% CI = 0.79, 0.81). Whereas adding socioeconomic and lifestyle information to age and gender ($C_{15y} = 0.77$; 95% CI = 0.77, 0.78) only slightly improved the predictive quality, the combination of age, gender, general health, disease, and physiology ($C_{15y} = 0.79$; 95% CI = 0.78, 0.80) predicted mortality almost as well as all covariates that remained after backward regression.

To allow comparison with other studies of cause-specific mortality and different population health status, we report the associations of the final model stratified by prevalent, baseline disease status and for cardiovascular disease mortality in Table D (available as a supplement to the online version of this article at http://www.ajph.org).

DISCUSSION

From a set of 162 established risk factors and candidate SNPs for mortality, we identified 36 (31 nongenetic, 5 genetic) independent and significant predictors of mortality. Specific genetic factors were independently associated with mortality and jointly predicted mortality better than chance. However, genetic information added little to age, gender, and other traditional predictors of mortality.

This analysis confirms prior findings that multiple diseases, as well as socioeconomics and lifestyle, jointly influence mortality in the aging adult population.[3,6] Numerous predictors remained independently and significantly associated with mortality. Although several markers of prevalent disease remained associated with mortality, their risk ratios were attenuated. Others, such as prevalent dementia, cerebrovascular accidents, and transient ischemic attacks, were not more effective at predicting mortality than indicators of disease severity and subclinical disease such as the Mini-Mental State Examination and serum C-reactive protein.

Several specific SNPs were independently associated with mortality in our analysis. In accordance with the literature, each additional copy of the *APOE* ε4 allele increased mortality in our study cohort.[1,36,37] Similarly, the *IGF1R* and *WRN* genes have been described before as being associated with longevity and aging, respectively, via improving stress resistance, innate immunity, metabolic maintenance and repair of DNA.[1] This study also confirmed 2 novel loci in the vicinity of the *TRIM32* and *MAT2B* genes as being associated with death. These 2 loci were identified from the pool of SNPs identified by the meta-analysis of the discovery cohorts in the genome-wide association studies. These genes have recently been associated with cancer proliferation.[38,39]

Interestingly, unlike the predictive ability of all other domains, the ability of genetic markers to predict death remained constant during the course of follow-up. The stability of the predictive power of the SNPs observed in this study is probably due to the permanent nature of the genetic makeup. Other variables showed decreasing predictive power over time that can be explained by changes in the value of these variables during the course of follow-up.

Our results support the view that specific SNPs can be identified that are associated with mortality and might be used for risk prediction.[40,41] The results also show, however, that these common SNPs have very limited predictive power and that, especially when used in combination

TABLE 2—C-Index for Different Combinations of Risk Factors at Different Time Points During 15-Year Follow-Up: The Rotterdam Study, 1990–2009

	0–1 Years, C-Index (95% CI)	0–3 Years, C-Index (95% CI)	0–5 Years, C-Index (95% CI)	0–10 Years, C-Index (95% CI)	0–15 Years, C-Index (95% CI)
Age and gender	0.80 (0.78, 0.82)	0.80 (0.78, 0.81)	0.79 (0.77, 0.8)	0.77 (0.76, 0.78)	0.76 (0.75, 0.77)
Genetics	0.55 (0.53, 0.58)	0.55 (0.53, 0.58)	0.55 (0.54, 0.57)	0.56 (0.54, 0.57)	0.56 (0.55, 0.57)

Age and gender + socioeconomics and lifestyle	0.82 (0.79, 0.84)	0.81 (0.79, 0.83)	0.80 (0.79, 0.82)	0.78 (0.78, 0.79)	0.77 (0.77, 0.78)
Age and gender + general health + disease + physiology	0.85 (0.82, 0.87)	0.84 (0.82, 0.86)	0.83 (0.81, 0.84)	0.81 (0.8, 0.82)	0.79 (0.78, 0.8)
Full model: age and gender + socioeconomics + lifestyle + general health + disease + physiology + genetics	0.85 (0.83, 0.88)	0.84 (0.82, 0.86)	0.83 (0.82, 0.85)	0.81 (0.81, 0.82)	0.80 (0.79, 0.81)

Note. CI = confidence interval. The C-indices in this table are the areas under the curve of the graphs in Figures 1 and 2 for 5 different time intervals (1, 3, 5, 10, and 15 y). A C-index of 0.50 indicates a prediction of mortality that is no better than chance, whereas a C-index of 1.0 reflects perfect predictive quality.

with traditional risk factors, they contribute very little, if anything at all, to improve the prediction of death in the general population aged 55 years and older.

Another finding relates to age and gender as predictors of mortality. In our study, the relative risk for mortality per year of age in the univariate model was only reduced by 25% in the fully adjusted model. This is compatible with the idea that aging is not merely the clinical manifestation of disease but an underlying, disease-independent accumulation of pathophysiological changes that favor mortality over time.[42–44]

The gender differences in this study were not due to differences in prevalent diseases at the onset of the study. Females exhibited even stronger reduced risks after adjustment for other risk factors. This strongly suggests that the gender difference in survival cannot be explained by differences in health behavior and disease at baseline.[45] We can only speculate that the survival benefits of females can be found in gender effects or different genetic origins not accounted for in this analysis. One of the potential genetic candidates that could contribute to the female survival advantage is the X chromosome.[46] Another genetic candidate is mitochondrial DNA (mtDNA). It has been suggested that, because mtDNA is inherited from the maternal line, a possible intergenomic conflict between mtDNA and nuclear DNA favors female survival.[47] We could not include markers on the X chromosome and mtDNA because the X chromosome is not commonly analyzed in all the discovery cohorts and mtDNA is also not available on all genotyping platforms.

Prediction of mortality by age and gender improved by only 5% upon inclusion of all independent mortality predictors over the entire 15 years of follow-up. This is particularly interesting considering the multitude of independent risk factors identified in this study, and because all groups contributed significant variables. From the time-dependent area-under-the-curve analyses, 2 observations are particularly noteworthy: first, most of the additional information beyond age and gender stemmed from indicators of physiology, disease, and general health; second, although socioeconomic factors were equally good at predicting mortality as indicators of disease, the combination of socioeconomics, lifestyle, and genetic markers contributed visibly to the explanation of mortality risk only after 10 years of follow-up and beyond. Thus, although socioeconomics and lifestyle were associated to mortality, they seemingly exerted their effects on mortality through physiological risk indicators and disease rather than by acting independently on mortality.[48] This underscores the importance of socioeconomics and living conditions for public policy aimed at reducing health inequalities.

To summarize the findings reported here and in other studies, one can insinuate a cascade from gene to individual health to death, in which every step is accompanied by environmental influences, some of which are controlled by the individual (such as physical activity and obesity) whereas others are defined by the individual's living circumstances, cultural heritage and surroundings. Figure A (available as a supplement to the online version of this article at http://www.ajph.org) illustrates at which stage during the course of aging different interventions (e.g., improvements in living circumstances or the introduction of a new therapeutic drug) can feasibly act and which health gains could be expected.

Limitations

Caution is needed in interpreting this study. It was not our aim to evaluate the size of the mortality risk associated with single risk factors. Several of the markers in this analysis describe the same underlying construct (e.g., body composition). Therefore, the specific relative risks must be interpreted cautiously. Other important aspects of health such as physical activity and mental health are barely represented among the risk factors analyzed, as only "riding a bike" and "self-perceived comparative

health" were available to approximate these important dimensions of health. Another limitation concerns the genetic markers used in this study. We included only autosomal SNPs. Genetic risk is transferred through several other mechanisms, including DNA methylation, copy number variations, and mitochondrial DNA. Furthermore, because this study has not been replicated externally, it probably cannot be used for constructing a risk score. We did not seek external replication because of the multitude of specific risk factors and instead relied on bootstrapping and cross-validation for guiding the LASSO analysis and the estimation of the C-index. At the same time, the selection of SNPs is among the strengths of this study, as the SNPs were identified from 2 sources, independent of the population under study. Other strengths are related to the multitude of risk factors and the prospective design with long follow-up.

Conclusions

We found 36 variables that independently and significantly predicted mortality in the Rotterdam Study population. Adding further risk indicators to age and gender improved our ability to predict death, but the gain in predictive quality was modest, particularly in the long run. Surprisingly, specific genetic risk factors, independently and as a group, predicted mortality, but their added value to conventional predictors of mortality was low. Our findings also support the importance of primary prevention in the areas of socioeconomics and lifestyle, as we could illustrate how these risk factors continuously influence mortality risk independently and through their impact on physiological risk status and disease. ■

Meta-analysis
Ethnicity

ABSTRACT

Background: Candidate gene association studies for peripheral artery disease (PAD), including subclinical disease assessed with the ankle-brachial index (ABI), have been limited by the modest number of genes examined. We conducted a two stage meta-analysis of ~50,000 SNPs across ~2100 candidate genes to identify genetic variants for ABI.

Methods and results: We studied subjects of European ancestry from 8 studies (n = 21,547, 55% women, mean age 44–73 years) and African American ancestry from 5 studies (n = 7267, 60% women, mean age 41–73 years) involved in the candidate gene association resource (CARe) consortium. In each ethnic group, additive genetic models were used (with each additional copy of the minor allele corresponding to the given beta) to test each SNP for association with continuous ABI (excluding ABI > 1.40) and PAD (defined as ABI < 0.90) using linear or logistic regression with adjustment for known PAD risk factors and population stratification. We then conducted a fixed-effects inverse-variance weighted meta-analyses considering a $p < 2 \times 10^{-6}$ to denote statistical significance.

Results: In the European ancestry discovery meta-analyses, rs2171209 in *SYTL3* ($\beta = -0.007$, $p = 6.02 \times 10^{-7}$) and rs290481 in *TCF7L2* ($\beta = -0.008$, $p = 7.01 \times 10^{-7}$) were significantly associated with ABI. None of the SNP associations for PAD were significant, though a SNP in *CYP2B6* ($p = 4.99 \times 10^{-5}$) was among the strongest associations. These 3 genes are linked to key PAD risk factors (lipoprotein(a), type 2 diabetes, and smoking behavior, respectively). We sought replication in 6 population-based and 3 clinical samples (n = 15,440) for rs290481 and rs2171209. However, in the replication stage (rs2171209, $p = 0.75$; rs290481, $p = 0.19$) and in the combined discovery and replication analysis the SNP–ABI associations were no longer significant (rs2171209, $p = 1.14 \times 10^{-3}$; rs290481, $p = 8.88 \times 10^{-5}$). In African Americans, none of the SNP associations for ABI or PAD achieved an experiment-wide level of significance.

Conclusions: Genetic determinants of ABI and PAD remain elusive. Follow-up of these preliminary findings may uncover important biology given the known gene-risk factor associations. New and more powerful approaches to PAD gene discovery are warranted.

1. Introduction

Peripheral artery disease (PAD) is associated with an increased risk for incident cardiovascular disease events and mortality [1,2]. In the reduction of atherothrombosis for continued health (REACH) registry, almost two-thirds of the individuals with PAD had concomitant clinically evident atherosclerotic disease in the cerebrovascular or coronary artery disease (CAD) territories whereas only one-quarter of the individuals with coronary disease had clinically evident atherosclerotic involvement of other arterial beds [3]. While PAD and CAD share many common risk factors, cigarette smoking and type 2 diabetes are stronger risk factors for PAD than for coronary artery disease [4]. The variable distribution of the burden of atherosclerosis across vascular beds among subjects at risk suggests that other factors exist, including possibly genetic factors, that may contribute to the predilection of atherosclerosis to develop in a given anatomic location. Currently, little is known about the genetic susceptibility to PAD but familial aggregation of PAD and heritability estimates suggest a significant genetic contribution [5–10].

The ankle brachial index (ABI) is an easy and reliable diagnostic test used to detect symptomatic as well as asymptomatic PAD [11]. A genome-wide linkage scan for ABI identified several potential candidate genes under six linkage signals in pathways of inflammation, coagulation, blood pressure regulation, and lipid metabolism [8]. A recent large genome-wide association study (GWAS) meta-analysis of European descent participants found variants in the 9p21 locus significantly associated with ABI [12]. However, there have been few candidate gene association studies for PAD, most of which have been limited by small sample size, modest number of genes examined, and lack of robust independent replication of initial findings [13]. We conducted a two stage large scale candidate gene association study of the ~2100 candidate genes included in a cardiovascular gene-centric 50K single nucleotide polymorphism (SNP) array [14] within the candidate gene association resource (CARe) consortium that included 21,547 individuals of European ancestry (1190 with ABI < 0.9) from eight cohorts and 7267 African American individuals (594 with ABI < 0.90) from six cohorts. In the second stage of the investigation, we sought to replicate our significant associations among individuals of European ancestry in 13,524 individuals from population-based cohort studies and 1916 individuals from clinically based studies. We hypothesized that this approach would lead to the identification of novel genetic variants associated with ABI and PAD (as defined by an ABI < 0.90). Furthermore, we hypothesized that some variants may influence both PAD risk factors and PAD itself, as has been observed

in genome-wide studies of lipids and coronary artery disease [15,16].

2. Methods

2.1. Discovery studies: CARe consortium and additional studies

The CARe consortium (http://public.nhlbi.nih.gov/GeneticsGenomics/home/care.aspx) was funded by the National Heart Lung and Blood Institute (NHLBI) in 2006 to explore the association of a custom cardiovascular gene centric SNP array [14] with a broad set of cardiovascular, metabolic, and inflammatory phenotypes collected across nine longitudinal cohort studies [17]. The following CARe consortium studies contributed data to the present analysis (Tables 1A and 1B): atherosclerosis risk in communities study (ARIC, $n = 9031$ European Americans, $n = 2853$ African Americans), the Cleveland family study (CFS, $n = 275$ European Americans, $n = 365$ African Americans), the cardiovascular health study (CHS, $n = 3826$ European Americans, $n = 722$ African Americans), the Framingham heart study (FHS, $n = 2701$ European Americans), the Jackson heart study (JHS, $n = 1734$ African Americans), and the multi-ethnic study of atherosclerosis (MESA, $n = 2280$ European Americans, $n = 1593$ African Americans). The Amish study ($n = 1008$), the cooperative research in the region of Augsburg (KORA F3, $n = 1807$), and the Penn diabetes heart study (PDHS, $n = 622$) cohort all used the same cardiovascular gene centric SNP array and joined the discovery stage analyses conducted in European Americans.

Description of each study is provided in the Supplementary Materials. For all studies, each participant self-identified as either White (European, European American) or African American and provided written informed consent. The Institutional Review Board at the parent institution for each respective study approved the study protocols.

The characteristics of the discovery study samples at the time of ABI measurement are presented in Tables 1A and 1B by ethnic group. More than half were women and the mean age ranged from 44 years (CFS) to 73 years (CHS) in samples of European ancestry, and from 41 years (CFS) to 73 years (CHS) in African Americans. The mean ABI was 1.10 and the prevalence of PAD (ABI < 0.90) varied across studies, ranging from 4% to 12% in European Americans and from 5% to 21% in African Americans. Risk factor burden appeared greater in African Americans, as demonstrated by higher prevalence of hypertension, type 2 diabetes, and obesity compared to European ancestry participants.

2.2. ABI phenotypes

The details of the ABI protocol for each study are provided in Supplementary Materials, Supplementary Methods Table 1. For each leg, the systolic blood pressure at each ankle was divided by the systolic blood pressure in the arm. In the ARIC study, ABI was measured in only one leg and one arm chosen at random. The lower of the two ABIs calculated with each leg was used for analyses with the exception of the Amish study which used the average of an individual's two ABIs in the analyses.

We defined two PAD phenotypes for genetic association analyses. First, we used the continuous range of ABI ≤ 1.40. Next, we defined PAD as ABI < 0.90 and conducted a case (ABI < 0.9)/control comparison (ABI ≥ 0.90 and < 1.40) analysis. Participants with an ABI > 1.40 were excluded as these subjects likely had medial artery calcification and therefore the artery would not be compressible to allow for determination of pressure in the artery. Excluding participants with ABI did not truncate the distribution substantially, and ABI was still normally distributed.

Table 1A

[a] ARIC = atherosclerosis risk in communities, CFS = Cleveland family study, CHS = cardiovascular heart study, JHS = Jackson heart study, MESA = multi-ethnic study of atherosclerosis.

2.3. Genotyping

Genotyping in the CARe cohorts and PDHS was conducted at the Broad Institute using the ITMAT-Broad-CARe (IBC) Illumina iSELECT custom array [14]. The Old Order Amish Study genotyping was also performed using the ITMAT IBC Illumina iSELECT custom array. For KORA F3 (Discovery stage) genotyping with the same array was performed in the Genome Analysis Centre, Helmholtz Zentrum München.

The IBC array was designed to capture genetic variation in loci known or postulated to be associated with cardiovascular disease, metabolic disease and inflammatory diseases [14]. Specifically, a cosmopolitan tagging approach was used to capture genetic diversity across ~2100 candidate genes [14]. Loci were primarily chosen in three groups as follows: (1) 435 loci were chosen areas with a high probability of functional significance, (2) 1349 loci were chosen as having involvement in phenotypes of interest (i.e. cardiovascular disease or cardiovascular disease-related traits such as inflammation, hemostasis, obesity, diabetes) or were well-established loci requiring a number of SNPs for coverage, and (3) 232 lower priority loci were chosen, which also included larger genes [14]. Further details on the IBC array can be found elsewhere [14]. Details of the genotyping and quality control procedures are provided in Supplementary Methods Table 2.

2.4. Statistical analysis

For each study, residuals of ABI stratified by gender and race were created from linear regression models and used as phenotypes in the association analysis; results of gender were pooled but all analyses were stratified by race. The ABI residuals were adjusted for age, clinic site for multi-site studies, principal components (participants of European ancestry) or global European ancestry (African American participants), ever smoking, type 2 diabetes, hypertension (>140/90 or use of anti-hypertensive medication), LDL cholesterol, HDL cholesterol, and body mass index (BMI). In each ethnic group, SNPs were modeled additively, and the association of each SNP with ABI was tested using linear regression. The PDHS study did not use diabetes as a covariate as all subjects were diagnosed with type 2 diabetes. For CFS and FHS, linear mixed effects (LME) models were used to account for familial correlations. Multivariable logistic regression was used to test for the association of each SNP with PAD. For CFS and FHS, generalized estimating equations (GEE) were used to account for familial correlations. The covariate adjustment for PAD was the same as used for the ABI phenotype.

A fixed effects meta-analysis with inverse-variance weighting was then conducted in PLINK V 1.0.6 [18] and Stata V 9.0 (College Station, TX) to combine the results for all studies. The association of each additional copy of the minor allele with ABI was quantified by the regression slope (β), its standard error [SE(β)] and the corresponding p-value. We calculated a meta-analysis odds ratio (OR) for each of the most significant SNP associations for PAD. The meta-analysis OR represents the increase/decrease in odds of PAD for each additional copy of the minor allele of the SNP. We also tested for heterogeneity of study-specific regression parameters using the Cochran's Q statistic in Stata V9.0, and report the p-values for heterogeneity. Associations were considered to be significant on an experiment-wide level at a p-value $\leq 2 \times 10^{-6}$ which was determined based on the estimate of the number of independent tests [19]. SNPs with MAF < 0.01 were excluded.

A gene-based test of association using the meta-analyzed p-values at the discovery stage was performed using the program Versatile Gene-Based Association Study (VEGAS) [20]; http://gump.qimr.edu.au/VEGAS/). The SNPs are matched to genes using the UCSC Genome Browser hg18 assembly with the gene region defined by ±50 kb up-and downstream of the gene. The test is based on the sum of chi-square-statistics and the linkage disequilibrium (LD) of these SNPs is taken into account according to the correlation structure in the HapMap CEU samples. An empirical p-value is provided based on all SNPs, as well as based on the SNPs within the top 20% with regard to their p-value. Since roughly 2100 genes are covered by the IBC chip, a p-value $< 2.4 \times 10^{-5}$ is considered significant.

2.5. Replication

Given that contemporary genetics consortia and results indicate that very large replication samples are needed to successfully replicate SNPs, and that false positives are an ongoing issue in studies such as these, we attempted to replicate only the two SNPs that met experiment-wide significance for ABI in European Americans in an additional 13,524 individuals of European ancestry from six population-based studies (Copenhagen city heart study, $n = 5182$; genetic study of aspirin responsiveness (GeneSTAR), $n = 618$; KORA F3 (independent of KORA F3 participants in the discovery sample), $n = 1440$; KORA F4, $n = 411$; national health and nutrition examination survey (NHANES), $n = 2358$, and prevention of renal and vascular end-stage disease (PREVEND), $n = 3515$) and 1916 individuals of European ancestry from clinically based samples (cardiovascular disease in intermittent claudication (CAVASIC), $n = 434$; genetic determinants of peripheral arterial disease (GenePAD), $n = 811$; and Linz peripheral arterial disease

Table 2A
Candidate gene SNP associations for ankle-brachial index: discovery meta-analysis, $p < 10^{-4}$. European and European Americans, $n = 21{,}547$.

(LIPAD), $n = 671$). GeneSTAR provided in silico genotyping (genotyped participants with the same candidate gene chip used in the discovery cohorts) while in the remaining studies genotyped the 2 SNPs de novo using Taqman or Sequenom genotyping platforms. Description of the replication studies, ABI protocol and calculation, and participant characteristics are provided in Supplementary Methods, Supplementary Method Table 1 and Supplementary Results Table 1.

2.6. Power and sample size for discovery and replication stages

Participants of European ancestry: With a minor allele frequency (MAF) of 0.10, additive SNP modeling, and experiment-wide significance level of 2×10^{-6}, for each additional copy of the risk allele, we have 80% power to detect a beta coefficient for ABI of 0.0092 and an OR for PAD of 1.45 in the discovery stage ($n = 21{,}547$). For European ancestry individuals in the replication stage for ABI ($n = 15{,}440$) using the more stringent significance level of 2×10^{-6} we have 80% power to detect a beta coefficient of 0.0106; using a less stringent level (i.e. $\alpha = 0.025$ based on carrying forward 2 SNPs for replication), we have 80% power to detect a beta coefficient of 0.0058. In the discovery plus replication stage for ABI ($n = 36, 987$), we have 80% power to detect a beta coefficient of 0.0065 using 2×10^{-6} as the type 1 error rate.

Participants of African-American ancestry: With a minor allele frequency (MAF) of 0.10, additive SNP modeling, and experiment-wide significance level of 2×10^{-6}, for each additional copy of the risk allele, we have 80% power to detect a beta coefficient for ABI of 0.0155 and an OR for PAD of 1.67 in the sample of 7267 individuals in the discovery stage. No replication sample was available for this ethnicity.

3. Results

3.1. European ancestry studies: meta-analysis of ABI and PAD

In European ancestry discovery samples, two SNPs were significantly associated with ABI (Table 2A, Figs. 1 and 2): each additional copy of the minor allele of rs2171209 in *SYTL3* was associated with a 0.007 lower ABI (95% CI −0.010, −0.004, $p = 6.02 \times 10^{-7}$, p for heterogeneity = 0.55) and each additional copy of the minor allele of rs290481 in *TCF7L2* was associated with a 0.008 lower ABI (95% CI −0.011, −0.005, $p = 7.01 \times 10^{-7}$, p for heterogeneity = 0.08). Rs290481 is located in intron 14 within the 3′ region of the *TCF7L2* gene on chromosome 10 is distinct from a cluster of SNPs in the 5′ region of *TCF7L2* (represented by rs7903146), previously reported to be associated with type 2 diabetes in genome-wide association studies ($r^2 = 0.001$ between rs290481 and rs7903146) [21]. Among those of European ancestry, rs2171209 was not significantly associated with the categorical PAD diagnosis made by the ABI threshold of 0.90 – each additional copy of the minor allele was associated with just a 1.09-fold greater odds of PAD (95% CI: 0.97, 1.22, $p = 0.14$); however, rs290481 was associated with PAD (OR = 1.20, 95% CI: 1.06, 1.35, $p = 0.004$), although this

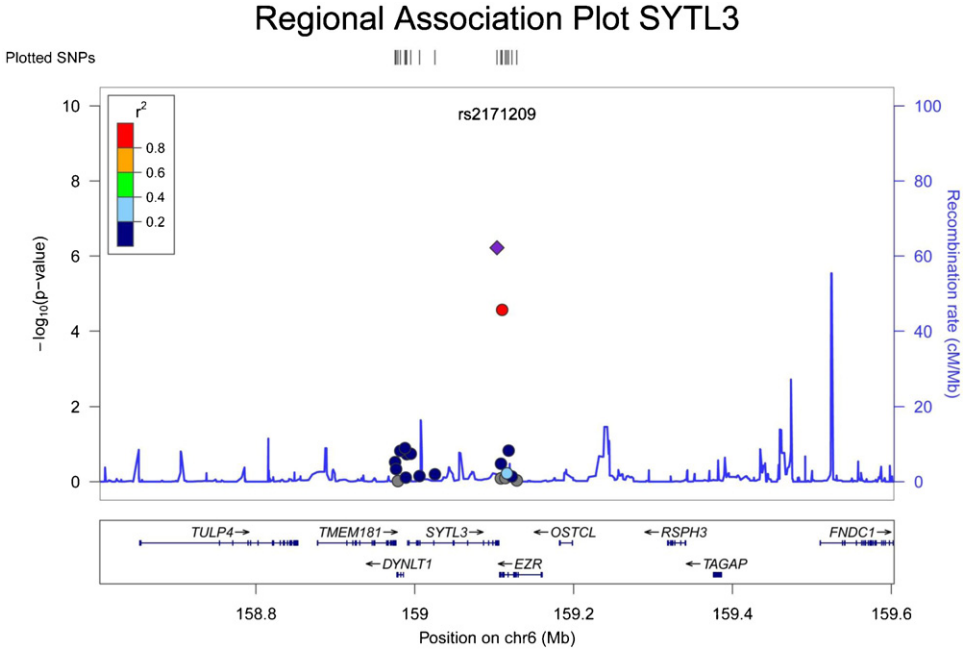

Fig. 1. This plot shows the p-values for rs2171209, as well as for SNPs in the region of rs2171209, with ABI in a meta-analysis of the discovery studies. The x-axis shows chromosomal location in Mb (chromosome 10), as well as genes residing in this region. The y-axis on the left displays the −log 10(p-value) for each SNP, and the y-axis on the right shows the recombination rate in this region. The top SNP, rs2171209 is represented as a purple diamond, while supporting SNPs and other SNPs in the area are color-coded by linkage disequilibrium with rs2171209 (see r^2 linkage disequilibrium legend on the plot). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

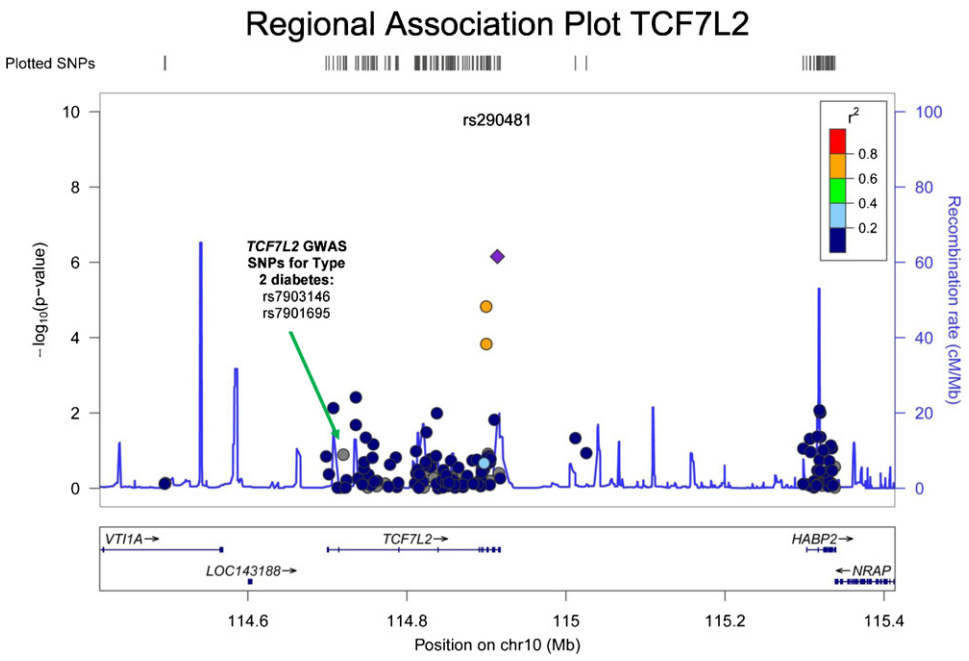

Fig. 2. This plot shows the *p*-values for rs290481, as well as for SNPs in the region of rs290481, with ABI in a meta-analysis of the discovery studies. The *x*-axis shows chromosomal location in Mb (chromosome 10), as well as genes residing in this region. The *y*-axis on the left displays the −log 10(*p*-value) for each SNP, and the *y*-axis on the right shows the recombination rate in this region. The top SNP, rs290481 is represented as a purple diamond, while supporting SNPs and other SNPs in the area are color-coded by linkage disequilibrium with rs290481 (see r^2 linkage disequilibrium legend on the plot). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of the article.)

association did not meet the experiment-wide significance level. There was no association between rs290481 and ABI ($\beta = -0.001$ 95% CI: −0.006, 0.005, $p = 0.80$) or rs2171209 and ABI ($\beta = -0.002$ 95% CI −0.009, 0.004 $p = 0.46$) detected in African Americans. One additional SNP was nominally associated with ABI in individuals of European ancestry at $p < 10^{-4}$ (Table 2A). The most significant SNP associations for ABI in models minimally adjusted for age, sex, and study site only remained similar to the fully adjusted models. When we removed all participants with type 2 diabetes from the analysis of the CARe studies (ARIC, CFS, CHS, FHS and MESA), the beta coefficients were essentially unchanged from those in Table 2A. Similarly, when we removed participants less than 60 years of age from the analysis in the CARe studies, beta coefficients were essentially unchanged from those in Table 2A.

Because rs290481 is located in a gene previously strongly associated with type 2 diabetes, we conducted a test for interaction of this genotype with type 2 diabetes for ABI within the CARe discovery cohorts (ARIC, CFS, CHS, FHS, MESA). The test for interaction was performed on an additive scale using linear regression within each CARe cohort, and then combining the results in the diabetes and no diabetes strata using fixed effect inverse-variance weighting meta-analysis. The magnitude of the effect with ABI was greater in diabetics (*p* for interaction 0.04, Supplementary Results Table 2, with each copy of the minor allele in participants with diabetes conferring a lower level of ABI ($n = 1896$, $\beta = -0.03$, $p < 0.001$) compared to participants without diabetes ($n = 16{,}685$, $\beta = -0.007$, $p = 0.007$).

The gene-based analysis using VEGAS at the discovery stage did not reveal any different significantly associated genes with continuous ABI from our individual SNP analysis (Supplementary Results Table 3). *SYTL3* and *TCF7L2* were among the most significant genes for both analyses using all SNPs and the top 20% of SNPs (*SYTL3*: *p*(all SNPs) = 0.00216, *p*(top20% of SNPs) = 0.00007; *TCF7L2*: *p*(all SNPs) = 0.03589 *p*(top20% of SNPs) = 0.00161).

In the replication stage, the association between ABI and rs2171209 in *SYTL3* was not significant in the population-based ($\beta = -0.0004$, $n = 13{,}510$, $p = 0.73$) and clinically based replication samples ($\beta = 0.001$, $n = 1890$, $p = 0.82$) (Fig. 3). Consequently, in the combined discovery plus replication meta-analysis the association was no longer significant ($n = 36{,}947$, β −0.003, $p = 1.14 \times 10^{-3}$) (Fig. 3). rs290481 in *TCF7L2* also failed to replicate in the population-based replication studies ($\beta = -0.001$, $n = 13{,}505$, $p = 0.38$) and in the clinically based replication studies ($\beta = -0.008$, $n = 1896$, $p = 0.20$) (Fig. 4). In the combined discovery and replication meta-analysis the association between rs290481 and ABI no longer met experiment-wide significance ($n = 36{,}855$, β −0.004, $p = 8.88 \times 10^{-5}$) (Fig. 4).

None of the SNP associations in individuals of European ancestry achieved experiment-wide significance for PAD (Table 2B). One of the most significant associations for PAD was in a coding, non-synonymous SNP rs3745274 on chromosome 19 in *CYP2B6* (OR 1.24, $p = 4.99 \times 10^{-5}$).

3.2. African-Americans: meta-analysis of ABI and PAD

In African Americans none of the SNP associations with ABI and PAD were statistically significant (Tables 3A and 3B). The strongest association for ABI was rs2243100 on chromosome 17 in *SLC25A11* (β 0.011 95% CI 0.006, 0.017, $p = 5 \times 10^{-5}$) and for PAD was rs4987756 on chromosome 18 in *BCL2* (OR 2.99, 95% CI 1.88, 4.76, $p = 3.78 \times 10^{-6}$).

4. Discussion

We conducted a large candidate gene association study of ~2100 cardiovascular candidate genes for ABI and PAD in over 21,000 individuals of European ancestry and over 7000 African Americans. In individuals of European ancestry, a SNP in the *TCF7L2* gene (rs290481) and a SNP in the *SYTL3* gene (rs2171209) were significantly associated in the discovery stage with variation in ABI measurements and a suggestive association was identified in a SNP in *CYP2B6* for PAD. These findings are intriguing as the genes are linked to key PAD risk factors. *TCF7L2* is the strongest

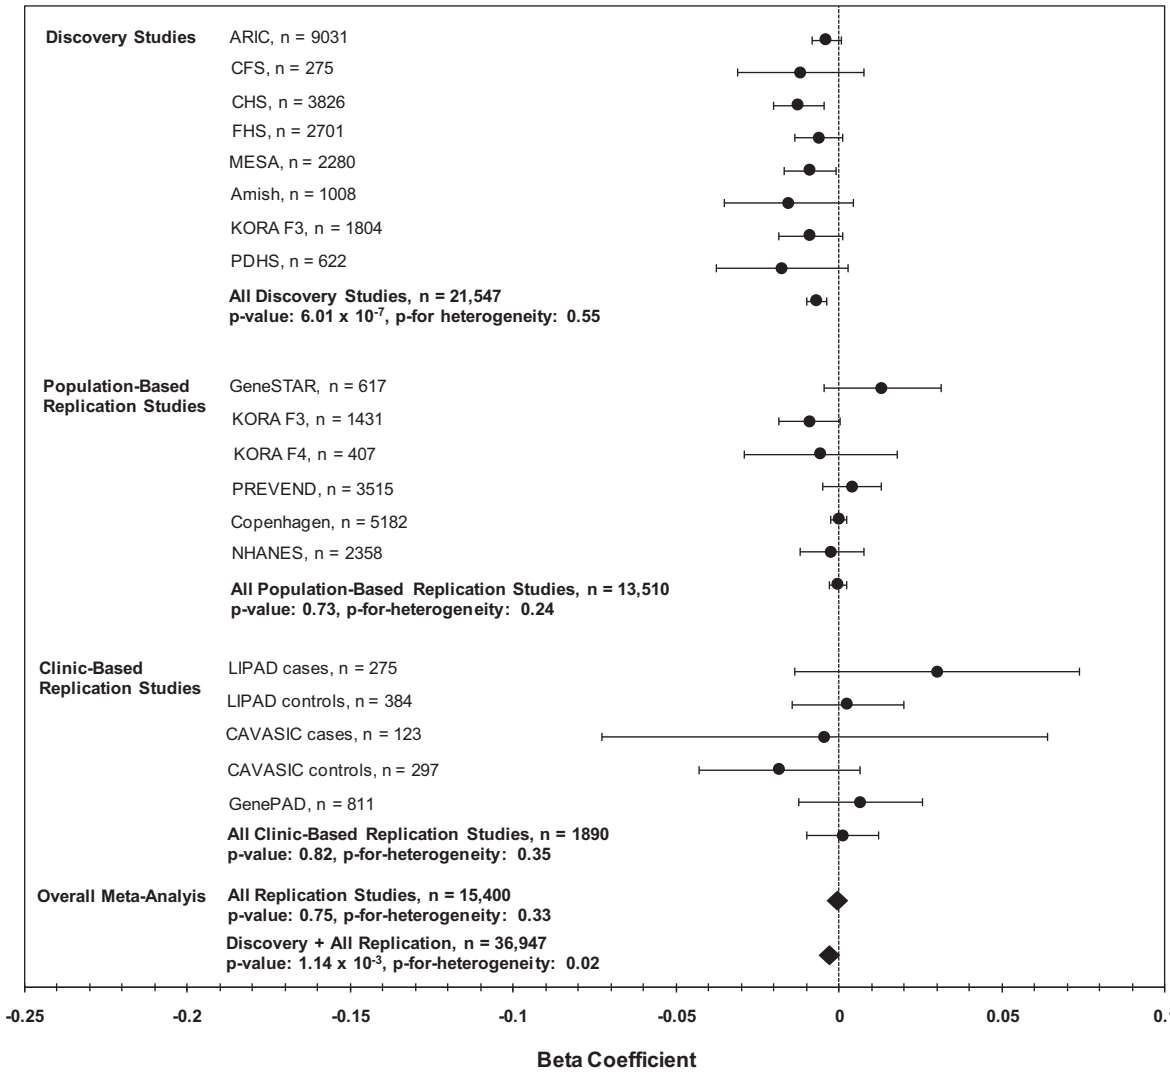

Fig. 3. This plot shows the association of rs2171209 with ABI for each of the discovery and replication studies, and then results with these studies combined by meta-analysis. The *x*-axis contains beta coefficients for the association of rs2171209 with ABI in the discovery and replication studies, and the *y*-axis shows studies or groups of studies. Circles represent the beta coefficient (except for overall replication and discovery + replication meta-analysis results, where beta coefficients are designated by a diamond), and error bars are 95% confidence intervals. *p*-Values for heterogeneity are by Cochran's Q. Study abbreviations are as follows: ARIC = atherosclerosis risk in communities, CFS = Cleveland family study, CHS = cardiovascular health study, FHS = Framingham heart study, MESA = multi-ethnic study of atherosclerosis, KORA F3 and KORA F4 = cooperative research in the region of Augsburg, PDHS = Penn diabetes heart study, GeneSTAR = genetic study of aspirin responsiveness, PREVEND = prevention of renal and vascular end-stage disease, Copenhagen = Copenhagen city heart study, NHANES = national health and nutrition examination survey, LIPAD = Linz peripheral arterial disease, CAVASIC = cardiovascular disease in intermittent claudication, and GenePAD = genetic determinants of peripheral arterial disease.

genetic risk factor for susceptibility to type 2 diabetes [22–25] and *CYP2B6* affects smoking behavior [26] and thus may be important in tobacco-related diseases such as PAD. However, we were unable to replicate the SNP–ABI associations in additional samples from population-based studies or clinically based samples. Furthermore, the associations were not detected in African Americans. We did not observe any significant associations for ABI or PAD in African Americans, possibly due to the relatively small sample size limiting our power to detect associations.

4.1. In the context of the current literature

Genetic factors leading to susceptibility to PAD remain largely unknown but are likely to be attributed to variants in many genes, each with small effects [13] or possibly from rare variants (minor allele frequency < 1%) with larger effects. While many of these variants may lead to risk for PAD through effects on established risk factors or shared effects with CAD and other atherosclerotic diseases [27], other variants may uniquely influence development

of arterial disease in the lower extremities. Although our findings after the discovery stage did not bear out in the replication samples, the two genes are interesting candidates for ABI in light of the current literature and deserve some discussion. Genome-wide association studies of individuals of European ancestry have consistently reported an association between genetic variants of *TCF7L2* and type 2 diabetes that has been confirmed in Japanese and African American samples [19,22–24,28–30]. However, our SNP in *TCF7L2*, rs290481 was not significantly associated with type 2 diabetes in large scale association analysis [21]. The replicated index SNP in *TCF7L2* associated with type 2 diabetes is rs7902146. Further, rs290481 is not in linkage disequilibrium with rs7902146 ($r^2 = 0.001$) [21]. *TCF7L2* encodes a high mobility group (HMG) box-containing transcription factor that is involved in the Wnt signaling pathway [31] and is associated with impaired beta cell function, impaired insulin secretion and increased hepatic glucose production. Therefore, the *TCF7L2* association in our discovery cohorts that presented even after adjusting for type 2 diabetes might deserve further attention in functional studies to elucidate its role in atherosclerosis.

The association between *SYTL3* and ABI may be mediated by lipoprotein(a) (Lp(a)). A genome-wide association study in a small founder population of 386 Hutterites identified an association between the extended *LPA* gene region on chromosome 6q26–q27 including *SYTL3* SNPs with Lp(a) levels[32]. Genetic variation within the *LPA* gene region including a very common copy number variation and other genetic variants explain up to 90% of Lp(a) concentrations[33]. Since Lp(a) concentrations and genetic variants within the *LPA* region are a strong risk factor for cardiovascular disease[34], it might well be that a SNP in the *SYTL3* gene reflects a signal from *LPA*. Polymorphisms within the *LPA* gene region were associated with PAD in a past study [35]. Lp(a) may be an independent risk factor for PAD [36] but results are conflicting [37,38].

4.2. Strengths and limitations

To our knowledge this study is the largest candidate gene association study concerning ABI conducted in both individuals of European ancestry and African Americans and includes the most extensive number of candidate genes investigated. In the CARe consortium, imputed GWAS data is available on the African-American participants; however, given our relatively modest African-American sample size, we chose to perform analysis of the IBC chip first. We have also chosen the IBC chip because it was specifically designed as a large scale cardiovascular-centric candidate gene array, and the genetic variants on the chip were informed by GWAS for vascular and inflammatory diseases as well as expression QTLs for atherosclerosis.

Several limitations of our candidate gene meta-analysis merit comment: (i) The ankle-brachial blood pressure measurement protocols used in the studies were heterogeneous. Hence, phenotype heterogeneity may have impacted our ability to detect associations. (ii) The ARIC study contributed over 40% of the European ancestry sample and measured ABI in only one leg which may have led to phenotype misclassification most problematic for the PAD phenotype. The mean ABI did differ significantly between European Americans in ARIC and European Americans from the other CARe cohorts (all $p < 0.05$) with mean ± SD of the ARIC ABI 1.12 ± 0.13, CHS ABI 1.06 ± 0.15, CFS ABI 1.08 ± 0.10, FHS ABI 1.13 ± 0.12, and MESA ABI 1.11 ± 0.12. However, a sensitivity analysis excluding the ARIC samples showed parameter estimates of similar size. (iii) Not all studies had information on lower extremity revascularization, which may also have contributed to PAD misclassification. In general, these misclassifications should cause bias toward the null. (iv) Control selection bias could have affected our PAD results in some way, although given that all of our studies except one (the PDHS) contributing to the PAD analysis were prospective cohort studies where knowledge of PAD would not affect exposure (i.e. genotype status) and the genotype precedes prevalent PAD, this is of lesser concern. For ABI analyses, we also analyzed our clinical replication samples separately by case-control status to avoid additional bias or heterogeneity. (v) Although we adjusted for population stratification using principal components in the European ancestry analysis and global ancestry in the African-American analysis, residual confounding could still be present. (vi) Our sample of African Americans was modest in size and likely limited our power to detect associations. For example, given the sample size of African-Americans we included and a risk allele frequency of 0.10, we only had 80% power to detect an increment in ABI of approximately 0.02 or greater per each copy of the risk allele. The observed effect size of the experiment-wide significant SNPs in European ancestry participants was much smaller than this value. According to our calculations in the methods section, for the European ancestry analyses, we can detect modest differences in ABI (similar to the ones we observed in this study), but are likely underpowered for PAD.

Some of the mentioned limitations might have contributed to the observation that the most important findings from the discovery phase could not be confirmed in the replication phase. However, it is unlikely that this fully explains the differences between the two study stages which necessitate additional large study samples.

5. Conclusions

The search for genes influencing ABI and PAD remains challenging. Although we cannot claim new findings in our study, two associations at the discovery stage for ABI (*SYTL3*, *TCF7L2*) may deserve further attention in other populations and functional studies. Further study of the genes identified in this study for ABI (*SYTL3*, *TCF7L2*) and PAD (*CYP2B6*) is warranted in other populations as further investigation of the function of these loci may uncover important biological insights into the pathogenesis of PAD. Identification of main effects may have been difficult in our study due to the presence of interactions and heterogeneity across participating studies. New and more powerful approaches to PAD gene discovery are sorely needed.

Funding

The Candidate Gene Association Resource (CARe) is supported by contract number HHSN268200625226C from the National Institutes of Health (NIH)/National Heart Lung and Blood Institute (NHLBI), and subcontract number 5215810-55000000041 to C.L.W. Randomised controlled trial of an automated, interactive telephone intervention (TLC Diabetes) to improve type 2 diabetes management: baseline findings and six-month outcomes

Emily D Williams[1*], Dominique Bird[1], Andrew W Forbes[1], Anthony Russell[2,3], Susan Ash[4], Robert Friedman[5], Paul A Scuffham[6] and Brian Oldenburg[1]

Abstract

Background: Effective self-management of diabetes is essential for the reduction of diabetes-related complications, as global rates of diabetes escalate.

Methods: Randomised controlled trial. Adults with type 2 diabetes (n = 120), with HbA_{1c} greater than or equal to 7.5 %, were randomly allocated (4 × 4 block randomised block design) to receive an automated, interactive telephone-delivered management intervention or usual routine care. Baseline sociodemographic, behavioural and medical history data were collected by self-administered questionnaires and biological data were obtained during hospital appointments. Health-related quality of life (HRQL) was measured using the SF-36.

Results: The mean age of participants was 57.4 (SD 8.3), 63% of whom were male. There were no differences in demographic, socioeconomic and behavioural variables between the study arms at baseline. Over the six-month period from baseline, participants receiving the Australian TLC (Telephone-Linked Care) Diabetes program showed a 0.8% decrease in geometric mean HbA_{1c} from 8.7% to 7.9%, compared with a 0.2% HbA_{1c} reduction (8.9% to 8.7%) in the usual care arm (p = 0.002). There was also a significant improvement in mental HRQL, with a mean increase of 1.9 in the intervention arm, while the usual care arm decreased by 0.8 (p = 0.007). No significant improvements in physical HRQL were observed.

Conclusions: These analyses indicate the efficacy of the Australian TLC Diabetes program with clinically significant post-intervention improvements in both glycaemic control and mental HRQL. These observed improvements, if supported and maintained by an ongoing program such as this, could significantly reduce diabetes-related complications in the longer term. Given the accessibility and feasibility of this kind of program, it has strong potential for providing effective, ongoing support to many individuals with diabetes in the future.

Background

The rapid increase in rates of diabetes poses a significant public health problem globally. Diabetes is currently estimated to affect 285 million adults worldwide, with the prevalence predicted to rise to 438 million by the year 2030 [1]. Its complications contribute significantly to ill health, disability, poor quality of life and premature death. The associated global economic burden is projected to reach at least US$376 billion in 2030 [2]. Although guidelines and targets for optimal diabetes management are well documented [3], it is estimated that 40% of individuals with diabetes have sub-optimal glycaemic control [4,5], significantly increasing their risk of costly and debilitating diabetes-related complications [6,7].

Diabetes self-management education facilitates the acquisition of knowledge and skills to improve disease management and has been found to improve glycaemic control [8], with program duration being a critical

predictor of this success [9]. Providing ongoing and long-term diabetes management support, particularly to those people living in rural and remote areas, is a major challenge for all health systems around the world. This highlights the need to develop and evaluate more feasible, accessible ways of providing such support for large numbers of people with diabetes than is traditionally offered. Using information and communication technology (ICT) to provide diabetes management education and support directly to patients offers such potential, by overcoming many of the barriers associated with more traditional modes of program delivery. Use of ICT has been shown to yield improvements in self-care knowledge and behaviour of patients and clinical outcomes associated with the prevention and control of chronic health conditions, including diabetes [10-12]. Some studies have evaluated the role of automated or semi-automated telephone-delivered diabetes management interventions on glycaemic control, however, the results have been inconsistent with varying levels of reliance upon health professionals [13-15].

The Telephone-Linked Care (TLC) program is an automated and interactive telephone system designed to emulate telephone encounters between patients and health professionals [16] and to complement standard medical care. TLC systems have been previously used to effectively screen people with specific health conditions [17,18], promote self-care behaviours [19-22] and provide monitoring of and feedback to patients with a range of chronic diseases [23-26].

A randomised controlled trial was conducted to evaluate a TLC program - the Australian TLC Diabetes program - designed to improve type 2 diabetes management. This paper presents the six-month results for the study's primary outcomes, glycosylated haemoglobin and health-related quality of life (HRQL), and it also describes the sample baseline characteristics, compared with a large Australian population study.

Methods

Study design

The study methodology has been detailed elsewhere [27]. In brief, the study was a two-arm prospective randomised controlled trial, with adults with type 2 diabetes randomised to either the intervention (Australian TLC Diabetes program) arm or 'usual care' control arm. Data were collected between July 2008 and December 2010. Ethics approval was received from the Human Research Ethics Committees for all collaborating hospitals and Monash University.

Participant recruitment and randomisation

Participants were recruited through advertisements in newspapers, flyers distributed to health professionals and to members of Diabetes Australia – Queensland, community newsletters and through diabetes clinics at three major hospitals in Brisbane (Princess Alexandra Hospital, Royal Brisbane and Women's Hospital, and Prince Charles Hospital).

There were two steps to the eligibility screening (Table 1). In the first step, which took place during the initial contact via telephone or in person, research staff excluded individuals who did not meet all of the Step 1 eligibility criteria or who met any of the Step 1 exclusion criteria. If potentially eligible, participants attended a baseline appointment at either Princess Alexandra or Royal Brisbane and Women's Hospital, where full information was provided, informed consent was obtained and baseline data collected. At that appointment, baseline questionnaires were completed and fasting blood specimens were taken, along with other clinical data (blood pressure, weight, height and waist circumference). Blood tests were conducted by Queensland Pathology using standardised assays. The second screening step verified the glycosylated haemoglobin (HbA_{1c}) inclusion criterion (≥ 7.5%). The final sample included 120 adults; n = 60 in each of the study arms. The allocation ratio was 1:1 and the allocation sequence was computer-generated. The arm allocation was conducted using a 4x4 block randomised block design with the participant as the unit of randomisation.

Study arms

All participants received a quarterly newsletter containing general health information; this aimed to maintain participation in both arms. Participants in both arms were advised to continue with their usual medical care. The usual care arm received no further intervention. The treating physicians were not blinded to the allocation.

Intervention arm

Australian TLC Diabetes program

The intervention took place over six months during which they received the Australian TLC Diabetes program. Its main component is the Telephone-Linked Care (TLC) Diabetes system, an automated interactive telephone system, developed collaboratively by the Australian research team and researchers at the Medical Information Systems Unit, Boston University, USA. The Australian TLC Diabetes system has been designed to improve diabetes management by targeting the following key self-management behaviours: blood glucose testing, nutrition, physical activity and medication-taking. Users were asked to call the system weekly using a landline or mobile phone. TLC's responses, including feedback and encouragement, were tailored according to information entered in the TLC database at the start and the answers that it received from participants during all calls.

Table 1 Inclusion and exclusion criteria for study recruitment

Inclusion criteria	Exclusion criteria
Eligibility Step 1	
Type 2 diabetes diagnosis of ≥ 3 months	Diagnosed with dementia/psychiatric co-morbidity
Aged 18–70 years	Currently enrolled in another intervention trial
Residing in greater Brisbane area, Australia	Undergone bariatric surgery in past 2 years
Stable diabetes pharmacotherapy type for ≥ 3 months	Pregnant, lactating, or planning to become pregnant within next 12 months
Ability to clearly speak/understand English via telephone	Diagnosed with condition likely to be fatal within 1 year
Stable pharmacotherapy dosage for ≥ 4 weeks	
Weekly access to telephone	
Eligibility Step 2	
HbA_{1c} ≥ 7.5%	

Training to use the TLC system

The TLC Coordinator met with participants within one week of their baseline data collection to instruct them on the use of the TLC Diabetes kit (containing the TLC Handbook, an ACCU-CHEK® Advantage glucose meter, test strips, and a Bluetooth™ device for uploading their blood glucose results to the TLC Diabetes system). For current smokers, a smoking cessation information pack was also provided. During this session, participants completed a training call to the TLC Diabetes system. Participants were asked to conduct all blood glucose self-monitoring with the study glucose meter and to upload its readings immediately preceding their weekly telephone conversations with the TLC system. Each participant chose a unique personal password that they keyed in at the start of each call that linked the call to their database file and ensured correct participant identification and confidentiality. Before the participants' first call to the TLC system, the TLC Coordinator obtained self-care clinical targets for the participants from their primary healthcare provider (including recommended number of weekly blood glucose tests and blood glucose range, and clearance for physical activity).

Content of weekly telephone calls

Participants were requested to make weekly calls to the system over six months, with calls lasting five-20 minutes, depending upon the call content and participant responses. Blood glucose monitoring was the first topic covered in each weekly call. It was followed by one of three other topics, with these being medication-taking, physical activity or healthy eating (calls 9 to 12 and 21 to 24). When diabetes medication was not prescribed, the medication-taking topic was replaced with physical activity. When clearance for physical activity was not provided by the patient's treating physician, physical activity was replaced by medication-taking. In cases when there was no clearance for physical activity and no pharmaceutical treatment of diabetes, the participant did not hear a second topic on some calls.

TLC Coordinator

The TLC Coordinator briefly telephoned participants after the first two calls and at weeks six, 12, and 20, to identify and resolve any technical issues with the TLC Diabetes system or to determine reasons for not calling. In addition, the TLC Diabetes system sent email "alerts" to a dedicated study email address if any unusual clinical or other issues arose during the conversations, for example, where there were two or more hypoglycaemic levels in the past week. In this instance, the Coordinator would advise the participant of the importance of visiting their primary care physician. More detail on the intervention is available elsewhere [27].

Measurement

Participants in both arms completed comprehensive clinical and self-report assessments at baseline (Time 1), six months following baseline (Time 2), and at 12 months (Time 3); this paper presents the baseline characteristics and six-month primary outcome findings.

Outcome variables

The primary outcomes were HbA_{1c} measured by fasting blood tests taken at the hospital appointment, and HRQL assessed by the participants' self-completion of the SF-36 version 2 (divided into mental and physical component summary scores) [28].

Figure 1 illustrates the stages of recruitment and randomisation.

Representativeness of study sample (Table 2)

To examine the representativeness of the Australian TLC Diabetes sample, the baseline characteristics were compared with data from the Australian Diabetes, Obesity and Lifestyle (AusDiab) study [29], the largest national, population-based sample of Australians measuring the

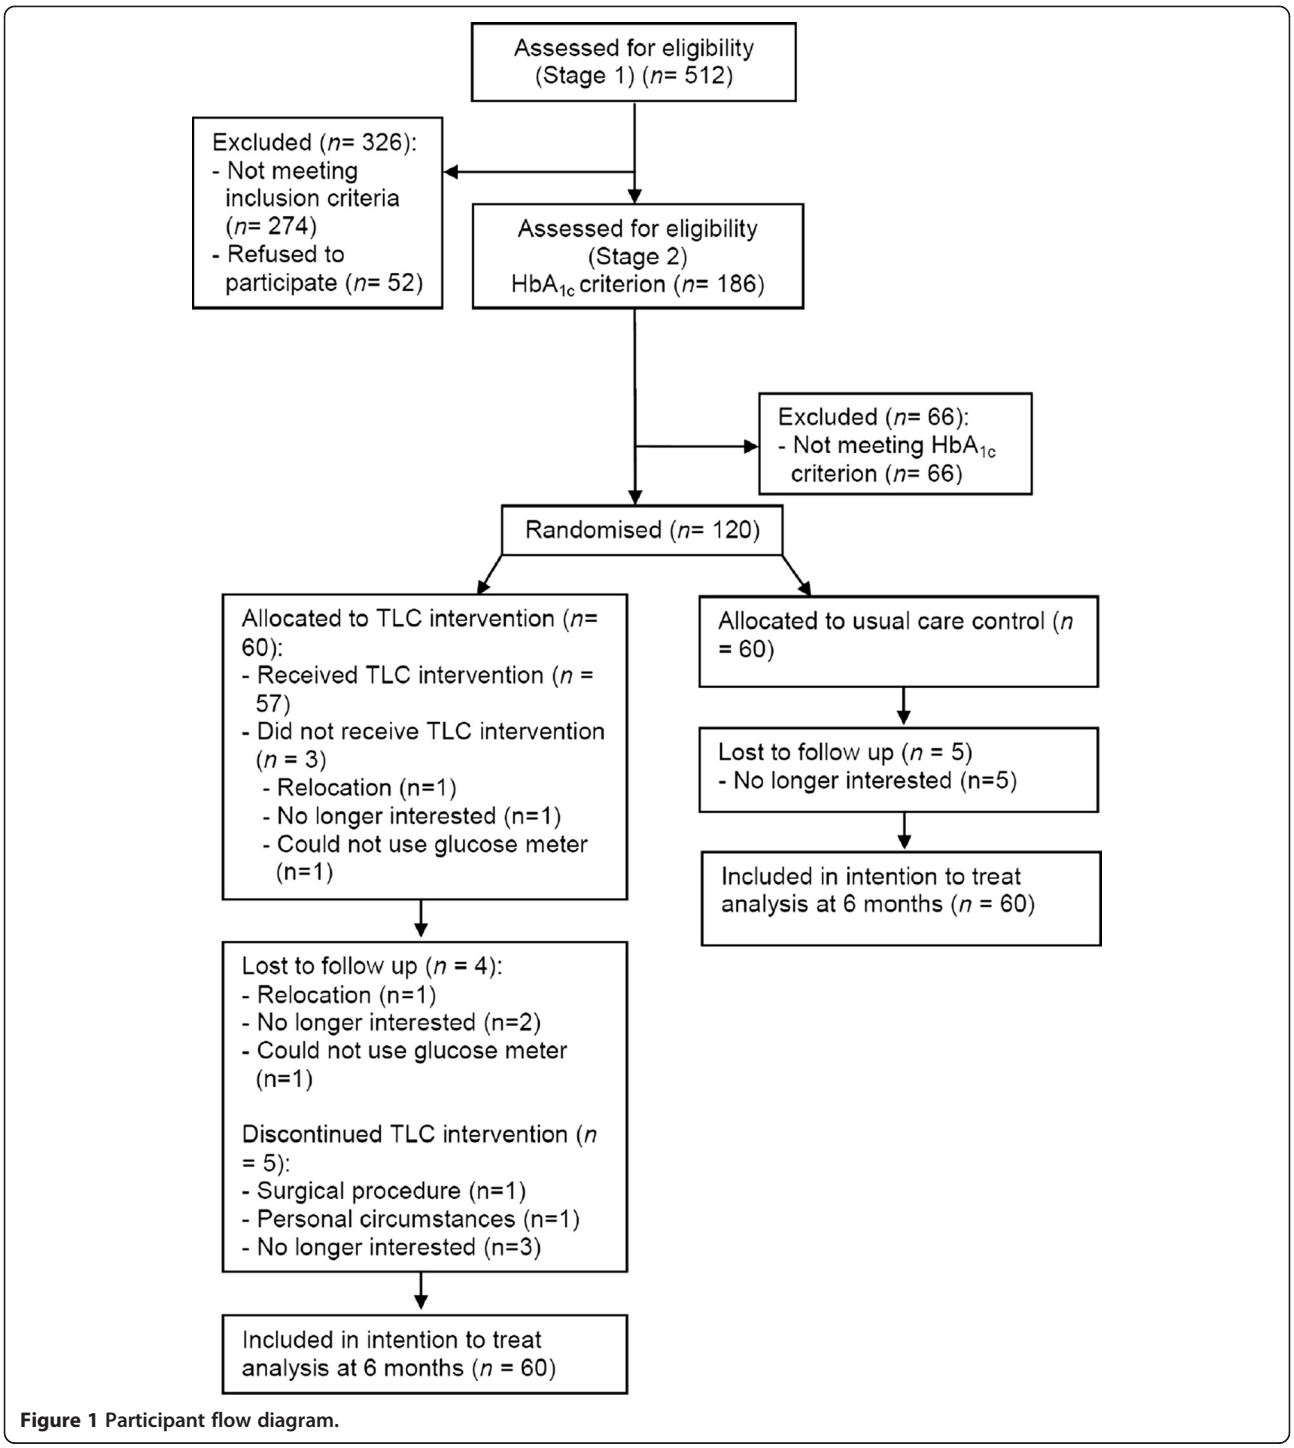

Figure 1 Participant flow diagram.

overall prevalence of diabetes and other chronic conditions. The AusDiab baseline study was conducted during 1999–2000 with data from 11,247 adults [29]. Demographic and behavioural data were collected during interview, and diabetes status was assessed using fasting plasma glucose and oral glucose tolerance tests. A subsample of this nationally representative study, those identified as having diabetes (and based on TLC inclusion criteria), provides the best comparison for the TLC study sample.

Statistical analyses

Detailed power calculations were described in an earlier paper [27], indicating the need to recruit 340 participants to detect a small clinical change of 0.4% in HbA_{1c} with 90% power assuming a 30% rate of loss to

Data are presented as means (SD) and percentages, or as ‡medians (inter-quartile range) for skewed data. Group comparisons between TLC study arms and between TLC and AusDiab samples of normally distributed data used independent samples t-tests and chi square tests. Group comparisons between TLC study arms and between TLC and AusDiab samples of non-normally distributed variables used Mann–Whitney U test, *p <0.05.

† Estimated glomerular filtration rate data highly skewed (values over 90 ml/min labelled 91).

HRQL: Health-related quality of life.

HOMA: Homeostasis model assessment.

High risk AusDiab group inclusion criteria are type 2 diabetes, within TLC age-range, and $HbA_{1c} \geq 7.5$ %; TLC-AusDiab group comparison are made with full TLC sample (n = 120).

NC: Not comparable - missing comparisons with AusDiab subsample due to incomparable methods of data collection between studies.

follow-up. However, due to the slowness of recruitment (described below), our final sample comprised a total of 120 participants (60 per study arm). Although the comprehensive recruitment effort achieved a very good response from individuals with diabetes (n = 512), a large proportion of these respondents either did not wish to participate or were ineligible due to either not meeting the HbA_{1c} or age eligibility criteria. Recruitment was stopped after 18 months with 120 participants having been recruited. Therefore, the power calculations were re-evaluated based on this number of participants, again assuming 30% loss to follow-up. With 80% power and a type 1 error of 5% (two-tailed), a difference in our primary outcome, HbA_{1c}, of 0.61% between the intervention and control arms (based on a standard deviation change of 1.0% between the randomised arms) at 12-month follow-up can be detected. This effect size would indicate a feasible outcome of clinical significance [30] for the intervention.

For the analysis of the six-month results, HbA_{1c} values were logarithmically transformed in order to achieve an approximate normal distribution. Analyses of covariance were used to examine the effects of the intervention (study arm allocation) on the primary outcomes (log HbA_{1c} and HRQL), with the inclusion of baseline values of the outcomes as covariates. Results for HbA_{1c} are presented as geometric means for each study arm and as a ratio of geometric means when comparing study arms. The geometric mean is a natural quantity to use for presenting the centre of skewed data and is computed by exponentiating the average of the logarithmically transformed HbA_{1c} values [31]. To assess heterogeneity of the effect of TLC according to baseline values, interactions between study arm allocation and baseline values were included in further regression models. Creatinine and e-GFR were included as covariates in these analyses, since their levels at baseline differed sizeably between study arms. The sensitivity of conclusions to imbalances in baseline characteristics was assessed via additional ANCOVA analyses adjusting for all characteristics exhibiting any potentially important imbalances. To account for subjects lost to follow-up in intention-to-treat

analyses, multiple imputation was performed using ten imputed datasets [32].

For the comparison of the baseline TLC sample characteristics with the AusDiab study sample, as well as for the attrition comparisons, independent samples t-tests (continuous data) and chi-square tests (categorical data) were used where the data were normally distributed, and Mann–Whitney U tests were employed for highly skewed data. All analyses were performed using SPSS 18.0, with the statistical significance level set at $p < 0.05$.

Results

Of the 52 individuals who did not wish to participate at the initial eligibility screening stage, the primary reason for non-participation was lack of interest (n = 21), with an additional 11 reporting potential difficulties with travel for the baseline data collection. Other reasons included lack of time due to work and other commitments. There were no age differences between those who were willing and unwilling to participate, although there was a higher proportion of women who were unwilling to participate compared with those who chose to participate (61.5% compared with 43%).

As shown in Table 2, which summarises the baseline characteristics of the TLC and usual care arms, the Australian TLC Diabetes sample had a mean age of 57.4 years (± 8.3), with a higher proportion of men (62.5%) than women. The vast majority of participants were born in Australia (70.0%), were married or cohabiting with a partner (75.0%), with education above secondary school level (65.0%). Approximately half of the sample were employed (45.8%) and had complementary private medical insurance (55.8%). The mean number of hours per week spent exercising was reported to be 6.1 (± 6.4), with the majority of the sample (55.9%) participating in the nationally-recommended level of weekly physical activity (>150 minutes of exercise per week in at least 5 sessions per week [33]). Only 1.7% of the sample were current smokers. Approximately three quarters of the sample rated their health as good or higher (74.2%). Nearly two-thirds of the sample had been previously diagnosed by a doctor with hypertension (65.8%) and hypercholesterolaemia (63.3%), and therefore were likely to be receiving treatment for these conditions as was reflected in their blood pressure and lipid profiles that predominantly fell within the normal range.

Comparison of baseline sample characteristics between study arms

The baseline sample characteristics were compared across the usual care and intervention arms to evaluate the randomisation process (Table 2). Comparison of the baseline characteristics across usual care and intervention arms revealed important differences in e-GFR, which showed a significantly greater impairment in renal function in the intervention compared with usual care arm, and creatinine. Other differences observed were in age, education, and self-care behaviours (adherence to blood glucose testing recommendations and daily insulin/diabetes medications, and foot inspections). Adjustments were made for these variables in sensitivity analyses.

Post-intervention results at six months

Attrition

Of the total sample, 92.5% completed the six-month assessment (see Figure 1). Overall, nine participants (two women and seven men) withdrew from participation in the study, four in the intervention arm and five in the usual care arm. The reasons given for withdrawal from the usual care arm were all related to frustration at 'missing out' on the intervention. The participants receiving the Australian TLC Diabetes intervention withdrew for a range of reasons, including relocation, being unable to use the blood glucose meter, and disappointment with the intervention. The sociodemographic, behavioural or biological profiles were compared between those people who remained in the study and the nine people who withdrew. There were no significant differences at baseline across any of the domains of risk factor profiles.

Use of Australian TLC Diabetes system

The mean number of completed calls for the Australian TLC Diabetes participants during the six-month intervention was 18 (± 6), ranging between 2 and 27 calls, with a mean call duration of 11 minutes (± 1). The mean percentage of completed calls out of the expected weekly calls for all individuals in the intervention condition was 76% (± 22). More detailed analyses of the usage of the Australian TLC Diabetes system are beyond the scope of this paper and are to be presented in a future manuscript.

A small number of people in the intervention arm (n = 5) discontinued participation in the intervention but still completed the six-month assessment (Figure 1). Out of these, two participants made less than five calls and one made only seven calls.

Study outcomes

These analyses were based on intention-to-treat. There was a statistically significant difference in HbA_{1c} at six months between the usual care and TLC Diabetes arms. The geometric mean (arithmetic means provided in parentheses) of HbA_{1c} decreased from 8.7% (8.8%) to 7.9% (8.0%) in the TLC Diabetes arm, compared with 8.9% (9.0%) to 8.7% (8.9%) in the usual care arm, with the adjusted ratio of six-month geometric means of 0.91 (95% CI 0.86-0.93, p = 0.002) (Table 3). The ratio of

Table 3 Baseline and post-intervention primary outcome values between usual care and Australian TLC Diabetes arms

	Baseline n = 60	Post-intervention n = 60	Difference between groups* (95% CI, *p*)
HbA_{1c} (%)			Ratio
Usual care	8.9 (8.6-9.2)	8.7 (8.7-9.0)	0.91 (0.86-0.93, $p = 0.002$)
TLC Diabetes	8.7 (8.4-9.0)	7.9 (7.6-8.3)	
Health-related quality of life - mental			
Usual care	49.5 (47.1-50.3)	48.7 (47.1-50.3)	3.0 (0.8-5.2 $p = 0.007$)
TLC Diabetes	49.8 (47.5-52.0)	51.7 (50.2-53.3)	
Health-related quality of life - physical			
Usual care	45.4 (43.0-47.9)	45.2 (43.8-46.6)	0.4 (−1.7-2.4, $p = 0.7$)
TLC Diabetes	45.5 (43.0-47.9)	45.6 (44.1-47.0)	

Data presented in the first two columns are geometric means (95 % CI) for HbA_{1c} values and arithmetic means (95 % CI) for HRQL values. The post-intervention values are adjusted for baseline values, e-GFR and creatinine.
*The result in the last column for HbA_{1c} is the ratio of the geometric means in the TLC Diabetes arm compared with usual care arm.
For HRQL, it is the difference in arithmetic means. All analyses were conducted based on the intention-to-treat principle and adjust for the baseline of the outcome variable, e-GFR and creatinine values.

0.91 means that the geometric mean HbA_{1c} at six months in the TLC arm is 0.91 of the value in the usual care arm after adjustment for baseline covariates. There was slight evidence that the difference in HbA_{1c} at six months between study arms increased with baseline HbA_{1c} ($p = 0.09$ for the interaction term in regression model). This suggested that the difference in six-month HbA_{1c} between TLC and usual care patients was greater in patients with high baseline HbA_{1c} values than in patients with low values. Of participants in the intervention arm, 20 % achieved HbA_{1c} levels of 7.0% or lower (95% CI 9.6-29.7), compared with 15% (95% CI 4.4-24.7) in the usual care arm ($p = 0.32$).

In terms of HRQL, the mental component summary score was found to be significantly different between the two arms at six months (difference = 3.0, $p = 0.007$), after controlling for baseline mental HRQL, plus other covariates (Table 3). Mental HRQL improved in the TLC Diabetes group, compared with those in the usual care group where mental HRQL decreased marginally. There was no interaction between study arm allocation and baseline levels for mental HRQL ($p = 0.4$). No differences were observed in physical HRQL between the usual care and intervention arms ($p = 0.7$).

Comparison of sample characteristics between Australian TLC and AusDiab samples

To determine the representativeness of the TLC sample at baseline, we used a comparable subsample of individuals from the AusDiab study, obtained from applying the Australian TLC Diabetes criteria for age range and HbA_{1c} levels (≥ 7.5%) to the subsample (n = 643) of those classified in AusDiab as having diabetes. 156 AusDiab participants were identified for comparison with the Australian TLC Diabetes sample. Overall, the AusDiab and TLC samples were similar (Table 2). There were no significant differences between the TLC sample and the AusDiab subsample across demographic variables, HRQL, and self-reported health variables. Behaviourally, there were no differences in nutrition self-reports between the study populations, however the TLC sample reported markedly lower smoking rates and were more likely to perform the recommended levels of exercise. In terms of their clinical profiles, the TLC sample appeared healthier, with lower systolic blood pressure, and generally better glucose and lipid profiles. These results, however, are likely to reflect the increased levels of doctor-diagnosed hypertension and hypercholesterolaemia, and therefore probably high levels of treatment in the TLC sample. Interestingly, despite their reported healthier behavioural profiles, the TLC sample were significantly more likely to be obese using both BMI and waist circumference classifications.

Discussion

This randomised controlled trial evaluated the efficacy of an automated, interactive telephone intervention for improving the management of diabetes. As far as we are aware, this is one of the first studies in the world to formally evaluate an automated telephone system for diabetes management that involves tailoring to individual needs and the findings offer promising results for the longer term use of this kind of program for people with diabetes. We have demonstrated that the Australian TLC Diabetes program significantly improved glycaemic control and mental HRQL after six months for those who participated in the program compared with the routine care condition.

Participation in the Australian TLC Diabetes intervention led to a significant improvement of HbA_{1c}, compared with the routine care available to people with diabetes in Brisbane, Australia. The mean reduction in HbA_{1c} of 0.8 % in the intervention arm is of substantial clinical significance if maintained long-term. Results

from the UKPDS study highlight the substantial reductions in all diabetes endpoints associated with 1% reduction in HbA_{1c} [7], such as 21% of deaths related to diabetes, 14% of myocardial infarction and 37% microvascular complications [30]. A meta-analysis reported comparable levels of HbA_{1c} improvement from the pooled effects of 31 previous interventions providing education on self-management of diabetes [9]. The majority of studies cited in the review, however, directly involved healthcare professionals/health workers for the provision of diabetes management education. Another meta-analysis evaluating the use of mobile phone interventions to improve glycaemic control showed a pooled change of 0.5% over six months, however, again with heavy involvement of healthcare personnel for intervention delivery [11]. One previous study of another fully-automated telephone intervention aimed at improving glycaemic control failed to show significant post-intervention differences between intervention and control groups in levels of HbA_{1c} [13]; however, that system did not provide tailored feedback to individuals. Therefore, a major advantage of the Australian TLC Diabetes program is its successful impact on glycaemic control and the potential for reduced costs and increased accessibility associated with an automated telephone-linked system for the provision of tailored diabetes management.

In addition to the observed improvements in glycaemic control, mental HRQL was significantly enhanced in people who received the intervention compared with those who did not, despite this not being a specific focus of the TLC program for the trial. The burden of daily management of diabetes and the development of complications lead to compromised HRQL in populations with diabetes [34,35], and therefore enhancing well-being, in addition to diabetes management per se, is an additionally important outcome. Despite this improvement reflecting only a small effect size (0.20) [36], the literature in this field indicates that even small effect sizes of HRQL improvement may be of clinical significance in the longer term [37-39]. Interestingly, the physical component of HRQL did not improve during the six-month intervention period. A brief computer-assisted diabetes self-management intervention on quality of life outcomes showed no change in HRQL, however, their two-month follow-up might not have been long enough to detect changes [40]. In contrast, the pooled results from 20 publications showed that people with diabetes experience improved HRQL after receiving interventions designed to develop their diabetes self-management behaviours [37], although this meta-analysis did not differentiate between the mental and physical components of HRQL.

Another important aspect of this study is the focus on people with poor glycaemic control ($HbA_{1c} \geq 7.5\%$), indicating difficulty in their self-management of diabetes with the available routine care. These people are likely to be most at risk of the development of complications associated with diabetes, and therefore, given the results achieved, Australian TLC Diabetes has the potential to improve the health of the highest risk groups. Consequently, this program also provides the opportunity to significantly reduce the financial burden of type 2 diabetes on the healthcare system. Subsequent analyses will examine the cost-effectiveness of the program, which will have important implications for the widespread implementation of the program.

Our comparison of the TLC sample with a 'matched' subgroup from the AusDiab study sample suggests that the TLC participants did not differ significantly in terms of demographic characteristics from the best available data from a general population-based diabetes sample in Australia. The baseline AusDiab study, conducted in 1999–2000, offers benchmark national data on the prevalence of diabetes, obesity, hypertension, and kidney disease in Australia. This indicates the representativeness and external validity of our results and their applicability to other diabetes populations.

The trial was completed in accordance with the Medical Research Council's guidelines for the effective design and evaluation of complex intervention trials [41]. Principal components of any effective complex intervention include feasibility, participant-engagement, identification of mechanisms for intervention outcomes, and trial fidelity [42]. The feasibility and relevance of the Australian TLC Diabetes program are demonstrable within the current context of type 2 diabetes. The accessibility of the telephone-delivered intervention over the long-term is particularly important for a widespread chronic condition, such as diabetes, which requires ongoing management and affects a large proportion of the population. The very high usage of the Australian TLC Diabetes system and results to date indicate that the participants in the intervention arm engaged with the program, with over three quarters of weekly calls being completed. Full details of system usage were recorded as part of the data collection and will be reported elsewhere for full process evaluation of the system's usability and participant satisfaction, as well as whether the cost of the intervention provides acceptable value for money. Furthermore, the intervention was able to affect pathways that led to improvements in glycosylated haemoglobin and therefore diabetes management, as well as improvement in mental health-related quality of life for the participants. The fidelity of the trial implementation in accordance with the original design and protocol [27] was strong. Difficulties were encountered during recruitment and this led to increased recruitment opportunities via enhanced presence at Diabetes Australia – Queensland shops and seminars and hospital

diabetes clinics. The sample size was smaller than originally planned, however, as discussed, the sample obtained is powered to detect group differences that will be both statistically and clinically significant at 12-month follow-up. No changes were applied regarding the randomisation process or implementation of the intervention.

Although only glomerular filtration rate significantly varied across the study arms at baseline, other baseline characteristics (Table 2) showed some differences. Separate analyses tested the impact of the inclusion of these variables individually on the main results and the main outcome results did not change. As with most research, it is possible that a selection bias operated in this study, with people willing to participate being more likely to prioritise their health and/or have the social, educational, and economic resources to accommodate participation. The study requirement of access to a telephone meant that there may have been a socioeconomic selection bias; however in the geographic area from which we recruited, over 96% of households have a fixed phone connection, so we are confident that this criterion did not appreciably influence participation. It is also possible that the reduced sample size and some of the challenges associated with trial recruitment may limit generalisability. More research is required to investigate generalisability and to explore uptake by others with diabetes. Although there was a suggestion of an increasing effect of intervention with increasing baseline HbA_{1c} values (from the interaction test), this did not reach conventional levels of statistical significance and should be reassessed in future studies.

A substantial body of research conducted over the last 30 years has drawn attention to the importance of ongoing support and follow-up to sustain improvements in diabetes management and management of other chronic conditions, with strong links to health and self-care behaviours [43-45]. Therefore a diabetes management support program such as this, designed to provide easy access to long-term (potentially cost-effective) support, is of paramount importance, and hence, this kind of program also requires detailed evaluation in the longer term as well. A subsequent paper will elucidate the changes in behaviour that may have facilitated the improvements observed.

Conclusions

Our results indicate that the six-month Australian TLC Diabetes program led to improvements in diabetes management, with significant benefits to mental health functioning and improved glycaemic control. If these results were maintained long term, such results would be expected to lead to important reductions in diabetes-related complications and mortality [30]. With the increasing accessibility to and feasibility of such telehealth interventions, the TLC program has excellent potential to be 'scaled up' and deliverable to large numbers of individuals with diabetes.

Competing interests

Dr. Friedman has stock ownership and a consulting agreement with Infomedics, the company that owns commercial rights to the TLC technology used in the computerized intervention. He is also a member of its Board of Directors. The other authors declare that they have no competing interests.

Authors' contributions

EDW analysed the data and wrote the manuscript. DB collected the data, contributed to study development, discussion and manuscript writing. AF, AR, SA, PS, RF and BO contributed to study development, and discussion, reviewing/editing of the manuscript. All authors read and approved the final manuscript.

Acknowledgements

The study is funded by a National Health Medical Research Council project grant (ID 443214), by the HCF Health and Medical Research Foundation and by Queensland Health. We wish to thank all study participants, Diabetes Australia for provision of educational material and Diabetes Australia - Queensland for its assistance with recruitment. We acknowledge the dedication of the investigator team: Prof Mary Courtney, Prof Richard Wootton, and Prof Kerrie Mengersen. We also acknowledge the commitment of the project staff: Mandy Cassimatis, Lyndall Kopp, Megan Rollo, Wei-I Wu, Adrienne O'Neil and Vivien Harris. We would like to acknowledge the Baker IDI Heart and Diabetes Institute for access to the AusDiab data. Furthermore, we would like to thank Dr Stephan Gaedhe, one of the principal developers of the TLC Diabetes system, and the Australian Diabetes Educators Association for their contributions. We are grateful for the input from staff at the Medical Information Systems Unit, Boston University. Finally, we also wish to thank Roche Diagnostics ACCUCHEK for their supply of the glucose meters and Alive Technologies for all of their technical advice. EDW was funded by a Diabetes UK Moffat Fellowship.

Risk of Thromboembolism, Recurrent Hemorrhage, and Death After Warfarin Therapy Interruption for Gastrointestinal Tract Bleeding

Daniel M. Witt, PharmD, FCCP, BCPS; Thomas Delate, PhD; David A. Garcia, MD; Nathan P. Clark, PharmD; Elaine M. Hylek, MD; Walter Ageno, MD; Francesco Dentali, MD; Mark A. Crowther, MD

Background: Patients who not only survive a warfarin-associated gastrointestinal tract bleeding (GIB) event but also have an ongoing risk for thromboembolism present 2 clinical dilemmas: whether and when to resume anticoagulation. The objective of this study was to determine the incidence of thrombosis, recurrent GIB, and death, as well as the time to resumption of anticoagulant therapy, during the 90 days following a GIB event.

Methods: In this retrospective, cohort study using administrative and clinical databases, patients experiencing GIB during warfarin therapy were categorized according to whether they resumed warfarin therapy after GIB and followed up for 90 days. Variables describing the management and severity of the index GIB were also collected. Kaplan-Meier curves were constructed to estimate the survival function of thrombosis, recurrent GIB, and death between the "resumed warfarin therapy" and "did not resume warfarin therapy" groups, with Cox proportional hazards modeling to adjust for potentially confounding factors.

Results: There were 442 patients with warfarin-associated index GIB included in the analyses. Following the index GIB, 260 patients (58.8%) resumed warfarin therapy. Warfarin therapy resumption after the index GIB was associated with a lower adjusted risk for thrombosis (hazard ratio [HR], 0.05; 95% CI, 0.01-0.58) and death (HR, 0.31; 95% CI, 0.15-0.62), without significantly increasing the risk for recurrent GIB (HR, 1.32; 95% CI, 0.50-3.57).

Conclusions: The decision to not resume warfarin therapy in the 90 days following a GIB event is associated with increased risk for thrombosis and death. For many patients who have experienced warfarin-associated GIB, the benefits of resuming anticoagulant therapy will outweigh the risks.

Arch Intern Med. 2012;172(19):1484-1491.

doi:10.1001/archinternmed.2012.4261

GASTROINTESTINAL TRACT bleeding (GIB) affects an estimated 4.5% of warfarin-treated patients annually and is associated with a significant risk for death.[1] A history of major bleeding is an important predictor for future serious bleeding, suggesting that patients with GIB might be considered for discontinuation of warfarin therapy.[2,3] However, interruption or permanent discontinuation of warfarin therapy increases the risk of thromboembolic complications.[4] Thus, patients with warfarin-associated GIB present 2 clinical dilemmas: should warfarin therapy be stopped and, if so, when should it be resumed?

Although some have suggested that anticoagulation can be safely restarted relatively soon after a major bleeding event, there is neither high-quality evidence nor consensus about the ideal timing or risk of reanticoagulation. Indeed, surprisingly little is known about warfarin therapy interruption and resumption following GIB.[2,5] An observational study of patients newly initiated on anticoagulation therapy for venous thrombosis who had

See Invited Commentary at end of article

major bleeding reported an association between resuming anticoagulation and rebleeding.[6] However, patients whose index bleeding event occurred during long-term anticoagulation therapy were not evaluated. Other studies examining the resumption of anticoagulation therapy following major bleeding have been limited by small numbers of patients, selection bias, or both.[2,5,7,8]

In this study of warfarin-treated patients who experienced GIB, we sought to

Author Affiliations are listed at the end of this article.

determine the incidence of subsequent thrombosis, recurrent GIB, and death as well as the time to resumption of warfarin therapy during 90 days of follow-up. We evaluated patient characteristics as well as the duration of warfarin therapy interruption to identify factors associated with thromboembolism, recurrent GIB, or death.

METHODS

STUDY DESIGN AND OUTCOMES OF INTEREST

We conducted a retrospective, cohort study using administrative and clinical databases from Kaiser Permanente Colorado (KPCO). Anticoagulation services at KPCO are provided by a centralized Clinical Pharmacy Anticoagulation Service (CPAS).[9] We used integrated, electronic medical, pharmacy, and laboratory record systems along with the CPAS database (DawnAC; 4S Systems Ltd) to identify patients, treatments, and outcomes for this study. Approval to conduct this study was obtained from the KPCO institutional review board.

We used administrative coding data (see the eAppendix for a complete listing of *International Classification of Diseases, Ninth Revision* [*ICD-9*] codes; http://www.archinternmed.com) to identify adult KPCO members who (1) were hospitalized or had an emergency department (ED) encounter for GIB (index GIB) between January 1, 2005, and December 31, 2008; (2) had an outpatient purchase of warfarin and an international normalized ratio (INR) in the 60 days prior to the index GIB; (3) had continuous KPCO membership in the 180 days prior to and 90 days after the index GIB (patients who died within 90 days after the index GIB were included); and (4) did not have a GIB diagnosis recorded during the 6 months prior to the index GIB.

The primary outcomes of interest were thrombosis (stroke, systemic embolism, and venous thromboembolism), recurrent GIB, and death from any cause during the 90 days following index GIB. Gastrointestinal tract bleeding (index and recurrent) and thrombotic events were identified first through electronic queries of inpatient and ED claims databases using *ICD-9* codes (see eAppendix) and then confirmed via manual medical record review by study investigators (D.M.W. and N.P.C.) using a standardized abstraction form. Validation of study outcomes required objective evidence of either clinically overt gastrointestinal tract hemorrhage (eg, visualization of blood in stool, vomit, or gastric aspirate; positive guaiac test result; evidence from endoscopy or colonoscopy) or thrombosis (eg, positive computed tomographic scan, magnetic resonance image, ventilation-perfusion scan, or ultrasonogram). Date and cause of death were ascertained from death certificates and medical record review. All records were independently reviewed by 2 investigators (D.M.W. and N.P.C.), with disagreements resolved by a third reviewer (E.M.H.).

The following variables describing the management and severity of the index GIB were collected: presentation INR, warfarin therapy interruption, plasma or blood transfusion, phytonadione administration, intensive care unit (ICU) admission, length of ED/inpatient stay, and warfarin therapy resumption. We also recorded age, sex, warfarin indication, INR range, time from warfarin therapy initiation to index GIB, aspirin and nonsteroidal anti-inflammatory drug (NSAID) use before index GIB, low-molecular-weight heparin use after index GIB, and proportion of INR values in range during the 3 months before index GIB. Information about comorbidities was collected using *ICD-9* codes. A validated aggregate measure of patient comorbidity, the Chronic Disease Score (CDS), was calculated for each patient using ambulatory prescription medication data recorded before the index GIB.[10,11] For patients with atrial fibrillation, the $CHADS_2$ score, a clinical prediction rule for estimating the risk of stroke, was calculated by assigning 1 point for diagnoses of congestive heart failure, hypertension, age 75 years or older, and diabetes mellitus and 2 points for prior stroke or transient ischemic attack.[12]

STATISTICAL ANALYSES

All patients were assigned to 1 of 2 groups defined by warfarin therapy resumption after the index GIB (ie, "resumed warfarin therapy" and "did not resume warfarin therapy" groups). When warfarin therapy was not interrupted, patients were included in the resumed warfarin therapy group. Categorical data were reported as percentages, and continuous data were reported as means (standard deviations)) and medians (interquartile ranges [IQRs]). Comparisons between groups for categorical data were made with the χ^2 or Fisher exact tests, whereas continuous data were compared using 2-sample *t* tests or Wilcoxon rank sum tests. Kaplan-Meier curves were constructed to estimate the survival function of thrombosis, recurrent GIB, and death between the resumed warfarin therapy and did not resume warfarin therapy groups. Patients were censored at thrombosis, recurrent GIB, death, or 90 days after index GIB, whichever came first.

A propensity score[13] for resumption of warfarin therapy after the index GIB was estimated for each patient using logistic regression (see the eAppendix for factors included in the propensity score). Cox proportional hazards modeling was used to adjust for potentially confounding factors in the assessment of the association of warfarin resumption with time to thrombosis, recurrent GIB, or death (see the eAppendix for factors included in each model).

To limit the effect of the severity of the index GIB on death, post hoc adjusted hazards modeling on time to death was performed, in which patients who died within 1 week of the index GIB were excluded. In addition, discrete time-varying and categorical variables were constructed based on length of time patients were off warfarin therapy after the index GIB to assess if there was a time-dependent effect of warfarin therapy interruption on the outcomes. Length of warfarin therapy interruption was categorized as 0 days, 1 to 7 days, 8 to 14 days, 15 to 90 days, and warfarin therapy not resumed. Individual post hoc adjusted hazards models for time to recurrent GIB, thrombosis, and death were constructed with the time-varying warfarin exposure variable. Because warfarin therapy was not interrupted in all cases, individual post hoc adjusted hazards models for time to recurrent GIB, thrombosis, and death were constructed with binary and time-varying warfarin exposure variables after removing patients who did not interrupt warfarin therapy and had an index GIB location of rectum-anus (n=24) and then all patients who did not interrupt warfarin therapy (n=41). Post hoc tests of association were performed with the categorical exposure variables and study outcomes. Because adjusted hazard modeling subanalyses using time-varying warfarin exposure and/or removing patient groups who did not have warfarin therapy interruption revealed similar results for the thrombosis, recurrent GIB, and death outcomes, only results of the initial analysis are reported.

Further analyses included comparisons of outcomes and patient characteristics between patients who did and did not experience a recurrent GIB and were and were not dead at the end of follow-up, respectively. Statistical analyses were performed using Intercooled STATA version 9.0 software (StataCorp). The α level was set at .05, and all tests were 2-sided.

Table 1. Baseline Characteristics According to Warfarin Therapy Status Following GIB[a]

Characteristic	Overall Cohort (N = 442)	Resumed Warfarin Therapy (n = 260)	Did Not Resume Warfarin Therapy (n = 182)	*P* Value[b]

[f] During the 90 days prior to the initial GIB event.

[g] Among patients with atrial fibrillation only.

RESULTS

Of 502 patients identified as having GIB using administrative data, the index GIB was not confirmed during medical record review in 57 patients, and 3 patients were not receiving warfarin. Therefore, 442 patients with warfarin-associated index GIB were included in the analyses (**Table 1**). The mean age was 74.2 years, 50.2% were male, and 46.4% used aspirin at some point during the 90 days prior to the index GIB. Indications for warfarin therapy included the following: prevention of atrial fibrillation–related stroke or systemic embolization (50.5%); treatment or secondary prevention of venous thrombosis (24.4%); and prevention of prosthetic heart valve thromboembolic complications (9.5%). The median (IQR) INR on presentation was 3.0 (2.3-4.3). Approximately one-third of patients (30.5%) were initially treated in the ICU; 24.2% were evaluated and discharged directly from the ED (**Table 2**). Following the index GIB, 260 patients (58.8%) resumed warfarin therapy, including 41 patients whose warfarin therapy was never stopped. Median (IQR) time to resumption of warfarin was 4 days (2-9 days). Prosthetic heart valve indication for warfarin therapy (15.4% vs 1.1%; $P<.001$) and GIB localized to the rectum-anus (representing predominately hemorrhoidal bleeds) (19.6% vs 7.1%; $P<.001$) were more

Table 2. Overall Outcomes Among Warfarin-Treated Patients With GIB[a]

Table 3. Description of Thrombotic Events

Patient No./ Sex/Age, y	Indication	Resumed Warfarin Therapy	Days From the Index GIB to Thrombosis	Thrombosis Type	Fatal
1/M/74	Deep vein thrombosis	No	90	Pulmonary embolism	No
2/F/85	Atrial fibrillation	No	8	Systemic embolism	No
3/M/75	Deep vein thrombosis	Yes	74	Deep vein thrombosis	No
4/M/85	Atrial fibrillation	No	27	Stroke	No
5/F/84	Atrial fibrillation	No	8	Stroke	Yes
6/M/76	Atrial fibrillation	No	23	Stroke	Yes
7/M/65	Pulmonary embolism	No	39	Pulmonary embolism and deep vein thrombosis	No
8/M/71	Stroke	No	8	Stroke	No
9/F/91	Atrial fibrillation	No	73	Stroke	Yes
10/M/62	Pulmonary embolism	No	13	Pulmonary embolism	No
11/F/95	Pulmonary embolism	No	17	Deep vein thrombosis	No

common among the 260 patients who resumed warfarin therapy compared with those who did not, respectively. In contrast, compared with those resuming warfarin therapy, older patients (mean age, 71.8 years [resumed warfarin therapy] vs 77.7 years [did not resume warfarin therapy]; $P < .001$) and patients for whom the GIB source was not identified (16.9% [resumed warfarin therapy] vs 26.9% [did not resume warfarin therapy]; $P = .01$) were less likely to resume warfarin therapy (Table 1).

90-DAY OUTCOMES: THROMBOSIS

During the 90-day follow-up period, 11 patients (2.5%) experienced a thrombotic event (6 arterial [5 strokes and 1 systemic embolus] and 5 venous [3 pulmonary emboli and 2 deep vein thromboses]), and 3 of the strokes were fatal (**Table 3**). Of the 260 patients who resumed warfarin therapy following the index GIB, 1 (0.4%) had a thrombotic event (deep vein thrombosis) compared with 10 of 182 patients (5.5%) who did not resume warfarin therapy ($P < .001$). Warfarin therapy resumption after the index GIB was associated with a lower risk for thrombosis (hazard ratio [HR], 0.05; 95% CI, 0.01-0.58) in a multivariable analysis that controlled for the propensity score, CDS, age, and sex (**Figure**, A). For patients resuming warfarin therapy, thrombosis rates were similar regardless of the duration of warfarin therapy interruption. Patients who either never interrupted warfarin therapy or resumed therapy within 14 days of the index GIB experienced no thromboses.

90-DAY OUTCOMES: RECURRENT GIB

Of the 442 patients, 36 (8.4%) had recurrent GIB (Table 2). Compared with those who did not resume warfarin therapy, a numerically higher proportion of patients resuming warfarin therapy had recurrent GIB, but

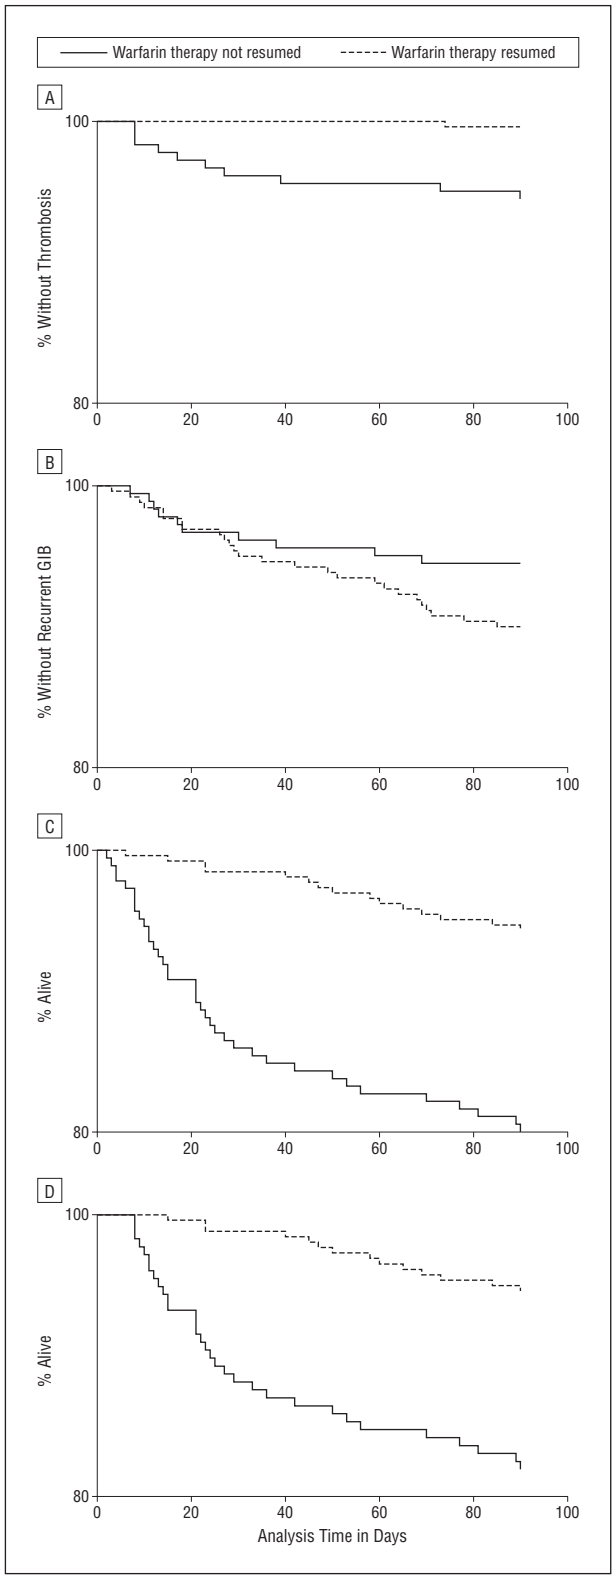

Figure. Time-to-outcome analysis according to resuming warfarin therapy status. A, Thrombosis ($P = .002$, log-rank test); B, recurrent gastrointestinal tract bleeding (GIB) ($P = .10$, log-rank test); C, death ($P < .001$, log-rank test); and D, death including only patients who died at least 7 days after the index GIB ($P < .001$, log-rank test).

this difference was not statistically significant (10.0% [resumed warfarin therapy] vs 5.5% [did not resume warfarin therapy]; $P = .09$). Multivariable analysis that controlled for the propensity score, CDS, age, sex, indication for warfarin use, prior heart failure diagnosis, location of GIB, pre-GIB target INR, pre-GIB percentage of INRs in range, reception of low-molecular-weight heparin, length of ED/inpatient stay, and acute GIB treatment (blood transfusion) also revealed that the risk for recurrent GIB associated with warfarin therapy resumption was not increased significantly (HR, 1.32; 95% CI, 0.50-3.57) (Figure, B). Compared with all other patients, the rate of recurrent GIB was significantly increased when warfarin therapy was resumed between 1 and 7 days after the index GIB (6.23% vs 12.4%, respectively; $P = .03$). Although 5 of the index GIB events were eventually fatal, no recurrent GIB resulted in death. The median (IQR) time from warfarin therapy resumption to recurrent GIB was 27 days (11-58 days). There was no association between more aggressive management of the index GIB (eg, ICU admission, use of blood products) and recurrent GIB (all $P > .05$) (**Table 4**).

90-DAY OUTCOMES: DEATH

During the 90-day follow-up period, 52 patients (11.8%) died (**Table 5**). The most common causes of death were related to malignancy (28.8%), infection (19.2%), and cardiac disease (17.3%). No deaths were attributed to recurrent GIB. Compared with survivors, patients who died were older ($P = .03$) and had higher CDS ($P = .004$). Patients with an index GIB localized to the mouth-esophagus died less frequently, and those with an index GIB with an unidentified bleeding source died more frequently. Warfarin therapy resumption after the index GIB was associated with a lower risk for death (HR, 0.31; 95% CI, 0.15-0.62) in multivariable analysis that controlled for the propensity score, CDS, age, sex, location of GIB, ICU admission, hypertension, prior stroke diagnosis, pre-GIB percent of INRs in range, reception of low-molecular-weight heparin, length of ED/inpatient stay, and acute GIB treatment (blood transfusion) (Figure, C). This strong association persisted in a post hoc analysis excluding all patients who died within 1 week of the index GIB (Figure, D). The death rate during follow-up was lowest when warfarin therapy was resumed between 15 and 90 days after the index GIB (2.3%, $P = .04$ compared with all other patients).

COMMENT

Gastrointestinal tract bleeding is a common complication of warfarin therapy. This retrospective cohort study evaluated 90-day outcomes among warfarin-treated patients with GIB. The results highlight the clinical dilemma of managing warfarin therapy following a hospitalization or ED visit for GIB. Although we observed a numerical increase in recurrent GIB associated with not interrupting or resuming warfarin therapy in the 90 days after the index GIB, this increase was not statistically significant. However, a decision not to resume warfarin therapy was associated with a significantly increased risk for both thrombosis and death from any cause. Furthermore, while no GIB recurrences were fatal, 3 patients with atrial fibrillation had fatal strokes during warfarin therapy

Table 4. Outcomes According to Recurrent GIB Status[a]

Outcome	Overall Cohort (N = 442)	Recurrent GIB (n = 36)	No Recurrent GIB (n = 406)	*P* Value[b]

[f] In the 90 days following the initial GIB event.

discontinuation following a GIB event. While the increased risk of thrombosis and death associated with any warfarin therapy interruption has been reported previously in a Danish registry of patients with atrial fibrillation,[14] to our knowledge, ours is the first study to report this observation in a cohort of patients receiving warfarin for diverse indications specifically in the context of recent GIB. In our study, the exact date and duration of warfarin therapy interruption and adverse events were verified through medical record review, whereas in the Danish study,[14] the date of warfarin therapy interruption was estimated from warfarin prescription claims data, the reasons why patients interrupted therapy were unknown, and adverse events were not confirmed by medical record review.

The theoretical concern that abrupt warfarin therapy discontinuation following GIB causes a temporary hypercoagulable state may be relevant to the observed increase in thrombosis in patients who did not resume warfarin therapy,[15] although no thrombotic events occurred within 7 days of warfarin therapy interruption. It is difficult, if not impossible, to determine the time course between thrombus formation and subsequent clinical manifestations. However, the laboratory evidence supporting the actual existence of "rebound hypercoagulability" is inconsistent, and clinical trials have failed to demonstrate increased thromboembolic risk associated with abrupt anticoagulant withdrawal.[15]

Our observation that a decision not to resume warfarin therapy is associated with higher overall mortality was unexpected and not readily explained, given that only 3 of the 37 deaths in the group not resuming warfarin therapy were attributed to thrombosis. We attempted to control for possible confounding of the warfarin therapy resumption indicator by including pertinent factors in multivariable analysis and by performing propensity score analysis; however, the association persisted. It is possible that patients with a more serious index GIB (who would presumably be more likely to die) were also less likely to resume anticoagulation. However, the association between resuming warfarin therapy and lower mortality persisted with modeling that adjusted for ICU admission as well as blood transfusions—interventions that would be expected to be markers of a more serious initial GIB. To further explore explanations for the association between a decision not to resume warfarin therapy and death, we reanalyzed the data after excluding patients who died during the first week after the index GIB because these patients would have had less opportunity to resume warfarin therapy. Despite this, we found that the association remained significant. We acknowledge that residual confounding was likely present despite rigorous efforts at mitigation through various analytical approaches. Therefore, the apparent increase in nonthrombotic deaths when warfarin therapy was not resumed may suggest that the treating physicians were reluctant to resume warfarin therapy in sicker patients with a higher risk of death in general.

Our results provide some guidance regarding the optimal timing of warfarin therapy resumption following GIB, but clinical judgment remains a critical factor in this difficult decision. Resumption of warfarin therapy between days 1 and 7 following a GIB event was associated with a higher risk of recurrent GIB but lower risk of thrombosis. A better understanding of the propensity for recurrent hemorrhage and its severity across the spectrum of anatomic lesions would help to inform the decision of optimal timing of anticoagulation resumption, an issue of major importance for individuals at highest risk of thromboembolism.

Our study is limited in that we used data from administrative databases, and thus not all factors that affect clini-

Table 5. Patient Characteristics by Death Status at End of Follow-up[a]

[e] During the 90 days prior to the initial GIB event.

[f] Among patients with atrial fibrillation only.

cal decision making could be collected. However, the confirmation of thrombosis, recurrent GIB, and death outcomes via medical chart and death certificate review strengthens the validity of our results. The observed results are biologically plausible because the thrombotic events correlated with the indication for warfarin therapy—patients with atrial fibrillation experienced strokes or systemic embolus, while patients with venous thromboembolism had recurrent venous thromboembolism (Table 2). Despite potential confounding, our study likely underestimates the strength of the association between thrombosis and not resuming warfarin therapy because patients at the highest risk of thrombosis (eg, presence of mechanical heart valve, high $CHADS_2$ score) were probably less likely to remain off warfarin therapy following GIB. Similarly, the strength of association between recurrent GIB and resuming warfarin therapy may be underestimated because patients perceived at high risk for further GIB probably were less likely to resume warfarin therapy. Accurate recording of baseline aspirin use status was facilitated by the records maintained by CPAS. However, aspirin use status was not routinely documented in index GIB discharge summaries, and a sizeable proportion of patients did not resume warfarin therapy and were thus not followed by CPAS after the index GIB. Therefore, we were not able to accurately record aspirin use following the index GIB and acknowledge that lack of information on post-GIB aspirin use and its potential influence on the risk of recurrent GIB, thrombosis, and death is a limitation.

Our study shows that the decision to not resume warfarin therapy in the 90 days following GIB is associated

with increased risk for thrombosis and death. Our analysis suggests that, for many patients who have experienced GIB, the benefits of resuming warfarin therapy will outweigh the risks. Further research will be needed to identify the optimal duration of warfarin interruption after a GIB event and the patients for whom a more prolonged interruption can be justified.

ABSTRACT

Objective: In the 30 days after hospital discharge, hospital utilisation is common and costly. This study evaluated the association between gender and hospital utilisation within 30 days of discharge.

Design: Secondary data analysis using Poisson regression stratified by gender.

Participants: 737 English-speaking hospitalised adults from general medical service in urban, academic safety-net medical centre who participated in the Project Re-Engineered clinical trial (clinicaltrials.gov identifier: NCT00252057).

Main outcome measure: The primary end point was hospital utilisation, defined as total emergency department visits and hospital readmissions within 30 days after index discharge.

Results: Female subjects had a rate of 29 events for every 100 people and male subjects had a rate of 47 events for every 100 people (incident rate ratio (IRR) 1.62, 95% CI 1.28 to 2.06). Among men, risk factors included hospital utilisation in the 6 months prior to the index hospitalisation (IRR 3.55, 95% CI 2.38 to 5.29), being unmarried (IRR 1.72, 95% CI 1.12 to 2.64), having a positive depression screen (IRR 1.53, 95% CI 1.09 to 2.13) and no primary care physician (PCP) visit within 30 days (IRR 1.64, 95% CI 1.08 to 2.50). Among women, the only risk factor was hospital utilisation in the 6 months prior to the index hospitalisation (IRR 3.08, 95% CI 1.86 to 5.10).

Conclusions: In our data, male subjects had a higher rate of hospital utilisation within 30 days of discharge than female subjects. For men—but not for women—risk factors were being retired, unmarried, having depressive symptoms and having no PCP visit within 30 days. Interventions addressing these factors might lower hospital utilisation rates observed among men.

ARTICLE SUMMARY

Article focus

- Early hospital readmission is a common and costly occurrence in the USA. Men often use hospital emergency departments for usual source of medical care.
- We aimed to study whether men are therefore more likely to be readmitted to the hospital within 30 days of an index discharge.

Key messages

- Men have higher rates of 30-day readmission to hospital than women in this study group. Men also were less likely to complete a follow-up appointment with their primary care physician after discharge.
- Interventions that promote connecting men to primary care, address social isolation and screen for depressive symptoms may reduce the risk for early readmission among men.

Strengths and limitations of this study

- This analysis was conducted with the Project RED data set, which included, and allowed controlling for certain clinical and social confounders in our analysis such as subjects' comorbidity burden, depression symptoms, homelessness, substance abuse and other similar risk factors, in our analysis.
- This study is limited in that it was conducted at an urban safety-net hospital and may not be generalisable to other types of hospital systems.
- We also relied on subject self-report of any rehospitalisation events outside of the study site, however, were able to confirm 91% of all events using our hospital electronic medical record system.

INTRODUCTION

Hospital utilisation in the 30 days after discharge is costly and may be a marker of poor quality of care. In 2004, the cost for hospital readmissions among Medicare recipients was estimated to be US $17.4 billion.[1] Accordingly, the Affordable Care Act includes multiple provisions designed to improve care transitions. The act includes both funding to stimulate hospitals and community-based providers to coordinate post-discharge services and a programme to withhold payments, of progressively increasing amounts, to hospitals that demonstrate higher rates of readmission within 30 days after discharge.[2] The extent to

which readmissions are preventable is debated.[3 4] However, given the magnitude of the problem, even a moderate reduction in unnecessary readmissions could have a large economic impact. In fact, we have shown that hospital readmissions can be moderately reduced.[5]

With prospective identification of patients at high risk of being readmitted, providers could potentially direct resources to prevent the readmission. In order to fulfil this goal in an efficient and effective manner, providers will need to be able to identify the patients with high risk and may need to understand how to adapt services according to the risk factors identified.

Several factor associated with 30-day rehospitalisation have been well characterised. These include older age,[6 7] comorbidity,[7] income level,[8] history of prior hospitalisation,[6 7] increased length of stay in the index hospitalisation,[9] minority ethnicity,[7 10] depressive symptoms,[11 12] alcohol and drug use[10] and specific clinical conditions (eg, congestive heart failure).[6 7] The role of male gender as a risk factor for post-discharge hospital utilisation has been noted in several disease-specific contexts; yet, to our knowledge, no study of post-discharge hospital utilisation has focused on gender. While gender is not typically considered a modifiable factor, established patterns of health service utilisation that are associated with gender (ie, lower rates of preventive care and fewer visits to primary care among men) may put men at higher risk for poor outcomes after hospital discharge.[13]

Therefore, we conducted a secondary analysis of the Re-engineered Discharge (RED) clinical trial data set to assess the association between gender and the rate of post-discharge hospital utilisation among a cohort of adult patients hospitalised in an urban safety-net hospital. In addition, we sought to identify potential factors contributing to gender-based differences.

METHODS

A full description of the methods for the Project RED trial has been described previously.[5] Briefly, the Project RED trial was a two-armed randomised controlled trial of English-speaking adult patients, 18 years or older, admitted to the teaching service of Boston Medical Center. Seven hundred and forty-nine subjects were enrolled and randomised: 376 in the usual care arm and 373 in the intervention arm. Patients had to have a telephone, be able to comprehend study details and the consent process in English and have plans to be discharged to a US community. Patients were not enrolled if they were admitted from a skilled nursing facility or other hospital, transferred to a different hospital service, admitted for a planned hospitalisation, on hospital precautions, on suicide watch, deaf or blind. A total of 3873 were assessed for eligibility. Due to a lack of available research staff, 1616 patients were not assessed. Of those assessed for eligibility, 1049 did not meet eligibility criteria, 120 were previously enrolled, 527 refused to participate, 474 were unavailable in their hospital room at the time of enrolment and 954 were not approached because the maximum enrolled subject number was reached that day. Seven hundred and forty-nine subjects were enrolled and randomised: 376 in the usual care arm and 373 in the intervention arm. The Institutional Review Board of Boston University approved all study activities. Baseline demographic and clinical characteristics were similar across the study arms.

Primary outcome

The primary outcome was the rate of post-discharge hospital utilisation, defined as the total number of emergency department (ED) visits and readmissions per subject, within 30 days of their index discharge. Any ED visit in which a subject was subsequently admitted to the hospital was only counted as a readmission.

Primary independent variable and covariates

The primary independent variable, gender (male or female), was defined by the hospital electronic medical record (EMR). Potential confounders were identified a priori from the literature on factors associated with post-discharge hospital utilisation and gender including age, marital status, health literacy score,[14] Charlson score,[15] insurance type, employment status, income level, homeless status, hospital utilisation within the 6 months prior to the index hospitalisation, educational attainment, length of hospital stay, race/ethnicity, depressive symptoms and Project RED study group assignment.

Data collection

Outcome data were collected by Project RED research staff, blinded to group assignment, by review of the hospital's EMRs and by contacting subjects by telephone 30 days post-discharge. Dates of subsequent ED visits and readmissions at Boston Medical Center were obtained from the EMRs, while those at other hospitals were collected through subject report. Those subjects who could not be reached within 60 days post-discharge were assumed alive and hospital EMRs were relied upon for primary outcomes. Randomisation provided a balanced study sample, with an equal proportion of male and female participants assigned to each arm of the original trial. Of 749 subjects who had participated in a randomised clinical trial (Project RED), 737 participants were included in this secondary analysis and 12 subjects were removed due to death prior to index discharge,[6] requested removal,[13] previously enrolled[1] and missing data.[1] Data for selected covariates were collected by self-report (age, race, income, marital status, education attainment, employment status, insurance type, homelessness) or using validated tools (health literacy, depressive symptoms) or EMR (length of stay, prior utilisation, Charlson score).

Statistical analysis

Socio-demographic and clinical characteristics of the subjects were compared by gender. Bivariate analyses were conducted to identify gender differences and

potential confounders between gender and post-discharge hospital utilisation within 30 days of index discharge. χ^2 Tests were utilised for categorical variables and t tests for continuous variables. A Poisson regression was conducted using relevant potential confounders to construct the final best-fit model determining the strength of association between gender and hospital utilisation. Several interaction terms in our initial Poisson regression were significant. We therefore decided to evaluate potential interactions between gender and hospital utilisation using a stratified Poisson regression analysis.

Age, length of stay and Charlson score were used as continuous variables. Gender (male or female), marital status (married, not married) and homelessness (homeless within the last 3 months) were treated as dichotomous variables. Categorical variables were created for prior hospital utilisation (no prior visits, one to two prior visits or three or more prior visits in the previous 6 months), educational attainment (less than high school graduate, high school graduate or GED or any college), insurance type (Medicare, Medicaid, private insurance or Massachusetts State Subsidised Free Care), income level (no income, <$10 000/year, $10 000–20 000, $20 000 or more or declined to answer), level of health literacy (grade 3 and below, grades 4–6, grades 7–8 or grade 9 and above) according to the Rapid Estimate of Adult Literacy in Medicine and employment status (employed, not employed, disabled, retired or other).

Hospital utilisation is defined as the sum of emergency room visits and hospitalisations (an emergency room visit that leads to a hospitalisation is counted only as a hospitalisation). Hospital utilisation incidence rates were calculated as the number of hospital utilisation events within 30 days of discharge per subject. Person-time was measured in months. The unadjusted incident rate ratio (IRR) was calculated as the ratio of the rate of hospital utilisation among male patients versus female patients using Poisson regression. p Values and CIs were corrected for over dispersion if necessary.

Poisson models were used to test for statistically significant differences in the number of post-discharge hospital utilisation events at 30 days. Two-sided significance tests were used. p Values of <0.05 were considered to indicate statistical significance. A Kaplan–Meier survival curve was generated for the time to multiple hospital utilisation events for the 30-day period following the index discharge and compared using a log-rank test. All data were analysed with S-Plus 8.0.

RESULTS

The analytic cohort included 367 male subjects and 370 female subjects. Socio-demographic, healthcare utilisation and health status indicator variables, stratified by gender, are shown in table 1. Gender differences existed among a number of variables. For example, male subjects were approximately 4 years younger and were more likely to be white non-Hispanic or Hispanic and less likely black non-Hispanic than female subjects. Men reported a relatively higher income, with almost 10% more men reporting an annual personal income of $20 000 or more compared with women. Male subjects were more likely to have private insurance, while female subjects were more likely to have Medicaid. Women reported having a primary care physician (PCP) at baseline at a significantly higher rate than men (88% vs 74%, p<0.001). Women also had higher levels of depressive symptoms (Patient Health Questionnaire-9, 2.5 vs 1.9), were more likely to report a history of having been diagnosed as having depression (46% vs 26%) and were more likely to report currently taking medicine for depression (26% vs 13%).

Hospital utilisation

Female subjects had a rate of 29 events per 100 people per month and male subjects had a rate of 47 events per 100 people per month (IRR 1.62, 95% CI 1.28 to 2.06) (table 2). This difference is largely attributable to a higher rate of ED visits among male subjects (IRR 2.04, 95% CI 1.45 to 2.86). Furthermore, Kaplan–Meier survival curves for the time to multiple hospital utilisation events in the 30 days following index discharge showed that men were more likely to return to the hospital (p=0.04) (figure 1). At the 30-day follow-up telephone call, fewer men reported understanding their appointments after leaving the hospital compared with women (78% and 87%, p=0.005, respectively) (table 2). In addition, at 30 days post-discharge, women reported visiting their PCPs at a higher rate within the 30 days after their hospital discharge (57% and 49%, p=0.04, respectively).

Risk factors for hospital reutilisation by gender

A Poisson regression that is stratified by gender is shown in table 3. The model is controlled for age, previous hospital visits, employment, marital status, depression, study group, having a PCP at baseline and attending a PCP appointment. Among women, the only predictive factor was hospital utilisation in the 6 months prior to the index hospitalisation. Prior hospitalisation was also a risk factor for returning to the hospital within 30 days among men; however, additional significant factors were (1) being retired, (2) not married, (3) having a positive depression screen, (4) reporting no PCP visit within 30 days and (5) not being reached for the follow-up call at 30 days.

DISCUSSION

Among our subjects, we found that men have a higher rate of hospital utilisation within 30 days of hospital discharge than women. ED visits accounted for most of this difference. Among both men and women, prior hospital utilisation is predictive of future utilisation; however, risk factors including being retired, unmarried and having a positive depression screen were identified as risk factors exclusively in men. Additionally, men fared more poorly at understanding and attending their follow-up appointments, which also appeared to be an

†Free care refers to a Massachusetts state programme for uninsured patients.
‡REALM health literacy categories correspond to total REALM scores of grade 3 and below (0–18), grades 4–6 (19–44), grades 7–8 (45–60), grade 9 and above (61–66).
§Prior hospital admissions and ED visits include those that occurred within 6 months prior to index admission.
¶Charlson comorbidity index reflects the cumulative increased likelihood of 1-year mortality; the higher the score, the more severe the burden of comorbidity; a 35% increase in risk of dying is reflected in a one-point increase in weights. Minimum score equals 0, no maximum score.
**Short Form-12 Health Survey (SF-12)—Physical Component Summary (PCS): range 0–100, mean score for US population=50 (SD=10), higher scores suggest greater physical functional status. Mental Component Summary (MCS): range 0–100, mean score for US population=50 (SD=10), higher scores suggest greater mental functional status.
††Patient Health Questionnaire (PHQ-9): 9-item 4-point Likert scale, standard scoring algorithm to diagnose major and minor depression and anxiety disorders.
ED, emergency department; PCP, primary care physician; REALM, Rapid Estimate of Adult Literacy in Medicine.

independent risk factor for returning to the hospital for men in this study.

Identifying and addressing risk factors associated with early post-discharge hospital utilisation is useful so that resources can be efficiently tailored to each individual patient's risk profile. Ideally, methods to ameliorate important risk factors are available. Some risk factors, like gender, however, may seem inherently immutable. Yet, as we demonstrated in this study, male gender is associated with other parameters that could potentially be effectively targeted.

Our findings raise the possibility that social isolation—as illustrated by the positive association with being retired, unmarried and symptoms of depression—may be important factors to target for intervention. Supporting these findings are studies examining

Table 2 Primary and secondary outcomes, by gender

	Men	Women	p Value
Primary outcomes ≤30 days after index hospitalisation			
Patients, n	367	370	
Hospital utilisations, n (visits/patient/mo)*	174 (0.474)	108 (0.292)	<0.01

Readmissions, n (visits/patient/mo)	73 (0.199)	58 (0.157)	0.09
IRR (95% CI)	1.27 (0.90 to 1.79)	REF	
Secondary outcomes†			
Patients reached for 30-day follow-up call, n (%)	292 (80)	322 (87)	<0.01
Able to identify PCP name, n (%)	224 (77)	284 (88)	<0.01
PCP appt scheduled prior to discharge, n (%)	223 (60)	230 (63)	0.41
Visited PCP, n (%)	142 (49)	183 (57)	0.04
Visited specialist, n (%)	81 (28)	105 (33)	0.19
Able to identify discharge diagnosis, n (%)	212 (73)	247 (77)	0.24
How well did you understand your appointments after you left the hospital?‡ (those reporting understood well or very well)	210 (78%)	263 (87%)	<0.01
How well did you understand how to take your medications after leaving the hospital? (those reporting understood well or very well)	227 (84%)	270 (88%)	0.12
How well did you understand your main problem or diagnosis when you left the hospital? (those reporting understood well or very well)	175 (62%)	190 (61%)	0.65
How prepared were you to leave the hospital? (those reporting well prepared or very well)	175 (62%)	185 (59%)	0.40

*Defined as sum of emergency department (ED) visits plus rehospitalisations. Note: An ED visit that leads to a rehospitalisation is counted only as a rehospitalisation.
†Denominators reflect those subjects reached at 30-day follow-up phone call and those that answered question.
‡Questions asked on a 5-point Likert scale; Per cent reflects subjects who responded with either of the top two categories on the scale (ie, 'very prepared' or 'prepared').
IRR, incidence rate ratios.

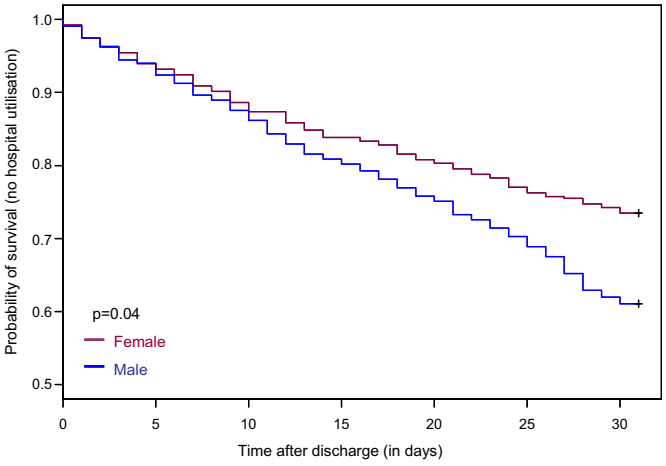

Figure 1 Kaplan–Meier curve: time to multiple hospitalisation events by gender.

the impact of social support and social networks. These studies have found that, in general, men are more socially isolated than women and that this contributes to worse health outcomes among men.[13 16] Men who were socially isolated were found to be less likely to undergo screening for blood pressure, cholesterol and cancer.[16]

Other studies suggest that men report less help-seeking behaviours, use primary care less[10] and are less likely to have a primary care physician when compared with women.[13] Overall, women use more health services than men due to pregnancy and cervical and breast cancer screening programmes.[6] However, lower rate of connectedness to primary care among men may also contribute to their excess use of hospital services and the finding that they may delay accessing care when it is needed.[17] Perhaps paradoxically, one study showed that increased access to primary care actually increased subsequent hospital utilisation; however, this study was conducted in the VA with almost exclusively male subjects and may have reflected appropriate use of hospital services among those who had been previously underserved.[18] Evidence suggests other factors that may impact a man's health-seeking behaviour including (1) men may have an overly optimistic perception of their health status, (2) the role women play in care-seeking decisions of men, (3) the influence of social networks and mood disorders and (4) the relatively lower value men appear to place on preventive care.[13 17]

Mood disorders can exacerbate the impact of social isolation on health. Men are far less likely than women to seek help for depression or anxiety.[19] Even when they do present for care, depression is often misdiagnosed or overlooked by providers.[20] These differences may be due to the differences in perceptions of distress experienced by men and women but may contribute to the low help-seeking behaviours exhibited by men. Still, given the effective treatment available for depression and anxiety disorders, depression represents a targetable risk for reducing unwarranted hospital utilisation by men.

Table 3 Adjusted incidence rate ratios (IRRs) and 95% CIs for socio-demographic characteristics on hospital utilisation in 30 days after index discharge

Variable	Total (n=737), IRR (95% CI)	Male (n=367), IRR (95% CI)	Female (n=370), IRR (95% CI)

IRR, incident rate ratio; PCP, primary care physician.

This analysis suggests that approaches to mitigate the risk of post-discharge rehospitalisations or ED visits among men may be to develop interventions that promote a connection to primary care, address social isolation and diagnose and treat depressive symptoms. Addressing these risks will require a creative and innovative approach including methods like routine screening for depressive symptoms, more aggressive empowerment of patients to engage the healthcare system proactively rather than reactively and establishing group visits within primary care to foster a social environment paired with the provision of primary care services and health education, as has been used in diabetes care and other chronic illnesses.[21]

This study has several limitations. Data on hospital utilisation outside Boston Medical Center were determined using patient self-report and not confirmed by EMR review at other hospitals. We were, however, able to confirm 91% of all events by consulting our own EMR. Second, our results may not be generalisable to populations other than those served by urban safety-net hospitals or other populations excluded from the RED trial (eg, non-English-speaking patients and patients admitted from nursing homes). Third, not all patients were reached at 30 days for the follow-up phone call, which is how the information regarding PCP follow-up was gathered. Finally, having done our project in Massachusetts, our population may have had an uncommonly high level of access to primary care.

In summary, our findings suggest that male gender is an important risk factor for early unplanned hospital utilisation within 30 days of discharge. This association may be linked to social behavioural patterns commonly associated with male gender, such as delayed help-seeking behaviours, often resulting in sporadic and episodic use of health services by men. Interventions targeting factors at the root of this phenomenon—such as social isolation, low rates of primary and preventive healthcare use and treatment of depressive symptoms—may help mitigate this gender effect. As health insurance reform and workforce development in primary care evolve, special efforts may be needed to acculturate men to the use of outpatient services.

ANTITHROMBOTIC THERAPY AND PREVENTION OF THROMBOSIS, 9TH ED: ACCP GUIDELINES

Antithrombotic Therapy for Atrial Fibrillation

Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines

John J. You, MD; Daniel E. Singer, MD; Patricia A. Howard, PharmD; Deirdre A. Lane, PhD; Mark H. Eckman, MD; Margaret C. Fang, MD, MPH; Elaine M. Hylek, MD, MPH; Sam Schulman, MD, PhD; Alan S. Go, MD; Michael Hughes, PhD; Frederick A. Spencer, MD; Warren J. Manning, MD; Jonathan L. Halperin, MD; and Gregory Y. H. Lip, MD

Background: **The risk of stroke varies considerably across different groups of patients with atrial fibrillation (AF). Antithrombotic prophylaxis for stroke is associated with an increased risk of bleeding. We provide recommendations for antithrombotic treatment based on net clinical benefit for patients with AF at varying levels of stroke risk and in a number of common clinical scenarios.**

Methods: **We used the methods described in the Methodology for the Development of Antithrombotic Therapy and Prevention of Thrombosis Guidelines: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines article of this supplement.**

Results: **For patients with nonrheumatic AF, including those with paroxysmal AF, who are (1) at low risk of stroke (eg, $CHADS_2$ [congestive heart failure, hypertension, age ≥ 75 years, diabetes mellitus, prior stroke or transient ischemic attack] score of 0), we suggest no therapy rather than antithrombotic therapy, and for patients choosing antithrombotic therapy, we suggest aspirin rather than oral anticoagulation or combination therapy with aspirin and clopidogrel; (2) at intermediate risk of stroke (eg, $CHADS_2$ score of 1), we recommend oral anticoagulation rather than no therapy, and we suggest oral anticoagulation rather than aspirin or combination therapy with aspirin and clopidogrel; and (3) at high risk of stroke (eg, $CHADS_2$ score of ≥ 2), we recommend oral anticoagulation rather than no therapy, aspirin, or combination therapy with aspirin and clopidogrel. Where we recommend or suggest in favor of oral anticoagulation, we suggest dabigatran 150 mg bid rather than adjusted-dose vitamin K antagonist therapy.**

Conclusions: **Oral anticoagulation is the optimal choice of antithrombotic therapy for patients with AF at high risk of stroke ($CHADS_2$ score of ≥ 2). At lower levels of stroke risk, antithrombotic treatment decisions will require a more individualized approach.**

CHEST 2012; 141(2)(Suppl):e531S–e575S

Abbreviations: AAD = antiarrythmic drug; ACS = acute coronary syndrome; ACTIVE = Atrial Fibrillation Clopidogrel Trial With Irbesartan for Prevention of Vascular Events; AF = atrial fibrillation; AFASAK = Atrial Fibrillation Aspirin and Anticoagulation; AFFIRM = Atrial Fibrillation Follow-up Investigation of Rhythm Management; $CHADS_2$ = congestive heart failure, hypertension, age ≥ 75 years, diabetes mellitus, prior stroke or transient ischemic attack; CHA_2DS_2-VASc = congestive heart failure (or left ventricular systolic dysfunction), hypertension, age ≥ 75 years, diabetes mellitus, prior stroke or transient ischemic attack, vascular disease, age 65 to 74 years, female sex; EAFT = European Atrial Fibrillation Trial; ESPS = European Stroke Prevention Study; INR = international normalized ratio; LAA = left atrial appendage; MI = myocardial infarction; PAF = paroxysmal atrial fibrillation; RCT = randomized controlled trial; RE-LY = Randomized Evaluation of Long-Term Anticoagulation Therapy; SPAF = Stroke Prevention in Atrial Fibrillation; TEE = transesophageal echocardiography; TIA = transient ischemic attack; VKA = vitamin K antagonist

Note on Shaded Text: Throughout this guideline, shading is used within the summary of recommendations sections to indicate recommendations that are newly added or have been changed since the publication of Antithrombotic and Thrombolytic Therapy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). Recommendations that remain unchanged are not shaded.

2.1.8. For patients with AF, including those with paroxysmal AF, who are at low risk of stroke (eg, $CHADS_2$ [congestive heart failure, hypertension, age ≥ 75 years, diabetes mellitus, prior stroke or transient ischemic attack] score = 0), we suggest no therapy rather than antithrombotic therapy (Grade 2B)**. For patients who do choose antithrombotic therapy, we suggest aspirin (75 mg to 325 mg once daily) rather than oral anticoagulation** (Grade 2B) **or combination therapy with aspirin and clopidogrel** (Grade 2B)**.**

Remarks: Patients who place an exceptionally high value on stroke reduction and a low value on avoiding bleeding and the burden associated with antithrombotic therapy are likely to choose antithrombotic therapy rather than no antithrombotic therapy. Other factors that may influence the choices above are a consideration of patient-specific bleeding risk and the presence of additional risk factors for stroke, including age 65 to 74 years and female gender, which have been more consistently validated, and vascular disease, which has been less well validated (see section 2.1.12). The presence of multiple non-$CHADS_2$ risk factors for stroke may favor oral anticoagulation therapy.

2.1.9. For patients with AF, including those with paroxysmal AF, who are at intermediate risk of stroke (eg, $CHADS_2$ score = 1), we recommend oral anticoagulation rather than no therapy (Grade 1B)**. We suggest oral anticoagulation rather than aspirin (75 mg to 325 mg once daily)** (Grade 2B) **or combination therapy with aspirin and clopidogrel** (Grade 2B)**. For patients who are unsuitable for or choose not to take an oral anticoagulant (for reasons other than concerns about major bleeding), we suggest combination therapy with aspirin and clopidogrel rather than aspirin (75 mg to 325 mg once daily)** (Grade 2B)**.**

Remarks: Patients who place an exceptionally high value on stroke reduction and a low value on avoiding bleeding and the burden associated with anticoagulant therapy are likely to choose oral anticoagulation rather than antiplatelet therapy. Other factors that may influence the choice among antithrombotic therapies are a consideration of bleeding risk and the presence of additional risk factors for stroke, including age 65 to 74 years and female gender, which have been more consistently validated, and vascular disease, which has been less well validated (see section 2.1.12). The presence of multiple additional non-$CHADS_2$ risk factors for stroke may favor oral anticoagulation therapy.

2.1.10. For patients with AF, including those with paroxysmal AF, who are at high risk of stroke (eg, $CHADS_2$ score = 2), we recommend oral anticoagulation rather than no therapy (Grade 1A)**, aspirin (75 mg to 325 mg once daily)** (Grade 1B)**, or combination therapy with aspirin and clopidogrel** (Grade 1B)**. For patients who are unsuitable for or choose not to take an oral anticoagulant (for reasons other than concerns**

about major bleeding), we recommend combination therapy with aspirin and clopidogrel rather than aspirin (75 mg to 325 mg once daily) (Grade 1B)**.**

2.1.11. For patients with AF, including those with paroxysmal AF, for recommendations in favor of oral anticoagulation (including 2.1.9, 2.1.10, and excluding 2.2, 3.1, 3.2, 3.3), we suggest dabigatran 150 mg twice daily rather than adjusted-dose vitamin K antagonist (VKA) therapy (target INR range, 2.0-3.0) (Grade 2B)**.**

Remarks: Dabigatran is excreted primarily by the kidney. It has not been studied and is contraindicated in patients with severe renal impairment (estimated creatinine clearance of 30 mL/min or less). Clinicians should be aware that there is no antidote for dabigatran.

2.2. For patients with AF and mitral stenosis, we recommend adjusted-dose VKA therapy (target INR range, 2.0-3.0) rather than no therapy, aspirin (75 mg to 325 mg once daily), or combination therapy with aspirin and clopidogrel (all Grade 1B)**. For patients with AF and mitral stenosis who are unsuitable for or choose not to take adjusted-dose VKA therapy (for reasons other than concerns about major bleeding), we recommend combination therapy with aspirin and clopidogrel rather than aspirin (75 mg to 325 mg once daily) alone** (Grade 1B)**.**

3.1. For patients with AF and stable coronary artery disease (eg, no acute coronary syndrome within the previous year) and who choose oral anticoagulation, we suggest adjusted-dose VKA therapy alone (target international normalized ratio [INR] range, 2.0-3.0) rather than the combination of adjusted-dose VKA therapy and aspirin (Grade 2C)**.**

3.2. For patients with AF at high risk of stroke (eg, $CHADS_2$ score of 2 or greater) during the first month after placement of a bare-metal stent or the first 3 to 6 months after placement of a drug-eluting stent, we suggest triple therapy (eg, VKA therapy, aspirin, and clopidogrel) rather than dual antiplatelet therapy (eg, aspirin and clopidogrel) (Grade 2C)**. After this initial period of triple therapy, we suggest a VKA (INR 2.0-3.0) plus a single antiplatelet drug rather than VKA alone** (Grade 2C)**. At 12 months after intracoronary stent placement, antithrombotic therapy is suggested as for patients with AF and stable coronary artery disease (see section 3.1).**

For patients with AF at low to intermediate risk of stroke (eg, $CHADS_2$ score of 0 or 1) during the first 12 months after placement of an intracoronary stent (bare metal or drug eluting), we suggest dual antiplatelet therapy rather than triple therapy (Grade 2C)**. At 12 months after intracoronary stent placement, antithrombotic therapy is suggested as for patients with AF and stable coronary artery disease (see section 3.1).**

Remarks: Patients who place an exceptionally high value on stroke reduction and a low value on avoiding bleeding and the burden associated with anticoagulant therapy are likely to choose triple therapy rather than dual antiplatelet therapy. Other factors that may influence this choice are a consideration of bleeding risk and the presence of additional non-$CHADS_2$ risk factors for stroke (see section 2.1.12).

3.3. For patients with AF at intermediate to high risk of stroke (eg, $CHADS_2$ score of 1 or greater) who experience an acute coronary syndrome and do not undergo intracoronary stent placement, we suggest for the first 12 months, adjusted-dose VKA therapy (INR 2.0-3.0) plus single antiplatelet therapy rather than dual antiplatelet therapy (eg, aspirin and clopidogrel) or triple therapy (eg, warfarin, aspirin, and clopidogrel) (Grade 2C)**. After the first 12 months, antithrombotic therapy is suggested as for patients with AF and stable coronary artery disease (see section 3.1).**

For patients with AF at low risk of stroke (eg, $CHADS_2$ score of 0), we suggest dual antiplatelet therapy (eg, aspirin and clopidogrel) rather than adjusted-dose VKA therapy (INR 2.0-3.0) plus single antiplatelet therapy or triple therapy (eg, warfarin, aspirin, and clopidogrel) (Grade 2C)**. After the first 12 months, antithrombotic therapy is suggested as for patients with AF and stable coronary artery disease (see section 3.1).**

Remarks: Patients who place an exceptionally high value on stroke reduction and a low value on avoiding bleeding and the burden associated with anticoagulant therapy are likely to choose adjusted-dose VKA therapy plus single antiplatelet therapy rather than dual antiplatelet therapy. Other factors that may influence this choice are a consideration of bleeding risk and the presence of additional non-$CHADS_2$ risk factors for stroke (see section 2.1.12).

3.4. For patients with AF being managed with a rhythm control strategy (pharmacologic or

catheter ablation), we suggest that antithrombotic therapy decisions follow the general risk-based recommendations for patients with AF in section 2.1, regardless of the apparent persistence of normal sinus rhythm (Grade 2C)**.**

3.5. For patients with atrial flutter, we suggest that antithrombotic therapy decisions follow the same risk-based recommendations as for AF.

4.1.1. For patients with AF of greater than 48 h or unknown duration undergoing elective electrical or pharmacologic cardioversion, we recommend therapeutic anticoagulation (adjusted-dose VKA therapy, target INR range 2.0-3.0, low-molecular-weight heparin at full venous thromboembolism treatment doses, or dabigatran) for at least 3 weeks before cardioversion or a transesophageal echocardiography (TEE)-guided approach with abbreviated anticoagulation before cardioversion rather than no anticoagulation (Grade 1B)**. We recommend therapeutic anticoagulation for at least 4 weeks after successful cardioversion to sinus rhythm rather than no anticoagulation, regardless of the baseline risk of stroke** (Grade 1B)**. Decisions about anticoagulation beyond 4 weeks should be made in accordance with our risk-based recommendations for long-term antithrombotic therapy in section 2.1.**

4.1.2. For patients with AF of documented duration of 48 h or less undergoing elective cardioversion (electrical or pharmacologic), we suggest starting anticoagulation at presentation (low-molecular-weight heparin or unfractionated heparin at full venous thromboembolism treatment doses) and proceeding to cardioversion rather than delaying cardioversion for 3 weeks of therapeutic anticoagulation or a TEE-guided approach (Grade 2C)**. After successful cardioversion to sinus rhythm, we recommend therapeutic anticoagulation for at least 4 weeks rather than no anticoagulation, regardless of baseline stroke risk** (Grade 2C)**. Decisions about long-term anticoagulation after cardioversion should be made in accordance with our risk-based recommendations for long-term antithrombotic therapy in section 2.1.**

4.2. For patients with AF and hemodynamic instability undergoing urgent cardioversion (electrical or pharmacologic), we suggest that therapeutic-dose parenteral anticoagulation be started before cardioversion, if possible (Grade 2C)**, but that initiation of anticoagulation must not delay any emergency intervention** (Grade 2C)**. After successful cardioversion to sinus rhythm, we suggest therapeutic anticoagulation for at least 4 weeks after successful cardioversion to sinus rhythm rather than no anticoagulation, regardless of baseline stroke risk** (Grade 2C)**. Decisions about anticoagulation beyond 4 weeks should be made in accordance with our risk-based recommendations for long-term antithrombotic therapy in section 2.1.**

4.3. For patients with atrial flutter undergoing elective or urgent pharmacologic or electrical cardioversion, we suggest that the same approach to thromboprophylaxis be used as for patients with atrial fibrillation undergoing cardioversion.

Atrial fibrillation (AF) is the most common sustained cardiac arrhythmia. One in four individuals aged 40 years will develop AF during his or her lifetime, and it has been estimated that by the year 2050, up to 16 million Americans will have AF.[1,2] Nonrheumatic AF is a strong, independent predictor of ischemic stroke associated with a fivefold increase in risk.[3] Without thromboprophylaxis, the risk of ischemic stroke in patients with nonrheumatic AF, as seen in the control arms of the original trials of antithrombotic therapy in AF, is ~5% per year.[4] Over the past 2 decades, considerable work has been done to evaluate antithrombotic therapies to prevent stroke in patients with AF, and the field continues to evolve with the emergence of a new generation of oral anticoagulants.

This article begins with a discussion of the methods used to develop our recommendations for antithrombotic therapy in patients with AF. Next, we provide our treatment recommendations, divided into the following sections:

1. Antithrombotic therapy in patients with AF in general (includes patients with permanent, persistent, or paroxysmal AF [PAF])
2. Antithrombotic therapy in patients with AF in special situations:
   - Stable coronary artery disease
   - Acute coronary syndrome (ACS)
   - Intracoronary artery stent
   - Acute ischemic stroke
   - Management with a rhythm control strategy
   - Chronic atrial flutter
3. Antithrombotic therapy for patients with AF undergoing cardioversion

The article ends with a discussion of practical issues in the use of adjusted-dose vitamin K antagonist (VKA) therapy in patients with AF and suggestions for future research.

Table 1 specifies the clinical question being addressed in this article (in PICO [population, intervention, comparator, outcomes] format) and the types of studies used. This article does not give recommendations for antithrombotic therapy in patients with AF around the time of surgical or invasive procedures (see Douketis et al[5]), at the time of presentation with acute stroke (see Lansberg et al[6]), or in patients with AF who have prosthetic heart valves (see Whitlock et al[7]). This article does not give recommendations for patients with AF who are pregnant. For general recommendations on antithrombotic therapy during pregnancy (ie, not specific to AF), see Bates et al.[8] Finally, the recommendations in this article apply to patients with persistent and permanent AF and to patients with PAF but do not apply to patients with a single, transient, self-limited episode of AF associated with acute illness.

1.0 Methods

To inform our guideline development, we searched for relevant articles published since the last literature search performed for the Antithrombotic and Thrombolytic Therapy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). Specifically, for literature regarding the assessment of stroke risk in patients with AF, we searched Medline for articles published from January 1, 2005, to October 2009 using the search terms "atrial fibrillation," "atrial flutter," "risk assessment," "risk factors," "risk stratification," "stroke," and "thromboembolism." For literature regarding prevention of stroke and thromboembolism in patients with AF, we searched Medline for articles published from January 1, 2005, to October 2009 using the search terms "coumarins," "warfarin," "dicumarol," "phenprocoumon," "acenocoumarol," "fondaparinux," "idraparinux," "aspirin," "triflusal," "indobufen," "dabigatran," "ximelagatran," "rivaroxaban," "apixaban," "ticlopidine," "clopidogrel," "catheter ablation," "watchman," "PLAATO," "cardioversion," "atrial fibrillation," and "atrial flutter."

1.1 Outcomes of Interest

The outcomes most relevant to patients with AF include death, nonfatal stroke, systemic embolism, nonfatal major extracranial bleeding, and the burden and lifestyle limitations associated with outpatient antithrombotic therapy. To facilitate decision-making, the term stroke in this article includes ischemic stroke and intracranial hemorrhage (intracerebral, subdural, and subarachnoid hemorrhage). Although there may be some differences in the impact of these intracranial events (eg, subdural hemorrhage) on quality of life, we judged that on average, the impact would be similar. We also explicitly considered that outpatient antithrombotic therapy was associated with a burden to the patient, which in some cases, such as aspirin, is a requirement to take a daily medication, or in other cases, such as adjusted-dose VKA therapy, is not only a requirement to take a daily medication but also a requirement to limit one's lifestyle, restrict one's diet, and undergo frequent blood testing and clinic visits. For recommendations about patients with AF and stable coronary artery disease, intracoronary stent placement, or recent ACS (sections 3.1-3.3), we also considered the effect of different treatment options on the outcome of nonfatal myocardial infarction (MI).

1.2 Patient Values and Preferences

In developing our treatment recommendations, we attempted to account for patient values and preferences regarding these health states. In this guideline, a systematic review of studies assessing values and preferences related to antithrombotic therapy found that values for health states and preferences for treatments vary appreciably among individuals (MacLean et al[9]). The available literature has several limitations. The studies eliciting preferences were small and used different methods and tools, and most included a sizeable proportion of participants who had previously taken or were currently taking VKAs. Furthermore, there are inconsistencies across studies that often are difficult to explain, leaving considerable uncertainty about average patient values. Nevertheless, to make our recommendations, we required an estimate of average patient values for the relevant outcomes so that we could judge whether the trade-offs between benefit and harm would favor one course of treatment over another.

As described by Guyatt et al[10] in this guideline, to obtain our estimates of average patient values, we have used ratings of key health states from participating guideline panelists informed by our systematic review of the relevant literature. The results of the panelist value rating exercise suggest that on average, patients would find a typical nonfatal stroke (ischemic or hemorrhagic) approximately three times as aversive as a nonfatal major extracranial bleed (typically a GI bleed) and a typical nonfatal MI as aversive as a nonfatal major extracranial bleed.

With the exception of the choice between VKA therapy and no therapy, the choice of one antithrombotic treatment over another for long-term stroke prevention in AF will not lead to differences in all-cause mortality (section 2). Thus, for these choices that are not expected to result in a difference in mortality, for every 1,000 patients treated for 1 year, if the number of nonfatal strokes prevented is less than one-third of the number of nonfatal major extracranial bleeds caused by a given antithrombotic therapy, we have recommended against that intervention. If the number of nonfatal strokes prevented is appreciably more than one-third of the number of nonfatal major extracranial bleeding events that result from a given antithrombotic therapy, we have recommended in favor.

Making these trade-offs requires not only estimates regarding average patient values for the relevant outcomes but also best estimates of (1) the effect of a given treatment on these outcomes against a given comparator (ie, relative risk) and (2) the absolute event rates for these outcomes in untreated patients (or, for PICO questions of a treatment vs an active comparator, the absolute event rates in patients receiving the active comparator). In the following section, we present the methods used to obtain these estimates for our guidelines.

1.3 Estimating the Magnitude of Treatment Effect

For each clinical question, we extracted data regarding the previously discussed outcomes from the relevant clinical trials. When there were multiple randomized controlled trials (RCTs) addressing the same clinical question, we conducted meta-analyses using random-effects models and the Mantel-Haenszel method to obtain pooled estimates of treatment effect, expressed as relative risk. For studies that did not report the proportion of strokes that were fatal and nonfatal, we used all available data in the published report to obtain a best estimate of the effect of

Table 1—*[Introduction] Clinical Questions Addressed in This Article*

Section	Population	Intervention	Comparator	Outcomes of Interest	Available Methodology
		2. Patients with AF in general			
2.1.1	Patients with nonrheumatic AF	Adjusted-dose VKA	No therapy	Death	RCTs
2.1.2		Antiplatelet monotherapy (eg, aspirin)	No therapy	Nonfatal strokes Nonfatal major extracranial bleeds	
2.1.3		VKA	Antiplatelet monotherapy (eg, aspirin)	Systemic embolism Procedural complications (for percutaneous closure of left atrial appendage only)	
2.1.4		VKA	Aspirin + clopidogrel		
2.1.5		Aspirin + clopidogrel	Aspirin		
2.1.6		New oral anticoagulants	VKA		
2.1.11		Dabigatran	VKA		
2.1.13		Percutaneous closure of left atrial appendage	VKA		RCTs Cohort studies
2.2	Patients with AF and mitral stenosis	VKA	No therapy, antiplatelet monotherapy (eg, aspirin), or aspirin + clopidogrel		Cohort studies
		3. Management of antithrombotic therapy for patients with AF in special situations			
3.1	Patients with AF and stable coronary artery disease	VKA + aspirin	VKA	Death Nonfatal strokes	Cohort studies
3.2	Patients with AF and placement of an intracoronary stent (with or without recent ACS)	VKA + aspirin + clopidogrel	Aspirin + clopidogrel	Nonfatal MI Nonfatal major extracranial bleeds Systemic embolism	
3.3	Patients with AF and ACS who do not undergo intracoronary stent placement	VKA + aspirin	Aspirin + clopidogrel VKA + aspirin + clopidogrel		
3.4	Patients with AF being managed with a rhythm control strategy	VKA	No VKA	Death Nonfatal strokes	
3.5	Patients with chronic atrial flutter	Antithrombotic therapy options as per section 2.1		Nonfatal major extracranial bleeds Systemic embolism	
		4. Patients with AF undergoing cardioversion			
4.1.1	Patients with AF of > 48 h or unknown duration undergoing elective cardioversion	Minimum 3 wk anticoagulation before and 4 wk after cardioversion	No anticoagulation	Death Nonfatal strokes Nonfatal major extracranial bleeds	Cohort studies
		Abbreviated precardioversion anticoagulation + TEE-guided cardioversion	No anticoagulation	Systemic embolism	RCTs Cohort studies
4.1.2	Patients with AF of ≤ 48 h duration undergoing elective cardioversion	Anticoagulation before cardioversion	No anticoagulation before cardioversion		Cohort studies
4.2	Patients undergoing urgent cardioversion for hemodynamically unstable AF	Anticoagulation before cardioversion	No anticoagulation before cardioversion		Cohort studies
4.3	Patients undergoing elective or urgent cardioversion for atrial flutter	Anticoagulation before and after cardioversion	No anticoagulation		Cohort studies

ACS = acute coronary syndrome; AF = atrial fibrillation; MI = myocardial infarction; RCT = randomized controlled trial; TEE = transesophageal echocardiography; VKA = vitamin K antagonist.

treatment on nonfatal stroke by assuming a case fatality rate of 50% for hemorrhagic stroke and 25% for ischemic stroke based on population-based stroke registry data and the case fatality rates observed in the RCTs of patients with AF that reported such data.[11] For nonfatal major extracranial bleeding, we accepted the definition of major bleeding from the individual studies, and when the proportion of major extracranial bleeds that were fatal vs nonfatal was not reported, we applied the average case fatality rate for major extracranial bleeding reported across the relevant clinical trials (~15%). For the outcome of systemic embolism, we used the total number of events (fatal and nonfatal) because systemic embolism was an infrequent event and typically not reported as fatal vs nonfatal.

1.4 Deriving Baseline Risk of Stroke in Patients With AF

The risk of stroke varies considerably across different groups of patients with AF.[12] Simple validated tools for the assessment of stroke risk in patients with AF help in identifying those who are more likely to benefit than be harmed from antithrombotic therapy.

1.4.1 Pattern of AF: Guidelines have categorized the pattern of AF into (1) PAF, in which recurrent episodes terminate spontaneously within 7 days and usually in < 48 h; (2) persistent AF, in which the episode of AF does not self-terminate within 7 days or is terminated by cardioversion; and (3) permanent AF, in which AF is present for some time and cardioversion either has failed or has not been attempted.[13]

For patients with PAF, periods of sinus rhythm theoretically should lessen the risk of stroke, yet transitions from AF to sinus rhythm may acutely heighten risk in a manner similar to the increase in risk caused by cardioversion. Although some studies suggest that PAF is associated with a lower risk of stroke than persistent or permanent AF, patients with PAF generally are younger and have a lower prevalence of other stroke risk factors, and clinical trial data suggest that PAF confers a relative risk of stroke similar to persistent or permanent AF when controlling for associated stroke risk factors.[14-17] Pending further evidence, it seems reasonable to treat patients with PAF in a manner similar to those with persistent and permanent AF; thus, our risk-based treatment recommendations apply to patients with PAF and persistent and permanent AF.

1.4.2 Independent Risk Factors for Stroke in Patients With AF: Two recent systematic reviews have identified clinical and echocardiographic factors that are independently associated with an increased risk of stroke in patients with AF.[18,19] The individual studies from these systematic reviews, in addition to articles identified in an updated literature search performed for this guideline, are summarized in Tables S1 through S12 (tables that contain an "S" before the number denote supplementary tables not contained in the body of the article and available instead in an online data supplement; see the "Acknowledgments" for more information). In terms of clinical applicability, the most consistently identified risk factors for ischemic stroke among patients with AF are a history of ischemic stroke or transient ischemic attack (TIA)—the strongest dichotomous predictor of stroke risk—older age, hypertension, and diabetes. Although impaired left ventricular systolic function is a risk factor for stroke in AF, there are conflicting data about whether a history of congestive heart failure per se raises the risk of ischemic stroke in AF. Although age thresholds often are used in stroke risk schemes, stroke risk in AF increases continuously with age, appreciably rising from age 65 years onward.[20] There is moderate-quality evidence that women face a higher risk of stroke than men.[18] A history of coronary artery disease has not consistently been found to be an independent risk factor for stroke in patients with AF.[18] However, there is low-quality evidence that the presence of atherosclerotic vascular disease (eg, complex aortic plaque in the descending aorta seen on transesophageal echocardiography [TEE] or a history of peripheral arterial disease) independently predicts stroke risk among patients with AF.[21-23]

1.4.3 Stroke Risk Stratification Schema: Many risk stratification schema, which use various combinations of the risk factors discussed previously, have been developed to aid clinicians in the assessment of stroke risk in patients with nonrheumatic AF (Table S13).[12] Despite substantial efforts in this field over the past several decades, all available schema have only modest ability to predict stroke in patients with AF, with C statistics typically between 0.55 and 0.70.[4,24-43] (A C statistic of 0.50 indicates a model that does not discriminate better than chance alone, and a C statistic of 1.00 indicates perfect discrimination.)

The $CHADS_2$ score is the most validated risk scheme, having been independently tested in at least 10 separate cohorts after its original derivation.[24,32,35-46] The $CHADS_2$ score gives a single point for each of congestive heart failure (originally defined as a recent exacerbation of congestive heart failure), hypertension (defined as a history of hypertension, rather than a presence of elevated BP), age ≥ 75 years, and diabetes mellitus and two points for prior stroke or TIA (Table 2).[30]

Despite its widespread adoption and ease of use, the $CHADS_2$ score has limitations. First, congestive heart failure is not a consistently demonstrated independent predictor of stroke. Second, the risk associated with a history of hypertension may differ among patients with well-treated vs poorly treated hypertension.[46-48] Third, in most studies, the $CHADS_2$ score has only a modest ability to predict stroke in patients with AF (C statistic, 0.56-0.70).[24,32,35-46] Finally, the threshold of stroke risk at which treatment with oral anticoagulation will be preferred is likely to decrease with the emergence of new oral anticoagulants that do not require regular monitoring of the international normalized ratio (INR) and that may be associated with greater reductions in stroke and less risk of bleeding compared with adjusted-dose VKA therapy.[49] Thus, stroke risk stratification schema will need to evolve to more accurately identify patients who are at sufficiently low risk of stroke and can be treated with aspirin or no antithrombotic therapy, whereas all other patients with AF can be considered for oral anticoagulation.

The CHA_2DS_2-VASc (congestive heart failure [or left ventricular systolic dysfunction], hypertension, age < 75 years; diabetes mellitus, prior stroke or transient ischemic attack, vascular disease, age 65 to 74 years, female sex) score is a new risk scheme that combines the $CHADS_2$ score with additional moderate risk factors, which were also included in the 2006 American College of Cardiology/American Heart Association/European Society of Cardiology and National Institute for Health and Clinical Excellence AF practice guidelines.[29,50] Specifically, the CHA_2DS_2-VASc score assigns points as in the original $CHADS_2$ score (Table 2) with the exception of age ≥ 75 years, which is assigned two points. It also assigns a single point for each of the following additional

Table 2—*[Section 1.4.3] $CHADS_2$ Score[30] for Assessment of Stroke Risk in Patients With Nonrheumatic AF*

Risk Factor	Points
Recent **C**ongestive heart failure exacerbation	1
History of **H**ypertension	1
Age ≥ 75 y	1
Diabetes mellitus	1
Prior history of **S**troke or transient ischemic attack	2

$CHADS_2$ = congestive heart failure, hypertension, age ≥ 75 years, diabetes mellitus, prior stroke or transient ischemic attack. See Table 1 legend for expansion of other abbreviation.

risk factors: female sex, age 65 to 74 years, and vascular disease (defined as a history of MI, peripheral arterial disease, or complex aortic plaque). The CHA_2DS_2-VASc score has been evaluated in at least five separate cohorts since its original description. With the exception of a recent study by Olesen et al,[24] all other studies have found that the predictive ability of CHA_2DS_2-VASc is similar to that of the $CHADS_2$ score (C statistics of each risk score is ~0.6 across the various studies) and not statistically significantly greater than that of $CHADS_2$.[36,40-43] Because the $CHADS_2$ score has been extensively validated and is easy for clinicians to remember and use, we use the $CHADS_2$ score as the principal approach for our risk-based treatment recommendations.

1.4.4 Estimating the Baseline Risk of Nonfatal Stroke by $CHADS_2$ Score: To develop our recommendations, we required estimates of the absolute rate of nonfatal stroke (ischemic or hemorrhagic) for patients according to their underlying risk of stroke, as characterized by their $CHADS_2$ score. Ideally, we would obtain these estimates of baseline risk from published annual rates of stroke, by $CHADS_2$ score, among untreated patients. However, such data are not available.

Therefore, to obtain estimates of annual stroke risk, we used pooled data from aspirin-treated patients enrolled in six clinical trials of antithrombotic therapy for stroke prevention in AF.[37] This published report presented data regarding ischemic stroke rates (fatal and nonfatal combined) on aspirin, stratified by $CHADS_2$ score. We used the following calculations to estimate the annual risk of nonfatal stroke (ie, ischemic and hemorrhagic) on aspirin: (1) multiplication of reported rates of ischemic stroke by 1.08 to account for additional hemorrhagic strokes on aspirin therapy (based on the observed ratio of ischemic:hemorrhagic strokes in aspirin arms of RCTs in patients with AF) and (2) an estimation that 50% and 25% of hemorrhagic and ischemic strokes, respectively, were fatal.

Depending on the clinical question being addressed by a particular recommendation, we adjusted these absolute rates of nonfatal stroke on aspirin to reflect the clinical scenario being addressed. For the recommendation addressing VKA therapy vs no treatment, for example, to estimate absolute rates of nonfatal stroke on no treatment, we increased our estimates of the rate of nonfatal stroke on aspirin by 21% to account for the estimated efficacy of aspirin in preventing stroke in AF). We therefore used the following absolute rates of nonfatal stroke in untreated patients to develop our recommendations: 0.8%, 2.2%, 4.5%, and 9.6% per year for patients with $CHADS_2$ scores of 0, 1, 2, and 3 to 6, respectively.

We have chosen to base our treatment recommendations on absolute rates of stroke derived from clinical trials, recognizing that these data have important limitations. Less than 10% of patients screened were enrolled in these historical trials, there was limited racial and ethnic diversity, and there is some evidence suggesting that stroke rates may now be lower than at the time these RCTs were conducted 2 decades ago possibly because of improved treatment of cardiovascular risk factors, such as hypertension.[51,52] However, despite these limitations, these clinical trial-based data regarding stroke events were systematically and prospectively collected, and they remain the best available source of stroke rates stratified by $CHADS_2$ score.

1.5 Deriving Baseline Risk of Death in Patients With AF

We used data from an observational health plan database study of 11,526 patients with nonvalvular AF (the Anticoagulation and Risk Factors in Atrial Fibrillation [ATRIA] Study) to obtain an estimate of the risk of all-cause mortality in patients with AF not treated with warfarin (53 deaths per 1,000 patient-years). Untreated patients in this cohort had a mean $CHADS_2$ score of 1.5, and a substantial majority (78%) of patients in the cohort had a $CHADS_2$ score of ≥ 1.[44] Although $CHADS_2$-specific rates of all-cause mortality are not available from this cohort, the risk of death is expected to be lower in low-risk patients with a $CHADS_2$ score of 0 because of their younger age, lower prevalence of vascular risk factors, and lower rates of fatal ischemic stroke.

1.6 Deriving Baseline Risk of Nonfatal Major Extracranial Bleeding

To develop our recommendations, we also required estimates of the baseline risk of nonfatal major extracranial bleeding in patients with AF. We obtained this estimate from observational studies of VKA therapy in cohorts that included exclusively or predominantly patients with AF (median rate of 1.3% per year across these studies).[44,53,54] To estimate the baseline risk of nonfatal major extracranial bleeding off VKA therapy, we used this median rate of bleeding on VKA therapy from the observational studies (1.3% per year) and divided by the pooled relative risk (2.58) of nonfatal major extracranial bleeding associated with VKA therapy, as obtained from RCTs of VKA therapy vs no therapy. Therefore, our estimate of the baseline risk of nonfatal major extracranial bleeding off therapy was 0.5% per year.

2.0 Antithrombotic Therapy for Patients With AF in General

Over the past 2 decades, numerous RCTs have investigated antithrombotic therapies to reduce the risk of thromboembolism, principally ischemic stroke, in patients with AF. In this section, we summarize the evidence and give treatment recommendations for VKA therapy, antiplatelet monotherapy (eg, aspirin), dual antiplatelet therapy with aspirin and clopidogrel, and new oral anticoagulants (eg, dabigatran) in patients with AF.

2.1 Patients With Nonrheumatic AF

2.1.1 VKAs vs No Therapy: Six RCTs that enrolled a total of 2,584 patients and address the primary prevention (Atrial Fibrillation Aspirin and Anticoagulation [AFASAK] 1, Boston Area Anticoagulation Trial for Atrial Fibrillation [BAATAF], Canadian Atrial Fibrillation Anticoagulation [CAFA], Stroke Prevention in Atrial Fibrillation [SPAF] I, Stroke Prevention in Nonrheumatic Atrial Fibrillation [SPINAF]) and secondary prevention (European Atrial Fibrillation Trial [EAFT]) of stroke in patients with AF provide high-quality evidence that VKA therapy reduces the risk of death by one-fourth and the risk of nonfatal stroke by two-thirds compared with no therapy (Table 3).[55-61] For patients with a $CHADS_2$ score of 0, the studies provide moderate-quality evidence that VKA therapy increases the risk of nonfatal major extracranial bleeding due to imprecision of the estimate (wide CIs). The studies provide high-quality evidence for patients with higher $CHADS_2$ scores.

Table 3—*[Sections 2.1.1, 2.1.8, 2.1.9, 2.1.10] Should VKAs Rather Than No Therapy Be Used in Patients With AF?*[a]

Quality Assessment								Summary of Findings			
						Study Event Rates (%)			Estimation of Absolute Effects 1 y Time Frame		
No. of Studies	Risk of Bias	Inconsistency	Indirectness	Imprecision	Publication Bias	With No Therapy	With VKA	Relative Effect (95% CI)	With No Therapy	With VKA (95% CI)	Quality of Evidence
Death (critical outcome) mean follow-up 1.7 y											
6 RCTs	No serious limitations	No serious inconsistency	No serious indirectness	No serious imprecision	Undetected	136/1,425 (9.5)	103/1,429 (7.2)	RR 0.72 (0.55-0.94)	53 per 1,000[b]	15 fewer deaths per 1,000[c] (from 3 fewer to 24 fewer)	High
Nonfatal stroke (critical outcome) mean follow-up 1.7 y; ischemic stroke and intracranial hemorrhage[d]											
6 RCTs	No serious limitations	No serious inconsistency	No serious Indirectness	No serious imprecision	Undetected	108/1,425[e] (7.6)	36/ 1,429[f] (2.5)	RR 0.34 (0.23-0.49)	$CHADS_2$ 0 points		High
									8 per 1,000[g]	5 fewer strokes per 1,000 (from 4 fewer to 6 fewer)	
									$CHADS_2$ 1 point		
									22 per 1,000	15 fewer strokes per 1,000 (from 11 fewer to 17 fewer)	
									$CHADS_2$ 2 points		
									45 per 1,000	30 fewer strokes per 1,000 (from 23 fewer to 35 fewer)	
									$CHADS_2$ 3-6 points		
									96 per 1,000	63 fewer strokes per 1,000 (from 49 fewer to 74 fewer)	
Nonfatal major extracranial bleeds (important outcome) mean follow-up 1.7 y											
6 RCTs	No serious limitations	No serious inconsistency	No serious indirectness	No serious imprecision	Undetected	7/1,425 (0.5)	23/1,429 (1.6)	RR 2.58 (1.12-5.97)	5 per 1,000[h]	8 more bleeds per 1,000 (from 1 more to 25 more)	High[i]
Systemic embolism (important outcome) mean follow-up 1.7 y											
6 RCTs	No serious limitations	No serious inconsistency	No serious Indirectness	Imprecise[j]	Undetected	10/1,425 (0.7)	4/1,429 (0.3)	RR 0.42 (0.15-1.20)	4 per 1,000[k]	2 fewer systemic emboli per 1,000 (from 3 fewer to 1 more)	Moderate

Burden of treatment (important outcome)											
N/A	No serious limitations	No serious limitations	No serious limitations	No serious limitations	N/A	N/A	N/A	VKA > no therapy	Warfarin: daily medication, lifestyle limitations, dietary restrictions, frequent blood testing and clinic visits		High

AFASAK = Atrial Fibrillation Aspirin and Anticoagulation; ATRIA = Anticoagulation and Risk Factors in Atrial Fibrillation; BAATAF = Boston Area Anticoagulation Trial for Atrial Fibrillation; CAFA = Canadian Atrial Fibrillation Anticoagulation; EAFT = European Atrial Fibrillation Trial; IPD = individual patient data; N/A = not applicable; RR = risk ratio; SPAF = Stroke Prevention in Atrial Fibrillation; SPINAF = Stroke Prevention in Nonrheumatic Atrial Fibrillation. See Table 1 and 2 legends for expansion of other abbreviations.

[a]Pooled estimates of treatment effect in this evidence profile are from a meta-analysis conducted for these guidelines, including data from 6 RCTs of adjusted-dose VKA therapy vs no antithrombotic therapy (AFASAK I, BAATAF, CAFA, EAFT, SPAF I, SPINAF).

[b]From Go et al,[44] which reported a mortality rate of 5.33 per 100 person-y in untreated (no warfarin) patients from an observational study (ATRIA cohort). The majority (78%) of the patients in ATRIA had a $CHADS_2$ score of ≥ 1.

[c]VKA therapy likely does not lead to any reductions in all-cause mortality compared with no therapy in low-risk patients with a $CHADS_2$ score of 0 because there is evidence suggesting that absolute reductions in ischemic stroke heavily depend on stroke risk (eg, small reductions at low $CHADS_2$ score), whereas the absolute increase in intracranial hemorrhage is relatively consistent across $CHADS_2$ categories (Singer et al[51]).

[d]Intracranial hemorrhage includes intracerebral, subdural, and subarachnoid bleeds. For studies that did not report the number of strokes that were fatal and nonfatal (CAFA, EAFT), we imputed values for the number of fatal and nonfatal strokes to estimate the pooled relative risk for nonfatal stroke across all eligible studies. Assumptions underlying these estimates are detailed in the section 1.3 of this article.

[e]Of the 108 nonfatal strokes on no therapy, an estimated 106 (98%) were ischemic, and two (2%) were hemorrhagic.

[f]Of the 36 nonfatal strokes on VKA therapy, an estimated 34 (94%) were ischemic, and two (6%) were hemorrhagic.

[g]We estimated the annual rates of nonfatal stroke (ischemic and hemorrhagic) on no therapy by extrapolating from observed annual rates of ischemic stroke (fatal + nonfatal), stratified by $CHADS_2$ score, in the aspirin arms of six historical RCTs in patients with AF (Gage et al[37]). Assumptions underlying these estimates are detailed in the section 1.4.4 of this article.

[h]Estimate of the rate of nonfatal major extracranial bleeding on no therapy is derived from rates in observational cohorts of predominantly patients with AF receiving adjusted-dose VKA therapy (median, 1.3%/y) and dividing by the relative risk of major bleeding on adjusted-dose VKA therapy observed in the RCTs (see section 1.6 of this article).

[i]Quality of evidence is moderate for patients with a $CHADS_2$ score of 0 because the recommendation would differ if the true increase in nonfatal major extracranial bleeding was one vs 25 bleeds per 1,000 patients in a given year.

[j]The 95% CI does not exclude the possibility of no effect.

[k]Based on rate of systemic embolism on aspirin of 0.3 per 100 patient-y reported in the IPD meta-analysis of warfarin vs aspirin by van Walraven et al[61] and a relative risk of 0.80 for aspirin vs no therapy for systemic embolism.

The studies also provide moderate-quality evidence that VKA therapy reduces the risk of systemic embolism (rated down for imprecision).

2.1.2 Antiplatelet Monotherapy (Aspirin) vs No Therapy: Several RCTs of antiplatelet monotherapy vs no therapy in patients with AF have shown that antiplatelet therapy leads to, at best, a modest reduction in the risk of nonfatal stroke. Antiplatelet monotherapy in these trials was either with aspirin alone (AFASAK 1; SPAF I; EAFT; United Kingdom Transient Ischaemic Attack Aspirin trial [UK-TIA]; Low-Dose Aspirin, Stroke, Atrial Fibrillation [LASAF]; European Stroke Prevention Study [ESPS]-2; and Japan Atrial Fibrillation Stroke Trial [JAST]), aspirin in combination with fixed (ineffective) minidose warfarin (Swedish Atrial Fibrillation Trial [SAFT]), or dipyridamole (ESPS-2).[55,58,60,62-66] Aspirin dosing in these trials typically ranged from 50 to 325 mg/d. In the LASAF, JAST, and SAFT trials, aspirin was compared with a no-treatment control arm, whereas in the remaining trials, comparison was to placebo.[63,64,66] ESPS-2 and UK-TIA were stroke prevention trials conducted primarily in non-AF populations, and only the data from the subset of patients with AF are considered here.[62,65]

Pooled data from these trials provide moderate-quality evidence (rated down for imprecision) that antiplatelet monotherapy is associated with a 21% relative reduction in risk of nonfatal stroke compared with no treatment (Table 4). Although our confidence in the benefits of aspirin therapy is moderate, our confidence in its bleeding risk is high. Although the trials of antiplatelet monotherapy in patients with AF were underpowered to precisely estimate the risk of nonfatal major extracranial bleeding, trials of aspirin for the primary and secondary prevention of cardiovascular disease have conclusively demonstrated that aspirin is associated with an increased risk of major hemorrhage. An individual patient data meta-analysis combining data from six cardiovascular primary prevention trials (95,000 subjects) and a meta-analysis of 60 cardiovascular secondary prevention trials (94,000 subjects) found that aspirin is associated with a significant 50% to 60% relative increase, respectively, in the risk of major extracranial bleeding.[67,68] For the outcomes of death and systemic embolism, pooled estimates of treatment effect from trials of antiplatelet monotherapy in patients with AF were imprecise, leaving uncertainty about the impact of antiplatelet monotherapy on these outcomes when compared with no treatment (Table 4).

2.1.3 VKAs vs Antiplatelet Monotherapy (Aspirin): The evidence summarized in sections 2.1.1 and 2.1.2 implies that adjusted-dose warfarin is far superior to aspirin for the prevention of stroke in patients with AF but is likely to be associated with a greater risk of bleeding complications. Direct evidence regarding this clinical question comes from 11 RCTs (total of 6,526 patients) comparing adjusted-dose VKA therapy to antiplatelet monotherapy (AFASAK 1, AFASAK 2, Birmingham Atrial Fibrillation Treatment of the Aged [BAFTA], EAFT, National Study for Prevention of Embolism in Atrial Fibrillation [NASPEAF], Primary Prevention of Arterial Thromboembolism in Nonrheumatic AF in Primary Care Trial [PATAF], Studio Italiano Fibrillazione Atriale [SIFA], SPAF II, SPAF III, Vemmos et al,[69] and Warfarin vs Aspirin for Stroke Prevention in Octogenarians With AF [WASPO]) (Table 5).[55,60,70-77] Antiplatelet therapy was typically with aspirin 75 to 325 mg/d, but in the SIFA and NASPEAF studies, it was with indobufen and triflusal, respectively.[72,74] In SPAF III and one of the two antiplatelet arms of AFASAK II, aspirin was given in combination with fixed minidose (ineffective) warfarin.[70,76]

These trials provide high-quality evidence that adjusted-dose VKA therapy reduces by one-half the risk of nonfatal stroke compared with antiplatelet monotherapy. These trials suggest that VKA therapy increases the risk of nonfatal major extracranial bleeding by about 50% compared with aspirin (pooled risk ratio, 1.42; 95% CI, 0.89-2.29), but the quality of evidence was rated down to moderate because of imprecision. Indirect evidence from RCTs of adjusted-dose VKA therapy vs aspirin in other populations suggest that VKA therapy is likely associated with a true twofold to 2.5-fold increase in major bleeding risk.[78,79] For the outcomes of death and systemic embolism, pooled estimates of treatment effect from trials of VKA therapy in patients with AF were imprecise, leaving uncertainty about the impact of VKA therapy on these outcomes compared with antiplatelet monotherapy.

2.1.4 VKAs vs Dual Antiplatelet Therapy With Aspirin and Clopidogrel: The Atrial Fibrillation Clopidogrel Trial With Irbesartan for Prevention of Vascular Events (ACTIVE) W trial assessed dual antiplatelet therapy with aspirin and clopidogrel as a potential alternative to VKA therapy (INR 2.0-3.0).[80] The trial was stopped early because of findings of superiority of VKA therapy (for their primary outcome of stroke, systemic embolism, MI, or vascular death) and did not find evidence of a difference in the risk of major bleeding (Table 6). Most patients (77%) were receiving VKA therapy before randomization, raising some concerns about generalizability of these findings to patients with AF who are being newly started on VKA therapy (ie, by enrolling mostly

Table 4—*[Section 2.1.2, 2.1.8] Should Antiplatelet (Aspirin) Monotherapy Rather Than No Therapy Be Used in Patients With AF?*[a,b]

Quality Assessment								Summary of Findings			
						Study Event Rates (%)			Estimation of Absolute Effects 1 y Time Frame		
No. of Studies	Risk of Bias	Inconsistency	Indirectness	Imprecision	Publication Bias	With No Therapy	With Antiplatelet	Relative Effect (95% CI)	With No Therapy	With Antiplatelet (95% CI)	Quality of Evidence
Death (critical outcome) mean follow-up 2.1 y											
6 RCTs	No serious limitations	No serious inconsistency	No serious indirectness	Imprecise[c]	Undetected	231/2,152 (10.7)	215/2,246 (9.6)	RR 0.89 (0.75-1.05)	53 per 1,000[d]	6 fewer deaths per 1,000 (from 13 fewer to 3 more)	Moderate
Nonfatal stroke (critical outcome) mean follow-up 2.1 y; ischemic stroke and intracranial hemorrhage[e]

Quality Assessment								Summary of Findings			
						Study Event Rates (%)			Estimation of Absolute Effects 1 y Time Frame		
No. of Studies	Risk of Bias	Inconsistency	Indirectness	Imprecision	Publication Bias	With No Therapy	With Antiplatelet	Relative Effect (95% CI)	With No Therapy	With Antiplatelet (95% CI)	Quality of Evidence
Systemic embolism (important outcome) mean follow-up 2.1 y											
5 RCTs	No serious limitations	No serious inconsistency	No serious indirectness	Precise[l]	Undetected	21/2,061 (1.0)	17/2,052 (0.8)	RR 0.80 (0.43-1.52)	4 per 1,000[m]	1 fewer systemic embolism per 1,000 (from 2 fewer to 2 more)	Moderate

ESPS = European Stroke Prevention Study; JAST = Japan Atrial Fibrillation Stroke Trial; LASAF = Low-dose Aspirin, Stroke, Atrial Fibrillation; SAFT = Swedish Atrial Fibrillation Trial; UK-TIA = United Kingdom Transient Ischaemic Attack Aspirin Trial. See Table 1-3 legends for expansion of other abbreviations.

[a]Pooled estimates of treatment effect in this evidence profile, with the exception of nonfatal major extracranial bleeding[b], are from a meta-analysis conducted for these guidelines, including data from RCTs of antiplatelet monotherapy (typically aspirin) vs no therapy (AFASAK I, SPAF I, EAFT, ESPS-2, UK-TIA, LASAF, JAST, SAFT).

[b]To obtain a best estimate of the risk of nonfatal major extracranial bleeding on antiplatelet monotherapy, we used data from the Antithrombotic Trialists' Collaboration[68] meta-analysis of aspirin for the secondary prevention of cardiovascular disease.

[c]The 95% CI does not exclude the possibility of no effect.

[d]From Go et al,[44] which reported a mortality rate of 5.33 per 100 person-y in untreated (no warfarin) patients from an observational study (ATRIA cohort).

[e]Intracranial hemorrhage includes intracerebral, subdural, and subarachnoid bleeds. For studies that did not report the number of strokes that were fatal and nonfatal (EAFT, ESPS-2, UK-TIA, JAST), we imputed values for the number of fatal and nonfatal strokes to estimate the pooled relative risk for nonfatal stroke across all eligible studies. Assumptions underlying these estimates are detailed in section 1.3 of this article.

[f]Restricting meta-analysis exclusively to RCTs evaluating aspirin alone vs no antithrombotic therapy (ie, excluding SAFT, which used aspirin in combination with fixed minidose warfarin, and excluding the dipyridamole monotherapy arm of ESPS-2) results in an estimate of relative risk that includes no effect (relative risk, 0.81; 95% CI, 0.66-1.01).

[g]Of the 197 nonfatal strokes on no therapy, an estimated 193 (98%) were ischemic, and four (2%) were hemorrhagic.

[h]Of the 174 nonfatal strokes on antiplatelet therapy, an estimated 170 (98%) were ischemic, and four (2%) were hemorrhagic.

[i]We estimated the annual rates of nonfatal stroke (ischemic and hemorrhagic) on no therapy by extrapolating from observed annual rates of ischemic stroke (fatal + nonfatal), stratified by $CHADS_2$ score, in the aspirin arms of six historical RCTs in patients with AF (Gage et al[37]). Assumptions underlying these estimates are detailed in section 1.1.4 of this article.

[j]We used evidence from RCTs of aspirin for the secondary prevention of cardiovascular events to obtain a best estimate of the risk of major extracranial bleeding with antiplatelet monotherapy. Note that the study event rates and relative risk are for the outcome of all major extracranial bleeding (nonfatal and fatal events) because specific data regarding nonfatal events were not reported.

[k]Rates of nonfatal major extracranial bleeding on no therapy are extrapolated from rates observed in observational cohorts of patients receiving adjusted-dose VKA therapy (median, 1.3%/y) and dividing by the relative risk of major bleeding on adjusted-dose VKA therapy observed in the RCTs.

[l]The 95% CI does not exclude the possibility of appreciable harm or benefit with antiplatelet therapy.

[m]Based on rate of systemic embolism on aspirin of 0.3 per 100 patient-y reported in the IPD meta-analysis of warfarin vs aspirin by van Walraven et al[61] and a relative risk of 0.80 for aspirin vs no therapy for systemic embolism.

Table 5—*[Sections 2.1.3, 2.1.8, 2.1.9, 2.1.10] Should VKAs Rather Than Aspirin Be Used in Patients With AF?*[a]

ASA = acetylsalicyclic acid; BAFTA = Birmingham Atrial Fibrillation of the Aged; NASPEAF = National Study for Prevention of Embolism in Atrial Fibrillation; PATAF = Primary Prevention of Arterial Thromboembolism in Nonrheumatic AF in Primary Care Trial; SIFA = Studio Italiano Fibrillazione Artiale; WASPO = Warfarin vs Aspirin for Stroke Prevention in Octogenarians With AF. See Table 1-3 legends for expansion of other abbreviations.

[a]Pooled estimates of treatment effect in this evidence profile are from a new meta-analysis of data from RCTs which included a comparison of warfarin and antiplatelet monotherapy (typically aspirin). In SPAF III and AFASAK II, aspirin was combined with fixed (ineffective) minidose warfarin (AFASAK I, AFASAK II, Vemmos et al[69], BAFTA, EAFT, NASPEAF, PATAF, SIFA, SPAF II, SPAF III, WASPO).

[b]The 95% CI does not exclude the possibility of appreciable harm or benefit with VKA therapy.

[c]Based on data from Go et al,[44] which reported a mortality rate of 5.33 per 100 person-y in untreated (no warfarin) patients from an observational study (ATRIA cohort) and an estimated relative risk of mortality of 0.89 for aspirin vs no therapy (Table 4).

[d]Intracranial hemorrhage includes intracerebral, subdural, and subarachnoid bleeds. For SPAF II, which did not report the number of strokes that were fatal and nonfatal, we imputed values for the number of fatal and nonfatal strokes to estimate the pooled relative risk for nonfatal stroke across all eligible studies. Assumptions underlying these estimates are detailed in section 1.3 of this article.

[e]Of the 209 nonfatal strokes on antiplatelet therapy, an estimated 202 (97%) were ischemic, and seven (3%) were hemorrhagic.

[f]Of the 94 nonfatal strokes on VKA therapy, an estimated 80 (85%) were ischemic, and 14 (15%) were hemorrhagic.

[g]We estimated the annual rates of nonfatal stroke (ischemic and hemorrhagic) on no therapy by extrapolating from observed annual rates of ischemic stroke (fatal + nonfatal), stratified by $CHADS_2$ score, in the aspirin arms of six historical RCTs in patients with AF (Gage et al[37]). Assumptions underlying these estimates are detailed in section 1.1.4 of this article.

[h]The 95% CI does not exclude appreciable harm with VKA therapy.

[i]Rates of nonfatal major extracranial bleeding on aspirin are extrapolated from rates observed in observational cohorts of patients receiving adjusted-dose VKA therapy (median, 1.3%/y), and relative risks of major extracranial bleeding associated with VKA therapy (RR, 2.56) and aspirin (RR, 1.60) compared with no therapy.

[j]The 95% CI does not exclude the possibility of appreciable benefit or harm with VKA therapy.

[k]Based on rate of systemic embolism on aspirin of 0.3 per 100 patient-y reported in the individual patient data meta-analysis of warfarin vs aspirin by van Walraven et al.[61]

ACTIVE = Atrial Fibrillation Clopidogrel Trial With Irbesartan for Prevention of Vascular Events. Clopid = clopidogrel. See Table 1-3 and 5 legends for expansion of other abbreviations.

[a]Results are based on a single RCT (ACTIVE W) that was stopped early for benefit.

[b]The 95% CI does not exclude appreciable harm or benefit with VKA therapy.

[c]Based on data from Go et al,[44] which reported a mortality rate of 5.33 per 100 person-y in untreated (no warfarin) patients from an observational study (ATRIA cohort), an estimated relative risk of 0.89 for mortality with aspirin vs no therapy (Table 4), and an estimated relative risk of 0.98 for mortality with aspirin + clopidogrel vs aspirin (Table 7).

[d]Intracranial hemorrhage includes intracerebral, subdural, and subarachnoid bleeds. The published report did not provide the number of strokes that were fatal and nonfatal; therefore, we imputed values for the number of fatal and nonfatal strokes to estimate the relative risk for nonfatal stroke. Assumptions underlying these estimates are detailed in section 1.3 of this article.

[e]Of the 72 nonfatal strokes on aspirin + clopidogrel therapy, an estimated 67 (93%) were ischemic, and five (7%) were hemorrhagic.

[f]Of the 41 nonfatal strokes on VKA therapy, an estimated 31 (76%) were ischemic, and 10 (24%) were hemorrhagic.

[g]We estimated the annual rates of nonfatal stroke (ischemic and hemorrhagic) on aspirin + clopidogrel by extrapolating from observed annual rates of ischemic stroke (fatal + nonfatal), stratified by $CHADS_2$ score, in the aspirin arms of six historical RCTs in patients with AF (Gage et al[37]). Assumptions underlying these estimates are detailed in section 1.1.4 of this article.

[h]The published report did not provide the number of major extracranial bleeds that were fatal and nonfatal; therefore, we imputed values for the number of fatal and nonfatal major extracranial bleeds to estimate the relative risk for nonfatal major extracranial bleeds. Assumptions underlying these estimates are detailed in section 1.3 of this article.

[i]The 95% CI does not exclude appreciable harm or benefit with VKA therapy.

[j]Rate of nonfatal major extracranial bleeding on aspirin + clopidogrel is extrapolated from rates observed in observational cohorts of patients receiving VKA therapy (median, 1.3%/y) and estimated relative risks of nonfatal major extracranial bleeding associated with VKA therapy compared with no therapy (RR, 2.56), aspirin compared with no therapy (RR, 1.60), and aspirin + clopidogrel compared with aspirin (RR, 1.50).

[k]Estimate is derived from rate of systemic embolism on aspirin (0.3 per 100 patient-y) reported in the IPD meta-analysis by van Walraven et al[61] and estimated relative risk of 0.97 (95% CI, 0.67-1.40) for systemic embolism with combination aspirin + clopidogrel therapy vs aspirin observed in ACTIVE A (Table 7).

prior users of VKA therapy, the study sample may be more representative of patients in whom VKA therapy is well tolerated). In prespecified subgroup analyses, the investigators did not find evidence of a difference in the effect of VKA therapy on primary outcome in patients who were and were not receiving VKA therapy at study entry. However, there was a significant difference (interaction $P = .03$) in the effect on major bleeding, depending on whether patients were prior users of VKA therapy. For patients who were not receiving VKA therapy at study entry, VKA therapy was associated with a nonsignificant trend toward a 69% relative increase in major bleeding compared with dual antiplatelet therapy, whereas in patients already receiving VKA therapy at study entry, VKA therapy was associated with a nonsignificant trend toward a 24% relative decrease in major bleeding compared with dual antiplatelet therapy.

2.1.5 Dual Antiplatelet Therapy With Aspirin and Clopidogrel vs Aspirin Alone: The ACTIVE A study compared combination aspirin and clopidogrel therapy with aspirin alone.[81] The trial enrolled 7,554 patients considered unsuitable for VKA therapy (approximately one-half because of a physician's judgment that VKA was inappropriate, one-fourth because of a specific risk of bleeding, and one-fourth because of the patient's preference not to take a VKA as the sole reason) and found that combination therapy is more effective in reducing the risk of nonfatal stroke in patients with AF but also increases the risk of nonfatal major extracranial bleeds compared with treatment with aspirin alone (Table 7).

2.1.6 New Oral Anticoagulants vs VKAs: Antithrombotic therapy for AF is evolving rapidly because of the development of new oral anticoagulants that directly target different parts of the coagulation pathway, have a more predictable anticoagulant effect, and do not require INR monitoring. Included in this new group of drugs are direct thrombin inhibitors (eg, dabigatran) and direct factor Xa inhibitors (apixaban, rivaroxaban, edoxaban). Results of large phase 3 clinical trials of these agents in patients with AF have been recently published or will be reported soon (Table 8). Although ximelagatran is no longer approved for use by regulatory agencies because of concerns about severe liver toxicity, the Stroke Prevention Using an Oral Thrombin Inhibitor in Patients With AF (SPORTIF) III and V trials were a proof of principle that a direct thrombin inhibitor can achieve similar protection against stroke compared with warfarin (ie, findings met the investigators' prespecified noninferiority criterion) with no evidence of increased bleeding risk.[82,83]

The Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY) trial reported the results of a three-arm RCT of 18,113 patients with AF in which dabigatran 110 mg bid, and dabigatran 150 mg bid, were compared with open-label, adjusted-dose warfarin (target INR 2.0-3.0).[84] Based on best estimates of the proportion of strokes and major extracranial bleeds that were nonfatal (the published report did not present the number or proportion of fatal and nonfatal events), dabigatran at a dose of 150 mg bid is associated with a statistically significant one-third reduction in nonfatal stroke, with no evidence of a difference in the risk of nonfatal major extracranial bleeding compared with warfarin. Moreover, the data raised the possibility that dabigatran 150 mg bid may reduce all-cause mortality compared with warfarin (relative risk, 0.89; 95% CI, 0.79-1.01) (Table 9). In contrast, dabigatran at a dose of 110 mg bid was not associated with a significant difference in the risk of death, nonfatal stroke, nonfatal major extracranial bleeding, or systemic embolism (Table 10).

ROCKET-AF (Rivaroxaban Once Daily Oral direct Factor Xa inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation) was a double-blind, double-dummy RCT comparing rivaroxaban 20 mg once daily to adjusted-dose warfarin (INR 2.0-3.0) in 14,264 patients with AF at increased risk of stroke (mean $CHADS_2$ score of 3.5).[85] In the intention-to-treat analysis, rivaroxaban was noninferior to warfarin for the primary end point of stroke (ischemic or hemorrhagic) or systemic embolism but was not superior to warfarin (hazard ratio, 0.88; 95% CI, 0.74-1.03). The trial did not find evidence of a difference in major bleeding between rivaroxaban and warfarin (hazard ratio, 1.04; 95% CI, 0.90-1.20). Major GI bleeding was more common with rivaroxaban than with warfarin (3.2% and 2.2%, respectively, $P < .001$). Mortality was not significantly different between rivaroxaban and warfarin.

The Apixaban vs Acetylsalicylic Acid to Prevent Strokes (AVERROES) RCT compared apixaban 5 mg bid to aspirin in 5,599 patients with AF who were demonstrated or expected to be unsuitable candidates for adjusted-dose VKA therapy.[86] The trial was stopped early for benefit and was consistent with the trials of VKA therapy vs aspirin (section 2.1.3), reporting that apixaban reduces by one-half the occurrence of the primary outcome of stroke and systemic embolism compared with aspirin (hazard ratio, 0.45; 95% CI, 0.32-0.62). The trial failed to demonstrate or exclude a difference in the risk of major extracranial bleeding with apixaban compared with aspirin (hazard ratio, 1.23; 95% CI, 0.74-2.05), and the results were consistent with those of earlier trials of VKA therapy vs aspirin (section 2.1.3), which suggest an increase in the risk of major extracranial

Table 7—*[Sections 2.1.5, 2.1.8, 2.1.9, 2.1.10] Should Aspirin Plus Clopidogrel Rather Than Aspirin Be Used in Patients With AF?*

Quality Assessment								Summary of Findings			
						Study Event Rates (%)			Estimation of Absolute Effects 1-y Time Frame		
No. of Studies	Risk of Bias	Inconsistency	Indirectness	Imprecision	Publication Bias	With ASA	With ASA/Clopid	Relative Effect (95% CI)	With ASA	With ASA/Clopid (95% CI)	Quality of Evidence
Death (critical outcome) median follow-up 3.6 y											
1 RCT	No serious limitations	No serious inconsistency	No serious indirectness	Imprecise[a]	Undetected	841/3,782 (22.2)	825/3,772 (21.9)	RR 0.98 (0.90-1.07)	47 per 1,000[b]	1 fewer death per 1,000 (from 5 fewer to 3 more)	Moderate
Nonfatal stroke (critical outcome) median follow-up 3.6 y; ischemic stroke and intracranial hemorrhage[c]											
1 RCT	No serious limitations	No serious inconsistency	No serious indirectness	No serious imprecision	Undetected	315/3,782[d] (8.3)	226/3,772[e] (6.0)	RR 0.72 (0.61-0.85)	$CHADS_2$ 0 points		High

Systemic embolism (important outcome) median follow-up 3.6 y											
1 RCT	No serious limitations	No serious inconsistency	No serious indirectness	Precise[i]	Undetected	56/3,782 (1.5)	54/3,772 (1.4)	RR 0.97 (0.67-1.40)	3 per 1,000[j]	0 fewer systemic emboli per 1,000 (from 1 fewer to 1 more)	Moderate

See Table 1-3, 5, and 6 legends for expansion of abbreviations.

[a]The 95% CI does not exclude the possibility of no effect.

[b]Based on data from Go et al,[44] which reported a mortality rate of 5.33 per 100 person-y in untreated (no warfarin) patients from an observational study (ATRIA cohort) and an estimated relative risk of mortality of 0.89 for aspirin vs no therapy (Table 4).

[c]Hemorrhagic stroke not clearly defined in published RCT report (ie, unclear whether subdural and subarachnoid bleeds were included in the definition of hemorrhagic stroke).

[d]The published RCT report did not present the proportion of nonfatal strokes in the aspirin arm that were ischemic vs hemorrhagic; however, of all strokes (fatal and nonfatal), 5% were hemorrhagic, and 95% were ischemic or of uncertain type.

[e]The published RCT report did not present the proportion of nonfatal strokes in the combination aspirin + clopidogrel arm that were ischemic vs hemorrhagic; however, of all strokes (fatal and nonfatal), 10% were hemorrhagic, and 90% were ischemic or of uncertain type.

[f]We estimated the annual rates of nonfatal stroke (ischemic and hemorrhagic) on aspirin by extrapolating from observed annual rates of ischemic stroke (fatal + nonfatal), stratified by $CHADS_2$ score, in the aspirin arms of six historical RCTs in patients with AF (Gage et al[37]). Assumptions underlying these estimates are detailed in section 1.1.4 of this article.

[g]The published report did not provide the number of major extracranial bleeds that were fatal and nonfatal; therefore, we imputed values for the number of fatal and nonfatal major extracranial bleeds to estimate the relative risk for nonfatal major extracranial bleeds. Assumptions underlying these estimates are detailed in section 1.3 of this article.

[h]Rates of nonfatal major extracranial bleeding on aspirin are extrapolated from rates in observational cohorts of patients receiving adjusted-dose VKA therapy (median, 1.3%/y) and relative risks of major extracranial bleeding associated with VKA therapy (RR, 2.56) and aspirin (RR, 1.60) compared with no therapy.

[i]The 95% CI does not exclude the possibility of no effect.

[j]Based on rate of systemic embolism on aspirin of 0.3 per 100 patient-y reported in the IPD meta-analysis of warfarin vs aspirin by van Walraven et al.[61]

Table 8—*[Section 2.1.6] Phase 3 RCTs of New Oral Anticoagulants in Patients With AF*

Trial	Intervention	Comparator	Status
SPORTIF III SPORTIF V	Ximelagatran	Warfarin (INR, 2.0-3.0)	Published[82,83]
RE-LY	Dabigatran (150 or 110 mg bid)	Warfarin (INR, 2.0-3.0)	Published[84]
AVERROES	Apixaban (5 mg bid)	Aspirin (81-324 mg daily)	Published[86]
ROCKET-AF	Rivaroxaban (20 mg once daily)	Warfarin (INR, 2.0-3.0)	Published[85]
ARISTOTLE	Apixaban (5 mg bid)	Warfarin (INR, 2.0-3.0)	Published[87]
ENGAGE-AF TIMI 48	Edoxaban (high- and low-dose regimens)	Warfarin (INR, 2.0-3.0)	Currently recruiting

ARISTOTLE = Apixaban for the Prevention of Stroke in Subjects With Atrial Fibrillation; AVERROES = Apixaban versus Acetylsalicylic Acid to Prevent Strokes; ENGAGE-AF TIMI 48 = Effective Anticoagulation With Factor xA Next Generation in Atrial Fibrillation-Thrombolysis In Myocardial Infarction Study 48; INR = international normalized ratio; RE-LY = Randomized Evaluation of Long-Term Anticoagulation Therapy; ROCKET-AF = Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared With Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation; SPORTIF = Stroke Prevention Using an Oral Thrombin Inhibitor in Patients With AF.

bleeding with oral anticoagulation compared with aspirin.

ARISTOTLE (Apixaban for the Prevention of Stroke in Subjects With Atrial Fibrillation) was a double-blind, double-dummy RCT comparing apixaban 5 mg bid to warfarin (INR 2.0-3.0) in 18,201 patients with AF (mean $CHADS_2$ score of 2.1).[87] Apixaban reduced by 21% the risk of the primary outcome of stroke (ischemic or hemorrhagic) or systemic embolism (hazard ratio, 0.79; 95% CI, 0.66-0.95) and reduced by 31% the risk of major bleeding (hazard ratio, 0.69; 95% CI, 0.60-0.80) compared with warfarin. There was no evidence of a difference in major GI bleeding between apixaban and warfarin (hazard ratio, 0.89; 95% CI, 0.70-1.15). All-cause mortality was lower with apixaban compared with warfarin (hazard ratio, 0.89; 95% CI, 0.80-0.998). In all three recently completed trials of novel anticoagulants vs warfarin (RE-LY, ROCKET-AF, and ARISTOTLE), the rate of intracranial hemorrhage (including both hemorrhagic stroke and other intracranial bleeds) was lower in patients assigned to the novel anticoagulant than in patients assigned to warfarin.[84,85,87,88]

2.1.7 General Approach to Recommendations About New Oral Anticoagulants in This Article: Our guideline panel elected to make recommendations only for those drugs that have received regulatory approval for use in AF (ie, dabigatran).[89] Although based on the results of a single trial, there is evidence from RE-LY that dabigatran is no worse than VKA therapy with respect to nonfatal major extracranial bleeding and that it is similar or superior to warfarin with respect to nonfatal stroke, systemic embolism, and all-cause mortality in patients with nonvalvular AF (section 2.1.6). Therefore, for patients with nonrheumatic AF, wherever we recommend (or suggest) VKA therapy, we also recommend (or suggest) the use of dabigatran, and in these situations, our recommendations simply refer to oral anticoagulation.[88] We address the specific question of whether to use dabigatran over adjusted-dose VKA therapy in section 2.1.11.

The data from RE-LY do not directly address the use of dabigatran in patients with AF and mitral stenosis (patients with hemodynamically relevant valvular disease were excluded from this study), or in patients with AF in other special situations (sections 2.2 and 3.0). Therefore, we have not extrapolated the data from RE-LY to these clinical situations and have instead restricted those recommendations for oral anticoagulation to adjusted-dose VKA therapy. There is direct evidence from RE-LY regarding the use of dabigatran in patients with AF undergoing cardioversion, and these data are summarized in section 4.1.1.

2.1.8 Recommendations for Patients With AF at Low Risk of Stroke (eg, $CHADS_2$ Score of 0): Patients at sufficiently low risk of ischemic stroke may opt for no treatment rather than antithrombotic therapy with either aspirin or an oral anticoagulant. For instance, for every 1,000 patients at low risk of stroke with a $CHADS_2$ score of 0, VKA therapy compared with no treatment is anticipated to result in five fewer nonfatal strokes at the expense of eight more nonfatal major extracranial bleeds and the additional burden of adjusted-dose VKA treatment (Table 3). Although VKA therapy is expected to reduce all-cause mortality in patients with AF in general, it is likely that this mortality benefit does not extend to low-risk patients. The absolute reduction in fatal ischemic stroke with VKA therapy will be far fewer such patients, whereas their absolute increase in fatal intracranial hemorrhage will be similar to those with higher $CHADS_2$ scores.[51]

For patients with a $CHADS_2$ score of 0, treatment with aspirin for 1 year may result in the prevention of two nonfatal strokes per 1,000 patients (moderate-quality evidence due to imprecision) at the expense of three additional nonfatal major extracranial bleeds per 1,000 patients compared with no treatment (Table 4). If stroke rates are truly declining over time,

N/A	No serious limitations	No serious limitations	No serious limitations	No serious limitations	N/A	N/A	N/A	VKA >dabigatran	Warfarin: daily medication, lifestyle limitations, dietary restrictions, frequent blood testing and clinic visits Dabigatran: daily medication only		High

Dabi = dabigatran. See Table 1-3 legends for expansion of other abbreviations.

[a]The 95% CI does not exclude the possibility of no effect.

[b]Based on data from Go et al,[44] which reported a mortality rate of 5.33 per 100 person-y in untreated (no warfarin) patients from an observational study (ATRIA cohort) and an estimated relative risk of mortality of 0.72 for VKA vs no therapy (Table 3).

[c]Intracranial hemorrhage includes intracerebral, subdural, and subarachnoid bleeds. The published report did not provide the number of strokes that were fatal and nonfatal; therefore, we imputed values for the number of fatal and nonfatal strokes to estimate the relative risk for nonfatal stroke. Assumptions underlying these estimates are detailed in section 1.3 of this article.

[d]Of the 149 nonfatal strokes on VKA therapy, an estimated 106 (71%) were ischemic, and 43 (29%) were hemorrhagic.

[e]Of the 101 nonfatal strokes on dabigatran therapy, an estimated 83 (82%) were ischemic, and 18 (18%) were hemorrhagic.

[f]We estimated the annual rates of nonfatal stroke (ischemic and hemorrhagic) on warfarin by extrapolating from observed annual rates of ischemic stroke (fatal + nonfatal), stratified by $CHADS_2$ score, in the aspirin arms of six historical RCTs in patients with AF (Gage et al[37]). Assumptions underlying these estimates are detailed in section 1.1.4 of this article.

[g]The published report did not provide the number of major extracranial bleeds that were fatal and nonfatal; therefore, we imputed values for the number of fatal and nonfatal major extracranial bleeds to estimate the relative risk for nonfatal major extracranial bleeds. Assumptions underlying these estimates are detailed in section 1.1.4 of this article.

[h]Rate of nonfatal major extracranial bleeding on warfarin is from observational cohorts of patients receiving adjusted-dose VKA therapy (median, 1.3%/y).

[i]Based on rate of systemic embolism on aspirin of 0.3 per 100 patient-y reported in the IPD meta-analysis of warfarin vs aspirin by van Walraven et al[61] and a relative risk for systemic embolism of 0.81 with VKA vs aspirin (Table 5).

N/A	No serious limitations	No serious limitations	No serious limitations	No serious limitations	N/A	N/A	N/A	VKA > dabigatran	Warfarin: daily medication, lifestyle limitations, dietary restrictions, frequent blood testing and clinic visits Dabigatran: daily medication only		High

See Table 1-3 and 9 legends for expansion of abbreviations.

[a]The 95% CI does not exclude the possibility of no effect.

[b]Based on data from Go et al,[44] which reported a mortality rate of 5.33 per 100 person-y in untreated (no warfarin) patients from an observational study (ATRIA cohort) and an estimated relative risk of mortality of 0.72 for VKA vs no therapy (Table 3).

[c]Intracranial hemorrhage includes intracerebral, subdural, and subarachnoid bleeds. The published report did not provide the number of strokes that were fatal and nonfatal; therefore, we imputed values for the number of fatal and nonfatal strokes to estimate the relative risk for nonfatal stroke. Assumptions underlying these estimates are detailed in section 1.3 of this article.

[d]Of the 149 nonfatal strokes on VKA therapy, an estimated 106 (71%) were ischemic, and 43 (29%) were hemorrhagic.

[e]Of the 132 nonfatal strokes on dabigatran therapy, an estimated 119 (90%) were ischemic, and 13 (10%) were hemorrhagic.

[f]We estimated the annual rates of nonfatal stroke (ischemic and hemorrhagic) on warfarin by extrapolating from observed annual rates of ischemic stroke (fatal + nonfatal), stratified by $CHADS_2$ score, in the aspirin arms of six historical RCTs in patients with AF (Gage et al[37]). Assumptions underlying these estimates are detailed in section 1.1.4 of this article.

[g]The published report did not provide the number of major extracranial bleeds that were fatal and nonfatal; therefore, we imputed values for the number of fatal and nonfatal major extracranial bleeds to estimate the relative risk for nonfatal major extracranial bleeds. Assumptions underlying these estimates are detailed in section 1.3 of this article.

[h]Rate of nonfatal major extracranial bleeding on warfarin is from observational cohorts of patients receiving adjusted-dose VKA therapy (median, 1.3%/y).

[i]Based on rate of systemic embolism on aspirin of 0.3 per 100 patient-y reported in the IPD meta-analysis of warfarin vs aspirin by van Walraven et al[61] and a relative risk for systemic embolism of 0.81 with VKA vs aspirin (Table 5).

then the already small benefits of antithrombotic therapy (number needed to treat for 1 year to prevent one nonfatal stroke of 500 for aspirin and 200 for VKA therapy) will be even smaller.

For patients who do choose antithrombotic therapy, the potential choices are aspirin, dual antiplatelet therapy with aspirin and clopidogrel, or oral anticoagulation. For every 1,000 patients with a $CHADS_2$ score of 0, treatment for 1 year with adjusted-dose VKA therapy or with combination aspirin and clopidogrel therapy compared with aspirin is anticipated to result in small reductions in nonfatal stroke and an increase in nonfatal major extracranial bleeding such that the net benefits of either VKA therapy or dual antiplatelet therapy with aspirin and clopidogrel would be small, particularly given the possibility of declining stroke rates over time (Tables 5, 7).

Recommendation

2.1.8. For patients with AF, including those with paroxysmal AF, who are at low risk of stroke (eg, $CHADS_2$ score = 0), we suggest no therapy rather than antithrombotic therapy (Grade 2B)**. For patients who do choose antithrombotic therapy, we suggest aspirin (75 mg to 325 mg once daily) rather than oral anticoagulation** (Grade 2B) **or combination therapy with aspirin and clopidogrel** (Grade 2B)**.**

Remarks: Patients who place an exceptionally high value on stroke reduction and a low value on avoiding bleeding and the burden associated with antithrombotic therapy are likely to choose antithrombotic therapy rather than no antithrombotic therapy. Other factors that may influence the choices above are a consideration of patient-specific bleeding risk and the presence of additional risk factors for stroke, including age 65 to 74 years and female sex, which have been more consistently validated, and vascular disease, which has been less well validated (see section 2.1.12). The presence of multiple non-$CHADS_2$ risk factors for stroke may favor oral anticoagulation therapy.

2.1.9 Recommendations for Patients With AF at Intermediate Risk of Stroke (eg, $CHADS_2$ Score of 1): For patients at intermediate risk of stroke with a $CHADS_2$ score of 1, compared with no therapy, 1 year of VKA therapy is expected to result in 15 fewer deaths and 15 fewer nonfatal strokes per 1,000 patients at the cost of eight more nonfatal major extracranial bleeds (Table 3). Regarding the choice between VKA therapy and aspirin, VKA therapy is anticipated to prevent nine nonfatal strokes for every 1,000 patients treated for 1 year compared with aspirin but will result in three additional bleeds and no reduction in all-cause mortality. However, because absolute rates of stroke may have fallen over the past 2 decades, we may be overestimating the absolute reduction in nonfatal stroke achieved with VKA therapy. Moreover, the true extent of bleeding risk with VKA therapy compared with aspirin therapy is unclear because the pooled estimate of the relative risk of bleeding from the relevant RCTs is imprecise (Table 5). The limited ability of $CHADS_2$ to accurately predict stroke risk (C statistic, 0.6-0.7), the considerable variability in patient values and preferences, and the burden and lifestyle limitations associated with adjusted-dose VKA therapy, introduce further uncertainty.

Compared with combination therapy with aspirin and clopidogrel, VKA therapy is expected to result in six fewer nonfatal strokes per 1,000 patients over a 1-year period, anywhere from four fewer to three more nonfatal major extracranial bleeds, and no reduction in all-cause mortality (Table 6). Uncertainty regarding the small net clinical benefit at a $CHADS_2$ score of 1 arises as a result of the limitations of the $CHADS_2$ score in estimating stroke risk and the possibility of declining absolute stroke rates over time. Uncertainty regarding the value of the small net benefit arises from the variability in patient values and preferences and the burden and lifestyle limitations associated with adjusted-dose VKA therapy.

For patients at intermediate risk of stroke with a $CHADS_2$ score of 1 who are unsuitable for or choose not to take an oral anticoagulant for reasons other than concerns about major bleeding (eg, difficulty maintaining a stable INR, lifestyle limitations of regular INR monitoring, dietary restrictions that are too burdensome, or costs of new anticoagulant drugs that are too high), combination therapy with aspirin and clopidogrel provides additional benefit of stroke reduction at the cost of additional bleeding (ACTIVE A trial) (Table 7). Patients opting for combination antiplatelet therapy rather than treatment with an oral anticoagulant should be informed that they are choosing an inferior treatment with regard to stroke prevention.

Recommendation

2.1.9. For patients with AF, including those with paroxysmal AF, who are at intermediate risk of stroke (eg, $CHADS_2$ score = 1), we recommend oral anticoagulation rather than no therapy (Grade 1B)**. We suggest oral anticoagulation rather than aspirin (75 mg to 325 mg once daily)** (Grade 2B) **or combination therapy with aspirin and clopidogrel** (Grade 2B)**. For patients who are unsuitable for or choose not to take an oral anticoagulant (for reasons other than concerns**

about major bleeding), we suggest combination therapy with aspirin and clopidogrel rather than aspirin (75 mg to 325 mg once daily) (Grade 2B)**.**

Remarks: Patients who place an exceptionally high value on stroke reduction and a low value on avoiding bleeding and the burden associated with anticoagulant therapy are likely to choose oral anticoagulation rather than antiplatelet therapy. Other factors that may influence the choice among antithrombotic therapies are a consideration of bleeding risk and the presence of additional risk factors for stroke, including age 65 to 74 years and female gender, which have been more consistently validated, and vascular disease, which has been less well validated (see section 2.1.12). The presence of multiple non-$CHADS_2$ risk factors for stroke may favor oral anticoagulation therapy.

2.1.10 Recommendations for Patients With AF at High Risk of Stroke (eg, $CHADS_2$ Score of ≥ 2, Which Includes Prior Ischemic Stroke or TIA): Patients at high risk of ischemic stroke, which includes patients with a history of ischemic stroke or TIA, can anticipate large benefits (ie, 15 fewer deaths and 30 fewer nonfatal strokes per 1,000 patients during 1 year of VKA therapy) with anticoagulation (Table 3).

For every 1,000 patients with a $CHADS_2$ score of 2 treated for 1 year with VKA therapy rather than aspirin, we anticipate 19 fewer nonfatal strokes at the expense of three more nonfatal major extracranial bleeds (Table 5). For every 1,000 such patients treated with VKA rather than combination therapy with aspirin and clopidogrel, we anticipate 11 fewer strokes and anywhere between four fewer to three more nonfatal major extracranial bleeds (Table 6). There is therefore a substantial net clinical benefit with oral anticoagulation.

For patients at high risk of ischemic stroke with a $CHADS_2$ score of ≥ 2 who are unsuitable for or who choose not to take an oral anticoagulant for reasons other than concerns about major bleeding (eg, difficulty maintaining a stable INR, lifestyle limitations of regular INR monitoring, dietary restrictions that are too burdensome, or costs of new anticoagulant drugs that are too high), aspirin and clopidogrel therapy will result in a substantial reduction in stroke compared with aspirin alone (ACTIVE A trial) (Table 7). Patients opting for combination antiplatelet therapy rather than treatment with an oral anticoagulant should be informed that they are choosing an inferior treatment with regard to stroke prevention.

Recommendation

2.1.10. For patients with AF, including those with paroxysmal AF, who are at high risk of stroke (eg, $CHADS_2$ score ≥ 2), we recommend oral anticoagulation rather than no therapy (Grade 1A)**, aspirin (75 mg to 325 mg once daily)** (Grade 1B)**, or combination therapy with aspirin and clopidogrel** (Grade 1B)**. For patients who are unsuitable for or choose not to take an oral anticoagulant (for reasons other than concerns about major bleeding), we recommend combination therapy with aspirin and clopidogrel rather than aspirin (75 mg to 325 mg once daily)** (Grade 1B)**.**

2.1.11 Recommendation Regarding Dabigatran vs Adjusted-Dose VKA Therapy: The RE-LY trial showed that dabigatran, at the higher dose of 150 mg bid, leads to reductions in nonfatal stroke, probable reductions in all-cause mortality, and no apparent increase in the risk of nonfatal major extracranial bleeding compared with VKA therapy (Table 9), whereas there was no evidence that dabigatran 110 mg bid leads to a significant reduction in relevant outcomes compared with VKA therapy (Table 10). In the United States, the Food and Drug Administration approved the use of dabigatran for the prevention of thromboembolism in patients with AF at a dose of 150 mg bid but not at a dose of 110 mg bid. However, the Food and Drug Administration did approve, based on pharmacokinetic considerations rather than direct evidence from RCTs in AF populations, a dose of 75 mg bid for patients with severe renal insufficiency (defined as a creatinine clearance 15-30 mL/min).[89]

For the question of whether to use dabigatran vs adjusted-dose VKA therapy, the evidence suggests net clinical benefit at the 150-mg dose. At the time of this writing, however, knowledge regarding the efficacy and safety of the new oral anticoagulants for patients with AF is still limited to one large randomized trial per agent. Uncommon but serious adverse effects may emerge with large-scale use of the drugs. Performance in usual clinical care may deteriorate because of less-restricted patient selection and suboptimal adherence to the unmonitored drug. For patients who do experience bleeding complications, clinicians need to be aware that there is no antidote to reverse the anticoagulant effects of dabigatran.[90] Given these concerns, it would be reasonable for VKA-experienced patients who are well controlled (ie, INR within therapeutic range a high proportion of the time) to continue on VKA therapy if they are satisfied with it and are tolerating it well rather than switching to dabigatran.

There is evidence from meta-analyses of RCTs[92] that home monitoring of VKA therapy reduces thromboembolic events by 42% compared with usual monitoring (see also Holbrook et al[91]), which is

similar to the 33% relative reduction in stroke achieved with dabigatran 150 mg bid compared with VKA therapy (Table 9).[84] Therefore, any advantages of dabigatran with respect to thromboembolism would likely not exist for motivated patients who are able to participate in home monitoring of their VKA therapy. Although home monitoring will reduce the burden of INR testing and VKA dose adjustment, the burdens of VKA therapy related to dietary restrictions and drug interactions will still exist, and there will be a cost for the home monitoring device and test strips. Therefore, depending on how patients value these burdens, some may choose dabigatran rather than home monitoring of VKA therapy.

Before prescribing dabigatran, clinicians need to judge whether the patient is similar enough to those enrolled in RE-LY that the clinical trial results are still likely to apply. In particular, the RE-LY study excluded patients with severe renal impairment (estimated creatinine clearance 30 mL/min or less).[84] The cost-effectiveness of the new anticoagulants compared with VKA therapy is another consideration. An economic analysis based on pricing of dabigatran in the United Kingdom (US $13 per day) estimated that dabigatran 150 mg bid would cost $45,372 more per quality-adjusted life year gained compared with warfarin for patients with AF aged 65 years with risk factors for stroke ($CHADS_2$ score of ≥ 1). The cost-effectiveness estimates in this model were sensitive to the pricing of dabigatran.[93]

Recommendation

2.1.11. For patients with AF, including those with paroxysmal AF, for recommendations in favor of oral anticoagulation (including 2.1.9, 2.1.10, and excluding 2.2, 3.1, 3.2, 3.3), we suggest dabigatran 150 mg twice daily rather than adjusted-dose VKA therapy (target INR range, 2.0-3.0) (Grade 2B)**.**

Remarks: Dabigatran is excreted primarily by the kidney. It has not been studied and is contraindicated in patients with severe renal impairment (estimated creatinine clearance of ≤ 30 mL/min). Clinicians should be aware that there is no antidote for dabigatran.

2.1.12 Tailoring These Recommendations to Individual Patients: As with all weak recommendations, treatment decisions should be individualized based on patient values and preferences, and in this case, an assessment of bleeding risk, and a consideration of additional risk factors for stroke.

Bleeding Risk Assessment—We have not made separate recommendations depending on patient bleeding risk because there are insufficient data to estimate reliably the absolute bleeding rates for patients in different categories of bleeding risk on different antithrombotic regimens. However, the following evidence regarding bleeding risk assessment may help to guide individualized treatment decisions for patients with AF.

One challenge in bleeding risk assessment for patients with AF is that many of the factors associated with an increased risk of major bleeding are also risk factors for ischemic stroke. For instance, older age, hypertension, congestive heart failure, and prior history of ischemic stroke—all of which are components of the $CHADS_2$ score—have been found in various studies of patients with AF to be independent predictors of bleeding while on VKA therapy.[94]

Several bleeding risk scores have been evaluated in cohorts of patients with AF (see Table 11).[53,95-98] However, these scores have not been extensively validated. Their ability to predict major bleeding is modest, with comparable C statistics across external validation studies (range, 0.61-0.66).[53,97-99] In scenarios where we make weak recommendations in favor of oral anticoagulation (eg, patients with a $CHADS_2$ score of 1), patients at high risk of major bleeding may decline oral anticoagulation.

Additional Risk Factors for Stroke in Patients With AF—In addition to consideration of bleeding risk and patient values and preferences, for patients with a $CHADS_2$ score of 0 or 1, clinicians may wish to consider additional stroke risk factors when individualizing decisions about antithrombotic therapy. For instance, there is high-quality evidence that stroke risk increases continuously with age (rather than as a dichotomous function of age <75 or ≥ 75 years) and moderate-quality evidence that female sex is an independent predictor of stroke risk in patients with AF.[18,20] Thus, patients may be inclined to choose the more aggressive treatment option (eg, antithrombotic therapy rather than no therapy for patients with a $CHADS_2$ score of 0 and oral anticoagulation rather than aspirin for patients with a $CHADS_2$ score of 1) when these additional risk factors for stroke are present. The presence of multiple non-$CHADS_2$ risk factors for stroke may favor oral anticoagulation therapy. There is less-consistent evidence supporting an independent association between vascular disease (ie, prior MI, complex aortic plaque seen on TEE, and peripheral arterial disease) and the risk of stroke in patients with AF (section 1.4.2).[21-23]

2.1.13 Percutaneous Closure of the Left Atrial Appendage: Percutaneous closure of the left atrial appendage (LAA) has recently been evaluated as a nondrug alternative for stroke prevention in patients with AF. The PROTECT-AF (WATCHMAN Left

Table 11—*[Section 2.1.12] Bleeding Risk Scores*

	Low	Moderate	High	Calculation of Bleeding Risk Score
Outpatient Bleeding Risk Index[95,96]	0	1-2	≥3	1 point for each of: Age ≥65 y GI bleed in past 2 wk Previous stroke Comorbidities (recent MI, Hct <30%, diabetes, or creatinine >1.5 mg/dL)

Atrial Appendage System for Embolic PROTECTion in Patients With Atrial Fibrillation) study randomized 707 patients with AF to percutaneous closure of the LAA using the WATCHMAN device (Atritech, Inc) or adjusted-dose warfarin to achieve a target INR of 2.0 to 3.0.[100] Percutaneous LAA closure was associated with a statistically nonsignificant reduction in the risk of their primary efficacy outcome of stroke (ischemic or hemorrhagic), cardiovascular or unexplained death, or systemic embolism compared with warfarin (absolute risk reduction, 1.9% per year; 95% CI, 3.2% per year less to 1.2% per year more, with percutaneous LAA closure compared with adjusted-dose warfarin). However, there was a significantly higher rate of adverse events (excessive bleeding, procedure-related complications) in the percutaneous LAA closure arm (absolute risk increase, 3.0% per year). In particular, serious pericardial effusion (ie, requiring percutaneous or surgical drainage) occurred in 4.8% of patients in the percutaneous LAA closure arm. Another occlusion device, PLAATO [percutaneous LAA transcatheter occlusion], has not been tested in a randomized trial but has been evaluated in prospective, multicenter cohort studies in patients ineligible for warfarin.[101,102] At this time, we make no formal recommendations regarding LAA closure devices, pending more definitive research in this field.

2.2 Patients With AF and Mitral Stenosis

Patients with AF in the setting of rheumatic mitral valve disease, particularly mitral stenosis, are at high risk of stroke. Most RCTs of adjusted-dose VKA therapy in AF excluded such patients. We believe that the results of randomized clinical trials in patients with nonrheumatic AF can be generalized to patients with mitral stenosis.

Recommendation

2.2. For patients with AF and mitral stenosis, we recommend adjusted-dose VKA therapy (target INR range, 2.0-3.0) rather than no therapy, aspirin (75 mg to 325 mg once daily), or combination therapy with aspirin and clopidogrel (all Grade 1B)**. For patients with AF and mitral stenosis who are unsuitable for or choose not to take adjusted-dose VKA therapy (for reasons other than concerns about major bleeding), we recommend combination therapy with aspirin**

and clopidogrel rather than aspirin (75 mg to 325 mg once daily) alone (Grade 1B)**.**

3.0 Antithrombotic Therapy for Patients With AF in Special Situations

3.1 Patients With AF and Stable Coronary Artery Disease

Approximately one-third of patients with AF also have coronary artery disease.[51] A recurring question is whether patients with AF for whom oral anticoagulation is indicated because of a high risk of stroke (eg, $CHADS_2$ score of ≥ 2) and who have concomitant stable coronary artery disease should also use aspirin to prevent coronary heart disease events. In this article, we define stable coronary artery disease as the presence (or absence) of angina but no revascularization procedure (percutaneous coronary intervention or coronary artery bypass graft surgery) or hospitalization for ACS (ie, unstable angina, non-ST-segment elevation MI, or ST-segment elevation MI) in the past year. The studies discussed next provide low-quality evidence that combination therapy with adjusted-dose VKA therapy plus aspirin is not associated with reductions in stroke or MI but that it does increase by 1.5 to 2 times the risk of major bleeding compared with adjusted-dose VKA therapy alone.

The FFAACS (Fluindione, Fibrillation Auriculaire, Aspirin et Contraste Spontane) trial is the only RCT that directly compared adjusted-dose VKA therapy and aspirin to adjusted-dose VKA therapy alone. In this study, patients in both arms received fluindione (INR 2.0-2.6), and patients in the combination therapy arm also received aspirin 100 mg/d. The trial was stopped early after enrollment of only 157 patients because of excessive hemorrhage in the group receiving fluindione plus aspirin.[103] No conclusion can be drawn regarding efficacy for prevention of stroke or MI because there were so few events during a short duration of follow-up.

There is direct evidence from a nonrandomized comparison of patients enrolled in the SPORTIF trials that combination therapy (with warfarin [INR 2.0-3.0] plus aspirin) is associated with a nearly twofold greater risk of major bleeding compared with warfarin alone, with no significant reduction in stroke or MI.[104] Patients receiving aspirin were different from those not receiving aspirin (eg, those receiving aspirin more often had diabetes, coronary artery disease, and previous stroke or TIA). Although the analyses were adjusted for baseline differences in patient characteristics, there remains a high risk for bias.

A similar nonrandomized comparison of patients enrolled in the RE-LY trial reported that rates (likely unadjusted) of major bleeding were roughly 2 times higher for patients receiving aspirin in conjunction with either warfarin (INR 2.0-3.0) or dabigatran.[105] Analyses of observational data from a large population-based registry of hospitalized patients with AF also found a nearly twofold increase in the risk of bleeding requiring hospitalization or causing death when patients with AF received combination therapy with warfarin and aspirin vs warfarin alone.[106]

A systematic review of RCTs in diverse (mostly non-AF) patient populations that compared aspirin plus VKA therapy with VKA therapy alone, in which VKAs were administered to achieve the same target INR or given at the same fixed dose in both arms, found that combination VKA plus aspirin therapy was associated with a lower risk of cardiovascular events compared with VKA therapy alone but that this benefit was restricted to RCTs enrolling patients with mechanical heart valves. No benefit was seen with combination therapy in studies of patients with AF or coronary artery disease, although estimates of treatment effect were very imprecise. Combination therapy with VKA and aspirin was associated with a greater risk of major bleeding (pooled OR, 1.43; 95% CI, 1.00-2.02) compared with VKA therapy alone.[107]

Recommendation

3.1. For patients with AF and stable coronary artery disease (eg, no acute coronary syndrome within the previous year) and who choose oral anticoagulation, we suggest adjusted-dose VKA therapy alone (target INR range, 2.0-3.0) rather than the combination of adjusted-dose VKA therapy and aspirin (Grade 2C)**.**

3.2 Patients With AF and Placement of an Intracoronary Stent (With or Without Recent ACS)

Patients benefit from dual antiplatelet therapy (eg, aspirin and clopidogrel) for a finite duration following placement of an intracoronary stent (4 weeks after placement of a bare-metal stent; 3 to 6 months after placement of a drug-eluting stent [typically 3 months for -olimus stents and 6 months for -taxel stents]) (see Vandvik et al).[108] The principal objective of dual antiplatelet therapy after placement of an intracoronary stent is the prevention of stent thrombosis. Before the adoption of dual antiplatelet therapy in clinical practice, stent thrombosis occurred in 6% to 24% of patients after bare-metal stent placement and was associated with a high case fatality rate of nearly 50%.[109-113] Concomitantly, a number of studies compared a new strategy, aspirin plus ticlopidine (a thienopyridine precursor to clopidogrel), to the previously most successful strategy of aspirin plus warfarin in patients undergoing stent placement. A Cochrane systematic review of four randomized

trials including 2,436 patients found that a 30- to 42-day course of ticlopidine plus aspirin vs warfarin plus aspirin reduced the 30- to 42-day risk of nonfatal MI (relative risk, 0.50; 95% CI, 0.30-0.83; number needed to treat, 55) and revascularization (relative risk, 0.29; 95% CI, 0.16-0.56; number needed to treat, 33) with a possible reduction in major bleeding (relative risk, 0.36; 95% CI, 0.14-1.02) (see Table 11 in Vandvik et al,[108] sections 3.1-3.5).[114]

Based on these data, we recommend aspirin and clopidogrel over warfarin plus aspirin for a finite period following stent placement. For patients with AF receiving oral anticoagulation who undergo placement of an intracoronary stent, the dilemma arises about whether patients should be continued on oral anticoagulation during the time they are recommended to be on dual antiplatelet therapy, given the lack of direct evidence from RCTs addressing this question.

Treatment decisions in this scenario must balance the effect of each drug combination on (1) the risk of stroke, systemic embolism, and mortality due to AF; (2) the risk of recurrent MI (including stent thrombosis); and (3) the risk of bleeding related to antithrombotic therapy. Because of the very high risk for bias in the available observational studies that compare cardiovascular event rates in patients receiving triple therapy vs dual antiplatelet therapy after stent placement,[115-120] we have instead used indirect evidence from relevant RCTs to inform our recommendations. We assumed that the relative impact of triple therapy on death, nonfatal MI, and nonfatal major extracranial bleeds compared with dual antiplatelet therapy would be similar to that seen in 10 RCTs of warfarin plus aspirin compared with aspirin in patients with ACS.[121] For nonfatal stroke and systemic embolism, we assumed that the relative impact of triple therapy vs dual therapy would be similar to that seen in the ACTIVE W trial, which compared warfarin vs aspirin plus clopidogrel in patients with AF (Table 6).[80] This assumption may be underestimating the true effect of triple therapy on stroke and systemic embolism compared with dual therapy.

We used the same annual baseline event rates (ie, on dual antiplatelet therapy) for death, nonfatal stroke, and systemic embolism as were used in the evidence profile comparing VKA to aspirin plus clopidogrel in the general AF population (Table 6). For the annual risk of nonfatal MI and nonfatal major extracranial bleeding on aspirin plus clopidogrel, we used the rates reported in the clopidogrel arm of the PLATO (Study of Platelet Inhibition and Patient Outcomes) trial, which compared ticagrelor to clopidogrel in patients with ACS receiving aspirin.[122]

The indirect data summarized in Table 12 suggest that triple therapy may be associated with net clinical benefit compared with dual antiplatelet therapy for patients at high risk of stroke (eg, $CHADS_2$ score of ≥ 2), whereas the net benefit at lower levels of stroke risk is uncertain. The duration of triple therapy should be kept as brief as possible given the associated increase in bleeding risk. Because the risk of stent thrombosis falls significantly after 30 days with bare-metal stents and 3 to 6 months after drug-eluting stents, triple therapy should be continued only during this high-risk period and only among patients at higher risk of stroke. After the initial period of triple therapy, patients may be given VKA therapy plus a single antiplatelet drug until 12 months have elapsed from the time of stent placement (particularly if stent placement was performed in the setting of a recent ACS [see section 3.3] or if a drug-eluting stent was used).

It should be noted that patients with AF who have received a drug-eluting stent and who are at increased risk of late stent thrombosis (eg, ACS at presentation, diabetes, long lesions, narrow diameter of target vessel)[123] may choose to continue triple therapy for a full 12 months after stent placement if they place a low value on avoiding bleeding. At 12 months after stent placement, antithrombotic therapy can be given according to our recommendations for AF and stable coronary artery disease (section 3.1).

Recommendation

3.2. For patients with AF at high risk of stroke (eg, $CHADS_2$ score of 2 or greater) during the first month after placement of a bare-metal stent or the first 3 to 6 months after placement of a drug-eluting stent, we suggest triple therapy (eg, VKA therapy, aspirin, and clopidogrel) rather than dual antiplatelet therapy (eg, aspirin and clopidogrel) (Grade 2C)**. After this initial period of triple therapy, we suggest a VKA (INR 2.0-3.0) plus a single antiplatelet drug rather than VKA alone** (Grade 2C)**. At 12 months after intracoronary stent placement, antithrombotic therapy is suggested as for patients with AF and stable coronary artery disease (see section 3.1).**

For patients with AF at low to intermediate risk of stroke (eg, $CHADS_2$ score of 0 or 1) during the first 12 months after placement of an intracoronary stent (bare metal or drug eluting), we suggest dual antiplatelet therapy rather than triple therapy (Grade 2C)**. At 12 months after intracoronary stent placement, antithrombotic therapy is suggested as for patients with AF and stable coronary artery disease (see section 3.1).**

Remarks: Patients who place an exceptionally high value on stroke reduction and a low value on avoiding

[a]We used the relative risk for all-cause mortality, nonfatal MI, and nonfatal major extracranial bleeding associated with warfarin + aspirin therapy vs aspirin alone in 10 RCTs of patients with acute coronary syndrome (Rothberg et al[121]) to estimate the effect of triple therapy vs dual antiplatelet therapy on all-cause mortality in patients with AF and acute coronary syndrome.

[b]The 95% CI does not exclude important harm or benefit with triple therapy.

[c]We used the same baseline estimates of mortality as for the general AF population receiving aspirin + clopidogrel. This was based on data from Go et al,[44] which reported a mortality rate of 5.33 per 100 person-y in untreated (no warfarin) patients from an observational study (ATRIA cohort), an estimated relative risk of 0.89 for mortality with aspirin vs no therapy (Table 4), and an estimated relative risk of 0.98 for mortality with aspirin + clopidogrel vs aspirin (Table 7).

[d]We used data from an RCT of warfarin vs aspirin + clopidogrel in patients with AF (ACTIVE W) to estimate the relative effect of triple therapy vs dual antiplatelet therapy on nonfatal stroke and systemic embolism in patients with AF and acute coronary syndrome. This assumption may be underestimating the potential benefit of triple therapy vs dual antiplatelet therapy in reducing nonfatal stroke.

[e]We estimated the annual rates of nonfatal stroke (ischemic and hemorrhagic) on aspirin + clopidogrel by extrapolating from observed annual rates of ischemic stroke (fatal + nonfatal), stratified by $CHADS_2$ score, in the aspirin arms of six historical RCTs in patients with AF (Gage et al[37]). Assumptions underlying these estimates are detailed in section 1.1.4 of this article.

[f]From clopidogrel (plus aspirin) arm of the PLATO trial of ticagrelor vs clopidogrel in patients with acute coronary syndrome.

[g]Based on the absolute rate of non-coronary artery bypass graft-related major bleeding (TIMI definition) reported in the clopidogrel (plus aspirin) arm of the PLATO trial minus the rate of fatal bleeding reported in this arm of the PLATO trial.

[h]Estimate is derived from rate of systemic embolism on aspirin (0.3 per 100 patient-y) reported in the individual patient data meta-analysis by van Walraven et al[61] and estimated relative risk of 0.97 (95% CI, 0.67-1.40) for systemic embolism with combination aspirin + clopidogrel therapy vs aspirin observed in ACTIVE A (Table 7).

bleeding and the burden associated with anticoagulant therapy are likely to choose triple therapy rather than dual antiplatelet therapy. Other factors that may influence this choice are a consideration of bleeding risk and the presence of additional non-$CHADS_2$ risk factors for stroke (see section 2.1.12).

3.3 Patients With AF and ACS Who Do Not Undergo Intracoronary Stent Placement

Dual antiplatelet therapy (eg, with aspirin and clopidogrel) rather than aspirin alone is recommended during the first 12 months after an ACS, regardless of whether patients also receive an intracoronary stent (Vandvik et al[108]). Many patients with AF (eg, $CHADS_2$ score of ≥ 1) will choose VKA therapy (eg, warfarin) to prevent future stroke (section 2.1). Therefore, treatment options in patients with AF and recent ACS may include warfarin plus dual antiplatelet therapy (ie, triple therapy), dual antiplatelet therapy, or warfarin plus single antiplatelet therapy. In this section, we specifically address patients with AF and ACS who do not undergo placement of an intracoronary stent.

The indirect data summarized in Table 12 suggest that triple therapy may not be associated with net clinical benefit compared with dual antiplatelet therapy unless patients are at substantially high risk of stroke (eg, $CHADS_2$ score of ≥ 2), whereas the net benefit at lower levels of stroke risk is uncertain. Rather than triple therapy, a third therapeutic option in this clinical scenario (where stent thrombosis is not a concern) is to use a VKA plus single antiplatelet therapy. Unfortunately, there are no RCTs comparing warfarin plus single antiplatelet therapy to dual antiplatelet therapy. As described in Author et al (section 2.4) in this guideline, warfarin plus aspirin is associated with a significant reduction in risk of subsequent MI (relative risk, 0.69; 95% CI, 0.54-0.88) and stroke (relative risk, 0.56; 95% CI, 0.39-0.82) compared with aspirin alone in patients post-ACS.[121] The point estimates for these reductions in MI and stroke are greater than those seen with clopidogrel plus aspirin (relative risk, 0.77; 95% CI, 0.67-0.89) vs aspirin alone (relative risk, 0.86; 95% CI, 0.63-1.18) in the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial.[124] These data suggest that warfarin plus aspirin is at least as effective, and potentially more effective, than clopidogrel plus aspirin for the prevention of cardiovascular events after ACS. Warfarin plus aspirin was not given a recommendation in Author et al either as an alternative or in preference to dual antiplatelet therapy for patients post-ACS because of pragmatic issues (physician reluctance, burden of use, etc). However, these issues are not relevant for patients already receiving warfarin for AF.

Finally, there are no studies comparing warfarin plus aspirin to triple therapy (eg, warfarin, aspirin, and clopidogrel) in patients with AF and recent ACS. Use of triple therapy in this situation would be appropriate only if the risk reduction in MI and stroke achieved by adding the second antiplatelet agent is greater than the increase in bleeding risk. This seems unlikely in patients who are not undergoing stent placement and, thus, where there is no concern regarding stent thrombosis. Given the lack of direct evidence and mindful of the principle to first do no harm, we do not advocate the use of triple therapy in patients with AF who experience ACS but do not receive an intracoronary stent. However, patients placing a high value on MI and stroke reduction and a low value on avoiding bleeding may opt for an initial period of triple therapy (eg, 3-6 months) followed by warfarin plus aspirin.

Recommendation

3.3. For patients with AF at intermediate to high risk of stroke (eg, $CHADS_2$ score of 1 or greater) who experience an acute coronary syndrome and do not undergo intracoronary stent placement, we suggest, for the first 12 months, adjusted-dose VKA therapy (INR 2.0-3.0) plus single antiplatelet therapy rather than dual antiplatelet therapy (eg, aspirin and clopidogrel) or triple therapy (eg, warfarin, aspirin, and clopidogrel) (Grade 2C)**. After the first 12 months, antithrombotic therapy is suggested as for patients with AF and stable coronary artery disease (see section 3.1).**

For patients with AF at low risk of stroke (eg, $CHADS_2$ score of 0), we suggest dual antiplatelet therapy (eg, aspirin and clopidogrel) rather than adjusted-dose VKA therapy (INR 2.0-3.0) plus single antiplatelet therapy or triple therapy (eg, warfarin, aspirin, and clopidogrel) (Grade 2C)**. After the first 12 months, antithrombotic therapy is suggested as for patients with AF and stable coronary artery disease (see section 3.1).**

Remarks: Patients who place an exceptionally high value on stroke reduction and a low value on avoiding bleeding and the burden associated with anticoagulant therapy are likely to choose adjusted-dose VKA therapy plus single antiplatelet therapy rather than dual antiplatelet therapy. Other factors that may influence this choice are a consideration of bleeding risk and the presence of additional non-$CHADS_2$ risk factors for stroke (see section 2.1.12).

3.4 Patients With AF Managed by a Rhythm Control Strategy

Some patients with AF will be managed with antiarrhythmic drugs (AADs) to achieve and maintain normal sinus rhythm. Increasingly, patients with AF are also receiving catheter radiofrequency ablation procedures (pulmonary vein isolation) to maintain normal sinus rhythm. In the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial, in which many patients in the rhythm control arm did not receive anticoagulation, patients in a rhythm control strategy had a similar risk of stroke compared with patients in a rate control strategy (see also section 4.1.1).[125]

There are several RCTs of catheter ablation vs AAD therapy in patients with AF, typically those who have failed first-line therapy with AADs.[126-132] All trials found a significant reduction in AF recurrence at ~1 year of follow-up. However, AF recurrence in the catheter ablation arms ranged from 11% to 44% at ~1 year. The studies rarely reported on stroke outcomes, and all were underpowered to address this question. Given the results of the AFFIRM trial, the lack of longer-term follow-up data from catheter ablation RCTs regarding AF recurrence rates, and poor reporting of stroke outcomes, it would be prudent to base decisions about long-term antithrombotic therapy on a patient's underlying risk for stroke as recommended in section 2.1, and not on their underlying rhythm.

Recommendation

3.4. For patients with AF being managed with a rhythm control strategy (pharmacologic or catheter ablation), we suggest that antithrombotic therapy decisions follow the general risk-based recommendations for patients with AF in section 2.1, regardless of the apparent persistence of normal sinus rhythm (Grade 2C)**.**

3.5 Patients With Atrial Flutter

Many patients with persistent atrial flutter have periods of atrial flutter alternating with periods of AF.[133,134] The prevalence of thrombus in the body of the atria and atrial appendage on TEE in patients with atrial flutter ranges from 1% to 21%.[135-138] There are few data from longitudinal studies assessing the risk of thromboembolism with well-documented sustained atrial flutter. A study describing a series of 191 consecutive, unselected patients hospitalized for treatment of atrial flutter reported thromboembolism in 7% of patients during a mean follow-up of 26 months.[134] The role of anticoagulant therapy for patients with atrial flutter has not been evaluated in clinical trials, but because these patients often have concomitant AF or are at increased risk of developing AF, it is reasonable to base decisions regarding antithrombotic therapy on the risk stratification schemes used for AF (section 1.1).

Recommendation

3.5. For patients with atrial flutter, we suggest that antithrombotic therapy decisions follow the same risk-based recommendations as for AF.

4.0 Antithrombotic Therapy for Patients With AF Undergoing Cardioversion

To minimize the risk of stroke and systemic embolism associated with cardioversion, therapeutic anticoagulation (eg, with adjusted-dose oral VKAs; INR 2.0-3.0) conventionally is recommended for a minimum of 3 weeks before, during, and for a minimum of 4 weeks after the procedure. For some patients with AF of documented short duration (eg, ≤48 h), a common practice is to cardiovert without prolonged precardioversion anticoagulation. For patients with AF duration of >48 h or unknown duration, a TEE-guided approach is an alternative strategy that can simplify anticoagulation management before cardioversion. In this section, we summarize the evidence and give recommendations for the use of antithrombotic therapy in patients undergoing electrical or pharmacologic cardioversion for AF (or atrial flutter).

4.1 Patients Undergoing Elective Cardioversion of AF

4.1.1 Cardioversion of AF of More Than 48 h or Unknown Duration: Evidence favoring the efficacy of pericardioversion anticoagulation is based on observational studies in mostly patients undergoing electrical rather than pharmacologic cardioversion. There is moderate-quality evidence from a systematic review of 18 observational studies suggesting that the risk of stroke or thromboembolism is substantially lower in patients receiving pericardioversion anticoagulation than in those who receive no anticoagulation (0.3% vs 2.0%), translating to a relative risk of 0.16 (95% CI, 0.05-0.48) in favor of anticoagulation.[139] No data regarding major hemorrhagic events were reported in this systematic review.

The conventional duration of a minimum of 3 weeks therapeutic anticoagulation before cardioversion and a minimum 4 weeks afterward is based on indirect pathophysiologic data and evidence from observational studies and remains arbitrary. Observational data showing that thromboembolism was significantly more common at an INR of 1.5 to 2.4 before

cardioversion than an INR of ≥ 2.5 (0.93% vs 0%, $P = .012$) suggests the importance of maintaining a therapeutic INR in the pericardioversion period.[140] After cardioversion, results of observational studies suggest that the highest risk of stroke and thromboembolism is in the first 72 h after cardioversion and that the majority of thromboembolic complications will occur within 10 days of cardioversion.[141] However, TEE studies have demonstrated that despite restoration of sinus rhythm on the ECG, atrial mechanical dysfunction may persist for several weeks postcardioversion.[142]

A nonrandomized comparison of 1,270 patients enrolled in the RE-LY trial who underwent 1,983 cardioversions suggests that there may be no excess harm with dabigatran compared with warfarin when used for pericardioversion anticoagulation. Most cardioversions in this study (~80%) were performed after the protocol-assigned study anticoagulant was given for a minimum of 3 weeks before the procedure, and rates of stroke and systemic embolism at 30 days after cardioversion were low when oral anticoagulation with either warfarin or dabigatran was given before cardioversion (0.8%, 0.3%, and 0.6% with dabigatran 110 mg bid, dabigatran 150 mg bid, and warfarin, respectively).[143]

A TEE-guided approach with abbreviated anticoagulation before cardioversion is an alternative to the conventional approach of using a minimum of 3 weeks therapeutic precardioversion anticoagulation.[144] Under a TEE-guided strategy, patients receive anticoagulation and once therapeutic, undergo screening TEE. If thrombus is seen in either atrial appendage or atrium at the time of TEE, cardioversion is postponed, given the presumed high risk of thromboembolism. If no thrombus is seen, the patient proceeds immediately to cardioversion. A TEE-guided strategy requires an experienced echocardiographer because accurate visualization of thrombus may be operator dependent.

The Assessment of Cardioversion Using Transesophageal Echocardiography (ACUTE) RCT compared a TEE-guided strategy of abbreviated therapeutic anticoagulation with IV unfractionated heparin (started 24 h before cardioversion) or warfarin (INR 2.0-3.0) (started 5 days before cardioversion) to a strategy of therapeutic anticoagulation for at least 3 weeks before cardioversion.[145] The evidence is of low quality given the wide 95% CIs around the point estimates of effect on patient-important outcomes (Table 13). Thus, the results do not exclude with confidence the possibility of important benefit or harm with a TEE-guided approach compared with a conventional approach of 3 weeks anticoagulation precardioversion.

Acknowledging these uncertainties, a TEE-guided approach may be best suited for patients who are very symptomatic while in AF because cardioversion can be done sooner if the TEE is negative for thrombus. It may also suit patients who would prefer to avoid prolonged oral anticoagulation before cardioversion and those at increased risk for bleeding. However, the ability to avoid anticoagulation with a TEE-guided strategy is most relevant for patients without stroke risk factors and at low risk of recurrent AF in whom long-term anticoagulation beyond 4 weeks after cardioversion would not be required.

For patients undergoing a TEE-guided approach, low-molecular-weight heparin at full VTE treatment doses or IV unfractionated heparin (to maintain an activated partial thromboplastin time prolongation

Table 13—*[Section 4.1] Abbreviated Anticoagulation With TEE-Guided Cardioversion vs Conventional Anticoagulation for at Least 3 Weeks Before Cardioversion*

	Anticipated Absolute Effects (Time Frame Is 8 wk)				
Outcomes	Risk With Conventional Anticoagulation	Risk Difference With TEE + Abbreviated Anticoagulation[a] (95% CI)	Relative Effect (95% CI)	No. of Participants (Studies), Follow-up	Quality of The Evidence (GRADE)
Death	10 per 1,000[b]	14 more deaths per 1,000 (0 more to 52 more)	RR 2.44 (0.95-6.24)	1,222 (1 RCT), 8 wk	Low[c]
Nonfatal strokes	3 per 1,000[b]	5 more strokes per 1,000 (2 fewer to 38 more)	RR 2.44 (0.47-12.50)	1,222 (1 RCT), 8 wk	Low[c]
Nonfatal major extracranial bleeds[d]	15 per 1,000[b]	7 fewer bleeds per 1,000 (12 fewer to 9 more)	RR 0.54 (0.18-1.61)	1,222 (1 RCT), 8 wk	Low[c]

ACUTE = Assessment of Cardioversion Using Transesophageal Echocardiography; GRADE = Grades of Recommendations, Assessment, Development, and Evaluation; TEE = transesophageal echocardiography. See Tables 1 and 8 for expansion of other abbreviations.

[a]Abbreviated anticoagulation refers to either IV unfractionated heparin (started 24 h before cardioversion) or adjusted-dose warfarin (INR 2.0-3.0) (started 5 d before cardioversion).

[b]Assumed risk is the observed event rate from the control arm (ie, conventional anticoagulation) of the RCT by Klein et al[145] (ACUTE trial).

[c]No statistically significant effect, and CIs are very wide. Trial was not sufficiently large to demonstrate comparable safety between conventional and TEE-based strategies.

[d]Most of these were GI bleeds.

that corresponds to plasma heparin levels of 0.3-0.7 International Units/mL antifactor Xa activity) should be started at the time of TEE and cardioversion performed within 24 h of the TEE if no thrombus is seen. A few observational studies and one RCT have suggested that low-molecular-weight heparin has similar efficacy compared with heparin or warfarin for immediate anticoagulation before TEE.[146-150] Outpatients undergoing a TEE-guided approach may be started on a VKA (INR 2.5; range, 2.0-3.0) and the TEE and subsequent cardioversion scheduled for 5 days later (if the INR is in therapeutic range at that time). The new oral anticoagulants may also be suitable for outpatient treatment before TEE-guided cardioversion given their ease of use (eg, dabigatran achieves steady-state concentrations in 2-3 days after bid administration),[151] but they have not yet been studied for this purpose.

There is no direct evidence to guide decisions about the long-term management of anticoagulation in patients who appear to be in sinus rhythm 4 weeks after cardioversion. Several observational studies indicate that approximately one-half of patients will have recurrence of AF at 1 year after cardioversion.[152-156] The AFFIRM study, in which many patients stopped anticoagulation after initial (apparently) successful restoration of sinus rhythm, found similar rates of thromboembolism with a rhythm control strategy compared with a rate control strategy.[125] Finally, patients with PAF often are asymptomatic during episodes of AF recurrence, with one series suggesting that only one in every 12 paroxysms are symptomatic.[157] These observations suggest that decisions about long-term antithrombotic therapy should be primarily based on a patient's risk for stroke (see section 2.1) rather than on the prevailing rhythm at 4 weeks postcardioversion.

Recommendation

4.1.1. For patients with AF of greater than 48 h or unknown duration undergoing elective electrical or pharmacologic cardioversion, we recommend therapeutic anticoagulation (adjusted-dose VKA therapy, target INR range 2.0-3.0, low-molecular-weight heparin at full venous thromboembolism treatment doses, or dabigatran) for at least 3 weeks before cardioversion or a TEE-guided approach with abbreviated anticoagulation before cardioversion, rather than no anticoagulation (Grade 1B)**. We recommend therapeutic anticoagulation for at least 4 weeks after successful cardioversion to sinus rhythm, rather than no anticoagulation, regardless of the baseline risk of stroke** (Grade 1B)**. Decisions about anticoagulation beyond 4 weeks should be made in accordance with our risk-based recommendations for long-term antithrombotic therapy in section 2.1.**

4.1.2 Cardioversion of AF of 48 h Duration or Less: There is uncertainty over the precise duration of AF necessary for thrombus to develop and, hence, the threshold of AF duration below which precardioversion anticoagulation can be safely avoided. For AF of short duration (eg, ≤48 h), a common practice is to cardiovert without a TEE or prolonged precardioversion anticoagulation. However, observational studies have found left atrial thrombus on TEE in as many as 14% of patients with acute AF of short duration.[158,159] Moreover, because many individuals develop AF asymptomatically, it is often difficult to accurately determine a patient's duration of AF, making the 48-h rule difficult to apply.[160] No RCTs have compared different anticoagulation strategies in patients with AF of documented duration of ≤48 h. Observational data suggest that the risk of stroke or thromboembolism in these patients is similar to those who have received conventional anticoagulation for a minimum of 3 weeks before cardioversion.[140,161]

Recommendation

4.1.2. For patients with AF of documented duration of 48 h or less undergoing elective cardioversion (electrical or pharmacologic), we suggest starting anticoagulation at presentation (low-molecular-weight heparin or unfractionated heparin at full venous thromboembolism treatment doses) and proceeding to cardioversion rather than delaying cardioversion for 3 weeks of therapeutic anticoagulation or a TEE-guided approach (Grade 2C)**. After successful cardioversion to sinus rhythm, we recommend therapeutic anticoagulation for at least 4 weeks rather than no anticoagulation, regardless of baseline stroke risk** (Grade 2C)**. Decisions about long-term anticoagulation after cardioversion should be made in accordance with our risk-based recommendations for long-term antithrombotic therapy in section 2.1.**

4.2 Patients Undergoing Urgent Cardioversion for Hemodynamically Unstable AF

There are no published data regarding the optimal anticoagulation strategy to use before or during urgent cardioversion for patients with AF and hemodynamic instability. Initiation of anticoagulation immediately before urgent cardioversion (eg, with IV unfractionated heparin or low-molecular-weight heparin) would be expected to reduce the risk of stroke or thromboembolism based on studies

of elective cardioversion. It is important to note that the initiation of anticoagulation therapy should not delay any emergency interventions to stabilize the patient.

Recommendation

4.2. For patients with AF and hemodynamic instability undergoing urgent cardioversion (electrical or pharmacologic), we suggest that therapeutic-dose parenteral anticoagulation be started before cardioversion, if possible (Grade 2C)**, but that initiation of anticoagulation must not delay any emergency intervention** (Grade 2C)**. After successful cardioversion to sinus rhythm, we suggest therapeutic anticoagulation for at least 4 weeks after successful cardioversion to sinus rhythm rather than no anticoagulation, regardless of baseline stroke risk** (Grade 2C)**. Decisions about anticoagulation beyond 4 weeks should be made in accordance with our risk-based recommendations for long-term antithrombotic therapy in section 2.1.**

4.3 Patients Undergoing Elective or Urgent Cardioversion for Atrial Flutter

There are no published data regarding the optimal anticoagulation strategy to use for patients undergoing cardioversion for atrial flutter. Although some observational studies suggest that the risk of thromboembolism after cardioversion for atrial flutter is low, even without anticoagulation, other studies have documented a similar risk of thromboembolism in patients after cardioversion for atrial flutter and AF.[140,162,163] This may be because AF and atrial flutter often coexist.

Recommendation

4.3. For patients with atrial flutter undergoing elective or urgent pharmacologic or electrical cardioversion, we suggest that the same approach to thromboprophylaxis be used as for patients with atrial fibrillation undergoing cardioversion.

5.0 Practical Issues in the Management of VKA Therapy

5.1 Optimal Target INR Range

For a full discussion of optimal target INR range with VKA therapy across a variety of indications, see Holbrook et al[91] regarding evidence-based management of anticoagulation in this guideline. With respect to patients with AF specifically, several studies assessed oral anticoagulation at very-low INR targets or fixed low doses compared with adjusted-dose anticoagulation targeted at an INR of 2.0 to 3.0 and found that anticoagulation targeted at an INR of 2.0 to 3.0 was more effective in reducing the risk of stroke.[164] Observational studies have shown that the risk of ischemic stroke is much greater once INR levels are <2.0 and that there are no appreciable gains in efficacy with levels >2.0. However, there is a sharp increase in the risk of bleeding complications, particularly intracranial hemorrhage, as INR levels rise to >3.0 to 4.0.[165-169] A target INR value of 2.0 will result in patients spending a substantial proportion of time at subtherapeutic INR levels (ie, <2.0).[170] Given that bleeding risk does not rise substantially until INR levels are >3.0, and particularly >4.0, these data from AF populations support an optimal target INR range of 2.0 to 3.0, with a target value of 2.5 to maximize the time spent in the optimal INR range.[165-170]

5.2 Time in Therapeutic Range

For a full discussion of the importance of time in therapeutic range while on adjusted-dose VKA therapy, see Ageno et al[171] regarding oral anticoagulation in this guideline. With respect to patients with AF, there are several observational studies indicating that increasing time out of range is associated with poorer outcomes (eg, mortality, ischemic stroke, thromboembolism, major bleeding).[172-175]

6.0 Future Research

Approximately one in every three patients with AF also has coronary artery disease.[51] However, the optimal approach to antithrombotic therapy in these patients is unclear. Research is needed to determine the effect of treatment with oral anticoagulation and aspirin compared with oral anticoagulation alone on patient-important outcomes of vascular death, nonfatal stroke, nonfatal MI, nonfatal major extracranial bleeding, and nonfatal systemic embolism. Research is also needed to inform recommendations about different antithrombotic therapy regimens for patients with AF undergoing placement of an intracoronary artery stent or who experience an ACS (eg, triple therapy with oral anticoagulation, clopidogrel, and aspirin; dual antiplatelet therapy with clopidogrel and aspirin; or combination oral anticoagulation and aspirin or clopidogrel). Finally, all existing stroke risk stratification and bleeding risk stratification schema for patients with AF have modest predictive value, and development of more-accurate risk stratification systems is needed to facilitate a more-accurate estimation of net clinical benefit for individual patients.

7.0 Conclusions

Stroke is a serious complication of AF, but its risk varies considerably across different groups of patients with AF. Antithrombotic prophylaxis for stroke is associated with an increased risk of bleeding. We provide recommendations for antithrombotic treatment based on net clinical benefit for patients with AF at varying levels of stroke risk. Oral anticoagulation is the optimal choice of antithrombotic therapy for patients with AF at high risk of stroke (eg, $CHADS_2$ score ≥ 2). At lower levels of stroke risk, antithrombotic treatment decisions will require a more individualized approach that takes into consideration patient values and preferences, bleeding risk, and the presence of non-$CHADS_2$ stroke risk factors. The role of oral anticoagulation for the prevention of stroke in patients with AF will evolve as the results of large, ongoing, phase 3 RCTs of new oral anticoagulants are published and as experience with these new agents in clinical practice continues to grow.

Acknowledgments

Author contributions: As Topic Editor, Dr You oversaw the development of this article, including the data analysis and subsequent development of the recommendations contained herein.

Financial/nonfinancial disclosures: The authors of this guideline provided detailed conflict of interest information related to each individual recommendation made in this article. A grid of these disclosures is available online at http://chestjournal.chestpubs.org/content/141/2_suppl/e531S/suppl/DC1. In summary, the authors have reported to *CHEST* the following conflicts of interest: Over the past 3 years, Dr Singer has received grant support from the Eliot B. and Edith C. Shoolman fund of Massachusetts General Hospital (MGH) to study stroke in atrial fibrillation. He has also received research grant support (through MGH) from Daiichi-Sankyo, Inc, to study hemorrhage risk in patients with atrial fibrillation taking warfarin. Dr Singer has been supported by the National Institutes of Health (National Heart, Lung, and Blood Institute and National Institute on Aging) grant funding to study stroke risk in patients with atrial fibrillation. He has served as a consultant on stroke prevention in atrial fibrillation to Bayer Healthcare Pharmaceuticals; Boehringer Ingelheim GmbH; Bristol-Myers Squibb; Daiichi-Sankyo, Inc; Johnson & Johnson; Merck and Co, Inc; Pfizer Inc; and Sanofi-Aventis LLC. Dr. Singer has published numerous articles on stroke prevention in atrial fibrillation and has given numerous lectures and research presentations on this topic. Dr Lane is in receipt of an investigator-initiated educational grant from Bayer Healthcare Pharmaceuticals and has participated in speaker activities for Bayer Healthcare Pharmaceuticals, Boehringer Ingelheim GmbH, Bristol-Myers Squibb/Pfizer Inc, and the Thrombosis Research Institute. She has also received support (travel and accommodation) to attend conferences from AstraZeneca and Boehringer Ingelheim GmbH. Dr Eckman has received a number of grants, including university grants for "Using Decision Analytic Modeling to Guide the ACCP Guideline Development Process for Antithrombotic Therapy in Atrial Fibrillation" (Foundation for Informed Medical Decision Making; $185,000) and has the following industry grants: "Cost-Effectiveness of Screening for Chronic Hepatitis C Infection" (Merck/Schering-Plough; September 2012; $58,000) and "Cost-Effectiveness of Screening for Chronic Hepatitis B Infection" (Gilead Sciences Inc; $56,000). He served as a consultant for Savient Pharmaceuticals (~$300). Dr Hylek has participated in a symposium sponsored by Boehringer Ingelheim, served on advisory boards (Bayer Healthcare Pharmaceuticals; Boehringer Ingelheim GmbH; Bristol-Myers Squibb; Daiichi-Sankyo, Inc; Johnson & Johnson; Merck and Co, Inc; Ortho-McNeil Pharmaceutical, Inc; and Pfizer Inc) for amounts totaling < $10,000 and participated at the steering committee level for several pharmaceutical-sponsored studies (ARISTOTLE trial sponsored by Bristol-Myers Squibb and Pfizer Inc [< $10,000] and ORBIT-AF Registry sponsored by Ortho-McNeil Pharmaceutical, Inc [< $10,000]). Dr Go has received research funding from the National Heart, Lung, and Blood Institute related to antithrombotic therapy in atrial fibrillation and was a site principal investigator for a clinical trial sponsored by Johnson & Johnson and Bayer Healthcare Pharmaceuticals. Dr Halperin has received consulting fees from the following pharmaceutical manufacturers for advisory activities involving the development of anticoagulant drugs, none of which are currently approved for clinical use in any indication in the United States: Astellas Pharma, US; Bayer AG HealthCare; Boehringer Ingelheim; Daiichi Sankyo; Johnson & Johnson; and Sanofi-Aventis. He has received honoraria from Portola Pharmaceuticals, Inc as a member of the Data Safety Monitoring Board of its Phase II EXPLORE-AF trial involving an investigational anticoagulant for prevention of thromboembolism in patients with atrial fibrillation. He has received consulting fees from Biotronik, Inc as co-chair of the Steering Committee for the IMPACT clinical trial evaluating the use ambulatory monitoring technology in approved implanted cardiac arrhythmia devices to guide anticoagulation therapy for stroke prevention. He has received a consulting fee from the Bristol-Myers Squibb/Sanofi Partnership for advisory activities related to the use of the platelet inhibitor drug, clopidogrel, for prevention of thromboembolism in patients with atrial fibrillation. He has been a speaker at CME Symposia that derived partial funding from the following sponsors involved in the development of anticoagulants for potential use in patients with AF: Bayer AG HealthCare, Boehringer Ingelheim, and Sanofi-Aventis. Dr Lip has served as a consultant for Bayer, Astellas, Merck, Daiichi-Sankyo, AstraZeneca, Sanofi-Aventis, BMS/Pfizer, Biotronik, Portola, and Boehringer Ingelheim and has been on the speakers bureau for Bayer, Bristol-Myers Squibb/Pfizer, Boehringer Ingelheim, and Sanofi-Aventis. Drs You, Howard, Fang, Schulman, Hughes, Manning, and Spencer have reported that no potential conflicts of interest exist with any companies/organizations whose products or services may be discussed in this article.

Role of sponsors: The sponsors played no role in the development of these guidelines. Sponsoring organizations cannot recommend panelists or topics, nor are they allowed prepublication access to the manuscripts and recommendations. Guideline panel members, including the chair, and members of the Health & Science Policy Committee are blinded to the funding sources. Further details on the Conflict of Interest Policy are available online at http://chestnet.org.

Other contributions: We thank Louis Kuritzky, MD, for sharing his perspective as a frontline clinician during the development of our recommendations.

Endorsements: This guideline is endorsed by the American Association for Clinical Chemistry, the American College of Clinical Pharmacy, the American Society of Health-System Pharmacists, the American Society of Hematology, and the International Society of Thrombosis and Hematosis.

Additional information: The supplement Tables can be found in the Online Data Supplement at http://chestjournal.chestpubs.org/content/141/2_suppl/e531S/suppl/DC1.

Antithrombotic Therapy for Atrial Fibrillation

Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines

John J. You, MD; Daniel E. Singer, MD; Patricia A. Howard, PharmD; Deirdre A. Lane, PhD; Mark H. Eckman, MD; Margaret C. Fang, MD, MPH; Elaine M. Hylek, MD, MPH; Sam Schulman, MD, PhD; Alan S. Go, MD; Michael Hughes, PhD; Frederick A. Spencer, MD; Warren J. Manning, MD; Jonathan L. Halperin, MD; and Gregory Y. H. Lip, MD

Table S1—*Studies Assessing Prior Stroke/TIA as an Independent Predictor of Stroke in Patients With AF*

Study/Year	Multivariate OR/RR (95% CI)	*P* Value
Pooled estimate[1]	2.5 (1.8-3.5)	.59 (for heterogeneity)
Studies included in pooled estimate:		
AFI[2]/1994	2.5 (NR)	< .05
SPAF I-III Aspirin[3]/1999	2.9 (NR)	< .001
Stöllberger et al[4]/1998	3.7 (1.5-7.5)	.002
Wang et al[5]/2003	1.9 (1.1-3.3)	NR
Studies not included in pooled estimate:		
AFI Echo[6]/1998[a]	3.5 (1.8-6.7)	< .001
Aronow et al[7]/1998	1.6 (1.1-2.2)	< .009
Hart et al[8]/2000 (intermittent AF)	4.1 (NR)	.01
Hart et al[8]/2000 (sustained AF)	2.7 (NR)	< .001
SPAF I[9]/1992	2.1 (NR)	.04
Stöllberger et al[10]/2004	2.14 (NR)	.045
van Latum et al[11]/1995	1.6 (1.0-2.6)	< .05
Van Staa et al[12]/2011	2.86 (2.53-3.22)	< .05

AF = atrial fibrillation; AFI = Atrial Fibrillation Investigators; NR = not reported; RR = risk ratio; SPAF = Stroke Prevention in Atrial Fibrillation; TIA = transient ischemic attack.

[a]Subset of patients from AFI[6] with echocardiographic data available.

 DOI: 10.1378/chest.11-2304

Table S2—*Studies Assessing Hypertension as an Independent Predictor of Stroke in Patients With AF*

Study/Year	Multivariate OR/RR (95% CI)	*P* Value
Pooled estimate[1]	2.0 (1.6-2.5)	.29 (for heterogeneity)
Studies included in pooled estimate:		
AFI[2]/1994	1.6 (NR)	< .05
Moulton[13]/1991	1.9 (1.2-3.1)	< .05
SPAF I-III Aspirin[3]/1999	2.0 (NR)	< .001
Stöllberger et al[4]/1998	3.6 (1.8-8.4)	.001
Studies not included in pooled estimate:		
AFI Echo[6]/1998[a]	1.5 (0.9-2.5)	.13
Aronow et al[14]/1989	12.5 (NR)	< .01
Aronow et al[7]/1998	NR	NS
Cabin et al[15]/1990	NR	NS
Hart et al[8]/2000 (intermittent AF)	3.4 (NR)	.003
Hart et al[8]/2000 (sustained AF)	1.8 (NR)	.008
Petersen et al[16]/1990	NR	NS
Seidl et al[17]/1998	6.5 (1.5-4.5)	< .05
SPAF I[9]/1992	2.2 (1.1-4.3)	.02
SPAF III[18]/1998[b]	3.3 (1.7-6.9)	.001
Stöllberger et al[10]/2004	NR	NS
Wang et al[5]/2003[c]	NR	NS
Studies assessing uncontrolled hypertension only[d]:		
Hart et al[8]/2000 (intermittent AF)	NR	NS
Hart et al[8]/2000 (sustained AF)	2.8 (NR)	< .001
SPAF I-III Aspirin[3]/1999	2.3 (NR)	< .001
van Latum et al[11]/1995	1.7 (1.0-2.9)	NS
Van Staa et al[12]/2011 (≥ 180 vs < 120 mm Hg)	2.74 (1.21-6.19)	< .05
Van Staa et al[12]/2011 (140-159 vs < 120 mm Hg)	2.74 (1.21-6.19)	< .05
Van Staa et al[12]/2011 (160-179 vs < 120 mm Hg)	1.49 (0.55-4.00)	NS
Wang et al[5]/2003	1.1/10 mm	< .05

NS = not significant. See Table S1 legend for expansion of other abbreviations.

[a]Subset of patients from AFI (1994)[2] with echocardiographic data available.

[b]Defines hypertension as diagnosed hypertension.

[c]Defines hypertension as use of BP-lowering medication.

[d]Defined as systolic BP > 160 mm Hg, unless otherwise stated.

 DOI: 10.1378/chest.11-2304

Table S3—*Studies Assessing Increasing Age as an Independent Predictor of Stroke in Patients With AF*

Study/Year	Multivariate OR/RR (95% CI)	*P* Value
Pooled estimate[1]	1.5 (1.3-1.7)/decade	.59 (for heterogeneity)
Studies included in pooled estimate:		
AFI[2]/1994	1.4 (NR)/decade	< .05
Moulton et al[13]/1991 (for age > 75)	1.7 (1.0-2.8)	< .05
SPAF I-III Aspirin[3]/1999	1.8 (NR)/decade	< .001
Stöllberger et al[4]/1998	1.1 (1.0-1.1)[a]	< .001
Wang et al[5]/2003	1.3 (NR)/decade	< .05
Studies not included in pooled estimate:		
AFI Echo[6]/1998[b]	1.5 (NR)/decade	.006
Cabin et al[15]/1990 (for age > 70)	NR	NS
Hart et al[8]/2000 (intermittent AF)	2.1 (NR)/decade	< .001
Hart et al[8]/2000 (sustained AF)	1.7 (NR)/decade	< .001
Inoue and Atarashi[19]/2000 (paroxysmal AF; for age > 65 y)	3.3 (1.92-5.81)	.0001
Nakagami et al[20]/1998	1.3 (1.0-1.7)/decade	NS
SPAF I[9]/1992	1.2 (0.9-1.6)/decade	NS
SPAF III[18]/1998	1.7 (1.1-2.6)/decade	.01
van Latum et al[11]/1995	NR	NS
Van Staa et al[12]/2011 (age, < 50 vs 60-69 y)	0.14 (0.06-0.34)	< .05
Van Staa et al[12]/2011 (age, ≥ 80 vs 60-69 y)	2.22 (1.78-2.76)	< .05
Van Staa et al[12]/2011 (age, 50-59 vs 60-69 y)	0.44 (0.28-0.69)	< .05
Van Staa et al[12]/2011 (age, 70-79 vs 60-69 y)	1.42 (1.12-1.78)	< .05

See Table S1 and S2 legends for expansion of abbreviations.
[a]Age entered as a continuous variable.
[b]Subset of patients from AFI (1994)[2] with echocardiographic data available.

Table S4—*Studies Assessing Diabetes as an Independent Predictor of Stroke in Patients With AF*

Study/Year	Multivariate OR/RR (95% CI)	*P* Value
Pooled estimate[1]	1.7 (1.4-2.0)	.69 (for heterogeneity)
Studies included in pooled estimate:		
AFI[2]/1994	1.7 (NR)	< .05
SPAF I-III Aspirin[3]/1999	1.9 (NR)	.02
Stöllberger et al[4]/1998	NR	NS
Wang et al[5]/2003	1.8 (1.4-3.1)	NR
Studies not included in pooled estimate:		
AFI Echo[6]/1998[a]	1.7 (1.0-2.9)	.05
Aronow et al[7]/1998	NR	NS
Petersen et al[16]/1990	NR	NS
Seidl et al[17]/1998	NR	NS
SPAF III[18]/1998	NR	NS
Van Staa et al[12]/2011	1.33 (1.14-1.55)	< .05

See Table S1 and S2 legends for expansion of abbreviations.
[a]Subset of patients from AFI[2] with echocardiographic data available.

 DOI: 10.1378/chest.11-2304

Table S5—*Studies Assessing Heart Failure as an Independent Predictor of Stroke in Patients With AF*

Study/Year	Multivariate OR/RR (95% CI)	*P* Value
AFI[2]/1994	1.4 (NR)	NS
AFI Echo[6]/1998[a] (with echocardiographic data)	1.4 (0.8-2.3)	.16
AFI Echo[6]/1998[a] (without echocardiographic data)	1.7 (1.1-2.7)	.03
SPAF[18]/1998	NR	NS
SPAF I[9]/1992	2.6 (1.0-4.2)	.01
SPAF I-III Aspirin[3]/1999	NR	NS
Stöllberger et al[8]/1998[b]	NR	NS
Stöllberger et al[10]/2004[b]	NR	NS
Van Staa et al[12]/2011	1.26 (1.11-1.42)	< .05

See Table S1 and S2 legends for expansion of abbreviations.
[a]Subset of patients from AFI[2] with echocardiographic data available.
[b]Defined as New York Heart Association functional class > II.

Table S6—*Studies Assessing LV Dysfunction/Hypertrophy (Using Echocardiography) as an Independent Predictor of Stroke in Patients With AF*

Study/Year	Multivariate OR/RR (95% CI)	*P* Value
AFI Echo[6]/1998	1.4 (0.8-2.3)	.16
Aronow et al[7]/1998	1.8 (1.2-2.7)	.003
Aronow et al[7]/1998 (LV hypertrophy)	2.8 (1.8-4.4)	.0001
Aronow et al[14]/1989 (LV hypertrophy)	6.56 (NR)	< .01
SPAF[21]/1992	2.6 (1.4-4.9)	.003
SPAF I-III Aspirin[3]/1999 (using 2D echocardiography)	NR	NS
SPAF I-III Aspirin[3]/1999 (using M-mode echocardiography)	NR	NS
Stöllberger et al[4]/1998	NR	NS

2D = two dimensional; LV = left ventricular. See Table S1 and S2 legends for expansion of other abbreviations.

Table S7—*Studies Assessing Valvular Heart Disease[a] as an Independent Predictor of Stroke in Patients With AF*

Study/Year	Multivariate OR/RR (95% CI)	*P* Value
AFI Echo[6]/1998 (mitral valve prolapse)	0.29 (NR)	NS
AFI Echo[6]/1998 (mitral valve regurgitation)	1.07 (NR)	NS
Aronow et al[7]/1998 (aortic stenosis)	NR	NS
Aronow et al[7]/1998 (mitral annular calcifications)	NR	NS
Nakagami et al[20]/1998 (mitral valve regurgitation)	0.45 (0.20-0.97)	< .05
van Staa et al[12]/2011	1.65 (1.01-2.71)	< .05

See Table S1 and S2 legends for expansion of abbreviations.
[a]Specific type of valvular heart disease in parentheses.

 DOI: 10.1378/chest.11-2304

Table S8—*Studies Assessing Female Sex as an Independent Predictor of Stroke in Patients With AF*

Study/Year	Multivariate OR/RR (95% CI)	*P* Value
AFI[2]/1994	NR	NS
AFI Echo[6]/1998[a]	NR	NS
Aronow et al[7]/1998	NR	NS
Aronow et al[14]/1989	0.85 (NR)	NS
Cabin et al[15]/1990	NR	.014
Fang et al[22]/2005 (all women)	1.6 (1.3-1.9)	< .05
Fang et al[22]/2005 (women aged > 75 vs men aged > 75 y)	1.8 (1.4-2.3)	< .05
Fang et al[22]/2005 (women aged ≤ 75 vs men aged ≤ 75 y)	1.6 (1.0-2.3)	NS
Hart et al[8]/2000 (intermittent AF)	NR	NS
Hart et al[8]/2000 (sustained AF)	1.8	.004
Inoue and Atarashi[19]/2000[b] (paroxysmal AF)	0.50 (0.27-0.93)	.0291
Moulton[13]/1991	NR	NS
Nakagami et al[20]/1998	0.98 (0.55-1.72)	NS
Petersen et al[23]/1990	NR	NS
SPAF III[18]/1998	NR	NS
SPAF I-III Aspirin[3]/1999 (all women)	1.6 (NR)	.01
SPAF I-III Aspirin[3]/1999 (women aged > 75 y)	3.0 (NR)	.002

Behavior, Knowledge, and Attitudes Towards Khat Among Yemeni Medical Students and Effects of a Seminar

Paul H. Yi, BA
John S. Kim, BA, MA
Khalil I. Hussein, BA
Richard Saitz, MD, MPH

ABSTRACT. This study describes khat behavior, knowledge, and attitudes among Yemeni medical students (MS) and the effects of a seminar. The students completed a survey ($n = 62$); a subgroup participated in a discussion-based seminar and follow-up survey ($n = 18$). Although the students demonstrated knowledge about khat's health effects and considered it unacceptable for health professionals to chew khat, they disagreed that health professionals should advise patients to quit. Knowledge and attitudes improved post-seminar (not significant, except for a borderline significant increase in students correctly identifying khat as addictive; $P = 0.063$). Although effects were small, seminars may help health professionals address khat use in Yemen.

KEYWORDS. Attitudes, khat, knowledge, medical students, seminar

INTRODUCTION

Khat (also spelled "qat") use is prevalent in Yemen and in many other parts of the Middle East and eastern Africa, especially Somalia and Ethiopia, and it has significant health and socioeconomic consequences (1). Khat is a plant whose active ingredient is cathinone, an amphetamine-like alkaloid with addictive properties that produces a pleasurable stimulant effect (1, 2). Although khat use is not prevalent in Western countries, synthetic cathinone use has risen in the past 4 years in Europe and in the past year in the United States (3). Khat's role in causing

This article was presented in abstract form at John McCahan Medical Education Day at Boston University School of Medicine on June 8, 2011.

The authors thank Park Street Church Boston for their administrative help and vision to improve global medical education and for helping finance our travel to Yemen; William G. Pearson for his guidance and leadership in organizing our trip; Bridges Intercultural Studies and MERCYemen for seminar curriculum design and logistics; Dr. Rafael Martinez for seminar logistics and survey translation accuracy check; Mohamed A. Kamel and Dr. Abdulmaged Traish for survey translation and accuracy checks; Arthur Celestin and Natalie Witek for helping with survey administration; and our Yemeni colleagues at Taiz University for their time and openness with us.

cardiovascular, oral, hepatic, neurobehavioral, and psychiatric illness is well documented (4). Estimates of daily khat chewing rates in Yemen are as high as 90% for men and 73% for women (1) and, in a country predicted to be the first in the world to run out of water, 40% of Yemen's water supply is directed towards khat irrigation (2).

To our knowledge, there has been no study of knowledge and attitudes towards khat focusing on health professionals who could intervene in Yemen or elsewhere. The recent surge in synthetic cathinone use in Europe and the United States (3) may make khat and cathinone a significant health issue in the western world in the years ahead.

The purpose of this descriptive report is twofold: (1) To describe the behavior, knowledge, and attitudes of medical students at a medical school in Yemen towards khat chewing and (2) to describe these measures in these students before and after a khat seminar conducted through English conversation.

METHODS

Population/Sample

We conducted a written survey of Yemeni medical students at Taiz University (TU) Faculty of Medicine in July 2010. A subgroup participated in one 3-hour seminar on Khat as part of a public health course, open to all TU medical students, entitled "Health Education Through English Conversation Course" (HETECC), and was surveyed a second time at the end of the course. The HETECC course and our survey were advertised by fliers placed around the TU campus and by word of mouth. The course required an English proficiency test.

Survey Administration

We administered the 10-minute survey before and 10 to 11 days after the khat seminar and during the HETECC course. At the beginning of each administration, we described our study to the students in English and informed them that the study would be anonymous, voluntary, and have no impact on their academic standing. Additionally, each survey came attached with a cover letter written in Arabic stating the purpose and the voluntary, anonymous nature of the study. The investigators were not present when the survey was completed and the participants had the option to not participate and to omit answering any survey questions. Participants were not compensated for survey completion.

Seminar

The stated goal of the khat seminar was "to clarify the medical, social, economic, and environmental effects of qat on Yemeni society." There were 3 seminar groups based on English proficiency level, each facilitated by native English speakers in groups of two. The seminar consisted of 6 activities conducted in English: (1) open discussion on an article, titled "A Medical View of Qat," from the *Yemen Times* newspaper; (2) fill-in-the-blank exercise for an article missing words, titled "Qat's Enormous Cost," also from *Yemen Times*; (3) oral reports and discussion of the results of students' informal surveys of friends' and families' weekly khat consumption and expenses, motivation for chewing khat, and willingness to give up khat; (4) discussion of the effects of khat on physical health, the environment, Yemen's economy, and Yemeni society; (5) role-play about 2 common scenarios in Yemeni society involving khat; and (6) discussion of the agricultural economics of khat.

Survey Content and Design

We developed a survey based on the World Health Organization Global Health Professional Survey (GHPS), a standardized questionnaire assessing behavior, knowledge, and attitudes of health care professional students towards tobacco; we modified the version of the GHPS used by Hodgetts et al. to be specific to khat (5). Our survey consisted of 35 questions covering 4 domains: (1) demographics; (2) khat and other substance use; (3) knowledge about khat; and (4) attitudes towards the role and use of khat in Yemeni society. We developed the survey and accompanying cover letter first in English; an Arabic speaker fluent in English subsequently

translated them into Arabic. Two Arabic speakers fluent in English then reviewed the translated survey and assured that the translation was accurate. The Boston University Medical Campus Institutional Review Board and the HETECC course director at TU approved all research activities. Our survey is available upon request.

Analyses

Analyses were descriptive and we used Mann-Whitney, Fisher exact, Wilcoxon signed-rank, and McNemar tests as appropriate.

RESULTS

A total of 62 students completed the survey; the mean age was 22 years, 74% were female, 97% were unmarried, 39% reported ever chewing khat (73% of males and 26% of females), 34% had drunk 8 or more cups of coffee in the previous 30 days, 3% reported ever smoking 100 or more cigarettes, and 3% reported knowing medical students who consume alcohol. Correct response rate to knowledge questions were 90% for khat containing cathinone, 79% for excessive khat use leading to psychosis, 60% for khat chewing (KC) being a risk factor for heart attack, and 90% for up to 90% of Yemeni men chewing khat 3 to 4 hours daily. Regarding attitudes, 87% agreed or strongly agreed that KC is harmful to health, 30% that khat is not addictive, 93% that most people in Yemen chew khat, 6% that khat is not a problem in Yemen, 97% that children and adolescents should not chew khat, 12% that khat chewers are immoral people, 51% that KC is not an immoral activity, 58% that KC makes people more popular with their friends, 27% that KC makes talking to people easier, 47% that KC does not help people to relax, 77% that KC helps people to stay awake, 87% that health professionals (HPs) serve as role models for patients and the public, 8% that it is acceptable for HPs to chew khat, 10% that HPs should routinely ask patients about their KC habits, 94% that HPs should not routinely advise patients to quit KC, 92% that HPs should get specific education on khat, and 50% that they had received education about khat in medical school prior to the survey.

Among khat chewers, 55% consumed 1 or more wraps per day, 29% had chewed khat on 20 or more days in the 30 days prior to the survey, 81% had chewed khat within the previous 7 months, 65% were ready to quit KC, and 20% were thinking about quitting KC. Coffee consumption did not differ between chewers and nonchewers, but chewers were more likely to have used greater than 100 cigarettes in a lifetime and more likely to know a medical student who had used alcohol in the previous 30 days (9.1% of chewers vs. 0% of nonchewers for both items), both borderline significant at $P = 0.064$ and $P = 0.061$, respectively. For all knowledge and attitude survey items, results were not significantly different between chewers and nonchewers, except for borderline significance at $P = 0.069$ towards acceptability of HPs to chew khat (17% of chewers vs. 3% of nonchewers agreed or strongly agreed that it is acceptable).

Of 23 students who participated in the discussion-based khat seminar, 18 completed an identical follow-up survey 10 to 11 days after the seminar. Although in general, knowledge and attitudes improved after the seminar, improvements were not statistically significant except for a borderline improvement in the number of students correctly identifying khat as addictive (33.3% of students pre-seminar vs. 61.1% post-seminar; $P = 0.063$).

DISCUSSION

Less than 50% of Yemeni medical students ever chewed khat, but the majority of males reported ever chewing khat. Of the chewers, two thirds expressed readiness to quit chewing khat. Overall, the students demonstrated good knowledge about khat chewing. Most students also agreed that khat chewing is harmful to health and a problem in Yemen, and that it is not acceptable for health professionals to chew khat. However, paradoxically, they did not agree that health professionals should inquire about or advise their patients to quit their khat chewing habits. Not surprisingly, more khat chewers than nonchewers agreed that it is acceptable for health professionals to chew khat. A seminar had modest effects on knowledge and attitudes towards khat.

The majority of adults and medical students in Yemen chew khat (1, 6), with higher use in males than females (2). Although we found that a minority of students chews khat, when stratified by gender, our results are more consistent with prior estimates. Yemeni citizens have knowledge regarding the physiological properties of khat (2) and Yemeni citizens and Yemeni expatriates in the United Kingdom report attitudes that khat is harmful to health and causes socioeconomic problems (2, 7), which is consistent with our results. The majority of medical students in over 48 countries agree that health professionals serve as role models and that they should advise patients to quit smoking cigarettes (8), which is consistent with our results regarding the students' views of health professionals as role models, but inconsistent with their attitudes towards advising patients to quit chewing khat. A 3-hour lecture-and-discussion–based seminar on tobacco performed at a medical school in Hong Kong was shown to be effective in improving medical students' knowledge of and attitudes towards tobacco control (9), which is not inconsistent with our findings regarding the khat seminar, although we found no statistically significant improvements.

The importance of khat in Yemeni culture and society (1, 2) may help explain why the medical students in our sample were reluctant to agree that health professionals should inquire about or advise their patients to quit khat chewing, even though they agreed that it is not acceptable for health professionals to chew khat themselves; to denounce khat, perhaps, is to denounce Yemeni culture. Another explanation may be in the use of khat for stress relief and academic enhancement within the medical profession. A study of Yemeni physicians concluded that *not* chewing khat was a predictor of burnout (10). In Saudi Arabia, Yemen's geographical neighbor to the north and where khat is prohibited, medical students smoke tobacco to overcome school-related stresses, despite being knowledgeable of its detrimental health effects (11). As the majority of the khat chewers in our sample agreed that khat chewing helps people to stay awake and to relax, khat chewing among Yemeni medical students can thus be considered a cultural analogue to tobacco use in Saudi Arabian medical students to relieve stress and coffee consumption in American medical students to aid in studying.

Our study should be viewed in light of its limitations. One limitation was that our sample was a small convenience sample. Additionally, our seminar subgroup demonstrated high levels of knowledge prior to the seminar, which made it difficult to detect a difference in knowledge after the seminar (ceiling effect).

Our study also had strengths. First, we are unaware of any other study assessing the knowledge, use, and attitudes of Yemeni medical students towards khat. In developing survey items, we took cultural and religious sensitivities into account. We asked about knowledge of alcohol use among medical students, rather than personal alcohol use, because alcohol is illegal in Yemen; however, when asking about additional stimulant use, we failed to take into consideration that tea is the caffeinated beverage of choice over coffee. Third, our survey was anonymous and voluntary and we had no control over the students' grades or standing at the university.

The solution to the paradox of students considering it unacceptable for health professionals to chew khat, but being unwilling to advise patients to quit, is not purely a matter of knowledge, as the students demonstrated good knowledge about khat. Khat's role in Yemeni culture may be a primary reason for these conflicting attitudes. Therefore, perhaps Yemeni public health officials need to make public statements on khat's health hazards before current and future health professionals in Yemen will feel that it is acceptable to get involved with their patients' chewing habits. Studies on khat policy have called for governments to actively pursue regulation of khat focused on harm and risk reduction (12). In this regard, the Yemeni government has made efforts in the past, such as limitations of khat use to certain days of the week (12) and former President Ali Abdullah Saleh has discouraged khat use on several occasions (1). Nevertheless, continued and increased efforts may be critical to empowering current and future health professionals in Yemen to advise their patients about khat. Another part of the solution may involve the clinical education of health professionals. Given khat's unique cultural place in Yemeni society, current and future health professionals

may benefit from being trained to ask about khat in culturally and socially appropriate ways, for example, to have an open discussion about khat and to leave the decision up to the patient. Although our seminar had few effects, the borderline significant effect observed, the likely need for a discussion forum to adequately address the problem, and the effects of such seminars on tobacco suggest that discussion-based seminars may be a part of the solution.

Attitudinal barriers towards analgesic use among primary care patients with chronic pain and substance use disorders (SUDs) are not well understood. We evaluated the prevalence of moderate to significant attitudinal barriers to analgesic use among 597 primary care patients with chronic pain and current analgesic use with 3 subscales from the Barriers Questionaire II: concern about side effects, fear of addiction, and worry about reporting pain to physicians. Concern about side effects was a greater barrier for those with opioid use disorders (OUDs) and non-opioid SUDs than for those with no SUD (OR (95% CI): 2.30 (1.44–3.68), $P < 0.001$ and 1.64 (1.02–2.65), $P = 0.041$, resp.). Fear of addiction was a greater barrier for those with OUDs as compared to those with non-opioid SUDs (OR (95% CI): 2.12 (1.04–4.30), $P = 0.038$) and no SUD (OR (95% CI): 2.69 (1.44–5.03), $P = 0.002$). Conversely, participants with non-opioid SUDs reported lower levels of worry about reporting pain to physicians than those with no SUD (OR (95% CI): 0.43 (0.24–0.76), $P = 0.004$). Participants with OUDs reported higher levels of worry about reporting pain than those with non-opioid SUDs (OR (95% CI): 1.91 (1.01–3.60), $P = 0.045$). Concerns about side effects and fear of addiction can be barriers to analgesic use, moreso for people with SUDs and OUDs.

1. Introduction

Chronic pain is commonly encountered in primary care [1], where the majority of patients with substance use disorders (SUDs) receive health care [2]. Patients with SUDs are at significant risk of pain [3, 4] and are likely to be undertreated for pain. Not only do patients with SUDs report continued pain despite engaging in medical care [5], but few providers caring for these patients follow recommended guidelines [6]. Many pathways may be responsible for such undertreatment, from health systems issues, like insurance coverage and limited access to specialists, to clinician attitudes and skills [7]. For example, clinicians may be appropriately reluctant to prescribe opioid pain medications to patients with histories of substance use disorders out of concern that patients may divert or misuse them [8]. One possible and relatively unexplored reason for undertreatment is patient attitudinal barriers to analgesic medications, such as concerns about side effects, fear of addiction, and worries about reporting pain to physicians. Indeed, patients with SUDs who are HIV positive or are enrolled in methadone maintenance programs report significant attitudinal barriers to pain medications, including concerns regarding addiction potential, need for escalating doses, and difficulty communicating with their clinicians regarding pain [9, 10]. However, such attitudinal barriers to analgesic use, such as opioid medication use, among patients with SUDs in primary care settings have not been well described.

Several patient characteristics have been associated with attitudes that may result in more barriers to the use of analgesic medications (i.e., higher attitudinal barriers) including non-White race, lower education, more physical symptoms

[10], older age [11], higher pain severity and disability [12], unemployment [13], and depression [14], while the data on gender are mixed [13, 15]. Other characteristics have not been explored but seem likely to impact attitudinal barriers, such as whether patients are currently or previously addicted to substances, the substances to which they may be addicted (e.g., opioids versus nonopioid drugs), and recent use of analgesics. For example, patients with past addiction, who are currently in recovery, may have more negative attitudes about opioid analgesics than those currently addicted. Similarly, patients with opioid use disorders (OUDs) may be more likely than patients with nonopioid SUDs to have negative attitudes regarding the addiction potential of opioid pain medications. Finally, though psychiatric illnesses, such as depression and anxiety, are known to be associated with more attitudinal barriers [14], the ways in which other psychiatric illnesses, like posttraumatic stress disorder, common among people with chronic pain [16, 17] and SUDs [18], affect attitudinal barriers has not yet been explored.

Our objective was to compare attitudinal barriers to analgesic use among patients with SUDs and those without, across three domains: concern about side effects, fear of addiction, and worries about reporting pain to physicians. We hypothesized that the majority of primary care patients with SUDs would have moderate-to-severe attitudinal barriers and that those with SUDs would have greater barriers in all three domains as compared to those without SUDs. We also explored whether two subcategories of SUDs—(1) current versus lifetime disorder and (2) OUD versus nonopioid SUD—report greater barriers. We hypothesized that people with lifetime SUDs as compared to current SUDs, and OUDs as compared to nonopioid SUDs, would have greater barriers in all three domains.

2. Materials and Methods

2.1. Participants and Setting. We conducted a cross-sectional study of a sample of primary care patients with chronic pain. We recruited participants between February 2005 and August 2006 from waiting rooms of an academic, urban hospital primary care practice. We approached patients waiting for appointments and included patients who were 18–60 years of age, spoke English, had pain for three months or more, reported use of any analgesic medication (over-the-counter or prescription) in the prior month, and had a scheduled primary care appointment. Informed consent was obtained from eligible patients. Trained interviewers administered surveys. We compensated participants with $10. The Boston University Medical Center Institutional Review Board approved the study, and a certificate of confidentiality was obtained from the National Institutes of Health.

2.2. Instruments

Dependent Variables. The dependent variables of interest were the Barriers Questionnaire II (BQ-II) subscale scores. The BQ-II, a validated 27-item self-report survey, was originally designed to measure barriers to obtaining pain relief for cancer patients [11]. We selected the BQ-II because it is a widely used instrument and has been adapted for use with adolescent cancer patients [19] and HIV/AIDS populations [10], and is used in ambulatory settings [10, 19]. We eliminated all questions referring to cancer pain and the immune system in order to make it applicable to a primary care population. The resulting 9-item version, displayed in Table 1, contains three subscales including concern about side effects, fear of addiction, and worries about reporting pain to physicians. The questionnaire refers to "pain medications" and does not specify opioid analgesics. The items are scaled on a 6-point Likert scale from 0 (do not agree) to 5 (agree very much). A-one point increase on the overall BQ-II has previously been shown to be associated with a twofold greater likelihood of being undermedicated for pain control [10]. A BQ subscale score cutoff of ≥ 3 has been previously used in the literature [10]; we considered a score of ≥ 3 to be indicative of moderate-to-significant barriers.

Independent Variables. The main independent variables of interest were mutually exclusive categories of substance use disorders identified using the Composite International Diagnostic Interview v. 2.1 Drug Use Disorder module, a well-validated interview instrument that yields current and past DSM-IV diagnoses [20, 21].

We assigned participants into three mutually exclusive categories of substance use disorders: those with "OUDs" (which included opioid abuse and dependence), "nonopioid SUDs" (met criteria for a substance use disorder but not an OUD—includes abuse and dependence on alcohol or other drug) and no SUD. If a participant met criteria for more than one substance use disorder and one was opioids, we categorized them as "OUD."

Covariates. We adjusted analyses for factors known to be associated with attitudinal barriers to analgesic use [11, 13–15], or, in the absence of data, due to clinical suspicion that a factor might be associated with attitudinal barriers. These factors were (1) sociodemographic variables including sex, race/ethnicity (Black/African American, Hispanic/Latino/Other, White), employment (unemployed, including receiving disability payments versus employed part or full time), education (<high school, high school+); (2) depression (major or other versus none) determined by the Patient Health Questionnaire (PHQ) for Depression, a 9-item validated measure correlated with past two-week major depression [22]; (3) somatic symptom severity (high versus others) determined by the Patient Health Questionnaire-15, a validated measure that correlates with somatization disorder [23]; (4) a lifetime history of posttraumatic stress disorder (PTSD) diagnosis derived from the CIDI v. 2.1 PTSD module [20]; (5) opioid prescription in the past year. We determined the proportion of participants meeting Prescription Drug Use Disorder (PDUD), defined as any opiate use disorder that was not heroin alone, but did not include PDUD as a covariate in the models because it is a subset of OUD. We determined the proportion of participants with moderate versus severe pain and disability using the Graded

Table 1: Modified Barriers Questionnaire.

Subscale	Item
Side effects	Drowsiness from pain medicine is difficult to control.
	When you use pain medicine, your body becomes used to its effects and pretty soon it will not work anymore.
	Using pain medicine blocks your ability to know if you have any new pain.
	Pain medicine can keep you from knowing what is going on in your body.
Addiction	There is a danger of becoming addicted to pain medicine.
	Pain medicine is very addictive.
Reporting pain to physicians	It is important to be strong by not talking about pain.
	It is important for the doctor to focus on curing illness, and not waste time controlling pain.
	Doctors might find it annoying to be told about pain.

Chronic Pain Scale [24], a 10-item validated measure of pain and disability; we did not include pain severity and disability as a covariate in the models because there is little variation in this measure (90% reported severe pain).

2.3. Statistical Analysis

Prevalence of Moderate-to-Significant Barriers. We compared the proportion of participants with moderate-to-significant barriers in each category of SUD using chi square analyses.

Current versus Lifetime SUD. We conducted a sensitivity analysis to examine the relationship between the nonmutually exclusive categories of lifetime (includes both current and past) and current SUDs, and prevalence of moderate-to-significant barriers. Because we did not detect large differences, we used lifetime disorders only for subsequent analyses.

OUD versus Nonopioid SUD. We conducted bivariate analyses using general linear models with the Duncan multiple range test for differences to examine the relationship between the independent variable of interest (OUD, nonopioid SUD and no SUD), and the BQ-II subscale scores. Because the three categories differed in their relationship to BQ-II subscale scores (data not shown), we maintained this variable as a three-part variable in further analyses.

Logistic Regression Analysis of Barriers. In bivariate analyses, the main independent variable impacted the subscales in opposite directions. We therefore examined the subscales separately. We first conducted bivariate analyses to examine the relationship between covariates and the barrier subscales. We then constructed three multivariable logistic regression models—one for each subscale—in order to examine the relationship between substance use category (OUD, nonopioid SUD, and no SUD) and the odds of having moderate-to-significant barriers. Each model was adjusted for the main independent variable and all covariates. Tests for colinearity among the covariates were carried out using correlation coefficients and any colinear variables were eliminated.

3. Results

3.1. Participant Characteristics. Of 822 eligible patients, 597 (73%) enrolled and completed the research interview. Enrollees were more likely than those who declined enrollment to be black (61% versus 55%, $P = 0.04$), less likely to take over-the-counter pain medication (66% versus 79%, $P < 0.001$), and more likely to take opioid pain medication (41% versus 30%, $P = 0.002$).

Participant characteristics are shown in Table 2. A majority of the study sample was female, unemployed, and nonwhite. Roughly half of participants had no SUD, one quarter had an OUD and one quarter had a nonopioid SUD. Of those with an OUD, 104/138 (75%) met criteria for a lifetime prescription drug use disorder. As noted in previous literature [25], the prevalence of OUD is higher among whites (28%) versus blacks (19%) and among males (32%) versus females (17%).

3.2. Attitudinal Barriers

Prevalence of Moderate-to-Significant Attitudinal Barriers. In the full sample, moderate-to-significant fear of side effects (60%) and concern about addiction (71%) were common while worry about reporting pain to physicians was relatively uncommon (27%). Participants with OUDs more often reported moderate-to-significant fears of addiction than those with no nonopioid SUDs (89% versus 78%, $P = 0.02$) and no SUDs (89% versus 75%, $P = 0.01$). Participants with nonopioid SUDs less often reported moderate-to-significant worries about reporting pain to physicians than those with no SUDs (18% versus 31%, $P = 0.01$).

Current Versus Lifetime SUD. There were no differences in prevalence of moderate-to-significant barriers between those with current and lifetime SUD for any of the subscales (concern about side effects (66% versus 64%), fear of addiction (83% versus 78%), and worries about reporting pain to physicians (23% versus 18%)).

Unadjusted Analyses. Unadjusted logistic regression analyses of moderate-to-significant barriers comparing substance use groups are presented in Table 3. Concern about side effects and fear of addiction scores were greater among participants with OUDs than they were for those with no SUDs. Similarly, participants with OUDs had greater fear of addiction than those with nonopioid SUDs. Conversely, scores reflecting worries about reporting pain to physicians

Table 2: Demographic and clinical characteristics of a sample of primary care patients, stratified by substance abuse ($N = 597$).

Variable	Group			P value

[*] Models adjusted for gender, employment, depression, somatic symptom severity, education, race, PTSD, and recent opioid use.

were lower for those with nonopioid SUDs than for those with no SUDs.

Adjusted Analyses. Multivariate logistic regression analyses of moderate-to-significant attitudinal barrier subscale scores among participants with OUDs, nonopioid SUDs, and no SUD are also shown in Table 3. The greater concerns about side effects and fear of addiction among participants with OUDs compared with those with no SUD persisted in adjusted analyses. Similarly, those with OUDs continued to report higher fears of addiction and higher concern about reporting pain as compared to those with nonopioid SUDs. Differences in worry about reporting pain to physicians between those with nonopioid SUDs remained lower than among those with no SUDs in adjusted analyses. After adjustment, participants with nonopioid SUDs had higher concerns about side effects than those with no SUDs, and participants with OUDs had higher concerns about reporting pain than those with nonopioid SUDs.

4. Discussion

In our sample of 597 primary care patients with chronic pain, moderate-to-significant fear about side effects and concern about addiction was common, and more so for participants with OUDs and nonopioid SUDs than those with no SUDs. Conversely, moderate-to-significant worries about reporting pain to physicians were less common overall, and less so for participants with nonopioid SUDs. In adjusted analyses, participants with OUDs reported more concern about side effects and fear of addiction yet similar worries about reporting pain to physicians as those with no SUD. Participants with nonopioid SUDs reported lower worries about reporting pain to physicians than those with no SUD and those with OUDs. Interestingly, those with current and lifetime substance use disorders reported similar barriers with regard to all three subscales.

Why might people with OUDs and chronic pain report a greater degree of attitudinal barriers to analgesic use than participants with nonopioid SUDs? In our study, there were no differences in baseline characteristics between those with OUDs and those with nonopioid SUDs, which suggests that there is something about the experience of the opioid itself (such as the potential addictive quality of opioids) that is associated with increased barriers. Because relapse or worse addiction may be triggered by exposure to opioid medications, those with OUDs may have heightened concern compared to those with nonopioid SUDs, who may perceive less risk of addiction with exposure to opioids. This finding is consistent with other studies showing that HIV-infected patients with a prior injection drug use history are more concerned than their noninjection drug using counterparts about the addictive potential of pain medications [10].

Greater attitudinal barriers among participants with OUDs are particularly interesting because this observation is in contradiction to the experience of many clinicians who describe patients with pain and opioid abuse as "drug seeking" [26]. In fact, while the majority of participants in our study reported attitudinal barriers to analgesic medications, in a study of physicians' perceptions of barriers to AIDS pain management, only a minority of physicians (24%) believed patient reluctance to take opioids to be a barrier to pain management [27]. This discrepancy between physician perception of patient reluctance to take opioids and patient concerns about taking opioids may be a source of miscommunication between patients and physicians. In fact, a clinical encounter for a patient with a substance use history that is focused on pain may have competing demands on the part of both the clinician and the patient. Clinicians balance ambiguity in pain assessment, treatment goals, and treatment risks [28]; similarly, though attitudinal barriers may play a role for the patient, these barriers may not be expressed due to a desire to obtain pain medications for pain relief or misuse, including for their euphoric effect or diversion, all of which are common among patients with prior substance use disorders [5].

The finding that attitudinal barriers were similar for those with current and lifetime opioid use disorders suggests that patients with past SUDs may harbor as many negative attitudes regarding concerns about side effects and fear of addiction potential as patients currently struggling with opioid addiction. This caution about taking pain medications in patients with past SUDs and chronic pain may be appropriate. While opioids may provide good short-term pain relief, chronic opioid use can produce a number of problems, including relapse [29]. However, these perceptions may also lead to undertreatment of pain.

Why might individuals with SUDs have lesser attitudinal barriers to reporting pain to doctors than individuals without SUDs? Patients in this study all suffered from chronic pain and may therefore have developed a certain level of comfort discussing pain. In addition, patients in our study also had ongoing relationships with regular primary care clinicians, a key characteristic identified by patients as essential to good communication and clinical decision making [30]. Finally, patients with SUDs may find it easier to talk about pain than other areas, such as addiction or mental health.

Several limitations apply to our findings. The sample was derived from a single academic urban hospital primary care practice and is therefore potentially subject to idiosyncratic practices, which may limit its generalizability. Nonetheless, the sample reflects a demographically heterogeneous group and is likely similar to patients in many other urban primary care practices in the US. In addition, the questions focused on possible side effects, addiction potential, and reporting of pain, and not about attitudes towards requesting or receiving prescriptions for opioid pain medications. Thus, we may have missed the potentially contentious part of the medical encounter: namely, the dispensation of opioid prescriptions. Finally, the questions did not explicitly delineate which classes of pain medications (e.g., opioid versus nonopioid analgesics) to consider. We expect that most participants assumed questions were referring to opioid medications; indeed recent opioid prescription was common in our sample, suggesting that many participants had experience with prescription opioids.

Despite these limitations, the study offers a preliminary look into the nature of patient attitudinal barriers to analgesic use in primary care patients with pain and addictions. It also offers an alternative perspective on patient-physician interactions than that previously described. Prior studies have demonstrated that the patient-physician interaction regarding pain medications is characterized by mutual mistrust and difficult communication [26]. Primary care providers display discomfort and avoidance in discussing unhealthy alcohol use [31], suggesting that physicians experience difficulty communicating about substance use. However, in this study, patients with SUDs reported low attitudinal barriers to reporting pain to clinicians. They also reported similar concerns to those of physicians, namely, concern regarding pain medication side effects and addiction potential of these medications [10]. These findings may therefore highlight common ground between patients and physicians that offers a basis for patient-physician alliance rather than the previously described "mutual mistrust" [26].

5. Conclusions

In summary, patients with opioid use disorders and chronic pain have greater attitudinal barriers to analgesic use than those without opioid use disorders. Patients with substance use disorders have lower attitudinal barriers to reporting pain to physicians. Given the substantial functional, social, and psychological consequences of undertreated pain, there is an imperative for physicians to work with patients who have comorbid pain and substance use disorders to address their attitudinal barriers to pain medications. This study highlights a modifiable barrier to effectively treating chronic pain in patients with SUD. Further clinical care and research should focus on addressing attitudinal barriers so that patients may have maximum pain relief without compromising recovery from addiction.
